Bonica’s
Management of Pain
FIFTH EDITION
Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings, and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Foreword

This, the fifth edition of Bonica’s Management of Pain, continues the tradition that John J. Bonica, MD, started with the publication of the first edition in 1953. That was a herculean endeavor and a monumental achievement, as no one had ever attempted to comprehensively describe all that was known about pain and how to diagnose and treat it. The first edition was almost exclusively the work of Dr. Bonica; only minor sections were contributed by his colleagues. It took him 30 years to bring out the second edition, which was the product of not only Bonica but also of a long list of contributors who in fact wrote more than half of the pages. This edition was characterized by extensive consideration of the anatomy and physiology underlying pain and by the discussion of multidisciplinary pain management and pain clinics.

The field of pain medicine, launched by Bonica’s own practice and teaching and by his founding of the International Association for the Study of Pain, had flourished by the time of the second edition, as pain medicine and research were developing rapidly. Bonica knew that another edition of the Bonica’s Management of Pain would have to be written to keep his textbook current. Unfortunately, his health limited his ability to undertake this task. Shortly before he died, I promised him that there would be a third edition that I would edit with the help of colleagues at the University of Washington. This was published in 2000, firmly based on the format of the prior editions but expanding the content to keep up with developments in both basic science and clinical pain management.

Another decade passed; the sciences basic to pain and clinical practice continued to rapidly expand. The fourth edition of this great book was
produced by new editors who assembled an all-star group of contributors to continue what Bonica began over 60 years ago. Now, it is time for the fifth edition to be created to set the pace for the coming decade of pain research, teaching, and patient care.

Whereas everyone active in pain research or patient care knew John Bonica in the last 30 years of the 20th century, we now have spawned a generation or two of workers in this field who know him only through his publications or the occasional prophetic story. Although this is an understandable reality, it is unfortunate. John Bonica was a truly great man whose efforts almost single-handedly caused pain to be put on the road maps of both basic science and health care. As I wrote in his obituary published in Pain1:

“He cared about his patients for whom he tirelessly worked. He cared about the research that scientists undertook to understand the mechanisms of pain. He cared about those who suffered in far-away places; he wanted their doctors to learn about pain management. He cared about how governments impacted the delivery of pain management services. He cared about his students, trainees, and colleagues. He really cared about those who attempted to continue what he had started. He cared about his children and his wife, although his career took time away from them.”(p2)

More than an inscription on his gravestone, the continued life of Bonica’s Management of Pain tells us of his accomplishments. It was a privilege to have known him and his family. Working for and with him and carrying on the traditions that he launched has been an honor. JJB, as he was known to all who worked alongside him, would have been thrilled to see the advances that he inspired. His greatness will live on through the publication of this fifth edition.

JOHN D. LOESER, M.D.
June 2018

---

Preface to the Fifth Edition (2019)

This book was first introduced 66 years ago, at a time that many believe marks the beginning of the multidisciplinary field of pain management. The idea for a clinical textbook devoted to the management of pain came from John Bonica, and in its first edition, he wrote that the book offers a synthesis of information from disparate disciplines to form a complete discussion on pain and its management. Such a book, he believed, would strengthen the field of medicine by assimilating new insights and growing knowledge from many interested disciplines. Since the first edition in 1953, the purpose of the book has remained the same despite extraordinary growth in the science and practice of pain management and the emergence of pain medicine as its own discipline. The book has remained a key reference for clinicians largely because of the high quality of the original book and its ability to attract world-class experts to engage in his project, even years after Dr. Bonica’s death in 1994. It was with trepidation and pride that we, the three chief editors, first accepted the task of shepherding the fourth edition of this essential book to publication. We quickly realized that we were no match for Bonica, who formulated and wrote large parts of the original book himself, and from the start, we solicited help from expert subeditors. As an editorial group, we made several key decisions: that we would keep the book near its original manageable size, that understanding anew the key role played by central mechanisms in pain, that we would shift the book’s emphasis from its focus on peripheral (anatomically based) mechanisms to one with a greater focus on neural (global) mechanisms, and that we would include new or updated chapters on issues that impact clinical pain management such as pain training,
In his first edition, John Bonica tells us that he was called to write his book out of the “... deep feeling for those who are afflicted with intractable pain, and by an intense desire to contribute something toward the alleviation of their suffering.” This commitment originated from his experiences in treating wounded soldiers with intractable pain during the Second World War. It is sad and ironic that this fourth edition was published in 2009 at a time when inadequate treatment of pain had come to be more widely recognized than ever and, in part, informed by wounded soldiers returning from the wars in Iraq and Afghanistan. In the year just prior to publishing the fourth edition, the US Congress passed, and the President of the United States signed into law, two bills that aimed to improve pain care for active military personnel and veterans, respectively. More than 50 years after Bonica began to raise awareness about the plight of those in pain, our society was coming to increasingly value safe and effective control of pain, and the trend echoed Bonica’s vision of a world free of suffering from treatable pain. Over the past 9 years, since the publication of the fourth edition of the textbook, there has been widespread recognition of a devastating crisis in opioid abuse and deaths as well as excessive prescribing of opioids. Much controversy has arisen regarding the use of opioids, particularly opioids for chronic pain. This controversy plays out in the pages of this the fifth edition, and you will find opposing and at times mutually exclusive opinions expressed. We, the editors, did not try to align the opinions of all of the experts expressed in the text. We allow readers to consider the disparate opinions on their own while we await the science we need to point us toward the best practices.

The fourth edition of the textbook remained faithful to Bonica’s original intent that his book should provide a comprehensive reference for practicing clinicians across all disciplines. In 1953, Bonica was one of few experts in a nascent new field that would become pain medicine, and he almost single-handedly undertook the task of producing the first clinical textbook. Now, there are many experts with a remarkable depth of knowledge. It is a testament to Bonica that the many leading authorities contributing to the fourth and now this fifth edition as authors and section editors feel sincerely indebted to him, and they have willingly given of
their time to maintain his legacy. Through its second and third editions, the book maintained a structure and organization similar to the first edition. In the fourth edition, every chapter was revised, substantially rewritten, or represented a completely new chapter and or topic. With a text of such broad scope, some degree of overlap was inevitable; indeed, we have often allowed significant overlap, so that each chapter would stand on its own during independent perusal or study.

Like the fourth edition, this fifth edition of the book is divided into six parts: (1) Basic Considerations; (2) Economic, Political, Legal, and Ethical Considerations; (3) Evaluation of the Pain Patient; (4) Pain Conditions; (5) Methods for Symptomatic Control; and (6) Provision of Pain Treatment. Basic Considerations offers an orientation to the history of pain management and the concepts and paradigms fundamental to this field, including taxonomy, basic science, anatomy, physiology, psychology, and social science. Economic, Political, Legal, and Ethical Considerations represents new content for this textbook, reflecting the emerging social impact of pain and pain management. Evaluation of the Pain Patient covers physical and psychological assessment and use of imaging and other technology-based testing as well as special assessment for function, disability, addiction, and multidisciplinary care. Pain Conditions is the largest single part of the text, comprising 9 sections and 53 chapters. These sections include neuropathic pain syndromes; psychological contributions to pain; vascular, cutaneous, and musculoskeletal pains; pain due to cancer; acute pain; pain in special populations; visceral pain; regional pain; and neck and low back pain. The section on pain in special populations addresses populations such as children, older persons, and those with pain and addiction. The regional pain section is a holdover from past editions and covers pain disorders that are associated with discrete parts of the body such as facial pain, cranial neuralgias, and pain syndromes associated with upper or lower extremities. Methods of Symptomatic Control is another large part of the text which is partitioned into the following six sections: pharmacologic therapies, psychological techniques, physical and other noninterventional therapeutic modalities, implanted electrical stimulators, interventional pain management, and surgical approaches. Provision of Pain Treatment is the final part of this text, addressing
systems for delivery of care and means for training pain specialists. Special areas of medicine in which pain has a prominent role are addressed, including primary care, end-of-life care, intensive care, and emergency care. The text concludes with a brief view toward the future of pain management.

This book would not be possible without the extensive contributions of the section editors and particularly the efforts of the chapter authors; the success of this work is directly attributable to these individuals. The editors are indebted to Brian Brown and Keith Donnellan of Wolters Kluwer who served critical roles in shepherding this project into existence and managed its development with skill and diplomacy.

As the field of pain medicine has evolved, so has this text. Despite much that is new or revised, the text remains incomplete, a reflection of an emerging field that awaits profound discoveries and development. Through the many chapters and pages of this new fifth edition of his classic text, we hope that John Bonica’s passion for an integrated, coherent, and compassionate field will live on. Like Bonica, our central purpose is to assist students and practitioners across all medical disciplines, advance their knowledge of pain medicine, and relieve suffering.
Preface to the First Edition (1953)

The purpose of this book is to present within one volume a concise but complete discussion of the fundamental aspects of pain, the various diseases and disorders in which pain constitutes a major problem, and the methods employed in its management, with special emphasis on the use of analgesic block as an aid in the diagnosis, prognosis, and therapy.

Although several books dealing with certain phases of this problem are available, none is complete from the standpoint of the practitioner; for it is necessary for him to consult several texts in order to obtain information regarding the cause, characteristics, mechanisms, effects, diagnosis, and therapy of pain and management of its intractable variety with analgesic block and certain adjuvant methods. The present volume is the product of the author’s desire to facilitate the task of the busy practitioner and to supply him easily accessible information with the conviction that this will induce more clinicians to employ these methods of diagnosis and therapy.

One need not elaborate on the reasons for writing on the management of pain, for reflection emphasized that this age-old problem is still one of the most difficult and often vexing phases of medical practice—a fact well appreciated by most physicians. This fact, as well as other reasons, are presented in the introduction and are emphasized throughout the book, particularly in Chapter 5.

I have been motivated to write this volume by a deep feeling for those who are afflicted with intractable pain, and by an intense desire to contribute something toward the alleviation of their suffering. The plan for its writing was germinated almost a decade ago during the Second World War, while I was Chief of the Anesthesia Section of a large Army hospital,
where I was afforded the opportunity to observe and manage an unusually large number of patients with severe intractable pain. The gratifying results obtained with analgesic block in some instances impressed me with the efficacy of this method in selected cases. In addition, the fact that these procedures effected relief which frequently was not only dramatic, but outlasted by hours and days the transient physiochemical interruption of nerve impulses, fascinated me and aroused my interest. Perusal of the literature revealed a paucity of material on this subject—a situation which has not changed much since then and which clearly indicated an obvious need for a practical source of information about this perplexing phenomenon and the application of analgesic block to its management.

This book is composed of three parts. The first part includes a discussion of the fundamental aspects of pain. While some of the material, on superficial thought, might be considered too detailed or entirely unnecessary, it has been included because of my conviction that in order to manage pain properly its anatomical, physiological and psychological bases must be understood. As is true in all fields of endeavor, a thorough knowledge of fundamental principles is an essential prerequisite without which optimal results are precluded. In order to diagnose and treat it properly, the physician must know the course of pain from its place of origin to the apperception centers in the brain and must be well versed in all the essentials and components of which pain consists; he must know its causes, mechanisms, characteristics, varieties, its localizations and significance, and the mental and physical effects it produces.

The second part deals with methods and techniques of managing pain. It was originally planned to include only the method which is the central theme of the book—analgesic block. However, it was soon realized that while this important phase is, to be sure, here treated in a comprehensive manner, it does not present the complete story of the management of pain; because frequently other adjuvant methods are employed in conjunction with nerve blocking. To illustrate the point, trigeminal neuralgia is frequently treated with neurolytic blocks, but sometimes this does not afford sufficiently long relief, and neurotomy is resorted to. The pain associated with malignancy is managed with alcohol nerve block, but roentgen therapy is frequently employed as an adjuvant. Moreover
physical and/or psychiatric therapy constitute integral phases of the management of pain without which optimal results cannot be hoped for. After careful consideration, it was decided to include another section in Part II in which are presented methods that are frequently employed in conjunction with analgesic block. It is hoped that such inclusion will give the book a wider scope and greater usefulness.

In the third part are presented various diseases or disorders with painful syndromes which have been and can be managed with analgesic block with or without the aid of other methods. The arrangement of this part is explained in detail on page 671. It is suggested that the reader refer to that page before proceeding further to read any on the pain syndromes. Though the material in this part mainly represents my observations, clinical impressions, and opinions, obtained or developed from experience with, and statistical analysis of, many thousands of cases, it also includes unpublished data of several outstanding authorities who have kindly placed them at my disposal. Moreover, it includes the published views and clinical experiences of others, with credit given where it is due.

In writing this comprehensive treatise, which has involved no small amount of time and effort, the one principle which has always been kept in mind and adhered to has been to present the fundamental considerations and principles of the problem before the practical aspects are discussed.

I have endeavored to make this book as complete as possible, and to this end have thoroughly searched the literature, both English and foreign, and have taken from it all that I thought might be valuable to the reader. In order to comply with the aim of completeness and still keep the book concise and within reasonable size, the material has been selected with care and discretion. In a field so vast and complex as pain, it is unavoidable that what might be thought sufficiently important to deserve detailed discussion is presented in an abbreviated manner or entirely omitted. In other instances, mere mention or omission represents a reluctant compliance with the requirements dictated by the size of the volume. Nonetheless, I believe thoroughness and important detail have not been sacrificed. The bibliography represents the most important references, and many excellent articles on each subject were also reluctantly omitted for that reason.
The book is intended for practitioners of every field of medicine, because pain is universal and provides the main reason why patients seek the aid of the doctor. It is hoped that it will prove useful, not only to the anesthesiologist, neurologist, neurosurgeon, orthopedist, and physiatrist to whom especially is relegated the task of caring for patients with intractable pain, but also to the general practitioner, surgeon, internist, psychiatrist, and any other physician who may be confronted with this problem. It is especially intended for general practitioners, particularly those practicing in smaller communities where the services of a specialist in analgesic blocking are not available. With this aim in mind the techniques of analgesic block are presented in such a manner that most of them may be effectively accomplished by any physician, even though he may be a novice with regional analgesia. In order to facilitate the task of the busy reader, less relevant facts—material which has been included because of its academic importance, for the sake of completeness, or for consumption by students and those who wish to delve deeper into the problem—are presented in small type. These can be omitted without losing continuity of thought. In this manner, while completeness, detail, and thoroughness are not sacrificed, emphasis is laid on the practical aspects of the problem at hand.

The unusually large number of illustrations, many of which are original and composed from dissected material or clinical cases, have been included with the conviction that these frequently tell the story much better than words.

A book of this nature is made possible only by the contribution of many individuals. The information set forth in the first part of the volume represents the fruition of the joint effort of anatomists, physiologists, pharmacologists, neurologists, neurosurgeons, anesthesiologists, psychiatrists, and many other laboratory and clinical investigators who have spent untold time, labor, and effort to discover the mystery of pain. I am grateful for their elucidating knowledge. To clinicians who have reported their experiences, and to others who have placed at my disposal unpublished data, observations, and opinions, my sincere thanks. I am particularly obliged to General Maxwell Keeler, and Col. Clinton S. Lyter, of Madigan Army Hospital for their continuous cooperation in obtaining
much of the clinical data embraced in this volume. I want to express my
gratitude to Mr. Harold Woodworth for his friendship, sympathetic
understanding and devotion to the cause of medicine. I also want to thank
the other members of the Board of Trustees of Tacoma General Hospital,
but particularly Mr. Alex Babbit, and Mr. Walter Heath and John Dobyns,
Directors of the hospital. Their continuous cooperation has facilitated the
activities of the Department of Anesthesia, Nerve Block Clinic, and Pain
Clinic.

I am very grateful to Dr. Robert Johnson, Associate Professor of
Anatomy of the University of Washington School of Medicine, for his
encouragement and criticism of some parts of the manuscript; to Doctor
Frederick Haugen for his assistance, criticism and suggestion.

My collaborators, Professor Robert Ripley, Doctors Wendell Peterson,
Frank Rigos, John T. Robson, Col. Clark Williams, M.C., and Lieut. Col.
Walter Lumpkin, M.D., have my heartfelt thanks for their contributions
and cooperation.

My appreciation is extended to Miss Joy Polis, Miss Virginia Coleman,
and other artists for the illustrations and to Mr. Kenneth Ollar for the
photography; to Mrs. Louise Cameron for her cooperation in obtaining the
roentgenograms; to Mrs. Katherine Rogers Miller, Miss Eleanor Ekberg
and the late Mrs. Blanch DeWitt of Tacoma, Miss Bertha Hallam,
Portland, and Mr. Alderson Fry, Seattle—all librarians whose cooperation
has facilitated a difficult task, and to Mr. John Morrison for editorial work.

This preface would be incomplete if I did not acknowledge my
indebtedness to my secretaries, Miss Katherine Stryker and Mrs. Dorothy
Richmond, for the inestimable aid they have given me in the preparation of
the manuscript.

My appreciation is extended to my publishers for their courtesy,
cooperation, and considerateness throughout the preparation of this
volume.

JOHN J. BONICA
Tacoma, Washington
Acknowledgments

Jane C. Ballantyne and James P. Rathmell thank Dr. Warren Zapol, immediate past Chair of the Department of Anesthesiology and Critical Care at Massachusetts General Hospital, for his encouragement and support.

Scott M. Fishman thanks the exceptional faculty of the Division of Pain Medicine and Dr. Richard Applegate, Chair of the Department of Anesthesiology and Pain Medicine at the University of California, Davis, for encouragement and support.

CHAPTER 9

Functional Neuroanatomy of the Nociceptive System
ROBERT GRIFFIN, EZEKIEL FINK, AND GARY J. BRENNER

Organization of the Peripheral Nociceptive System
Peripheral Nervous System Structures of Pain Sensation

Functional Anatomy of the Central Nervous System
DORSAL HORN
SPINOThALAMIC TRACT
THALAMUS
SENSORY CORTEX
DESCENDING PATHWAYS OF THE CENTRAL NERVOUS SYSTEM
CENTRAL PAIN
CENTRAL PAIN AFTER SPINAL CORD INJURY

Autonomic Nervous System
PERIPHERAL AUTONOMIC NERVOUS SYSTEM
PARASYMPATHETIC DIVISION
CRANIAL PARASYMPATHETICS
SACRAL PARASYMPATHETICS
SYMPATHETIC (THORACOLUMBAR) DIVISION
PART TWO

Economic, Political, Legal, and Ethical Considerations

CHAPTER 11

Transdermal Pain: A Sociocultural Perspective
DAVID B. MORRIS

What Is Transdermal Pain?
Ethnicity, Race, Sex, Gender, Age: Whose Pain?
Across Cultures: Beliefs, Attitudes, Perceptions, Behaviors
Pain and Narrative: Culture, Meaning, Ethics
Beyond the Gate: Consciousness and the Limits of a Molecular Gaze
Pain and Globalization: Power, Money, Systems
Conclusion: Summary and Synthesis
ACKNOWLEDGMENT

CHAPTER 12

Ethical Issues in Pain Management
BEN A. RICH

Pain, Suffering, and the Core Values of Health Care
THE DUTY TO RELIEVE PAIN AND SUFFERING
CURATIVE VERSUS PALLIATIVE PARADIGMS OF PATIENT CARE
The Phenomenon of Undertreated Pain

IDENTIFYING THE BARRIERS TO PAIN RELIEF
  Professional Barriers
  Patient Barriers
  Societal Barriers

Ethical Implications of the Barriers

Embracing a New Ethic of Pain Relief

Conclusion

CHAPTER 13
Ethical Issues in the Care of Dying Patients
DAVID BARNARD

Introduction

THE QUEST FOR MORAL ORDER AMID EXISTENTIAL DISORDER

THE CONTRIBUTIONS AND LIMITATIONS OF ETHICAL ANALYSIS IN END-OF-LIFE CARE

The Transition from Curative to Palliative and End-of-Life Care

NEGOTIATING TREATMENT PREFERENCES: THE IDEAL DECISION-MAKING PROCESS

DEPARTURES FROM THE IDEAL
  Prognosis and Clinical Judgment
  Patients’ Attitudes and Values
  Physicians’ Attitudes and Values

COMMUNICATION WITH PATIENTS ABOUT TREATMENT PREFERENCES NEAR THE END OF LIFE

Surrogate Decision Making

ASSESSING DECISIONAL CAPACITY

RULING OUT OR ELIMINATING REVERSIBLE CAUSES OF INCAPACITY

IDENTIFYING A SURROGATE

THE SURROGATE’S ROLES AND RESPONSIBILITIES

A REALISTIC PROCESS OF ADVANCE CARE PLANNING
  Three Basic Problems
  A Realistic Approach

Responding to Demands for Nonbeneficial Treatment
CHAPTER 14
Laws and Policies Affecting Pain Management in the United States
AARON M. GILSON AND JAMES F. CLEARY

Introduction

PREVALENCE OF UNRELIEVED PAIN IS A PUBLIC
HEALTH PROBLEM
BARRIERS TO THE SAFE AND EFFECTIVE USE OF OPIOID
ANALGESICS FOR PAIN MANAGEMENT
POLICIES GOVERNING THE USE OF OPIOID ANALGESICS
FOR PAIN MANAGEMENT

International Treaties: Establishing Balance between Drug Control
and Medical Use
US Federal Law: Preserving Balance between Drug Control and
Medical Use

THE FEDERAL FOOD, DRUG, AND COSMETIC ACT
US FEDERAL CONTROLLED SUBSTANCES LAW
The Controlled Substances Act Ensures Availability of
Controlled Substances for Medical Purposes
The Controlled Substances Act Does Not Regulate Medical
Practice
The Controlled Substances Act Distinguishes Treatment of
Addiction from Treatment of Pain, but Legal Definitions Create
Confusion
The Controlled Substances Act and Regulations Do Not Limit Prescription Amount or Duration
Regulations Implementing the Controlled Substances Act Now Authorize a Greater Variety of Secure Disposal Opportunities for Controlled Substances

US State Laws: Striving for Balance between Drug Control and Medical Use
STATE PAIN POLICY DEVELOPMENT: AN EMERGING TREND
EVALUATING THE QUALITY OF STATE PAIN POLICY
Policy Evaluation Findings
A PROGRESS REPORT CARD TO MEASURE CHANGES IN THE QUALITY OF STATE PAIN POLICIES
Progress Report Card Findings
THE IMPORTANCE OF IMPROVING STATE PAIN POLICY
The Need to Implement and Communicate Policy

Considering Additional US Policies
Taking Diversion into Account

Conclusions

CHAPTER 15
Litigation Involving Pain Management
BEN A. RICH

Administrative Proceedings
IN THE MATTER OF DILEO
HOOVER V AGENCY FOR HEALTH CARE ADMINISTRATION
OREGON BOARD OF MEDICAL EXAMINERS V BILDER ACCUSATION OF EUGENE WHITNEY, MD

Civil Litigation
ESTATE OF HENRY JAMES V HILLHAVEN CORPORATION
BERGMAN V CHIN, MD, AND EDEN MEDICAL CENTER
TOMLINSON V BAYBERRY CARE CENTER, ET AL.

Criminal Litigation
STATE V NARAMORE
Federal Criminal Prosecutions
  UNITED STATES V ROSEN (1978)
  UNITED STATES V HURWITZ
  UNITED STATES V MCIVER

Constitutional Cases
Lessons from the Litigation

CHAPTER 16
International Access to Therapeutic Opioids
JAMES F. CLEARY, MARTHA A. MAURER, AND S. ASRA HUSAIN

Pain Relief Is Part of Cancer and HIV/AIDS Control
PAIN AND PALLIATIVE CARE

Opioids Are Essential Medicines and Controlled Substances
GOVERNMENTS MUST ENSURE ADEQUATE OPIOID AVAILABILITY

Disparities in Opioid Consumption
MORPHINE EQUIVALENCE METRIC
GLOBAL OPIOID CONSUMPTION TRENDS
DISPARITIES IN CONSUMPTION BY INCOME LEVEL

Regional Opioid Consumption Trends
WORLD HEALTH ORGANIZATION REGION FOR AFRICA (AFRO)
WORLD HEALTH ORGANIZATION REGION FOR THE AMERICAS (AMRO)
WORLD HEALTH ORGANIZATION REGION FOR THE EASTERN MEDITERRANEAN (EMRO)
WORLD HEALTH ORGANIZATION REGION FOR EUROPE (EURO)
WORLD HEALTH ORGANIZATION REGION FOR SOUTHEAST ASIA (SEARO)
WORLD HEALTH ORGANIZATION REGIONS FOR THE WESTERN PACIFIC (WPRO)

Barriers to Opioid Availability and Accessibility
KNOWLEDGE AND ATTITUDES ABOUT PAIN, OPIOIDS, AND DEPENDENCE SYNDROME
  Inadequate Education of Health Care Professionals

79
Concerns about Dependence Syndrome (Addiction)
Concerns about Potential Side Effects
Health Care Professionals’ Fear of Prosecution or Sanction
EXCESSIVELY STRICT LAWS OR REGULATORY POLICIES
MEDICATION DISTRIBUTION SYSTEM BARRIERS
ECONOMIC FACTORS INCLUDING AFFORDABILITY
United Nations’ Recommendations
Efforts to Address Barriers and Improve Opioid Availability and Accessibility
Conclusion

PART THREE
Evaluation of the Pain Patient
CHAPTER 17
Evaluation of the Chronic Pain Patient
GORDON IRVING AND PAMELA SQUIRE

Introduction
GENERAL GUIDELINES FOR ASSESSMENT OF PERSISTENT PAIN

Outline of a Multidimensional Assessment Questionnaire for Persistent Pain History
SUMMARY OF SOME NONPROPRIETARY QUESTIONNAIRES
OTHER POTENTIALLY USEFUL QUESTIONS TO CONSIDER FOR GAUGING EFFECTIVENESS OF THERAPY
SUMMARY OF PROPRIETARY QUESTIONNAIRES TO CONSIDER

The Pain History
O: ONSET OF PAIN
P: PROVOCATIVE/PALLIATIVE
Q: QUALITY OR CHARACTER
R: REGION/RADIATION
S: SEVERITY/INTENSITY OF PAIN
T: TIMING OF PAIN
ALTERED PERCEPTION

Past Medical and Surgical History
MOOD ASSESSMENT
PSYCHOSOCIAL FACTORS
COPING STRATEGIES
SLEEP DISORDERS
COGNITIVE IMPAIRMENT
VOCATIONAL HISTORY AND CURRENT VOCATIONAL DISABILITY
HABITS

Risk of Opioid Misuse, Abuse, or Dependence
Assessment of Function
Current and Past Treatments
CURRENT AND PAST MEDICATIONS INCLUDING OVER-
THE-COUNTER MEDICATIONS
ALLERGIES
INVESTIGATIONS AND CONSULTATIONS

Goals

Physical Examination

GENERAL EXAM: OBSERVE, IDENTIFY AND DOCUMENT SITE OF PAIN

Observe
Palpate
Test

NEUROLOGIC EXAM

Observe or Ask About
Palpate
Test

BEDSIDE METHOD FOR QUANTITATIVE SENSORY TESTING

Light Touch
Vibration
Punctate/Pinprick
Warm and Noxious Heat
Cool and Noxious Cold
Grading the Tests

CAVEATS TO QUANTITATIVE SENSORY TESTING

INTERPRETATION

FURTHER INVESTIGATIONS OR CONSULTS

Follow-up Visits

Conclusion

GOALS

Considering the Right Goal for You
Setting SMART Goals

Appendix 17.1: Initial Visit Questionnaire
Appendix 17.2: Pain Diagram
Appendix 17.3: Goal Setting
Appendix 17.4: Follow-up Questionnaire

CHAPTER 18
Electrodiagnosis in Pain Medicine
NATHAN J. RUDIN
The Electrodiagnostic Laboratory
Electrodiagnostic Tests
  NERVE CONDUCTION STUDIES
  NEEDLE ELECTROMYOGRAPHY
Application in Selected Conditions
Conclusion
CHAPTER 19
Diagnostic Imaging of Pain
RICHARD F. CODY Jr, ASAKO MIYAKOSHI, AND KENNETH R. MARAVILLA
Headache
  ACUTE HEADACHE
    Computed Tomography Angiography and Magnetic Resonance Angiography
  CHRONIC HEADACHE
  INTRACRANIAL HYPOTENSION
  INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI)
Facial Pain
Spinal Pain
  OVERVIEW
  COMPRESSION FRACTURES
  BENIGN VERSUS MALIGNANT;
  INFECTION/INFLAMMATION
  DISCOGENIC PAIN
Limb Pain and Magnetic Resonance Neurography
  MAGNETIC RESONANCE NEUROGRAPHY
  THORACIC OUTLET SYNDROME
  PIRIFORMIS SYNDROME
  PERIPHERAL NERVE ENTRAPMENT SYNDROMES
Imaging Guided Injection
Future Application of Pain Imaging
Conclusion
CHAPTER 20
Measurement of Pain
Introduction

VALIDITY, RELIABILITY, AND UTILITY IN THE CONTEXT OF PAIN ASSESSMENT

Validity
Reliability
Utility

HOW MANY PAIN PROBLEMS SHOULD BE ASSESSED?
WHICH PAIN DOMAIN(S) SHOULD BE ASSESSED?
RECALL RATINGS VERSUS SUMMARY SCORES FROM MULTIPLE RATINGS USING DIARIES

Measuring Pain’s Domains

MEASURING PAIN INTENSITY
Recommendations for Assessing Pain Intensity

MEASURING PAIN AFFECT
Recommendations for Assessing Pain Affect

MEASURING PAIN QUALITY
Using Pain Quality Measures as Diagnostic Aides
Strengths and Weaknesses of Pain Quality Measures as Diagnostic Aides
Pain Quality Scales as Descriptive and Outcome Measures
Strengths and Weakness of Descriptive and Outcome Measures of Pain Quality

MEASURING PAIN’S SPATIAL CHARACTERISTICS
Recommendations for Assessing Pain Site

MEASURING PAIN’S TEMPORAL CHARACTERISTICS
Recommendations for Assessing Pain’s Temporal Characteristics

MEASURING PAIN INTERFERENCE
Brief Pain Inventory Pain Interference Scale
Patient-Reported Outcomes Measurement Information System Pain Interference Item Bank and Short Forms
Recommendations for Assessing Pain Interference

Measuring Pain in Special Populations

SIMPLIFIED MEASURES OF PAIN
Simple Pain Measures to Consider
Selecting the Best Measure for a Patient or Population

BEHAVIOR OBSERVATION MEASURES
Measuring Pain in Busy Clinical Settings

Summary and Conclusions

CHAPTER 21
Pain Psychology Evaluation
RAVI PRASAD, DESIREE AZIZODDIN, AND AMIR RAMEZANI

Psychosocial History
EARLY LIFE EXPERIENCES
VOCATIONAL HISTORY
EDUCATIONAL HISTORY

Current Functioning
BELIEF STRUCTURES
SOCIAL SUPPORT
CULTURAL FACTORS

Substance Use
NICOTINE
ALCOHOL
PRESCRIBED AND NONPRESCRIBED DRUG USE

Psychiatric Functioning
BEHAVIORAL OBSERVATIONS
DEPRESSION
ANXIETY
POSTTRAUMATIC STRESS DISORDER
SOMATIZATION

Psychological Screening for Advanced Intervventional Procedures

Conclusion

CHAPTER 22
Disability Evaluation of Patients with Chronic Pain
JAMES P. ROBINSON AND LEE GLASS

Basic Concepts
Conceptual and Empirical Issues
IMPAIRMENT AND DISABILITY
Impairment
Disability

ASSOCIATIONS BETWEEN IMPAIRMENT AND
DISABILITY
THE “EMBEDDEDNESS” PROBLEM
PRACTICAL PROBLEMS IN IDENTIFYING THE ROLE OF PAIN IN DISABILITY DETERMINATIONS

Methods for Evaluating Chronic Pain in Applicants for Disability Benefits

EVALUATION METHODS IN THE SOCIAL SECURITY ADMINISTRATION
OUTCOMES OF SOCIAL SECURITY ADMINISTRATION EVALUATIONS
DISABILITY EVALUATION AND DISABILITY MANAGEMENT IN THE WASHINGTON STATE DEPARTMENT OF LABOR AND INDUSTRIES
WASHINGTON STATE DEPARTMENT OF LABOR AND INDUSTRIES PROGRAMS TO REDUCE DISABILITY METHODS USED BY WASHINGTON STATE DEPARTMENT OF LABOR AND INDUSTRIES TO EVALUATE INJURED WORKERS FOR PERMANENT DISABILITY BENEFITS
OUTCOMES OF WASHINGTON STATE DEPARTMENT OF LABOR AND INDUSTRIES EVALUATIONS

Conclusion

CHAPTER 23
Multidisciplinary Assessment of Patients with Chronic Pain
DENNIS C. TURK AND JAMES P. ROBINSON

Conceptual Issues
CONUNDRUMS IN THE ASSESSMENT OF PAIN
A CONCEPTUAL MODEL FOR ASSESSING PAIN
Pain Behavior
Classes of Variables Underlying Pain Behavior

Assessment of Medical Factors
ARE THERE RED FLAGS?
ARE THERE RISK FACTORS FOR DELAYED RECOVERY?
SPECIFIC EVALUATION PROCEDURES
History
Physical Examination
Ancillary Studies

CONCLUSION
Assessment of Central Nervous System Sensitization
Assessment of Psychosocial Factors

PSYCHOLOGICAL FACTORS AS CAUSES VERSUS CONSEQUENCES OF CHRONIC PAIN
Psychological Factors as Causal Agents in Development of Chronic Pain
Psychological Consequences of Chronic Pain

ELEMENTS OF THE PSYCHOLOGICAL EVALUATION
Interviews
Self-report Inventories

PROBLEM AREAS TO ASSESS
Assessment of Pain
Assessment of Overt Expressions of Pain
Assessment of Emotional Distress
Assessment of Fear
Assessment of Beliefs, Coping, and Psychosocial Adaptation to Pain
Assessing Functional Impact

SELF-REPORT MEASURES OF FUNCTION
Assessment of Physical Capacity
Assessment of Social Factors
Organization of Multidisciplinary Evaluations
Conclusion

PART FOUR
Pain Conditions
NEUROPATHIC PAIN CONDITIONS

CHAPTER 24

Painful Neuropathies

GEORGIOS MANOUSAKIS, MIROSLAV BACKONJA, AND DAVID WALK

Pain as a Symptom of Neuropathy

The Evaluation and Diagnosis of Neuropathy

NEUROPATHY CLASSIFICATION

HISTORY, EXAMINATION, AND DIAGNOSTIC STUDIES

Painful Neuropathies

DISTAL SYMMETRIC POLYNEUROPATHIES

Metabolic Causes
Infectious Causes
Toxic Neuropathies
Nutritional Neuropathies
Hereditary Neuropathies

OTHER WIDESPREAD BUT NONLENGTH-DEPENDENT NEUROPATHIES

Neuropathy with Paraproteinemia
Autoimmune Demyelinating Neuropathies

PAINFUL MONONEUROPATHY MULTIPLEX AND FOCAL NEUROPATHIC SYNDROMES

Vasculitic Neuropathy
Neuralgic Amyotrophy
Diabetic Amyotrophy
Other Diabetic Mononeuropathies

SENSORY NEURONOPATHIES

Postherpetic Neuralgia
Sjögren’s Syndrome
Paraneoplastic Sensory Neuronopathy
Toxic Neuronopathy

Treatment of Painful Neuropathies

GENERAL PRINCIPLES OF THERAPY
ANALGESIA THERAPY: GUIDELINES FOR PHARMACOTHERAPY

Tricyclic Agents
CHAPTER 25
Complex Regional Pain Syndrome
MICHAEL T. MASSEY AND ROBERT NORMAN HARDEN

Epidemiology
Pathophysiology
  ANIMAL MODELS
  HUMAN MODELS
  INFLAMMATION
  IMMUNOLOGIC FACTORS
    Afferent Dysfunction
  CENTRAL DYSFUNCTION
  SYMPATHETIC DYSFUNCTION
  TROPHIC, DYSTROPHIC, AND NUTRITIONAL
  ABNORMALITIES
  MOTOR AND MOVEMENT DISORDERS
  IMMOBILIZATION AND DISUSE
  Genetics
    A Convergent Pathophysiologic Theory

Diagnosis
  THE INTERNATIONAL ASSOCIATION FOR THE STUDY
  OF PAIN CRITERIA
  THE BUDAPEST CRITERIA
  SEQUENTIAL STAGES AND SUBSETS OF COMPLEX
  REGIONAL PAIN SYNDROME
  PSYCHOLOGICAL FACTORS IN COMPLEX REGIONAL
  PAIN SYNDROME
CHAPTER 26

Phantom Pain
KELLY A. BRUNO, HOWARD S. SMITH, IRFAN LALANI, AND CHARLES E. ARGOFF

Epidemiology
Modulation of Phantom Pain
Pathophysiology of Phantom Pain
Prevention of Phantom Pain
Treatment of Phantom Pain
Pharmacologic Interventions
ANTIDEPRESSANTS
ANTIEPILEPTIC DRUGS
OPIOIDS
NMDA RECEPTOR ANTAGONISTS
CALCITONIN
TRANSIENT RECEPTOR POTENTIAL CATION CHANNEL SUBFAMILY V MEMBER 1 (TRPV1) MODULATORS
INTERVENTIONAL THERAPY
NEUROMODULATION
SURGICAL INTERVENTIONS
BEHAVIORAL MEDICINE INTERVENTIONS
MISCELLANEOUS TREATMENTS FOR RESIDUAL LIMB PAIN

Summary

CHAPTER 27

Herpes Zoster and Postherpetic Neuralgia
SIDDARTH THAKUR, ROBERT H. DWORIN, AND RAJBALA THAKUR

Clinical Picture and Natural History of Herpes Zoster
PRODROME
RASH
PAIN
DISTRIBUTION OF HERPES ZOSTER
CLINICAL VARIANTS
Herpes Zoster Ophthalmicus
Herpes Zoster Oticus (Ramsay-Hunt Syndrome)
Zoster Sine Herpetic
Diagnosis of Herpes Zoster
LABORATORY TESTING
Viral Culture
Direct Immunofluorescence Assay
Viral DNA Testing
Biopsy
Testing for Underlying Disorders
Epidemiology of Herpes Zoster
Pathophysiology of Herpes Zoster and Mechanisms of Acute Pain
Complications Associated with Herpes Zoster
OPHTHALMIC COMPLICATIONS
MOTOR NEUROPATHY
RARE NEUROLOGIC COMPLICATIONS
VISCERAL COMPLICATIONS
DECREASED QUALITY OF LIFE
Treatment of Herpes Zoster
PATIENT EDUCATION
ANTIVIRAL THERAPY
ANALGESIC TREATMENT
CORTICOSTEROIDS
Lidocaine Patch
NEURAL BLOCKADE
COMPLEMENTARY AND ALTERNATIVE MEDICINE
SPINAL CORD STIMULATION
Prevention of Herpes Zoster
CHILDHOOD VACCINATION
VARICELLA-ZOSTER IMMUNOGLOBULIN
HERPES ZOSTER VACCINATION FOR ADULTS
Clinical Picture of Postherpetic Neuralgia
DIAGNOSIS AND ASSESSMENT OF POSTHERPETIC NEURALGIA

Laboratory Diagnosis

Epidemiology and Natural History of Postherpetic Neuralgia

RISK FACTORS FOR POSTHERPETIC NEURALGIA

Pathophysiology of Postherpetic Neuralgia

Treatment of Postherpetic Neuralgia

ANTICONVULSANTS: GABAPENTIN AND PREGABALIN

ANTIDEPRESSANT MEDICATIONS

- Tricyclic Antidepressants
- Selective Serotonin and Norepinephrine Reuptake Inhibitors (Dual Reuptake Inhibitors)

OPIOID ANALGESICS

TRAMADOL

TAPENTADOL

TOPICAL THERAPIES

- Topical Lidocaine
- Topical Capsaicin
- Other Topical Treatments

COMBINATION THERAPY

N-METHYL-D-ASPARTIC ACID ANTAGONISTS

OTHER PHARMACOLOGIC THERAPIES

INVASIVE TREATMENTS FOR POSTHERPETIC NEURALGIA

- Botulinum Toxin
- Dorsal Root Ganglion Blocks
- Peripheral Nerve Blocks
- Neuroaugmentive Techniques
- Sympathetic Nerve Blocks
- Neuraxial Blocks

PSYCHOLOGICAL INTERVENTIONS

ELECTROANALGESIA

- Transcutaneous Electrical Nerve Stimulation
- Scrambler Therapy

Surgical Approaches
CHAPTER 28
Central Pain States
NANNA BRIGGIN FINNERUP AND SHARON BEN-HAIM
Diagnosis
Clinical Characteristics
Clinical Assessment
Specific Central Pain Conditions
CENTRAL POSTSTROKE PAIN
CENTRAL PAIN IN MULTIPLE SCLEROSIS
CENTRAL PAIN IN SPINAL CORD INJURY
OTHER CENTRAL PAIN CONDITIONS
Preclinical Models
Mechanisms
Treatment of Central Pain
PHARMACOLOGIC TREATMENT
First-line Pharmacologic Treatments
Second- and Third-Line Pharmacologic Treatments
Other Drugs, Combination Therapy, and Intrathecal Drug Administration
PSYCHOLOGICAL AND PHYSIOTHERAPY TREATMENT
NEUROSURGICAL MANAGEMENT
Targeted Drug Delivery
Neuroablation
Neuromodulation

PSYCHOLOGICAL CONTRIBUTIONS TO PAIN
CHAPTER 29
The Psychophysiology of Pain
C. RICHARD CHAPMAN AND FADEL ZEIDAN
Historical Perspective: Mind–Body Issues
Emotions: Definition and Mechanisms
WHAT ARE EMOTIONS?
EMOTION IN A SOCIOBIOLOGIC PERSPECTIVE
ADAPTIVE FUNCTIONS OF EMOTION
EMOTIONS AND BEHAVIOR
THE CENTRAL NEUROANATOMY OF EMOTION: LIMBIC STRUCTURES
PERIPHERAL NEUROANATOMY OF EMOTION: THE AUTONOMIC NERVOUS SYSTEM
  Autonomic Arousal and Subjective Experience
  The Role of Feedback
  Relationship of Central and Peripheral Mechanisms
NOXIOUS SIGNALING AND CENTRAL LIMBIC PROCESSING
  Central Neurotransmitter Systems
LOCUS COERULEUS AND THE DORSAL NORADRENERGIC BUNDLE
THE VENTRAL NORADRENERGIC BUNDLE AND THE HYPOTHALAMO-PITUITARY-ADRENOCORTICAL AXIS
PRIMARY AND SECONDARY FEATURES OF THE AFFECTIVE DIMENSION OF PAIN
SUMMARY OF THE CONSTRUCTION AND MODULATION OF PAIN

Emotion and Cognition
The Sense of Self
  COGNITIVE PERSPECTIVE
  MULTIPLE PERSPECTIVES ON THE SELF

Stress, Sickness, and Pain
BASIC DEFINITIONS: STRESS, HOMEOSTASIS, AND ALLOSTASIS
PHYSIOLOGIC MECHANISMS OF STRESS
  Neural Substrates
  Immune Mechanisms
  The Sickness Response
  The Sickness Response and Depression
SUMMARY OF THE PHYSIOLOGIC MECHANISMS OF STRESS
STRESS AND CHRONIC PAIN

Future Directions
CHAPTER 30
Pain and Learning
ROBERT J. GATCHEL, BRIAN R. THEODORE, AND NANCY D. KISHINO

Overview of the Three Major Principles of Learning
CLASSICAL CONDITIONING
OPERANT CONDITIONING
OBSERVATIONAL LEARNING

Operant Conditioning and Pain
THE HALLMARK WORK OF WILBERT FORDYCE
OPERANT CONDITIONING AND CHRONIC PAIN: THE BASICS

Classical Conditioning and Pain
aversive classical conditioning and pain
classically conditioned fear/avoidance and pain

Observational Learning and Pain

Integrating Learning Principles in the Treatment of Pain
COGNITIVE-BEHAVIORAL THERAPY AND PAIN
COGNITIVE-BEHAVIORAL THERAPY AS AN ESSENTIAL COMPONENT OF A COMPREHENSIVE INTERDISCIPLINARY APPROACH TO PAIN MANAGEMENT

Conclusion

CHAPTER 31
Psychiatric Illness, Depression, Anxiety, and Somatic Symptom Disorder
JOSEPH GREGORY HOBELMANN, MARK D. SULLIVAN, MICHAEL R. CLARK, AND AJAY D. WASAN

Psychiatric Nosology and Diagnostic and Treatment Approaches Framework for Describing Psychiatric Symptoms
Depression
SUCIDAL IDEATION AND BEHAVIOR WHICH CAME FIRST, DEPRESSION OR PAIN?
DIFFERENTIAL DIAGNOSIS
BIOLOGIC TESTS FOR DEPRESSION
DYSTHYMIC DISORDER
EPIDEMIOLOGY OF DEPRESSION
PAIN AND DEPRESSION: MECHANISMS OF ASSOCIATION

Biologic Theories
Psychological Theories
Anthropologic Theories

DEPRESSION TREATMENT
Pharmacologic Agents

PSYCHOTHERAPY
Psychodynamic Psychotherapy
Behavioral Model
Cognitive Model
Cognitive-Behavioral Model

Anxiety Disorders
GENERALIZED ANXIETY DISORDER
PANIC DISORDER
EPIDEMIOLOGY
TREATMENT

Posttraumatic Stress Disorder
DIAGNOSIS
EPIDEMIOLOGY OF POSTTRAUMATIC STRESS DISORDER IN CHRONIC PAIN PATIENTS
POSTTRAUMATIC STRESS DISORDER AND ASSOCIATIONS WITH PAIN
TREATMENT

Personality Disorders
EPIDEMIOLOGY
OVERVIEW OF PERSONALITY DISORDERS
PERSONALITY AND PAIN TREATMENT OUTCOME

Somatic Symptom Disorders, Illness Behavior, and Sick Role
DEFINITIONS
OVERVIEW OF SOMATOFORM DISORDERS AND SOMATIC SYMPTOM DISORDERS

Somatic Symptom Disorder
Conversion Disorder (Functional Neurologic Symptom Disorder)
CHAPTER 32

Treatment of Pain in Patients with Addiction
PEGGY COMPTON, FRIEDHELM SANDBRINK, AND MARTIN D. CHEATLE

Substance Use Disorder

Clinical Implications of Substance Use Disorders on Pain

NEUROBIOLOGIC OVERLAP BETWEEN PAIN AND ADDICTION SYSTEMS

Tolerance
Dependence
Analgesic Effects of Drugs of Abuse

EFFECTS OF SUBSTANCE USE DISORDER ON PAIN

EFFECTS OF OPIOID USE DISORDER ON PAIN

Genetics of Pain and Opioid Use Disorder
Tolerance
Physical Dependence
Opioid-Induced Hyperalgesia

Pain Management in Persons with Substance Use Disorder

PREVALENCE OF SUBSTANCE USE DISORDERS IN PATIENTS WITH PAIN

PRINCIPLES OF PAIN TREATMENT IN PATIENTS WITH SUBSTANCE USE DISORDERS

Provide Effective Pain Relief
Reinforce or Introduce Substance Use Disorder Treatment
Document Pain Treatment Plan and Involve Patient and Family in the Plan of Care
Pain, Substance Use Disorder, and Suicide

Conclusions

CHAPTER 33

The Doctor–Patient Relationship in Pain Management: Dealing with Difficult Clinician–Patient Interactions
ROBERT N. JAMISON

Difficult Patients and Difficult Doctor–Patient Relationships

PSYCHIATRIC AND PERSONALITY ISSUES

OPIOID THERAPY
DIFFICULT “NORMAL” PATIENTS
COMORBID MEDICAL CONDITIONS
SUBSTANCE USE DISORDERS

Physician Factors
Health Care System Factors
Patient Interaction Strategies

PATIENT-FOCUSED CARE

Communication Framework: WIPS and E’s

Clinical Scenarios
SCENARIO 1
SCENARIO 2
SCENARIO 3
SCENARIO 4
SCENARIO 5
SCENARIO 6
SCENARIO 7

Summary and Conclusions

ACKNOWLEDGMENT

VASCULAR, CUTANEOUS, AND MUSCULOSKELETAL PAINS

CHAPTER 34

Arthritis
GREGORY C. GARDNER

Basic Considerations

PROBLEM IN PERSPECTIVE

JOINT ANATOMY

Nerve and Blood Supply

Clinical Approach to Joint Pain

HISTORY

Number of Joints Affected
Pattern Recognition
Systemic Features of Arthritis

PHYSICAL EXAMINATION

EXAMINATION OF SYNOVIAL FLUID

Clinical Considerations

OSTEOARTHRITIS

98
Epidemiology and Pathophysiology
Symptoms and Signs
SECONDARY OSTEOARTHRITIS
Laboratory Findings
Treatment
RHEUMATOID ARTHRITIS
Etiology and Pathophysiology
Symptoms and Signs
Laboratory Findings
Treatment Philosophy
Current Management of Rheumatoid Arthritis
Important Complications of Rheumatoid Arthritis Presenting with Pain
THE SPONDYLOARTHROPATHIES
Ankylosing Spondylitis
Spondylodiskitis
REACTIVE ARTHRITIS
Symptoms and Signs
Laboratory Findings
Treatment
Complications of Reactive Arthritis Associated with Chronic Pain
PSORIATIC ARTHRITIS
Symptoms and Signs
Laboratory Findings
Treatment
ARTHRITIS ASSOCIATED WITH INFLAMMATORY BOWEL DISEASE
Treatment
ARTHRITIS CAUSED BY CRYSTALS
Calcium Pyrophosphate Deposition Disease
Pathophysiology
Symptoms and Signs
Treatment
URATE GOUT
Etiology and Pathophysiology
Pathophysiology of Acute Gouty Arthritis
Signs and Symptoms
Laboratory Findings
Treatment
INFECTIOUS ARTHRITIS
Nongonococcal Bacterial Arthritis
Gonococcal Arthritis
POLYMYALGIA RHEUMATICA

CHAPTER 35
Myofascial Pain Syndrome
JAN DOMMERHOLT AND JAY P. SHAH

Brief Historical Overview
Basic Myofascial Pain Concepts
Muscle Physiology
The Motor Endplate
Sensitization and Activation of Muscle Nociceptors
Central Sensitization
The Biochemical Milieu of Myofascial Trigger Points
pH and Muscle Pain
Neuropeptides, Inflammatory Mediators, and Tissue Injury and Pain
Catecholamines and the Autonomic Nervous System
Cytokines and Pain
Clinical Management

TRIGGER POINT DIAGNOSIS
PHYSICAL EXAMINATION AND DIAGNOSIS

TREATMENT OPTIONS
Patient Education
Physical Therapy
Needling Therapies

NONINVASIVE TREATMENT OPTIONS

Summary

CHAPTER 36
Fibromyalgia: A Discrete Disease or the End of the Continuum
DANIEL J. CLAUW AND CHAD BRUMMETT

Historical Perspective
Epidemiology

CHRONIC WIDESPREAD PAIN
FIBROMYALGIA
SIGNIFICANCE OF TENDER POINTS
OTHER FEATURES OF FIBROMYALGIA GLEANED FROM EPIDEMIOLOGIC OR OBSERVATIONAL STUDIES

Etiology

ANIMAL MODELS OF FIBROMYALGIA
GENETIC FACTORS
EVIDENCE OF CENTRAL NERVOUS SYSTEM DISTURBANCES IN PAIN AND SENSORY PROCESSING
EVIDENCE OF A GLOBAL INCREASE IN SENSORY PROCESSING OF NONPAINFUL STIMULI
BRAIN IMAGING STUDIES
THE ROLE OF NEUROENDOCRINE OR AUTONOMIC ABNORMALITIES
THE ROLE OF PERIPHERAL FACTORS IN FIBROMYALGIA
EVIDENCE OF ABNORMAL CYTOKINES OR OF IMMUNE DYSFUNCTION IN FIBROMYALGIA
THE ROLE OF “SMALL FIBER NEUROPATHY” IN FIBROMYALGIA

Diagnosis

DIAGNOSIS OF FIBROMYALGIA

Treatment

GENERAL APPROACH
PHARMACOLOGIC THERAPY
Tricyclic Agents
Serotonin and Norepinephrine Reuptake Inhibitors
Anticonvulsants
Combination Drug Therapy
Other Central Nervous System–Acting Drugs
Classic Analgesics
NEUROSTIMULATORY THERAPIES
NONPHARMACOLOGIC THERAPIES

Prognosis
Conclusion
Key Points

CHAPTER 37
Pain of Dermatologic Disorders
SHELLEY YANG AND JOHN E. OLERUD

Basic Considerations: Anatomy and Physiology of the Skin

Clinical Disorders

LEUKOCYTOCLASTIC VASCULITIS
Etiology
Pathogenesis
Treatment

POLYARTERITIS NODOSA
Symptoms and Signs
Treatment

ANTINEUTROPHILIC CYTOPLASMIC ANTIBODIES-ASSOCIATED VASCULITIDES: GRANULOMATOSIS WITH POLYANGIITIS (FORMERLY KNOWN AS WEGENER’S GRANULOMATOSIS)
Symptoms and Signs
Treatment

MICROSCOPIC POLYANGIITIS
Treatment

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (FORMERLY KNOWN AS CHURG-STRAUSS SYNDROME)
Symptoms and Signs
Treatment

RHEUMATOID VASCULITIS
Treatment

LIVEDOID VASCULOPATHY
Treatment

Other Vascular Disorders

ANTIPHOSPHOLIPID SYNDROME
Symptoms and Signs
Treatment

WARFARIN (COUMADIN) SKIN NECROSIS
Pathophysiology
Symptoms and Signs
Treatment

COCAINE LEVAMISOLE TOXICITY
CALCINOSIS CUTIS
CALCIPHYLAXIS
Treatment

Ulcers
ISCHEMIC ULCERS
Treatment
VENOUS ULCERS
Treatment
PYODERMA GANGRENOsum

Painful Infections
NECROTIZING SOFT TISSUE INFECTION/NECROTIZING FASCIITIS
HERPES ZOSTER
HERPES SIMPLEX
Symptoms and Signs
Diagnosis
Treatment
ERYSIPELAS AND CELLULITIS
Treatment
FURUNCULOSIS AND CARBUNCLE
Treatment
ERYSIPELOID

Inflammations
PANNICULITIS
Erythema Nodosum
Treatment
DERCUM DISEASE (ADIPOSA DOLOROSA)
Treatment
HIDRADENITIS SUPPURATIVA
Etiology
Symptoms and Signs
Diagnosis
Treatment

INFLAMED EPIDERMAL CYST
BULLOUS DERMATOSES WITH EROSIONS
  Stevens-Johnson/Toxic Epidermal Necrolysis Syndrome
  Pemphigus Vulgaris
  Paraneoplastic Pemphigus
  Bullous Pemphigoid
  Epidermolysis Bullosa

Disorders of Connective Tissue Structure (Cartilage Disorders)
RELAPSING POLYCHONDRIESIS

Treatment

CHONDRODERMATITIS NODULARIS HELICIS

Neurovascular Cutaneous Disease
SENSORY MONONEUROPATHIES

Treatment

ERYTHROMELALGIA
FABRY’S DISEASE

Symptoms and Signs
Treatment

Other Painful Dermatologic Disorders

CUTANEOUS ENDOMETRIOSIS
PAINFUL NEOPLASMS

ACKNOWLEDGMENTS

CHAPTER 38
Pain Due to Vascular Causes

KAJ JOHANSEN

Basic Neuroanatomic and Neurophysiologic Considerations
Vascular Pain Syndromes

INTERMITTENT CLAUDICATION
AORTIC AND OTHER LARGE ARTERY PAIN
REST PAIN, ULCERS, AND GANGRENE
PAIN SYNDROMES FOLLOWING STROKE
PAIN ASSOCIATED WITH DISEASES INVOLVING SMALL ARTERIES
PAIN ASSOCIATED WITH VENOUS DISORDERS
PAIN ASSOCIATED WITH LYMPHATIC DISEASES
PAIN ASSOCIATED WITH AMPUTATION
Differentiating Vascular from Nonvascular Pain
The Relief of Vascular Pain
Conclusion

CHAPTER 39
Pain Due to Thoracic Outlet Syndrome
KAJ JOHANSEN, THOMAS TAI CHUNG, AND GEORGE I. THOMAS
Anatomy and Pathophysiology
Clinical Presentation: Symptoms and Signs
Diagnostic Tests
Differential Diagnosis
Management
Outcomes

CHAPTER 40
Pain Following Spinal Cord Injury
KEVIN N. ALSCHULER, MARIA REGINA REYES, AND THOMAS N. BRYCE
Extent and Impact of the Problem
Assessment and Classification of Pain Following Spinal Cord Injury
MUSCULOSKELETAL PAIN
    Shoulder Pain
    Elbow and Wrist Pain
    Back Pain
    Muscle Pain Related to Spasticity
VISCERAL PAIN
OTHER NOCICEPTIVE PAIN
AT- AND BELOW-LEVEL SPINAL CORD INJURY PAIN
OTHER NEUROPATHIC PAIN
PSYCHOSOCIAL ASPECTS OF PAIN AFTER SPINAL CORD INJURY
INJURY
    Psychological Factors
    Social and Environmental Factors
Management of Pain in People with Spinal Cord Injury
NOCICEPTIVE PAIN
    Musculoskeletal Pain
COMORBIDITIES ASSOCIATED WITH SPECIFIC CANCERS: LUNG DISEASE, LIVER DISEASE, RENAL DISEASE, AND NEUROLOGIC DISEASE
CANCER PAIN AND SUBSTANCE ABUSE
CANCER PAIN IN INMATES

Components of the Comprehensive Medical Evaluation of a Patient with Chronic Cancer Pain

Pain History

DEFINITION OF PAIN
DEFINITION OF SUFFERING
VALIDATED ASSESSMENT TOOLS
TYPES OF PAIN
PRESENTING COMPLAINT

  Pain Onset
  Pain Progression
  Focality
  Symptoms That Accompany Pain
  Formulating the Presenting Complaint

DETAILS OF THE PAIN HISTORY

Physical Examination

GENERAL PHYSICAL EXAMINATION

Interventional Pain Therapies

SHANE E. BROGAN, JILL SINDT, AND ASHWIN VISWANATHAN

Intrathecal Drug Therapy

INDICATIONS

INTRATHecal DRUG DELIVERY SYSTEMS

Simple Percutaneous Intrathecal Catheter
Tunneled Intrathecal Catheter
Implantable Drug Delivery Systems

INTRATHecal VERSus EPIDURAL DRUG DELIVERY

IMPLANTABLE OR EXTERIORIZED INTRATHecal DRUG DELIVERY: COST ANALYSIS

OUTCOME STUDIES

PATIENT-CONTROLLED INTRATHecal ANALGESIA

PHARMACOLOGY

Opioids
Ziconotide
Local Anesthetics
Clonidine
Other Drugs

CONTRAINdications AND RISK MANAGEMENT

COMPLICATIONS AND SIDE EFFECTS

INTRATHecal THERAPy AND ONGOING ONCOLOGIC CARE

Spinal Chemoneurolysis

SPINAL CHEMONEUROLYSIS TECHNIQUE

Lumbosacral Neurolysis
Cervical and Thoracic Neurolysis

ADVERSE EFFECTS

CONTRAINDICATIONS

Celiac Plexus Block

INDICATIONS

ANATOMY OF THE CELIAC PLEXUS

GENERAL CONSIDERATIONS

ADVERSE EFFECTS

CELIAC PLEXUS BLOCK TECHNIQUES

   Posterior Approach to the Splanchnic Nerves and Celiac Plexus
   Anterior Approaches

OUTCOME STUDIES

LINKED ANGINA
ESOPHAGEAL DYSMOTILITY
SUSTAINED ESOPHAGEAL CONTRACTIONS
ESOPHAGEAL HYPERSENSITIVITY
ALTERED AUTONOMIC ACTIVITY
PSYCHOLOGICAL COMORBIDITY

Diagnosis of Noncardiac Chest Pain
CARDIOLOGY EVALUATION
GERD-RELATED NCCP
BARIUM ESOPHAGRAM
UPPER ENDOSCOPY
AMBULATORY 24-HOUR ESOPHAGEAL pH MONITORING
THE WIRELESS pH SYSTEM
THE PROTON PUMP INHIBITOR TEST
MULTICHANNEL INTRALUMINAL IMPEDANCE
ESOPHAGEAL DYSMOTILITY
ESOPHAGEAL MANOMETRY
PROVOCATIVE TESTING
EDROPHONIUM (TENSILON) TEST
ERGONOVINE STIMULATION TEST
PENTAGASTRIN STIMULATION TEST

Sensory Testing of the Esophagus
ACID PERFUSION TEST (BERNSTEIN TEST)
ELECTRICAL STIMULATION
INTRALUMINAL ULTRASONOGRAPHY
BALLOON DISTENSION
ESOPHAGEAL EVOKED POTENTIALS
BRAIN IMAGING
SENSORY TESTING—PITFALLS IN STUDY DESIGN
PSYCHOLOGICAL EVALUATION

Treatment
GERD-RELATED NCCP
NON–GERD-RELATED NCCP
PAIN MODULATORS
  Trazodone
  Serotonin Norepinephrine Reuptake Inhibitors
  Selective Serotonin Reuptake Inhibitors
  Adenosine Antagonists
  Octreotide
  Benzodiazepines
ENDOSCOPIC TREATMENT AND SURGERY FOR NCCP
JOHREI THERAPY
PSYCHOLOGICAL TREATMENT
FUTURE THERAPY

CHAPTER 63
Abdominal, Peritoneal, and Retroperitoneal Pain
DAVID JUSTIN LEVINthAL AND KLAUS BIELEFELDT

Clinical Approach to Abdominal Pain
PAIN LOCALIZATION AND CHARACTER
TIME COURSE
CONTEXTUAL INFORMATION
PHYSICAL EXAMINATION
DIAGNOSTIC TESTING IN ABDOMINAL PAIN

Mechanisms of Visceral Pain
CHAPTER 64

Pelvic Pain in Females
KATY VINCENT AND JANE MOORE

Acute Pelvic Pain
INTRODUCTION
OVERVIEW OF ASSESSMENT
GYNECOLOGIC FACTORS
Pelvic Inflammatory Disease
Adnexal Pathology
Hematometra/Hematocolpos
Acute Exacerbation of Chronic Pelvic Pain

COMPLICATIONS SPECIFIC TO PREGNANCY
Ectopic Pregnancy
Miscarriage
Fibroid Degeneration
Ovarian Cyst Accident
Ligamentous Stretch
Urinary Retention and Uterine Incarceration

COMPLICATIONS OF ASSISTED CONCEPTION
Ovarian Hyperstimulation Syndrome
Pelvic Infection

Dysmenorrhea
NONSTEROIDAL ANTI-INFLAMMATORY DRUGS
HORMONAL TREATMENTS
SURGICAL TREATMENTS
NONPHARMACOLOGIC INTERVENTIONS

Mittelschmerz
Chronic Pelvic Pain

INTRODUCTION
FACTORS ASSOCIATED WITH CHRONIC PELVIC PAIN
Social
Abuse
Psychological
Personality

OVERVIEW OF ASSESSMENT
History
Examination
Investigations
Therapeutic Trial
Diagnostic Laparoscopy
Empirical Treatment

THE IMPORTANCE OF VISCERAL HYPERSENSITIVITY IN
CHRONIC PELVIC PAIN
GYNECOLOGIC FACTORS IN CHRONIC PELVIC PAIN
   Endometriosis
   Adenomyosis
   Adhesions
   Chronic Pelvic Inflammatory Disease
   Pelvic Venous Congestion

GASTROINTESTINAL FACTORS IN CHRONIC PELVIC PAIN
   Irritable Bowel Syndrome
   Constipation

UROLOGIC FACTORS IN CHRONIC PELVIC PAIN
   Interstitial Cystitis/Bladder Pain Syndrome
   Urethral Syndrome

MUSCULOSKELETAL FACTORS IN CHRONIC PELVIC PAIN
   Fibromyalgia
   Trigger Points
   Pelvic Floor Abnormalities
   Hernia
   Sacroiliac Joint Pain

NEUROLOGIC FACTORS IN CHRONIC PELVIC PAIN
   Pudendal Neuropathy
   Neuropathy Secondary to a Pfannenstiel Incision

Dyspareunia

OVERVIEW
   Vaginismus
   Vulval Pain Syndromes
   Conclusion

CHAPTER 65
Pelvic Pain in Males
ANDREW BARANOWSKI

Taxonomy and Phenotyping Chronic Pelvic Pain
CLASSICAL PATHOLOGIES
PELVIC PAIN SYNDROMES AND NONPELVIC PAIN
SYNDROMES
   Male Urogenital Pain Syndromes
MALE-SPECIFIC PELVIC PAIN SYNDROMES
SUBCLASSIFICATION OF THE PELVIC PAIN SYNDROMES
BY ORGAN
THE IMPORTANCE OF TAXONOMY AND PHENOTYPING

Epidemiology
   INCIDENCE/PREVALENCE
      Prostate Pain Syndrome
      Scrotal Pain Syndrome
      Penile Pain Syndrome
   PRECIPITATING FACTORS

Mechanisms
   DIFFERENCES BETWEEN VISCERAL AND NONVISCERAL SOMATIC PAINS
   PERIPHERAL MECHANISMS
   CENTRAL MECHANISMS
   MUSCLES AND PELVIC PAIN
      Pelvic Muscle Pain Syndromes
      Spinal and Abdominal Muscle Pain Syndromes
   PELVIC NERVES AND PAIN
      Peripheral Nerve Pain Syndromes

Functional Problems and Male Pelvic Pain
Psychological Consequences of Male Pelvic Pain

Male Urogenital Pelvic Pain Syndromes—Treatment
   SEX DIFFERENCES AND THERAPIES
   SPECIFIC PAIN SYNDROME TREATMENTS
      Prostate Pain Syndrome
      Scrotal/Testicular/Epididymal Pain Syndromes

GENERIC TREATMENT APPROACH
   Psychology and Sexual Counseling
   Trigger Point Therapy
   Nerve Blocks
   Surgery
   Drugs
Neuromodulation
Overview and Conclusion

REGIONAL PAIN
CHAPTER 66
Cranial Neuralgias
MUHAMMAD HASSAN MAJEED AND ZAHID H. BAJWA

Classical Trigeminal Neuralgia

HISTORY
EPIDEMIOLOGY
ETIOLOGY AND PATHOPHYSIOLOGY
SYMPTOMS AND SIGNS
DIFFERENTIAL DIAGNOSIS
TREATMENT
Treatment—Medical Management
Treatment—Nerve and Neurolytic Blockade
Treatment—Surgical

Conclusion

CHAPTER 67
Facial Pain
ALAA ABD-ELSAYED, PAMELA J. HUGHES, AND AHMED M.T. RASLAN

Trigeminal and Other Cranial Nerve Neuropathic Conditions

TRIGEMINAL NEUROPATHY
Trigeminal Neuralgia Type 1
Trigeminal Neuralgia Type 2
Symptomatic Trigeminal Neuralgia
Neuropathic Trigeminal Neuralgia
Postherpetic Trigeminal Neuralgia
Deafferentation Trigeminal Neuralgia
Atypical Facial Pain

GLOSSOPHARYNGEAL NEURALGIA
NERVUS INTERMEDIUS NEURALGIA

Odontogenic and Temporomandibular Joint Disorders

ODONTOGENIC PAIN
Steps for Diagnosis
Dental Findings
Oral Soft Tissue Findings
Radiographic Examination

TEMPOROMANDIBULAR DISORDERS
Chronic Headache Disorders Causing Facial Pain
PRIMARY HEADACHE CONDITIONS
Migraine Headache
Tension Headache
Cluster Headache
Exertional Headache
Hypnic Headache

Secondary Headache Conditions
MEDICATION OVERUSE HEADACHE
SINUS HEADACHES
HEAD INJURY HEADACHES
SHORT-LASTING, UNILATERAL, NEURALGIFORM
HEADACHE ATTACKS WITH CONJUNCTIVAL INJECTION
AND TEARING
SHORT-LASTING, UNILATERAL, NEURALGIFORM
HEADACHE ATTACKS WITH CRANIAL AUTONOMIC
FEATURES
PAROXYSMAL HEMICRANIAS
CONTACT POINT HEADACHE

CHAPTER 68
Neck and Arm Pain
ANITA H. HICKEY AND ZAHID H. BAJWA
Anatomy of the Neck and Arm
CERVICAL SPINE
Ligaments of the Cervical Spine
MUSCULATURE OF THE NECK
THE VERTEBRAL CANAL
VERTEBRAL ARTERIES
CERVICAL NERVES
THE CERVICAL AND BRACHIAL PLEXUS
PECTORAL GIRDLE AND SHOULDER ANATOMY

Epidemiology of Neck and Arm Pain

History
Location/Radiation
Onset
Modifying Factors and Drug History
Associated Symptoms
Family History
Age and Psychosocial History
Past Medical History and Review of Systems
Surgical History
Physical Examination
LABORATORY EVALUATION
RADIOGRAPHIC STUDIES
Common Causes of Neck and Arm Pain
MECHANICAL NECK PAIN AND CERVICOGENIC HEADACHE
  Cervical Spondylosis and Radiculopathy
  Cervicogenic Headache
DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS
CERVICAL RADICULOPATHIES
UPPER EXTREMITY PERIPHERAL NERVE ENTRAPMENT SYNDROMES AND BRACHIAL PLEXUS NEUROPATHY
  Carpal Tunnel Syndrome
  Cubital Tunnel Syndrome
LESIONS OF THE BRACHIAL PLEXUS
  Acute Brachial Plexus Neuritis
  Thoracic Outlet Syndrome

CHAPTER 69
Chest Wall Pain
NARASIMHA R. GUNDAMRAJ AND STEVEN H. RICHEIMER
General Considerations
Anatomy of the Chest Wall
  SKELETAL STRUCTURES OF THE CHEST WALL
    Thoracic Spine
    Ribs
    Sternum
  JOINTS OF THE CHEST WALL
INTERCOSTAL SPACES
INTERCOSTAL NERVES
Neoplastic Chest Wall Pain
   EPIDURAL SPINAL CORD COMPRESSION
   SUPERIOR VENA CAVA SYNDROME
   COSTOPLEURAL SYNDROME
Nonneoplastic Chest Wall Pain
   NEUROPATHIC PAIN
       Neuropathic Pain of Central Origin
       Peripheral Neuropathic Chest Wall Pain
   CHEST WALL PAIN OF SKELETAL ORIGIN
       Abnormalities of the Thoracic Spine
       Costochondral Dislocation
       Chest Wall Pain of Sternal Origin
       Chest Wall Pain of Myofascial Origin
       Breast Pain
       Postsurgical Chest Wall Pain
   CHEST PAIN AND PSYCHOLOGICAL FACTORS
   CHEST WALL PAIN OF CARDIAC ORIGIN

Conclusion

Provisional Diagnosis

Ancillary Investigations

CLEARANCE
NOT INDICATED
MAGNETIC RESONANCE IMAGING
DISK STIMULATION
SINUVERTEBRAL NERVE BLOCKS
LUMBAR MEDIAL BRANCH BLOCKS
SACROILIAC JOINT BLOCKS
SACRAL LATERAL BRANCH BLOCKS

Treatment

GENERAL TREATMENTS

DRUG THERAPY
   Paracetamol (Acetaminophen)
   Nonsteroidal Anti-inflammatory Drugs
   Muscle Relaxants
   Benzodiazepines
   Antidepressants
   Pregabalin
Opioids

PHYSICAL MODALITIES
Physiotherapy
Massage
Traction
Manual Therapy
McKenzie Therapy
Transcutaneous Electrical Nerve Stimulation
Other Physical and Electrical Modalities
Lumbar Supports
Exercise Therapy

SIMPLE NEEDLE TREATMENTS
Acupuncture
Trigger Point Injection
Prolotherapy

BACK SCHOOL

PSYCHOLOGICAL INTERVENTIONS

MULTIDISCIPLINARY PAIN MANAGEMENT

FUNCTIONAL RESTORATION

SPECIFIC, TARGETED TREATMENTS
Discogenic Pain
Zygapophysial Joint Pain
Sacroiliac Pain

INVASIVE TREATMENTS
Implanted Devices
Spinal Surgery

Conclusion

CHAPTER 74

Surgery for Low Back Pain
YOUSSEF GHABRIAL AND NIKOLAI BOGDUK

Rationale
Effectiveness

BEFORE EVIDENCE-BASED MEDICINE
ADVENT OF EVIDENCE-BASED MEDICINE
SINCE EVIDENCE-BASED MEDICINE
Causes of Failed Back Surgery

MISMATCH: SURGERY NEEDED VERSUS SURGERY PERFORMED (“WRONG SURGERY”)
INCOMPLETE EVALUATION AND/OR DIAGNOSIS (“RESIDUAL PATHOLOGY”)
COMPLICATIONS
TECHNICAL FAILURE
RESIDUAL PATHOLOGY
  Spinal Pathology
  Extraspinal Pathology
RECURRENT PATHOLOGY
NEW PATHOLOGY

Structural Etiologies of Failed Back Surgery

FORAMINAL STENOSIS
PAINFUL DISK (DISCOGENIC PAIN)
DISK HERNIATION
FACET JOINT PAIN
SACROILIAC JOINT PAIN
SPINAL STENOSIS AND AXIAL LOW BACK PAIN
NEUROPATHIC PAIN
EPIDURAL FIBROSIS
DECONDITIONING

Psychological Factors in Failed Back Surgery (“Right Patient”)

Establishing the Diagnosis

ROLE OF THE HISTORY
  Preoperative Versus Current Pain
  Location of Pain (Especially Low Back Pain Versus Leg Pain)
  Response to Mechanical Changes
  Quality of Pain
TIME COURSE OF APPEARANCE OF PAIN
  Preoperative Low Back Pain or Leg Pain Never Improves or
Early Onset of Old Symptoms
New Leg Pain Soon after Surgery
Pain Improves but Recurs 1 to 6 Months after Surgery
Pain Improves but Recurs and Is Different

ROLE OF RADIOLOGIC EVALUATION OF FAILED BACK SURGERY
ROLE OF DIAGNOSTIC INJECTIONS
Anesthetic Injections
Provocation Disk Injections (Discography)

Treatments
NONSPECIFIC TREATMENTS
Rehabilitation and Exercise
Medications

SOME OF THE SPECIFIC TREATMENTS FOR SPECIFIC DISORDERS
Discogenic Pain
Facet Joint Pain
Sacroiliac Joint Pain
Spinal Stenosis
Neuropathic Pain
Lysis of Adhesions
Psychological Interventions
Reoperation

CHAPTER 76
Psychological Screening of Candidates for Spine Surgery or Placement of Implanted Devices
ROBERT EDWARDS AND ROBERT N. JAMISON

Introduction
SPINAL SURGERY
SPINAL CORD STIMULATION AND INTRATHECAL DRUG DELIVERY SYSTEMS
AFFECTIVE DISORDERS AS PREDICTORS OF OUTCOME
SOMATIZATION
PAIN SENSITIVITY
ANGER
Cognitive Factors
  COPING STRATEGIES
Behavioral Factors
  EARLY-LIFE TRAUMA AND ABUSE
  SUBSTANCE ABUSE
  COMPONENTS OF PSYCHOLOGICAL EVALUATIONS
  VALIDATED PSYCHOLOGICAL MEASURES
    Pain Intensity Measures
    Mood and Personality
    Functional Capacity and Activity Interference Measures
    Pain Beliefs
  ELECTRONIC PAIN ASSESSMENT PROGRAMS
Conclusion

PART FIVE
Methods for Symptomatic Control
PHARMACOLOGIC THERAPIES

CHAPTER 77
Rational Pharmacotherapy for Pain
ARTHUR G. LIPMAN

Drugs Are Both Underused and Overused in Pain Management
Pharmacotherapy Alone Is Rarely Optimal Therapy for Chronic Pain
EVERY USE OF MEDICATION FOR PAIN IS AN EXPERIMENT
PATIENT PREFERENCE: SYMPTOM CONTROL VERSUS SIDE EFFECTS
WHENEVER POSSIBLE TREAT THE CAUSE OF THE PAIN
SYNERGISM AND POTENTIATION
OUTCOMES ANALYSES OF PAIN PHARMACOTHERAPY
APPROVED DRUGS AND DRUGS FOR NONAPPROVED USES
RATIONAL PHARMACOTHERAPY

Conclusion

CHAPTER 78
Nonsteroidal Anti-inflammatory Drugs and Acetaminophen
ADAM C. YOUNG AND ASOKUMAR BUVRANENDRAN

Mechanism of Action
PROSTAGLANDIN SYNTHESIS AND PHARMACOLOGY
CENTRAL SITES OF ACTION
PERIPHERAL SITES OF ACTION
COX-1 AND COX-2 SELECTIVITY
  Induction of COX-2
Pharmacokinetics
ABSORPTION
  Oral
  Injectables
  Topical
  Intranasal
DISTRIBUTION
ELIMINATION
PATHOPHYSIOLOGIC CONDITIONS AFFECTING THE
KINETICS OF NSAIDS
Renal Failure
Hepatic Disease

Specific Drugs

SALICYLATES
Aspirin
Diflunisal

ACETIC ACID DERIVATIVES
Indomethacin
Sulindac
Tolmetin and Etodolac
Ketorolac
Diclofenac

PROPIONIC ACID DERIVATIVES
Ibuprofen
Ketoprofen
Fenoprofen
Naproxen
Oxaprozin

OXICAM DERIVATIVES
Meloxicam

COX-2 SELECTIVE NSAIDs
Celecoxib
Etoricoxib
Valdecoxib and Parecoxib

ACETAMINOPHEN
NSAID Combination Medications

SIDE EFFECTS, WARNINGS, AND CONTROVERSIES
Cardiovascular Effects
Allergy and Hypersensitivity
Gastrointestinal Toxicity
Hematologic Effects
Renal Toxicity
Hepatic Toxicity
Central Nervous System Effects

162
CHAPTER 79

Opioid Analgesics

CHARLES E. INTURRISI, DAVID S. CRAIG, AND ARTHUR G. LIPMAN

Classification Based on Interactions with an Opioid Receptor
Classification Based on Opioid Agonist or Antagonist Activity

Opioid Pharmacodynamics

CELLULAR, SYNAPTIC, AND CIRCUIT LEVEL EVENTS THAT INHIBIT PAIN TRANSMISSION

The Pharmacodynamic Effects of Opioids

Central Nervous System Opioid Effects

ANALGESIA
MOOD EFFECTS
SEDATION
NAUSEA AND VOMITING
RESPIRATORY DEPRESSION
CONSTRUCTION OF THE PUPIL
ANTITUSSIVE EFFECT
HYPOTHALAMIC EFFECTS
CENTRAL NERVOUS SYSTEM EXCITATION

OPIOID TOLERANCE, DEPENDENCE, AND ADDICTION

THE OPIOID-TOLERANT PATIENT AND OPIOID-INDUCED HYPERALGESIA

Clinically Observable Tolerance
Proposed Mechanisms of Tolerance

THE OPIOID-DEPENDENT PATIENT
THE OPIOID-ADDICTED PATIENT WITH PAIN

PERIPHERAL EFFECTS OF OPIOIDS

EFFECTS ON SMOOTH MUSCLE AND THE CARDIOVASCULAR SYSTEM
PRURITUS

OPIOID EFFECTS IN PREGNANCY AND ON THE NEONATE
ROUTES FOR OPIOID ADMINISTRATION
ALTERNATIVE NONINVASIVE ROUTES
SUBLINGUAL ADMINISTRATION
EPIDURAL, INTRATHECAL, AND INTRAVENTRICULAR ADMINISTRATION

Characteristics of Specific Opioids
MORPHINE
HYDROMORPHONE
METHADONE
LEVORPHANOL
OXYMORPHONE
OXYCODONE
FENTANYL
MEPERIDINE
CODEINE
HYDROCODONE
PROPOXYPHENE
TRAMADOL
TAPENTADOL
PENTAZOCINE, NALBUPHINE, AND BUTORPHANOL
BUPRENORPHINE

Abuse-Deterrent Opioid Formulations
Selecting among the Opioids for Clinical Use
Conclusions and Insights into the Future of Opioids for Pain
BIASED LIGANDS
DEDICATION

CHAPTER 80
Skeletal Muscle Relaxants and Analgesic Balms
AUSIM CHAGHTAI AND CHARLES E. ARGOFF

Skeletal Muscle Relaxants
MECHANISM OF ACTION
Types of Skeletal Muscle Relaxants
CENTRALLY ACTING SEDATIVE-HYPNOTIC MUSCLE RELAXANTS
Chlorzoxazone
Metaxalone
Methocarbamol
Carisoprodol

**ANTIHISTAMINE MUSCLE RELAXANT**
Orphenadrine Citrate

**TRICYCLIC ANTIDEPRESSANT-LIKE MUSCLE RELAXANT**
Cyclobenzaprine

**γ-AMINOBUTYRIC ACID AGONIST MUSCLE RELAXANTS**
Diazepam
Baclofen

**CENTRAL \( \alpha_2 \) AGONIST MUSCLE RELAXANTS**
Tizanidine

Acute Low Back Pain
Chronic Low Back Pain
Topical Analgesic Balms

**TOPICAL COUNTERIRRITANTS**

Conclusion

CHAPTER 81
Neuropathic Pain Pharmacotherapy
ELON EISENBERG, SIMON VULFSONS, AND DAVID M. PETERSON

**Antidepressants**

TRICYCLIC ANTIDEPRESSANTS
SELECTIVE SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS
SELECTIVE SEROTONIN REUPTAKE INHIBITORS

**Antiepileptics**
PREGABALIN
GABAPENTIN
CARBAMAZEPINE
OXCARBAZEPINE
LAMOTRIGINE
VALPROATE
OTHER ANTICONVULSANTS

**Opioids**
Tramadol
Tapentadol
NMDA Receptor Antagonists
Systemic Sodium Channel Blockers
Simple Analgesics
Nonsteroidal Anti-inflammatory Agents
Topical Agents
  CAPSAICIN
  TOPICAL LIDOCAINE PATCHES
  TOPICAL KETAMINE
Cannabinoids
Drug Combinations
Future Drugs
Evidence-Based Recommendations for Drug Therapy in Neuropathic Pain
Intrathecal Drugs for Neuropathic Pain
Neuropathic Pain—Not Only Pharmacotherapy

CHAPTER 82
Local Anesthetics
MICHAEL M. BOTTROS, LARA WILEY CROCK, AND SIMON HAROUTOUNIAN
Physicochemical Properties of Local Anesthetics
  MOLECULAR STRUCTURE
  CHIRALITY
  ACID–BASE BALANCE
  LIPOPHILIC–HYDROPHILIC BALANCE
Local Anesthetic Pharmacology
  PHARMACODYNAMICS
  PHARMACOKINETICS
    Absorption
    Distribution
    Biotransformation and Excretion
    Effects of Disease States on Local Anesthetic Pharmacokinetics
Regional Administration of Local Anesthetics for Pain Relief
  DIFFERENTIAL BLOCKADE
  SITE OF INJECTION
PSYCHOLOGICAL TECHNIQUES

CHAPTER 83

Anger and Pain

R. JOSHUA WOOTTON

Cultural Background
Psychoanalytic Background
Current Research in Anger and Its Relation to Pain
  PHYSIOLOGIC MECHANISMS IN ANGER AND PAIN RESEARCH
  PSYCHOLOGICAL CONSTRUCTS IN ANGER AND PAIN RESEARCH
ANGER MANAGEMENT STYLE
  Anger-In
  Anger-Out
Opioid Deficit Hypothesis and the Role of Endogenous Opioid
CHAPTER 84
Cognitive-Behavioral Therapy for Chronic Pain
LAYNE A. GOBLE, CHRISTOPHER D. SLETTEN, TAYLOR CROUCH, AND KELLY BARTH

Introduction
HISTORY AND DEVELOPMENT OF COGNITIVE-BEHAVIORAL THERAPY FOR PAIN
EVIDENCE FOR COGNITIVE-BEHAVIORAL THERAPY FOR CHRONIC PAIN

Components of Cognitive-Behavioral Therapy for Chronic Pain
CHRONIC PAIN PSYCHOEDUCATION
  Education about the Neurobiology of Chronic Pain
  Resetting Expectations about the Outcomes of Chronic Pain—the A-B-C Model
  Changing Behaviors—SMART Method
RELAXATION TECHNIQUES
BEHAVIORAL ACTIVATION AND TIME-BASED PACING
SLEEP HYGIENE
COGNITIVE RESTRUCTURING
COMMUNICATION SKILLS
MAINTENANCE AND RELAPSE PREVENTION
   Maintaining Treatment Gains
THIRD-WAVE THERAPIES—ACCEPTANCE AND
COMMITMENT THERAPY
TREATING COMORBID CONDITIONS
   Depression and Anxiety
   Posttraumatic Stress Disorder
COGNITIVE-BEHAVIORAL THERAPY WITHIN
INTERPROFESSIONAL PAIN PROGRAMS AND PAIN
REHABILITATION PROGRAMS
   Effectiveness of Interprofessional Pain Management Programs
   and Pain Rehabilitation Programs
COGNITIVE-BEHAVIORAL THERAPY TO PREVENT THE
TRANSITION FROM ACUTE TO CHRONIC PAIN

Summary

CHAPTER 85
Pain and Anxiety and Depression
LIN YU AND LANCE M. McCracken
   Prevalence of Anxiety and Depressive Disorders in Chronic Pain
   Impact of Anxiety and Depressive Disorders on Functioning
   The Interaction of Anxiety, Depression, and Chronic Pain
      THE FEAR-AVOIDANCE MODEL
A Contextual Behavioral Approach to Anxiety and Depressive
Disorders
Treatment of Anxiety and Depressive Disorders
   EVIDENCE FROM PHARMACOLOGIC APPROACHES
   EVIDENCE FROM PSYCHOLOGICAL APPROACHES
   COGNITIVE-BEHAVIORAL THERAPY FOR CHRONIC
PAIN: EFFECTS ON DEPRESSION AND ANXIETY
Developments in Cognitive Behavioral Therapy
Summary

CHAPTER 86
Hypnosis
JEANNE HERNANDEZ
   History of Hypnosis in Pain and Symptom Control
Hypnosis by Definition

CONSCIOUS, UNCONSCIOUS, AND CONTENT OF CONSCIOUSNESS

Central Mechanisms

CENTRAL MECHANISMS OF HYPNOSIS
HIGH AND LOW HYPNOTIZABILITY
CENTRAL MECHANISMS OF HYPNOTIC ANALGESIA

Pain as a Plastic Experience

Testing Hypnotizability

Current Research and Applications of Medical Hypnosis for Pain

EFFICACY AND EFFECTIVENESS

REVIEW OF RESEARCH STUDIES ACCORDING TO PAIN PROBLEMS OR SITUATIONS
  Perioperative and Procedural Uses
  Complex Regional Pain Syndrome
  Phantom Limb Pain
  Burns
  Dentistry
  Pediatric Pain
  Irritable Bowel Syndrome
  Headaches
  Cancer
  Osteoarthritis

Medical Hypnosis Techniques

PRINCIPLES OF PREPARATION, INDUCTION, AND SUGGESTIONS

COMMON INDUCTION PROCEDURES
SUGGESTIONS AND IMAGERY

Chronic Pain Management

ERICKSONIAN NATURALISTIC APPROACHES TO PAIN AND SYMPTOM MANAGEMENT

Conclusions

CHAPTER 87

Group Therapy for Chronic Pain

MELISSA A. DAY AND BEVERLY E. THORN
Rationale and Basic Considerations of Group Treatment for Pain

EVIDENCE FOR EFFICACY OF GROUP TREATMENT FOR CHRONIC PAIN MANAGEMENT
GROUP VERSUS INDIVIDUAL TREATMENT
GROUP COGNITIVE-BEHAVIORAL THERAPY VERSUS WAIT-LIST, TREATMENT AS USUAL, OR OTHER GROUP TREATMENTS
BEHAVIORAL VERSUS EXERCISE AND PHYSICAL THERAPY GROUP TREATMENTS
MINDFULNESS-BASED APPROACHES TO PAIN MANAGEMENT
ACCEPTANCE-BASED APPROACHES TO PAIN MANAGEMENT

Factors Affecting Psychotherapeutic Outcome
THE IMPORTANCE OF COGNITIVE CHANGE
COMPLIANCE WITH HOMEWORK AND SKILLS PRACTICE TO MAINTAIN TREATMENT GAINS
IMPORTANCE OF THERAPIST SKILL AND ADEQUATE TIME WITH THERAPIST
IMPORTANCE OF GROUP PROCESS

Advantages of Group Treatment
EFFICIENCY AND COST-EFFECTIVENESS
SOCIAL PROXIMITY AND SUPPORT
VICARIOUS LEARNING AND MODELING OF COLLABORATIVE APPROACH
INTERPERSONAL GROUP PROCESS

Practical Issues
OPEN VERSUS CLOSED GROUPS
LENGTH OF GROUP
NUMBER OF PARTICIPANTS
INDIVIDUALS WHO MAY BE INAPPROPRIATE FOR GROUPS

Summary and Conclusions
Future Directions
Appendix 87.1: Search Strategies
CHAPTER 88
Motivating Chronic Pain Patients for Behavioral Change
AKIKO OKIFUJI, EMILY HAGN, CHRISTINA ELISE BOKAT, AND DENNIS C. TURK

Neural Mechanisms of Motivation
Concept of Readiness to Change: Transtheoretical Model of Behavior Change
MOTIVATION ENHANCEMENT THERAPY
Help Patients Recognize the Problems and Goals
DECISIONAL BALANCE
SELF-MOTIVATIONAL STATEMENTS
What Not to Do in Motivation Enhancement Therapy
Dealing with Setbacks and Resistance
SIMPLE REFLECTION
AMPLIFIED REFLECTION
DOUBLE-SIDED REFLECTION
AGREEMENT WITH TWIST
PERSONAL CHOICE AND CONTROL
SHIFTING FOCUS
Research Outcomes
Volitional Approach: Implementation Intentions
IMPLEMENTATION INTENTIONS: OUTCOMES
Conclusion

PHYSICAL AND OTHER NONINTERVENTIONAL THERAPEUTIC MODALITIES

CHAPTER 89
Basic Concepts in Biomechanics and Musculoskeletal Rehabilitation
MAUREEN YOUNG SHIN NOH, BENJAMIN C. SOYDAN, AND ANAND B. JOSHI

Basic Considerations
KINETIC CHAIN THEORY
ADVERSE NEURAL TENSION
  Lower Limb
  Upper Limb
NEUROMUSCULAR CONTROL
BIOMECHANICAL CONSIDERATIONS IN THE SETTING OF COMMON PHYSICAL EXAMINATION TECHNIQUES
Biomechanical Considerations in Common Musculoskeletal Pain Syndromes

CERVICALGIA
PERISCAPULAR AND THORACIC PAIN
LUMBAR PAIN
SACROILIAC AND HIP GIRDLE PAIN

Conclusion

CHAPTER 90

Pain Rehabilitation
STEVEN P. STANOS AND WILSON J. CHANG

Historical Overview: Pain Rehabilitation and Functional Restoration

HISTORY OF PAIN REHABILITATION
HISTORY OF FUNCTIONAL RESTORATION AND WORK REHABILITATION
WHAT IS PAIN REHABILITATION?
STAKEHOLDERS IN REHABILITATION

Models of Rehabilitation

BIOPSYCHOSOCIAL APPROACH VERSUS BIOMEDICAL MODEL FOR PAIN MANAGEMENT

TREATMENT APPROACHES: PAIN REHABILITATION
Acute Rehabilitation
More Comprehensive Team Models: A Pain Continuum
Multidisciplinary Treatment
Interdisciplinary Treatment
Outcomes of Multi- and Interdisciplinary Treatment Programs

Team Building and Stakeholder Coordination

CASE MANAGEMENT
APPLYING TEAM VALUES

Assessment, Goal Setting, and Progression through Treatment

PAIN REHABILITATION PRINCIPLES

Rehabilitation Specialists: Activities and Conceptual Models

THE THERAPIST’S ROLE: BUILDING AN EFFECTIVE THERAPEUTIC RELATIONSHIP

CHAPTER 115
The Future of Pain Medicine: An Epilogue
SCOTT M. FISHMAN AND JAMES P. RATHMELL

Index
In order to treat something we first must learn to recognize it.
—Sir William Osler

In order to treat something we first must learn to recognize it.
—Sir William Osler

Through the ages, pain and suffering have been the primary reasons why patients sought medical care. But what pain is (an independent sense, an emotion, an experience, . . . ) has been considered and argued by philosophers and investigators alike to the present day. The International Association for the Study of Pain (www.iasp-pain.org) defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” Pain is always a subjective, personal, and unpleasant experience. This chapter reviews ideas and concepts about pain, including how our mental constructs shape our understanding, and then treatment of this complex experience we call pain. This chapter closes with a discussion of how the medical subspecialty is evolving within the broader context of medical specialization and thoughts for future development.
Pain Understood as Part of a Larger Philosophy or Worldview

Since the beginning of time, humans have been born through a painful process, and the experience of suffering remains universal. The meaning of pain reflects the contemporary spirit of the age and, therefore, has changed over recorded history as worldviews changed. Among the earliest systems of pain management, dating back to the Stone Age, was Chinese acupuncture, theoretically based on the philosophy of imbalances of yin and yang affecting qi and blood flow. Thousands of years ago, Egyptians considered the experience of pain to be a god or disincarnate spirit afflicting the heart, which was conceptualized as the center of emotion. Galen, and later Aristotle, described pain as an emotional experience, or “a passion of the soul.”

An important concept dating from antiquity that persisted until the 19th century was the theory of importance of the four humors. This worldview was espoused by Greek philosophers in approximately 400 BC and later applied to medicine by Hippocrates, who described humors as related to one of the four constitutions, shown in Table 1.1. Seasonal changes evoked pain, and certain disorders, such as migraine, were associated with specific humors (e.g., excessive cold humors thought to result in a mucus discharge requiring application of “hot effusions” to the head).

<table>

</tr>
</tbody>
</table>

Consistent with this ideology was the custom of treating pain by applying “opposites” such as hot applications to the head to counterbalance and evacuate “cold” humors of headaches. Based on the humor theory and treatment by “opposites” was a technique called cupping. Warm suction cups were applied to the skin that on cooling resulted in raised reddened welts thought to “draw out” any unbalanced...
humors.\textsuperscript{6}

Later, during the Middle Ages, coincident with the spread of Christianity, pain, not surprisingly, was explained in a spiritual, religious context. Medieval life has been described as short, cheap, and brutish, especially for the lower classes, with pain accepted as the universal lot of mankind. Little is known of how pain was actually treated during this period, but a suffering Christ, martyred saints, and the concept of physical pain in purgatory originated around the 12th century AD.\textsuperscript{6,7} Commonly revered was the iconography of tortured saints with ecstatic faces depicting pain as a spiritual discipline bringing the saints closer to God, relieved primarily by prayer and meditation. A clear example of pain as ennobling was St. Ignatius Loyola’s habit of wearing ropes and chains cutting into the skin and encouraging other humiliations of the flesh to enhance his spiritual development.\textsuperscript{3}

An interesting example of pain as a function of the sociologic concepts of the day is the rise and fall of the diagnosis of hysteria, common in the 17th century and virtually nonexistent today. Thomas Sydenham (Fig. 1.1), in 1681, wrote, “Of all chronic diseases hysteria—unless I err—is the commonest.”\textsuperscript{8} The cardinal symptom of this condition was unexplained pain. In mid-19th century Europe and America, hysteria was virtually everywhere, found in every community. Invalids, mostly females, filled homes, spas, and convalescent facilities at the turn of the 19th century. This mysterious syndrome, afflicting only middle and upper class females, was treated by complete social isolation, confinement to bed, and a total prohibition on any form of intellectual activity, even sewing or reading (CP Gilman as quoted in Rey\textsuperscript{9}). As the social situation and educational opportunities for women improved, this disorder almost totally disappeared, a public health success on the order of magnitude of the eradication of yellow fever. In the 21st century, fibromyalgia, although a commonly diagnosed condition in Western countries, interestingly enough, is either underreported or not significantly present in Asian and developing country populations.
Another very clear link between mental state and the perception and control of pain is apparent in the work of the German physician Franz Anton Mesmer. In 1766, he published his doctoral dissertation entitled “On the Influence of the Planets on the Human Body,” describing animal (or life spirit) magnetism as a force to cure many ills. He used iron magnets to treat various diseases, amplifying the magnetic fields with room-sized Leyden jars. His demonstrations of his technique, combining hypnotism with spectacle, included the wearing of brightly colored robes in dimly lit ritualistic séances, with soft music playing from a glass harmonium. He invoked magnetic power with poles either held or waved over the patient and his techniques were an early rival to ether anesthesia as a way to relieve pain during surgical procedures. Mesmerism was such a common form of pain therapy during his day that Robert Liston reportedly exclaimed after the successful administration of ether anesthesia in an early above-knee operation, “This Yankee Dodge beats mesmerism hollow.” Mesmerism was based on the larger generally accepted theory...
of vitalism which posited that every part of a living thing was endowed with sensibility. The energy or force which animated a living organism was capable of being stimulated or consumed. In disease, pain was necessary to produce a “crisis” which rid the patient of original pain by stimulating the diminishing energy.6

A further development of the link between mind and body and the understanding of pain was the landmark development of Freudian theory in understanding subconscious influences on pain perception and behavior. The link between the unconscious mind and physical sensation in hysterical conversion disorders was posited as an explanation for psychogenic pain and continues to be influential today. This conceptual paradigm was expanded in the 1970s by the psychiatrist George L. Engel who demonstrated the link between chronic pain and psychiatric illness.13 Later, psychiatrists, psychologists, and social scientists, including Thomas Szasz,14 Allan Walters,15 and Harold Merskey,16 explored social situations, psychological character traits, and the effects of past life experiences in understanding chronic pain in patients. Depression, stress, and personality, in addition to physiologic mechanisms, have proven to be critical grounds for investigation and therapy. From these early studies, investigating the mind–body interface of pain grew the cognitive-behavioral school of pain therapy in the 1980s that is widely employed today, emphasizing the development of coping mechanisms to deal with chronic pain as a basic component of interdisciplinary pain programs. The concept of pain, not only as a physiologic response to stimuli but as a more complicated construct, incorporating social, behavioral, and psychological responses as well, is an intellectual milestone that has inspired a wealth of investigations and patient treatment options. New areas of investigation now include pain in relationship to social setting, gender, national, ethnic, and racial background as well as differences in coping ability and psychiatric comorbidities. Considerations of vocational and legal environment as well as family and interpersonal dynamics are also relevant to the understanding and care of individual patients.

This global philosophy of pain as only part of an entire life experience can best be summed up in the words of Alexander Pope in his Essay on Man in 1733:
Say what the use, were finer optics giv‘n,
T’ inspect a mite, not comprehend the heav’n?
Or touch, if tremblingly alive all o’er,
To smart and agonize at ev’ry pore?
Or, quick effluvia darting thro’ the brain,
Die of a rose in aromatic pain?\(^{17}\)

**Mechanistic Views of Pain**

In counterpoint to the holistic philosophical consideration of pain was mechanism, the philosophical mind set suggesting that the human body functions as a simple machine with pain being the result of its malfunction.\(^{18}\) This viewpoint is clearly seen in Descartes’ *Passions of the Soul* in 1649 where he compares a human being to a watch:

> [T]he difference between the body of a living man and that of a dead man is just like the difference between, on the one hand, a watch or other automaton (that is, a self-moving machine) when it is wound up and contains in itself the corporeal principle of the movements for which it is designed . . . ; and, on the other hand, the same watch or machine when it is broken and the principle of its movement ceases to be active.\(^{19}\)

How did the mechanistic view of the body develop and even supersede traditional theologic and philosophical explanations for pain? Early anatomical studies were conducted beginning with Galen of Pergamum (130–201 AD) and Avicenna (*Fig. 1.2*), the Persian Muslim polymath (980–1037 AD), forming an intellectual basis for pain as an actual physical sensation rather than as a mental, spiritual dilemma. Later, in the 14th through 17th centuries, the Renaissance cultural movement questioned the basis of all knowledge, including ideas about the human body and the experience of pain. Empiricism and the development of scientific inquiry with direct observation into the mysteries of life became the basis for advances in both medical understanding and treatment, including the now commonly accepted neurologic basis of pain. Extended wars on the continent between France and Spain resulted in bullet and musket ball injuries that tore the skin, forcing surgical removal and amputation.
Wounds were bound and foreign bodies extracted, originally posited to prevent leakage of the “vital force” or to inhibit the entrance of animal spirits into the injured body. Gradually, direct observation of the circulation of the blood by William Harvey\textsuperscript{20} in 1628 and the direct anatomical studies of Descartes (Fig. 1.3)\textsuperscript{19} in 1662, elucidating sensory physiology became the theoretical basis for further exploration in the 18th and 19th centuries.

\textbf{FIGURE 1.2} Avicenna. (Courtesy of the National Library of Medicine.)
19TH CENTURY—PAIN AS A SPECIFIC SENSE
In 1811, Charles Bell (Fig. 1.4), an anatomist in Edinburgh, Scotland, published a monograph in which he described new and important evidence for the specificity of function of peripheral nerves. Bell proposed differences in function between the dorsal and ventral roots of the spinal cord, writing that “. . . the nerves of sense and nerves of motion . . . are distinct . . .” Bell’s discovery that ventral root stimulation controlled muscle contraction was followed by François Magendie’s (Fig. 1.5) report in 1822 that sectioning posterior (dorsal) nerve roots resulted in paralysis and insensitivity of the corresponding limbs, confirming that the dorsal roots are afferent. The result of these discoveries regarding the functions of the spinal roots is now known as the Bell-Magendie law (confirmed in 1831 by Johannes Müller).
FIGURE 1.4  Sir Charles Bell. (Courtesy of the National Library of Medicine.)

FIGURE 1.5  François Magendie. (Courtesy of the National Library of Medicine.)
Johannes Müller (Fig. 1.6)\textsuperscript{23} was a precocious and influential German investigator who advanced in 1826 at the age of 25 years the Law of Specific Nerve Energies, which laid out the basic concept of modern sensory physiology (cf. Handwerker and Brune\textsuperscript{24}). Müller’s “law” emphasized that the quality of sensation depends not on the stimulus but on the sense organ and sensory pathway stimulated. Müller’s law was not advanced in the context of pain as he was studying at that time vision. He considered the sensation of sound to be the “specific energy” of the acoustic nerve, and the sensation of light the particular “energy” of the visual nerve. In 1858, Moritz Schiff\textsuperscript{25} established, based on studies of the effects of spinal cord lesions, that separate spinal pathways conveyed tactile, temperature, and pain sensations. On the basis of his studies, Schiff proposed that pain was an independent sensation (a specific sense). Schiff’s findings were subsequently confirmed and extended by Charles-Édouard Brown-Séquard and Sir William Richard Gowers, establishing the importance of spinal pathways for conducting information about painful stimuli applied in the periphery.
Alfred Goldscheider (Fig. 1.7) and Max von Frey (Fig. 1.8) were contemporaries, adversaries, and also important to the history of pain research. Their divergent interpretations and conclusions from their research fostered and supported debate about the “pain” sensitivity of pressure points in skin well into the 20th century. In 1881, Goldscheider, a German army physician, demonstrated in his dissertation (and independently of the Swedish physiologist Magnus Blix), spatially discontinuous warm and cold spots in the skin, thus confirming Müller’s Law of Specific Nerve Energies. Goldscheider reported that stimulation of a cold point always produced the sensation of cold whether activated by a cold metal rod or by electrical stimulation. Goldscheider also reported that stimulation of temperature points did not produce a sensation of pain and advanced therefore the existence of tactile and pain points in skin.24,26

**FIGURE 1.7** Alfred Goldscheider. (Courtesy of the National Library of Medicine.)
Max von Frey was a systematic and methodical investigator interested in the skin as a sense organ and who today is largely (and incorrectly) credited with first documenting “pain points” in skin (Fig. 1.9). Using pig bristles and horsehairs of various diameters and stiffness, thus requiring different forces to bend when applied perpendicular to the skin, von Frey carefully mapped pressure points (Druckpunkte) and pain points (Schmerzpunkte) on the back of the hand.\textsuperscript{24,27} Max von Frey believed that the critical event producing pain from the skin was excitation of pain-conducting nerve fibers in peripheral nerves and that different types of sensory spots (warm, cool, pressure, pain) were associated with distinct structural elements in the skin. In the aggregate, at the turn of the 20th century, it was generally agreed that skin contained a number of nonuniformly distributed, distinct receptive end organs, each representing a particular kind of sensibility—pressure, warmth, cold and pain—and each responding only to its appropriate stimulus (termed subsequently by
AFFERENT SIGNALING

In the latter part of the 19th century and into the 20th century, however, arguments against pain as a specific skin sense were advanced. In particular, the advent of electrophysiology as a research approach contributed specific information about afferent fiber types (i.e., A and C fibers) and their responses to applied stimuli. The pioneering contributions of anatomists and physiologists in this period of time, several of whom were subsequently recognized with Nobel Prizes for revealing the structure and physiology of the nervous system (e.g., Adrian, Erlanger, Gasser, Golgi, Ramón y Cajal, Sherrington), were relevant to but did not specifically focus on pain (cf. Perl\textsuperscript{28}). The contributions of the eminent British physiologist, Charles Scott Sherrington (Fig. 1.10), however, are remarkable for several reasons. Aware that pain commonly arises from injured tissue, Sherrington avoided labeling stimuli based on their physical character, instead naming stimuli that threatened or caused tissue damage “nocuous” (noxious). Importantly, he understood the distinction between pain and the neural encoding of noxious events, which he termed nociception, and named the sense organ in skin that responded to noxious stimuli a nociceptor.\textsuperscript{29,*}
Alfred Goldscheider, who initially supported the existence of pain sensory points, subsequently denied their existence and instead adopted the idea that pain arose from intense stimulation of pressure points. This “intensity theory” did not survive evidence that intense, even maximal stimulation of sense organs that respond to innocuous stimuli does not generate pain-associated reactions. In light of these and other evidence, John Paul Nafe, an American psychologist, formalized what became referred to as pattern theory. He posited that all sensation arises from the spatial and temporal patterns of responses of afferent neurons rather than the result of activation of specific receptors or pathways. In 1955, Sinclair and Weddell expanded the concept, emphasizing that all afferent endings, except those innervating hair follicles, are similar, and it is only the pattern that is important in sensory discrimination. Based largely on clinical observations, other investigators focused on the role of the spinal dorsal horn, suggesting that pain resulted from the “summation” of afferent inputs rather than the “intensity” of the input or its spatiotemporal pattern. The American physician, William K. Livingston, suggested that pathologic input from the body activates reverberating circuits in spinal interneurons that subsequently can be triggered by normally innocuous afferent input (cf. Melzack and Wall). The concept of central summation, coupled with growing appreciation of spinal modulation of afferent input, led to the introduction in 1965 by
Ronald Melzack and Patrick Wall of a new theory of pain, the gate control theory.

**GATE CONTROL THEORY**

As reviewed earlier, specificity, intensity, and pattern theories about pain were not entirely exclusive in the writings of Goldscheider and von Frey. Even Müller, whose “laws” underlie the foundation of “specificity theory,” understood that peripheral nerves did not feel pain and that it was their excitation of the central nervous system that determined modality and quality of sensation. Although Goldscheider embraced concepts of “intensity theory,” he also was aware of the notion of central inhibition, a component of pattern and summation theories of pain. The complexity of pain, today recognized as comprising sensory, emotional, and drive state components, however, could not be adequately explained as either a specific (“labeled line”) pathway, spatiotemporal pattern of afferent input, or central summation of inputs. These often conflicting paradigms were reviewed and critically evaluated, and the prevailing basic and clinical evidence formulated as a new theory of pain by the Canadian psychologist Melzack and the British physiologist Wall (Figs. 1.11 and 1.12) while working together at the Massachusetts Institute of Technology. The gate control theory most directly challenged specificity theory and generated both high praise and strong opposition to the underlying assumptions on which the theory was based (cf. Perl28). The gate control theory was (and remains) heuristically important, providing (1) a conceptual framework that challenged long-held views about pain mechanisms as well as (2) an experimentally testable model that continues to the present day to stimulate research into mechanisms of pain. The basic proposition of the theory is that information arriving in the spinal cord via C fibers is modulated through presynaptic inhibition exerted by Aβ fibers. The gate was placed by Melzack and Wall in the substantia gelatinosa and, importantly, its output modulated by supraspinal influences. Many of the underlying assumptions of the gate control theory were immediately challenged and then or since shown to be incorrect (cf. Perl28). For example, specific end organs that encode intensities of noxious stimuli (nociceptors) have been widely documented in virtually all tissues, the
roles of A and C fibers in pain are far more complex than envisioned in 1965, and the spinal dorsal horn substantia gelatinosa is not the location of a presynaptic “gate” for pain. Like Müller’s Law of Specific Nerve Energies, introduction of the gate control theory was a seminal event in the pain field that has shaped thinking and research to the present day. It is now more than 50 years since its introduction, having been cited nearly 5,500 times through 2017, and remains a facile means of “explaining” pain to the layman.

Treatments for Pain

The rationale for choosing one form of pain treatment over another more often reflects the philosophical worldview of the physician more than the patient’s presenting condition. Physicians who are focused on the patient’s adaptation to life might focus on issues of lifestyle, stress, and emotional upheaval and assist the patient to work toward more adaptive behavioral responses to their pain. Physicians who see pain in mechanistic terms most likely will look for the anatomic foci of pain and be confounded if the source of the suffering is unclear. In the first, older, historical paradigm, pain is a part of an entire life and the enhancing adaptation to life is also needed to manage painful conditions. In the second, a specific anatomical or physiologic lesion is sought with therapy specifically directed toward the underlying pathology.
Cognitive Treatment for Pain

The fundamental significance of the word pain in English is derived from the Latin word poena, meaning punishment, and its relief was through prayer. This reflects the supposed cause of the pain being harm inflicted by the powers above for putative wrongdoing. Prior to the 18th century, nonspecific therapies were employed for many types of pain, including acupuncture, the application of humoral opposites, bloodletting, purging, topical and oral herbal compounds, and distraction by creating a competing, more severe pain. To better define why patients experienced pain and, presumably, how to treat it, physicians attempted classification by causes. However, treatment options were still limited. During the Roman emperor Trajan’s time, a noted physician recorded 13 causes of pain. Avicenna, a noted Muslim healer in the early 11th century, described 15 separate causes. And Hahnemann, the founder of homeopathy, listed 75. However, nonspecific treatments such as mesmerism and hypnotism, and even general anesthetics, were based on a whole body cure rather than a mechanistic view of pain. Later, cognitive-behavioral therapy and palliative care focused on the care of the whole person as a human being in need of adaptive coping skills. Early work in the 1950s by Engel, based on Freud’s theoretical ideals, explored the link between suffering from pain and psychiatric diagnosis. Merskey and Spear, in the mid-1960s, confirmed that chronic pain patients also often had coexisting psychiatric morbidity. Henry Beecher, in the battlefields of World War II, observed that seriously wounded soldiers reported less pain than civilian patients in the Massachusetts General Hospital recovery room. Their injury may have been subjectively interpreted as a cause of removal from harm and their return home as a war survivor. Later, however, these same patients would complain loudly about a minor insult such as venous puncture, causing Beecher to conclude that the experience of pain was derived from a complex interaction between physical sensation, cognition, and an emotional reaction.

Dame Cicely Saunders (Fig. 1.13), founder of the hospice movement in Great Britain and throughout the world, championed the idea of “total pain” emphasizing the holistic concept of patient-centered pain.
management. Similarly, John Bonica (Fig. 1.14) instituted in 1947 a multidisciplinary approach to treat pain in World War II veterans with complex multifocal persistent pain. Cultivating the multidisciplinary approach to pain management, Bonica later organized a multidisciplinary conference held in Issaquah, Washington, in May 1973 that was attended by more than 300 pain clinicians and researchers of various disciplines. Discussions among attendees at this meeting provided the impetus for the foundation on which the International Association for the Study of Pain was established.

Pharmacologic Treatment of Pain

The development of pharmacology as a science parallels the treatment of painful conditions by medications. Alcohol and morphine were proven antidotes to pain. In the mid-17th century, Thomas Sydenham concocted laudanum, the ubiquitous mix combining sherry, wine, opium, saffron, cinnamon, and clove and used to treat everything from dysentery to hysteria and gout. In South America, coca leaves were in common use, both as an orally chewed remedy for altitude sickness and physical pain and as a topical treatment. The alkaloid cocaine was isolated by Albert Niemann in his 1860s autoexperimentation and was originally touted as a cure for alcohol and morphine addiction. Carl Koller, in 1884, demonstrated the local anesthetic effects of cocaine in reducing corneal movement during eye surgery.

As chemical analysis became more sophisticated, opium, a long known
treatment for pain, was studied by the pharmacist Serturner who isolated “the soporific principle” from the compound in 1806. Despite being well-known to herbalists, the first scientific report of the power of willow derivatives was reported in a paper to the Royal Society of Medicine in London in 1763 by the Reverend Edmund Stone from Chipping Norton, Oxfordshire.\(^{42}\) The overuse of quinine in the early 19th century led to a shortage of the Peruvian cinchona trees, and therefore, there were increased efforts to isolate, characterize, and then commercially synthesize pain-relieving compounds. In 1829, the French pharmacist Henri Leroux extracted the active compound in willow leaves and bark that had been used in application to painful joints.

Later, in 1873, Charles von Gerhardt prepared salicylic acid by combining sodium salicylate with acetyl chloride to produce acetylsalicylic acid, or aspirin. The benefit of adding the acetyl group was decreased irritation to mucous membranes of the mouth, esophagus, and stomach and avoidance of the bitter alkaloid taste.\(^{43}\) Clinically, the benefits of this newly synthesized product were reported in treating acute rheumatism by Thomas J. MacLagan in 1876, over a century after Reverend Stone’s first report.\(^{44}\)

Two other landmarks that marked clear leaps forward in the pharmacologic treatment of pain were the development of the hypodermic needle by Rynd\(^{45}\) and the syringe by Wood (RD Mann as cited in Birk\(^{46}\)), permitting injection of analgesics and anesthetics. Morton’s 1846 landmark demonstration of ether anesthesia, following Crawford Long’s earlier application of ether anesthesia in 1843, marked a new era of surgical anesthesia.

**Anatomically Specific Treatments for Pain**

In contrast, the majority of the treatment options for pain in the last two centuries have been inspired by specificity theory and its refined derivatives. Surgical cures have been employed for pain relief by interruption of specific sensory tracts in neurotomies, division of the anterolateral column of the spinal cord, dorsal roots excision, thalamectomy, mesencephalic lesioning, psychosurgical lobotomies, and
other procedures that specifically alter the anatomy of the central nervous system. This paradigm shift developed over time, paralleling the scientific advances in understanding the mechanisms of pain transmission.

As knowledge of the importance of the central nervous system in the transmission of pain increased, cures based on this new science proliferated. An early treatment, neurocompression, was developed by James Moore, a Glasgow-born London surgeon. In 1784, he demonstrated that compression of specific nerves provided anesthesia in patients via clamps in both upper and lower limbs, inducing reversible neurapraxia to anesthetize a limb.47

Before his time, Ambroise Paré (1510–1590), the great French surgeon of the Renaissance and “physician to the kings of France,” linked observable injury to the development of chronic pain. He not only sustained a prolific medical practice but wrote 10 books of surgery (Dix Livres de la Chirurgie). These books were based on his extensive experience in treating gun and sword wounds and the pain that attended them.48 He was the first to describe pain after the amputation of limbs, 300 years before the conceptualization of “phantom limb pain” was ever expressed. Remarkably, contrary to the current philosophy of his time, he resisted the prevailing wisdom that pain was either inevitable and to be passively tolerated or in some way the will of God to be accepted by man as a path to holiness by actively treating pain in his suffering patients. Some of his innovations included the development of prosthetic devices for missing limbs, a steam bath chair for urethral stone pain, and combinations, called “allodynes,” of opium and other drugs to treat the symptoms of pain.11

Other compassionate physicians observing their tormented pain patients, primarily as a result of catastrophic war injuries, continued to develop options to treat pain out of necessity. The US Civil War resulted in untold numbers of soldiers who suffered damaged nerves after amputation and injury, with resultant chronic “nerve” disease. The persistent burning pain long after the initial injury was first called reflex paralysis by Silas Weir Mitchell (Fig. 1.15) in 1864. Dr. Mitchell, born in Philadelphia as the seventh physician within three generations, was told at an early age by his physician father, “You are wanting in nearly all the qualities that go to
make a success in medicine.” Despite this, he graduated from Jefferson Medical College in 1848 and, at the outbreak of hostilities in 1861, was placed in charge of Turner’s Lane Hospital in Philadelphia, a 400-bed hospital for nervous diseases. With colleagues, William Williams Keen Jr. and George Read Morehouse, he personally transported railroad cars full of wounded soldiers from the Gettysburg battlefield and undertook their care. Based on daily patient observation and review of literally thousands of pages of careful clinical notes, he described causalgia for the first time in 1864 in the work Gunshot Wounds and Other Injuries of Nerves.

![Silas Weir Mitchell, MD.]( Courtesy of the National Library of Medicine. )

An early example of injecting specific nerves to produce analgesia was the work of Schloesser in 1903. He injected alcohol to produce long-lasting interruption of neural conduction in patients with convulsive facial tics, obtaining paralysis that lasted from days to a month. He recommended lytic injections for the patients with clinical supraorbital neuralgia and tic douloureux.
Later, war injuries in World War I soldiers inspired a practical French surgeon, René Leriche, to study pain and its treatment in various forms of pathology. He identified patients with sympathetic nerve injuries—his “pariahs of pain”—that he treated by injecting the local anesthetic procaine and surgical sympathectomy, which later became standard therapy in the 1930s. He was a clinician’s clinician, describing pain from direct personal observation: “Physical pain is not a simple affair of an impulse, traveling at a fixed rate along a nerve. It is the resultant of a conflict between a stimulus and the whole individual.”

Following the theory of pain arising from specific nerve injuries, surgeons in the 1920s performed nerve ablation procedures for chronic unexplained pain syndromes. Following this model, anesthesiologists experimented with various local anesthetic nerve blocks to provide analgesia for surgery. The first nerve block clinic for pain relief was started by Emery Rovenstine at Bellevue Hospital in New York City, New York, in 1936. Eleven years later, the first nerve block clinic in the United Kingdom was established at University College Hospital in London.

Current therapies based on central nervous system plasticity modulating input from peripheral nerves include spinal cord stimulation, sympathetic nerve blocks, radiofrequency modulation (both pulsed and lesioning), and cognitive therapies and are now commonly available in modern pain practice.

The Specialty of Pain Medicine

How did pain as a medical specialty and physicians specializing in the diagnosis and treatment of pain conceive of chronic pain as an original and new field of clinical practice? A sociologist, Isabelle Baszanger, observed two clinics in Paris that had very different constructs of pain and pain treatment, which she described as the two poles of pain. The first—“curing through techniques”—considers pain as a function of physiologic abnormalities, with diagnosis aimed at confirming the pathology and using medication and technical therapies to treat it. As more technologic possibilities develop, the treatments become more focused and
sophisticated. The second pole is “healing through adaptation,” which considers pain a poorly adaptive behavior, and therefore, behavioral and cognitive therapies are necessary to alleviate pain and suffering.56

Whereas Emery A. Rovenstine established in 1936 one of the first outpatient clinics devoted to the treatment of chronic pain,57 the founding father of interdisciplinary pain care was John J. Bonica, who established in 1947 in Seattle the first multidisciplinary clinic to treat the pain in wounded World War II veterans. He published the first edition of his comprehensive textbook, Management of Pain, in 1953.7 His clinical practice increased and gained support after aligning with the University of Washington in Seattle in 1960. As his reputation grew, he encouraged other centers to recognize and treat pain as an integral part of health care.58 He then proceeded to work internationally to foster the study and treatment of pain. He was the driving force behind the Issaquah, Washington, multidisciplinary pain conference in 1973 which, as noted earlier, led to the subsequent establishment of the International Association for the Study of Pain. This association currently represents over 60 scientific disciplines in active research and clinical practice in a wide variety of pain related fields. The journal, Pain, supported by this organization, foreshadowed the numerous peer reviewed scholarly publications now focused on all levels of pain research.59 The American Board of Anesthesiology (ABA) approved a certificate of added qualification in pain management in 1991, followed by subspecialty certification from the American Board of Psychiatry and Neurology (ABPN) and the American Board of Physical Medicine and Rehabilitation (ABPMR) in 2000.60

It is an exciting time for the study and treatment of pain. New research approaches, including elegant molecular biologic and genetic approaches and imaging techniques that allow real-time investigation of information processing in the nervous system with improved resolution and power, are informing our improved understanding of pain mechanisms and central nervous system contributions to the experience of pain. The chapters that follow in this, the 5th edition of Bonica’s Management of Pain, highlight the impressive developments in the understanding and managing of pain.

ACKNOWLEDGMENTS
This is an updated version of this chapter written originally by Dr. Doris Cope for the 4th edition of Bonica’s Management of Pain.

*It should be appreciated that theories about pain as a specific sense were advanced largely based on stimulation of the skin and assumed/implied to apply generally to other tissues. It is now known that stimuli adequate to produce pain differ in different tissues and that nociceptors are heterogeneous.

References
The inherent subjectivity of pain presents a fundamental impediment to increased understanding of its mechanisms and control. The language used by any two individuals attempting to describe a similar injury and their pain experience often varies markedly. Similarly, clinicians and clinical investigators commonly use multiple terms that at times have idiosyncratic meanings. Needless to say, appropriate communication requires a common language and a classification system that is used in a consistent fashion. Thus, we have two primary goals in this chapter: (1) to provide definitions for many commonly used terms in the pain literature, in an effort to bring about consistency and thereby improve communication, and (2) to describe and discuss different classification systems or taxonomies that have been used or proposed, in an attempt to improve communication and bring consistency to research and treatment of patients reporting pain.

Definition of Commonly Used Pain Terms

Discussions of pain involve many terms. The meaning and connotation of these different terms may vary widely. For example, some authors use the term pain to relate to a stimulus, others to a thing, and still others to a response. Such inconsistent usage creates difficulties in communication. As Merskey\(^1\) noted, it would be most convenient and helpful if there were some consensus on technical meanings and usage. Based on this belief, the editors of the two editions of the International Association for the Study of Pain (IASP) Classification of Chronic Pain included a set of definitions of commonly used pain terms\(^2,3\) (note that a third adaptation of chronic pain for the International Classification of Diseases 11th revision [ICD-11]...
does not include any listing of definitions). In the second edition of this text, Bonica reproduced a list of the terms and in some cases provided annotations. We adopt a similar strategy. We follow the convention of IASP; we begin with the definition of pain and then proceed alphabetically. Terms preceded by an asterisk come directly from the IASP descriptions of pain terms.

*Pain: An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage (emphasis added). It should be noted that some have argued that inclusion of the phrase “described in terms of such damage” is problematic because it assumes an ability to verbally communicate that may not be present in very young children and individuals with limitations in their verbal abilities. They also suggest that the use of the term unpleasant may trivialize the experience which may greatly exceed the unpleasant nature of the experience. Moreover, the original IASP definition fails to incorporate advanced knowledge as to the important role of cognitive, social, and contextual factors. Williams and Craig suggest a revised definition, “Pain is a distressing experience associated with actual or potential tissue damage with sensory, emotional, cognitive, and social components,” (p2420) to take these factors into consideration.

Pain, acute/chronic: Definitions of acute, chronic, recurrent, and cancer pain are not specifically included in the IASP list of pain terms. We believe, however, that it is important to clarify these because they are commonly used in the literature.

Traditionally, the distinction between acute and chronic pain has relied on a single continuum of time, with some interval since the onset of pain used to designate the onset of acute pain or the transition point when acute pain becomes chronic. The two most commonly used chronologic markers used to denote chronic pain have been 3 months and 6 months, most recently by IASP as lasting longer than 3 months since the initiation of pain; however, these distinctions are arbitrary. Moreover, these criteria do not take into consideration intensity of pain, the severity and nature of its impact on functioning or treatment-seeking behaviors, or whether pain must be present every day or how frequent it occurs in this interval. These features are important because they may influence estimates of the
prevalence of pain and effects on physical activity and treatment requirements and may explain some of the inconsistencies reported.

Another criterion for chronic pain is “pain that extends beyond the expected period of healing.” This is relatively independent of time because it considers pain as chronic even when it has persisted for a relatively brief duration. Unfortunately, how long the expected process of healing will (or should) take is ambiguous. One suggestion has been to differentiate “chronic pain” from “impactful chronic pain.”

Some hold that pain that persists for long periods of time in the presence of ongoing pathology should be considered an extended “acute” pain state. In this case, treatment targets the underlying pathology. This is not to encourage a Cartesian dualistic perspective of pain that treats mind and body as independent entities with distinctive functions. Historically, such distinction led to a faulty assumption of acute pain as “real,” whereas chronic pain without known pathology was suspect and viewed as being merely “functional.” As the IASP definition clearly states, any pain, acute or chronic, regardless of the presence of identifiable tissue damage, is an unpleasant experience, inherently influenced by various cognitive, affective, and environmental factors. We hold that the weighing of psychological and environmental factors is often greater in chronic pain than acute pain, and the importance of these factors escalates over time, contributing to the experience of pain and associated disability.

We propose conceptualizing acute and chronic pain on two dimensions: time and physical pathology. Figure 2.1 schematically depicts this two-dimensional conceptualization of acute and chronic pain. From this perspective, any case falling above the diagonal line (short duration or high physical pathology) is acute pain, whereas cases falling below the diagonal line (low physical pathology or long duration) suggest chronic pain. The perspective presented in Figure 2.1 leads to the following definitions of acute and chronic pain.
Acute pain: Acute pain is the physiologic response to and experience of noxious stimuli that can become pathologic, is normally sudden in onset, is time-limited, and motivates behaviors to avoid potential or actual tissue injury. Pain is elicited by the injury of body tissues and activation of nociceptive transducers at the site of local tissue damage. The local injury alters the response characteristics of the nociceptors and perhaps their central connections and the autonomic nervous system in the region. In general, the state of acute pain lasts for a relatively limited time and remits when the underlying pathology resolves (however, see the following definition of central sensitization). This type of pain often serves as the impetus to seek health care, and it occurs following trauma, some disease processes, and invasive interventions.

Chronic pain: May be elicited by an injury or disease but is likely to be perpetuated by factors that are both pathogenetically and physically remote from the originating cause. Chronic pain extends for a long period of time and/or represents low levels of underlying pathology that does not explain the presence and extent of pain (e.g., mechanical back pain, fibromyalgia [FM] syndrome). There have been suggestions that chronic pain in the apparent absence of pathology may be attributable to modification of nerves and sensitization of the peripheral or central nervous system. There have also been suggestions that genetic factors and prior life experiences might predispose some to develop chronic pain problems following an initiating insult that resolves in others who do not have the predisposition.
Just as the brain is modified by experience, especially in early life, the brain may alter the way noxious information is processed to reduce or augment its impact on subjective awareness.

Chronic pain frequently is the impetus for people to seek health care. Currently available treatments are rarely capable of totally eliminating the noxious sensations and thereby “curing” chronic pain. Because the pain persists, it is likely that environmental, emotional, and cognitive factors will interact with the already sensitized nervous system, contributing to the persistence of pain and associated illness behaviors (see following description of pain behaviors). It is also possible that, just as the brain is modified by experience, especially in early life, the brain may alter the way noxious information is processed to reduce or augment its impact on subjective awareness.

The acute–chronic pain continuum is based solely on duration. There is an implication that those with chronic pain will have progressed from an acute pain state to a chronic pain state and that once the threshold to chronic pain is crossed, it becomes fixed and relatively immutable with the implication that worsening, and deterioration over time is inevitable. The reality in contrast is there in the presence of considerable variability within individuals who have transitioned into the classification based on arbitrary time points. A range of psychosocial, behavioral, and contextual factors as well as physical ones will influence the adaptation and responses to pain.

**Cancer pain:** Pain associated with cancer includes pain associated with disease progression as well as treatments (e.g., chemotherapy, radiotherapy, surgery) that may damage the nervous system. Although some contend that pain associated with neoplastic disease is unique, in the majority of instances, we view it as fitting within our description of acute and chronic pain, as depicted in Figure 2.1. Moreover, pain associated with cancer can have multiple causes, namely, disease progression, treatment, and co-occurring diseases (e.g., arthritis). Regardless of whether the pain associated with cancer stems from disease progression, treatment, or a co-occurring disease, it may be either acute or chronic. Thus, we do not advocate a separate classification of cancer pain as distinct from acute and chronic pain.

Some concerns have also been raised regarding the common usage of
chronic malignant and chronic benign pain\(^4\); often, pain unrelated to cancer is implicitly view as “benign” to distinguish it from cancer-related pain. Certainly, people who have pain associated with neoplastic disease experience a unique and disease-specific situation, but from a mechanistic perspective, there may be little to substantiate continued use of this dichotomy. Moreover, patients who have chronic noncancer pain who are told that their pain is “benign” may feel denigrated because, from their perspective, the inference is that their pain is not a serious concern.

**Recurrent pain:** Episodic or intermittent occurrences of pain, with each episode lasting for a relatively short period of time but recurring across an extended period of time (e.g., migraine headaches, tic douloureux, sickle cell crisis, dysmenorrhea). Our distinction between acute and chronic pain using the integration of the dimensions of time and pathology does not specifically include recurrent pain. In the case of recurrent pain, patients may experience episodes of pain interspersed with periods of being completely pain-free. Although recurrent pain may seem acute because each pain episode (e.g., headache) is of relatively short duration, the pathophysiology of many recurrent pain disorders (e.g., migraine) is not well understood. Syndromes characterized by recurrent acute pain share features in common with both acute and chronic pain. The fact that these syndromes extend over time, however, suggests that psychosocial and behavioral factors, not only physical pathology, may be major contributors to emotional and behavioral responses. IASP\(^4\) now includes recurrent pain lasting longer than 3 months within its definition of chronic pain. However, it is not clear whether multiple episodes lasting several days within 3 months would meet the chronic pain criterion or whether the pain must last at least 3 months. That is, would multiple migraines in a 3-month period be chronic even if there were pain-free periods within the 3 month period?

**Transient pain:** Pain elicited by activation of nociceptors in the absence of any significant local tissue damage. This type of pain is ubiquitous in everyday life and is rarely a reason to seek health care. It is seen in the clinical setting and only in incidental or procedural pain, such as during a venipuncture or injection. This type of pain ceases as soon as the stimulus is removed. There are situations where sources of transient
pain may be treated by providers with preventive analgesic or topical medication.

**Acceptance:** A choice to acknowledge pain experiences (intensity, thoughts, emotions) and to cease efforts to control them while simultaneously engaging in valued behaviors, particularly when control efforts have led to restrictions.

**Addiction:** A behavioral pattern of substance, including prescribed medication, abuse characterized by overwhelming involvement with the use of a drug (i.e., compulsive use), the securing of its supply, and a high tendency to relapse. The compulsive use of the drug results in physical, psychological, and/or social harm to the user, and use continues despite this harm. (See also physical dependence.)

* **Alldynia:** Pain due to a stimulus that does not normally provoke pain.

* **Analgesia:** Absence of the spontaneous report of pain or pain behaviors in response to stimulation that would normally be expected to be painful. The term implies a defined stimulus and a defined response. Analgesic responses can be tested in nonhuman as well as humans.

* **Anesthesia dolorosa:** Spontaneous pain in an area or region that is anesthetic.

**Breakthrough pain:** A transient increase in pain to greater than moderate intensity superimposed on baseline pain that is fairly well managed. Breakthrough pain includes (1) incident pain that may arise from some activity or physical function (e.g., coughing, ambulating), (2) pain that routinely increases as the duration of analgesic medication is reaching its limit (end-of-dose failure), and (3) spontaneous exacerbation of a stable level of pain for nonspecific reasons.

**Catastrophizing:** A cognitive and emotional process that involves magnification of pain-related stimuli, feelings of helplessness, and a negative orientation to pain and life circumstances. Catastrophizing has been shown to be an important predictor of response to both acute and chronic pain.10

* **Central pain:** Pain initiated or caused by a primary lesion or dysfunction in the central nervous system.

**Central sensitization:** Increase in the excitability and responsiveness of neurons in the spinal cord. Central sensitization may explain the
persistence of pain beyond the removal or resolution of the initiating stimulus.

**Chronic widespread pain:** A complex condition with a range of disabling physical and psychological symptoms that does not fit neatly into any medical specialty and has a myriad of possible causes and triggers, both physical and psychological. A set of disparate disorders is often lumped into chronic widespread pain including nonradicular back pain, FM, irritable bowel syndrome, pelvic pain, temporomandibular disorders (TMD), and tension-type headache. This diagnosis is based on the presence and distribution of symptoms in the absence of another defined pathologic process: The features in the history or clinical examination are generally more important than laboratory investigations.

*Complex regional pain syndrome type 1 (formerly reflex sympathetic dystrophy):* A syndrome that usually develops after an initiating noxious event, is not limited to the distribution of a single peripheral nerve, and is apparently disproportionate to the inciting event. It is associated at some point with evidence of edema, changes in skin blood flow, abnormal pseudomotor activity in the region of the pain, or allodynia or hyperalgesia. Specific criteria for the diagnosis of complex regional pain syndrome (CRPS) have been proposed.11

*Complex regional pain syndrome type 2 (formerly causalgia):* A syndrome of sustained burning pain, allodynia, and hyperpathia following a traumatic nerve lesion, often combined with vasomotor dysfunction and later trophic changes.

**Conditioned pain modulation:** Altered endogenous pain modulation is considered as a mechanism involved with diverse chronic pain syndromes (e.g., TMD, FM, chronic tension-type headache, and irritable bowel syndrome). It is assessed by measuring phasic pain response after a conditioned tonic pain stimulus. Conditioned pain modulation is at least partially mediated by the diffuse noxious inhibitory control (DNIC) system characterized by inhibition of wide dynamic range neurons in the dorsal horn of the spinal cord by heterosegmental noxious afferent input.12

**Cost–benefit analysis:** Evaluation of the costs and effects of an intervention in a common, usually monetary unit. The standardization of unit has an advantage because it permits comparisons across dissimilar
intervention programs. On the other hand, the conversion of treatment effects to monetary units may not always be feasible. Estimation of the cost to outcome ratio is possible, as are comparisons between interventions using the rates of improvement (e.g., return to work) with common denominators.

**Cost-effectiveness analysis:** Estimation of treatment outcome entails criteria other than monetary terms, such as lives saved or return to work. An intervention is cost-effective when it satisfies one of the following conditions:

1. It is more effective than an alternative modality at the same cost;
2. It is less costly and at least as effective as an alternative modality;
3. It is more effective and more costly than an alternative treatment, but the benefit exceeds the added cost; or
4. It is less effective and less costly, but the added benefit of the alternative is not worth the additional cost.

**Disability:** Any restriction or loss of capacity to perform an activity in the manner or within the range considered normal for a human being, such as climbing stairs, lifting groceries, or talking on a telephone. It is a task-based concept that involves both the person and the environment. Disability is essentially a social and not a medical term or classification. Level of disability should be determined only after a patient has reached maximum medical improvement following appropriate treatment and rehabilitation.

* **Dysesthesia:** An unpleasant abnormal sensation, whether spontaneous or evoked.
* **Hyperalgesia:** An increased response to a stimulus that is normally painful.
* **Hyperesthesia:** Increased sensitivity to stimulation, excluding special senses.
* **Hyperpathia:** A painful syndrome characterized by an abnormally painful reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold.
* **Hypoalgesia:** Diminished pain in response to a normally painful stimulus.

**Hypochondriasis:** An excessive preoccupation with bodily sensations
and fears that they represent serious disease despite reassurance to the contrary.

**Impairment:** Any loss of use of, or abnormality of, psychological, physiologic, or anatomical structure or function that is quantifiable. It is not equivalent to disability. Impairment is to disability as disease is to illness.

**Malingering:** A conscious and willful feigning or exaggeration of a disease or effect of an injury in order to obtain a specific external gain. It is usually motivated by external incentives such as financial compensation, avoiding work, or obtaining drugs.

**Maximum medical improvement:** The state beyond which additional medical treatment is unlikely to produce an improvement in function.

**Minimum clinically important difference (MCID):** The magnitude of reduction in pain or related problems that a patient would consider minimally important. In considering the determination of clinically important differences, two different aspects of the interpretation of clinical trial results must be distinguished. One is establishing the difference in the magnitude of response between the treatment and control groups that will be considered large enough to establish the scientific or therapeutic importance of the results. The other is establishing what change in the outcome measure represents a meaningful difference for patients. This later consideration has come to be referred to as the minimum clinically important difference. The development of criteria for determining what are important changes in an individuals’ scores on the outcome measures used in chronic pain trials would provide clinicians and researchers with essential methods for evaluating treatment responses of individuals in clinical trials and clinical practice. Such individual-level criteria make it possible to conduct responder analyses that classify each trial participant as “improved,” “stable,” or “worse” on the basis of validated criteria of important change. (See description of patient global impression of change.)

**Multidisciplinary (interdisciplinary) pain center:** An organization of health care professionals and basic and applied scientists that includes research, teaching, and patient care related to acute and chronic pain. It includes a wide array of health care professionals including physicians,
psychologists, nurses, physical therapists, occupational therapists, and other specialty health care providers. Multiple therapeutic modalities are available. These centers provide evaluation and treatment and are usually affiliated with major health science institutions.

*Neuralgia:* Pain in the distribution of a nerve or nerves.

*Neuritis:* Inflammation of a nerve or nerves.

*Neurogenic pain:* Pain initiated or caused by a primary lesion, disease, dysfunction, or transitory perturbation in the somatosensory nervous system. It may be spontaneous or evoked, as an increased response to a painful stimulus (hyperalgesia), a painful response to a painful stimulus (hyperalgesia), or a painful response to a normally nonpainful stimulus (allodynia).

Neuropathic pain: Pain arising as a direct consequence of a lesion or disease affecting the somatosensory system.

*Neuropathy:* A disturbance of function or pathologic change in a nerve: in one nerve, mononeuropathy; in several nerves, mononeuropathy multiplex; if diffuse and bilateral, polyneuropathy.

Nocebo: Negative treatment effects induced by a substance or procedure containing no toxic or detrimental substance.

Nociception: Activation of sensory transduction in nerves by thermal, mechanical, or chemical energy impinging on specialized nerve endings. The nerve(s) involved conveys information about tissue damage to the central nervous system.

*Nociceptor:* A receptor preferentially sensitive to tissue trauma or to a stimulus that would damage tissue if prolonged.

*Noxious stimulus:* A stimulus that is capable of activating receptors for tissue damage.

Pain behavior: Verbal or nonverbal actions understood by observers to indicate that a person may be experiencing pain and suffering. These actions may include audible emissions (e.g., signs, moans); facial expressions (e.g., grimacing); abnormal postures or gait (e.g., limping, bracing, moving in a guarded fashion); motor behavior (e.g., rubbing a body part); use of prosthetic devices; avoidance of activities; and verbal indications of pain, distress, and suffering. An important feature is the observable nature of these behaviors that can be subjected to the
conditioning process. Once conditioned, the same behavior is exhibited as a learned response rather than expression of actual pain experience. Thus, pain behavior can either reflect internal experience of pain or is exhibited as a learned behavior in response to certain cues.

**Pain clinic:** Facilities focusing on diagnosis and management of patients with pain problems. It may specialize in specific diagnoses or pain related to a specific area of the body.

**Pain relief:** Report of reduced pain after a treatment. It does not require reduced response to a noxious stimulus and is not a synonym for analgesia. The term applies only to humans.

**Pain threshold:** The least level of stimulus intensity perceived as painful. In psychophysics, this is defined as a level of stimulus intensity that a person recognizes as painful 50% of time.

**Pain tolerance level:** The greatest level of noxious stimulation that an individual is willing to tolerate.

**Pain sensitivity range:** The difference between the pain threshold and the pain tolerance level.

**Paresthesia:** An abnormal sensation whether spontaneous or evoked.

**Patient global impression of change (PGIC):** Patients’ overall evaluation of improvement or worsening of symptoms over the course of treatment. This measure is often a single-item rating by patients on a scale, often 5-point or 7-point scale that ranges from “very much improved” to “very much worse” with “no change” as the midpoint.

**Peripheral neurogenic pain:** Pain initiated or caused by a primary lesion or dysfunction or transitory perturbation in the peripheral nervous system.

**Physical dependence:** A pharmacologic property of a drug (e.g., opioid) characterized by the occurrence of an abstinence syndrome following abrupt discontinuation of the substance or administration of an antagonist. It does not imply an aberrant psychological state or behavior or addiction.

**Placebo:** An inert substance or procedure without a specified therapeutic ingredient that is provided as a treatment. It is frequently used to control patients’ expectations for the efficacy in testing a treatment.

**Placebo effects:** Refers to the positive benefit(s) from a placebo (i.e.,
inert) preparation or procedure when such benefit is generally achieved only with an active treatment intervention. Active treatments also are likely to have a placebo component that augments the active component associated with the treatment.

**Plasticity, neural:** Nociceptive input leading to structural and functional changes that may cause altered perceptual processing and contribute to pain chronicity.

**Pseudoaddiction:** Refers to drug-seeking behavior or misuse by patients who have severe pain and are undermedicated or who have not received other effective pain treatment interventions. Such patients may appear preoccupied with obtaining opioids, but the preoccupation reflects a need for pain relief and not drug addiction. Pseudoaddictive behavior differs from true addictive behavior because when higher doses of opioid are provided, the patient does not use these in a manner that persistently causes sedation or euphoria, the level of function is increased rather than decreased, and the medications are used as prescribed without loss of control over use.

**Psychogenic pain:** Report of pain attributable primarily to psychological factors usually in the absence of any objective physical pathology that could account for pain. This term is commonly used in a pejorative sense. It often suggests a Cartesian dualism and is not usually a helpful method of describing a patient.

**Quality of life/health-related quality of life:** Quality of life (QOL) refers to an individual’s perception of his or her position in life in the context of the culture and value systems in which he or she lives and in relation to his or her goals, expectations, standards, and concerns. Concerns with this all-encompassing description have led a number of investigators to use a more circumscribed construct, health-related quality of life (HRQOL). Although HRQOL has been used interchangeably with terms such as health status and functional status, HRQOL is a narrower term than QOL because it does not include aspects of work, environmental conditions, housing, and other variables that are often considered relevant to QOL but that do not involve health directly.\(^7\)

**Rehabilitation:** Restoration of an individual to maximal physical and mental functioning in light of his or her impairment.
**Residual functional capacity:** The capacity to perform specific social and work-related physical and mental activities following rehabilitation related to impairment or when a condition has reached a point of maximum medical improvement.

**Resilience:** Capacity and dynamic process of adaptively overcoming stress and adversity while maintaining normal psychological and physical functioning.\(^ \text{15} \)

**Summed pain intensity difference (SPID):** A strategy for combining relief magnitude and duration in a single score. It is calculated by the sum of the time-weighted pain intensity difference (difference between current pain and pain at baseline) multiplied by the interval between ratings.

**Symptom magnification:** Conscious or unconscious exaggeration of symptom severity in an attempt to convince an observer that one is truly experiencing some level of pain. It differs from malingering as it is an effort to be believed, not necessarily to achieve a positive outcome (i.e., secondary gain) such as financial compensation.

**Suffering:** Reaction to the physical or emotional components of pain with a feeling of uncontrollability, helplessness, hopelessness, intolerability, and interminability. Suffering implies a threat to the intactness of an individual’s self-concept, self-identify, and integrity.

**Tolerance, drug:** A physiologic state in which a person requires an increased dosage of a psychoactive substance to sustain a desired effect.

**Total pain relief (TOPAR):** Is used in clinical trials to assess pain relief over time. It is a cumulative measure that is composed of the sum of time-weighted pain relief score multiplied by the interval between ratings. TOPAR is frequently used in clinical trials of medications designed to ameliorate pain.

**Wind-up:** Slow temporal summation of pain mediated by C fibers due to repetitive noxious stimulation at a rate faster than one stimulus every 3 seconds. It may cause the person to experience a gradual increase in the perceived magnitude of pain.

---

**Taxonomies**

The lack of a classification of chronic pain syndromes that is used on a
consistent basis inhibits the advancement of knowledge and treatment of chronic pain and makes it hard for investigators as well as practitioners to compare observations and results of research. Bonica referred to this language ambiguity as “a modern tower of Babel.”

In order to identify target groups, conduct research, prescribe treatment, evaluate treatment efficacy, and for policy and decision making, it is essential that some consensually validated criteria are used to distinguish groups of individuals who share a common set of relevant attributes. The primary purpose of such a classification is to describe the relationships of constituent members based on their equivalence along a set of basic dimensions that represent the structure of a particular domain. Infinite classification systems are possible, depending on the rationale about common factors and the variables believed to discriminate among individuals. The majority of the current taxonomies of pain are “expert-based” classifications.

**EXPERT-BASED CLASSIFICATIONS OF PAIN**

Classifications of disease are usually based on a preconceived combination of characteristics (e.g., symptoms, signs, results of diagnostic tests), with no single characteristics being both necessary and sufficient for every member of the category, yet the group as a whole possesses a certain unity. Most classification systems used in pain medicine (e.g., ICD, classification and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain, IASP Classification of Chronic Pain, CRPS, whiplash-associated disorders, and the Analgesic, Anesthetic, and Addiction Clinical Trial Translations, Innovations, Opportunities, and Networks [ACTTION]-American Pain Society Pain Taxonomy [AAPT] and ACTTION-American Pain Society-American Academy of Pain Medicine [AAPM] Pain Taxonomy [AAAPT] and dentistry (i.e., Research Diagnostic Criteria [RDC] for Temporomandibular Disorders) are based on the consensus arrived at by a group of “experts.” In this sense, they reflect the inclusion or elimination of certain diagnostic features depending on agreement.

“Expert-based” classification tends to result in preconceived categories and “force” individuals into the most appropriate one even if not all
characteristics defining the category are present. Expert-based classification systems do not explicitly state the mathematical rules that should exist among the variables used in order to assign a case to a specific category.

In an ideal classification, the categories comprising the taxonomy should be mutually exclusive and completely exhaustive for the data to be incorporated. Every element in a classification should fit into one, and only one, place, and no other element should fit into that place. An example of such an ideal, natural taxonomy is the periodic table in chemistry. We can also develop artificial classifications such as a telephone directory. The criterion for the classification, namely, the sequence of letters in the alphabet, bears no relation to the people, addresses, and telephone numbers being classified; but it is quite satisfactory for the intended purpose. No classification in medicine or dentistry has achieved such aims. For example, the RDC (now Diagnostic Criteria as the RDC has been adopted for clinical diagnostic purposes based on the research evidence) for Temporomandibular Disorders includes eight different diagnoses. In one study, over 50% of the sample received three or more RDC diagnoses. Thus, the classifications or diagnoses are not mutually exclusive.

The most commonly used classification system of pain is the ICD published by the World Health Organization. In the most recent draft edition, the ICD-10 conditions are classified along a number of different dimensions including causal agent; body system involved; pattern and type of symptoms; and whether or not they are related to the artificial intervention of an operation, time of occurrence or grouped as signs, symptoms, and abnormal clinical and laboratory findings. Within major groups, there are subdivisions by symptom pattern, the presence of hereditary or degenerative disease, extrapyramidal and movement disorders, location, and etiology. Overlapping occurs repeatedly in such approaches to categorization; thus, they are not ideal even if they serve a useful function. Recently, IASP has created its adaptation of the original IASP classification (described in the following discussion) in an effort to have chronic pain included within the ICD-11 (described in the following discussion).
Further complications arise when clinicians require a separate coding system. In the United States, for example, in addition to the ICD codes, a clinician must select current procedural terminology (CPT) coding schemes for billing purposes. This has created a tendency where the fulfillment of the CPT coding may dictate the ICD selections to justify the procedures. Such practices often needlessly create diagnoses and additional treatments for billing purposes only.

It is clear that the classification of pain cannot approach the ideal found in chemistry or telephone books, but this is not unique to pain; it characterizes medical classification systems in general. Classification in medicine, dentistry, and psychology is pragmatic. It does not provide absolute truth but rather provides categories with which we can work to identify individuals with similar phenomena, prognoses, or causes. Currently, the majority of pain classifications in pain medicine rely on various parameters of pain experience such as anatomy, system, severity, duration, and etiology.

CLASSIFICATION BASED ON ANATOMY
Several pain syndromes are classified by body location. For example, low back pain, pelvic pain, and headache, each refers to the specific location of symptoms. However, the extent to which the anatomy-based classification of pain is clinically meaningful is limited, at least partially, due to the lack of anatomically defined specificity in the neurophysiology of pain.

CLASSIFICATION BASED ON DURATION
As previously discussed, one common way to classify pain is to consider it along a continuum of duration. Thus, pain associated with tissue damage, inflammation, or a disease process that is of relatively brief duration (i.e., hours, days, or even weeks), regardless of how intense, is frequently referred to as acute pain (e.g., postsurgical pain). Many pain problems can be classified as chronic. For example, pain that persists for extended periods of time (i.e., months or years), accompanies a disease process (e.g., rheumatoid arthritis), or is associated with an injury that has not resolved within an expected period of time (e.g., low back pain, phantom limb pain) are all referred to as chronic. As noted, however, a single dimension of
duration is inadequate because pathologic factors may be relatively independent of duration.

**CLASSIFICATION BASED ON THE ETIOLOGY OF PAIN**

Another way to classify pain is based on etiology, by lumping a range of potentially disparate diagnoses within general categories, for example, somatogenic-psychogenic, nociceptive-neuropathic, and nociceptive-neuropathic-widespread.

Historically, crude efforts were made to subdivide or classify patients reporting pain dichotomously based on the putative basis for their report. A classical approach to classify patients based the presence of physical pathology that to which the pain report was attributed—somatogenic versus pain with unknown physical pathology and with the implication on nonphysical causal mechanism such as psychopathology (psychogenic) or motivation to achieve some desired outcome such as disability attention or disability compensation (i.e., malingering), seeking of mood altering drugs, or avoidance of undesirable activities (e.g., work, homemaking responsibilities) (reinforcement). The processes by which clinicians determine whether pain is somatogenic or psychogenic are distinctive. The classification of somatogenic pain is established by identification of positive organic findings, whereas psychogenic pain is indicated only in the absence of positive signs.

More recently, a dichotomous classification has been advocated by the AAPM\textsuperscript{26} with the somewhat analogous concepts of “eudynia” (good pain) and “maldynia” (bad pain). Eudynia (nociceptive pain) conceptualizes pain that serves as an alarm signal and that is mediated by specialized primary sensory neurons that respond to sufficiently intense thermal, mechanical, or chemical stimuli and transmit signals via well-defined pathways in the central nervous system. Eudynia is triggered and maintained by the presence of noxious stimuli. When local inflammation ensues, certain features of the nociceptive response are modified and magnified to aid healing and repair; hence, good pain. Little consideration is given to the involvement of psychosocial, behavioral, or contextual factors in the development, amplification, or maintenance of symptom or response to
treatment. In contrast, maldynia is classified when pain is reported to be present when neural tissues in the peripheral or central nervous system are directly damaged or become dysfunctional. Here, in contrast to eudynia, different sequence of events unfolds. Under these conditions, pain can manifest and eventually persist in the absence of typical nociceptive generators. Such pain can be considered maladaptive because it occurs in the absence of ongoing noxious stimuli and does not promote healing and repair. In the instance of maldynia, there is an acknowledgment that psychosocial, behavioral, and contextual factors may become enmeshed. Accordingly, the AAPM and other proponents in the pain medicine community have advanced the notion that under such conditions, pain becomes the disease process itself.

Other variations on the dichotomous somatogenic versus psychogenic classification exist. For example, Portenoy\textsuperscript{27} proposed that three primary categories of pain be used: nociceptive, neuropathic, and psychogenic. In this system, somatogenic pain is subdivided into two subtypes that contrast with psychogenic pain. More recently, a suggested broad classification into subgroups has proposed three categories, namely, nociceptive, neuropathic, and widespread (sometimes referred to as central sensitivity syndromes, with the causal mechanisms of central nervous system plasticity and the resulting central sensitization, combining such apparently disparate diagnoses as back pain, FM, irritable bowel syndrome, pelvic pain, TMD, tension-type headaches).\textsuperscript{28,29}

**CLASSIFICATION BASED ON BODY SYSTEM**

Classification may focus on the body system involved. For example, Friction\textsuperscript{30} proposed the use of five categories, namely, myofascial, rheumatic, causalgic, neurologic, or vascular. In this case, patients are assigned to one of five rather than two or three categories as proposed by Portenoy.\textsuperscript{27} However, the decision regarding classification is still based on a single dimension system for the experience of pain.

**CLASSIFICATION BASED ON SEVERITY**

Frequently, pain is classified unidimensionally on the basis of severity (0- to 10-point scale with 0 = no pain and 10 = the worst pain that can be
imagined). That is, regardless of the scale’s level of measurement—nominal, ordinal, or interval—the construct involves a single dimension. When pain is classified on the basis of severity, it is dependent on the subjective report of patients. Assuming pain threshold is normally distributed, there will be significant variability among patients’ rating severity of what might be objectively the same nociceptive stimulation.

Ratings of pain severity will be anchored to how questions are asked, and responses may vary widely depending on the question. For example, if the ratings associated with “pain right now,” “over the past week?” “usual severity,” “severity at its worst,” “severity at its lowest,” “during specific movements,” or “at rest?” pain severity may be very useful in evaluating individual patients but less so for comparison among groups.

CLASSIFICATION BASED ON FUNCTIONING
The International Classification of Functioning, Disability and Health (ICF)\(^31\) aims to provide a standard framework for the comparison and understanding of health outcomes. For any given health outcome, including chronic pain, the ICF identified three main outcomes: impairment, activity limitations, and participation restrictions. To date, the efforts of the ICF have been largely focused on identification of common domains across measures that can be used to evaluate patients and treatment outcomes. It has less emphasis on classification of patients, but it can be used for this purpose. The empirical approach described in the following discussion can be readily applied to the ICF conceptual model.

CLASSIFICATION BASED ON INTENSITY AND FUNCTIONING
The Emory Pain Estimate Model (EPEM) was the first attempt to integrate the biophysiologic and psychosocial domains in classifying pain patients.\(^32,33\) Brena and colleagues\(^32,33\) arbitrarily labeled the dimensions “pathology” and “behavior.” The pathology dimension included the quantification of physical examination procedures (e.g., ratings of joint mobility, muscle strength) as well as assigning numerical indices to reflect the extent of abnormalities determined from diagnostic procedures such as radiographic studies. The behavioral dimension comprises a composite of
activity levels, pain verbalizations, drug use, and measures of psychopathology based on the elevations of scales of the Minnesota Multiphasic Personality Inventory (MMPI).

Using median divisions on the pathology and behavior dimensions, the EPEM defines four classes of chronic pain patients. Class I patients are characterized by higher scores on the behavior dimension and lower scores on the pathology dimension. The EPEM describes these patients as displaying low activity levels, high verbalizations of pain, prominent social and psychological malfunctions, and frequent misuse of medications. Class II patients are those who display lower scores on both the pathology and behavioral dimensions. These patients are described as displaying dramatized pain complaints with ill-defined anatomical patterns. However, they do not display significant behavioral dysfunction. Class III represents patients with higher scores on both dimensions, characterized as showing clear evidence of physical pathology and high intensity illness behavior. Finally, Class IV patients are those who have higher scores on the pathology dimension and a lower score on the behavior dimension, thus demonstrating competent coping in the presence of a physical pathologic condition.

Although Brena and his colleagues\textsuperscript{32,33} appropriately emphasized the importance of integrating physical and psychological data in order to develop a classification system for chronic pain patients, some of the basic theoretical and quantitative characteristics of the EPEM are problematic. We see this framework as a conceptual model rather than an adequately operationalized empirical one. For example, from a theoretical standpoint, the inclusion of activity levels, pain verbalizations, and measures of psychopathology under a single dimension labeled “behavioral” is troubling because research shows that there is little association between pain behaviors and psychopathology. Thus, the behavioral dimension is most likely not unidimensional and, therefore, cannot measure behavior directly.

Von Korff and colleagues\textsuperscript{34} developed a similar model, the Chronic Pain Grade, which integrates the conceptual approach of the EPEM but adds greater emphasis of empirical determination of criteria for subgroup classification and empirical validation. The Chronic Pain Grade classifies
patients into one of five categories: (1) pain-free, (2) low pain intensity and low disability, (3) high pain intensity and low disability, (4) low pain intensity and high disability, and (5) high pain severity and high disability. More recently, Deyo et al.\textsuperscript{6} have based the core data set that they recommend for research on back pain on the Chronic Pain Grade.

**CLASSIFICATION BASED ON PROGNOSIS**

Chronic pain is typically viewed by definition as being fixed with progressive dysfunction over time; however, there is considerable variability in its course. An alternative view, based on prognosis such that chronic pain is defined by the risk, that clinically significant pain and associated dysfunction will be present at some future time point, where the likelihood of future pain and dysfunction is predicted by multiple biopsychosocial prognostic factors.\textsuperscript{35,36} As a consequence, subgroups of pain patient should be based on prognosis. This approach is based on several propositions. The first proposition is that chronic pain is better characterized by a failure of the resolution of pain and associated dysfunction rather than progression based on time. The argument is that severe pain, pain-related activity limitations, and emotional distress often used to characterize chronic pain are observable soon after pain onset. What typically differentiates “chronic pain” from “acute pain” is the lack of meaningful improvement. The second proposition is that the seeds of chronic pain can be observed early in the pain course. The third proposition is that varied prognostic indicators can be combined into a prognostic risk score and this risk score will predict clinically significant pain and dysfunction in the future better than pain duration in isolation. In this view, risk of future clinically significant pain is probabilistic and not immutable. In contrast, chronic pain status can change over time and that, rather than being hopeless, it can improve.

We must exercise caution, however, because duration does have some prognostic value.\textsuperscript{37} Some classification system has included duration alongside prognostic indicators.\textsuperscript{38} Other classifications are consistent with the prognostic approach.\textsuperscript{34,39}

**MECHANISM-BASED CLASSIFICATION OF PAIN**
The conventional classifications of pain disorders based on anatomy, duration, and systems have drawn criticism for their deficiency in sensibility for guiding treatment or research. Woolf et al. support developing a mechanism-based classification of pain, proposing a potential list of pain mechanisms (Table 2.1). They argue that the list needs to include affective, behavioral, and cognitive factors relevant to pain, although they do not specify what these factors may be or how they would be incorporated within the proposed classification system.

| TABLE 2.1 Categories of Pain and Possible Mechanisms |
|---------------------------------|---------------------------------|
| **Transient Pain**              |                                 |
| Nociceptor specialization       |                                 |
| **Tissue Injury Pain**          |                                 |
| **Primary Afferent**            |                                 |
| Sensitization                   |                                 |
| Recruitment of silent nociceptors|                                 |
| Alteration in phenotype         |                                 |
| Hyperinnervation                |                                 |
| **CNS Mediated**                |                                 |
| Central sensitization recruitment, summation, amplification | |
| **Nervous System Injury Pain**  |                                 |
| **Primary Afferent**            |                                 |
| Acquisition of spontaneous and stimulus-evoked activity by nociceptor axons and somata at loci other than peripheral terminals | |
| Alteration in phenotype         |                                 |
| **CNS Mediated**                |                                 |
| Central sensitization           |                                 |
| Deafferentation of second-order neurons | |
| Disinhibition                   |                                 |
| Structural reorganization        |                                 |

CNS, central nervous system.

The mechanism-based classifications of pain differ from the conventional classification in that the former frees pain from diseases that may accompany reports of pain. Mechanism-based classification groups patients who are homogeneous in pain mechanisms but heterogeneous in disease conditions or diagnoses. Woolf et al. emphasize that their proposal is not to replace but rather to supplement the current system.
The basic premise underlying the mechanism-based classification of pain\textsuperscript{40} is helpful, both in guiding treatment and in bridging research to clinical practice in pain medicine. However, such a system is still at the conceptual stage. Ongoing efforts to synthesize findings from various areas of pain research will help to formulate this new classification system.

This approach contrasts with our description of the use of two dimensions, time and severity, to distinguish acute and chronic pain (see Fig. 2.1). An explication of attempts to develop multidimensional classification systems incorporating features of several of the classifications is reviewed in the next section.

**Multiaxial Classifications**

Ever since the gate control model underscored the importance of cognitive–evaluative and motivational–affective factors in the process of pain experience, the importance of integrating the psychosocial domains in the classification of pain has been proposed by a number of clinical investigators. However, as in other domains of pain medicine, the psychosocial classifications of pain have largely depended on psychiatric diagnoses to identify psychopathology. Although the psychiatrically defined classification of pain patients may help identify patients with specific psychiatric disorders, thereby directing treatments for those disorders, psychological classification systems aim to identify the specific psychosocial and behavioral contributions.

**Empirically Based Classification of the Psychological Components of Pain**

Many taxonomies of pain recognize that the conceptualization and operationalization of cognitive, affective, and behavioral factors associated with pain merit consideration (e.g., IASP,\textsuperscript{4} AAPT\textsuperscript{21}/AAAPT\textsuperscript{22} described in the following discussion). Numerous instruments assess pain-related psychosocial constructs, but most are unidimensional, inadequate for pain populations, or lack predictive validity for treatment outcomes. We describe one specific multidimensional, psychosocial classification system used primarily with patients with chronic pain conditions.

The Multidimensional Pain Inventory (MPI)\textsuperscript{41} consists of a set of
empirically derived scales designed to assess chronic pain patients’ (1) pain severity, (2) pain interferes, (3) their dissatisfaction with present levels of functioning in main life domains, (4) appraisals of support received from significant others, (5) perceived life control, (6) their affective distress, and (7) activity levels.

Turk and Rudy\textsuperscript{39} performed cluster analyses on a heterogeneous sample of chronic pain patients’ responses on the MPI scales. Three distinct profiles were identified: (1) dysfunctional (DYS): patients who perceived the severity of their pain to be high, reported that pain interfered with much of their lives, reported a higher degree of psychological distress due to pain, and reported low levels of activity; (2) interpersonally distressed (ID): patients with a common perception that significant others were not very supportive of their pain problems; and (3) adaptive copers (AC): patients who reported high levels of social support, relatively low levels of pain and perceived interference, and relatively high levels of activity. Reliable, external scales supported the uniqueness of each of the three subgroups of patients. Performing a 12-dimension Bayesian calculation to test goodness of fit can identify the profile that best fits a patient.

The empirical–statistical approach has a distinct advantage of permitting judgments about how well an individual patient matches the central features of that classification. This is especially useful in complex pain syndromes that involve various clinical characteristics with large individual variability even within a single diagnostic group. Based on a set of patient characteristics, signs, and symptoms, a prototype for a diagnosis can be established. It is possible to statistically determine how close an individual case matches that prototype. Assume that a perfect match to a prototype is 0.99. A particular case may fit within the diagnosis but not be a perfect fit; thus, the fit might be 0.80. Some statistical rule can decide the minimum fit to the characteristics of the diagnosis; for example, 0.67. Thus, any two individuals with the same diagnosis must share certain characteristics but not necessarily all; the similarity of two patients with the same diagnosis has a statistical definition.

Subsequent testing of the MPI profiles across various pain disorders suggests that the MPI psychosocial classification is independent of the conventionally defined pain syndromes, such as low back pain, TMD,
migraine headaches, FM, and pain associated with cancer. In other words, two patients whose pain pathologies are likely to differ (e.g., cancer and migraine headaches) could have a homogeneous psychological classification of pain. On the other hand, two patients, both having same type of TMD based on the RDC\textsuperscript{24} for comparable duration, may fare differently in the psychological classification of pain. Clinical trials using the MPI-based classification have yielded differential responses to a cognitive-behavioral approach.\textsuperscript{42,43} Such results strongly suggest that the psychosocial treatment components need to conform to the psychological classification of pain.\textsuperscript{44}

A number of other empirical classifications based on patterns of psychosocial and behavioral factors have been reported.\textsuperscript{45,46} These approaches are similar but as with any empirically derived system that classification will depend on the variables assessed and entered into classification algorithms.

We suggest that disease classification should reflect physical assessment leading to medical/physical treatment plans (e.g., 2), whereas that a psychosocial–behavioral taxonomy should determine complementary psychological treatment strategies. Both physical and psychosocial diagnoses are important in the person with a chronic pain syndrome. Several groups\textsuperscript{24,46,47} have proposed the use of a dual-diagnostic approach, whereby two diagnoses are assigned concurrently: physical and psychosocial–behavioral. Treatment could then target both simultaneously. A chronic pain patient might have diagnoses on two different but complementary taxonomies; for example, IASP and MPI-based classification. Thus, a patient might be classified as having CRPS type 1 of the upper extremity (203.X1, Axis I Region = upper shoulder and upper limbs, Axis II Systems = nervous, Axis III Temporal Characteristics of Pain: Pattern of Occurrence = none of the codes listed, Axis IV Intensity and Time of Onset = based on patient report, Axis V Etiology = trauma) on the IASP taxonomy and be classified DYS on the MPI-based taxonomy. Note that not all CRPS type 1 patients would be classified as DYS and not all DYS patients would have CRPS type 1. A second patient might have the same IASP diagnosis CRPS type 1 but be ID on the MPI-based classification. Conversely, patients might have quite different
classifications on the IASP system but have an identical MPI-based classification. The most appropriate treatment for these different groups might vary, with different complementary components of treatments addressing the physical diagnosis (IASP) and the psychosocial diagnosis (MPI-based).

**COMPREHENSIVE, MULTIDIMENSIONAL CLASSIFICATION OF PAIN: INTERNATIONAL ASSOCIATION FOR THE STUDY OF PAIN TAXONOMY**

An alternative to the unidimensional approaches is a multidimensional approach that uses several relevant rather than a single dimension as the basis for developing the classification system and for assigning patients to a particular subgroup or diagnosis. The IASP has published an expert-based multiaxial classification of chronic pain\(^1,2\) intended to standardize descriptions of relevant pain syndromes and to provide a point of reference. The published taxonomy classifies chronic pain patients according to five axes based on the best published information and consensus:

1. **Region** of the body (Axis I),
2. **System** whose abnormal functioning could conceivably produce the pain (Axis II),
3. **Temporal characteristics of pain and pattern of occurrence** (Axis III),
4. **Patient’s statement of intensity and time since onset of pain** (Axis IV), and
5. Presumed **etiology** (Axis V) (**Table 2.2**).

**Axis II: Systems**

- Nervous system (central, peripheral, and autonomic) and special senses; physical disturbance or dysfunction: 00
- Nervous system (psychological and social): 10
- Respiratory and cardiovascular systems: 20
- Musculoskeletal system and connective tissue: 30
- Cutaneous and subcutaneous and associated glands (breast, apocrine, etc.): 40
- Gastrointestinal system: 50
- Genito-urinary system: 60
- Other organs or viscera (e.g., thyroid, lymphatic hemopoietic): 70
- More than one system: 80
- Unknown: 90

**Axis III: Temporal Characteristics of Pain: Pattern of Occurrence**

- Not recorded, not applicable, or not known: 0
- Single episode, limited duration (e.g., ruptured aneurysm, sprained ankle): 1
- Continuous or nearly continuous, nonfluctuating (e.g., low back pain): 2
- Continuous or nearly continuous, fluctuating (e.g., ruptured intervertebral disc): 3
- Recurring irregularly (e.g., headache, mixed type): 4
- Recurring regularly (e.g., premenstrual pain): 5
- Paroxysmal (e.g., tic douloureux): 6
- Sustained with superimposed paroxysms: 7
- Other combinations: 8
- None of the above: 9

**Axis IV: Patient’s Statement of Intensity: Time Since Onset of Pain**

- Not recorded, not applicable, or not known: .0
- Mild—1 mo or less: .1
- Mild—1 to 6 mo: .2
- Mild—more than 6 mo: .3
- Medium—1 mo or less: .4
- Medium—1 to 6 mo: .5
- Medium—more than 6 mo: .6
- Severe—1 mo or less: .7
- Severe—1 to 6 mo: .8
- Severe—more than 6 mo: .9

**Axis V: Etiology**

- Genetic or congenital disorders (e.g., congenital dislocations): .00
- Trauma, operation, burns: .01
- Infective, parasitic: .02
Inflammatory (no known infective agent), immune reaction
Neoplasm
Toxic, metabolic (e.g., alcoholic neuropathy) anoxia, vascular, nutritional, endocrine, radiation
Degenerative, mechanical
Dysfunctional (including psychophysiological)
Unknown or other
Psychological origin (e.g., conversion hysteria, depressive hallucination)

**IASP Chronic Pain Syndromes**

A. Relatively generalized syndromes
B. Relatively localized syndromes of the head and neck
   I. Neuralgias of the head and face
   II. Craniofacial pain of musculoskeletal origin
   III. Lesions of the ear, nose, and oral cavity
   IV. Primary headache syndromes, vascular disorders, and cerebrospinal fluid syndromes
   V. Pain of psychological origin in the head, face, and neck
   VI. Suboccipital and cervical musculoskeletal disorders
   VII. Visceral pain in the neck
C. Spinal pain—spinal and radicular pain syndromes
D. Spinal pain—spinal and radicular pain syndromes of the cervical and thoracic regions
E. Local syndromes of the upper limbs and relatively generalized syndromes of the upper and lower limbs
   I. Pain in the shoulder, arm, and hand
   II. Vascular disease of the limbs
   III. Collagen disease of the limbs
   IV. Vasodilating functional disease of the limbs
   V. Arterial insufficiency in the limbs
   VI. Pain of psychological origin in the lower limbs
F. Visceral and other syndromes of the trunk apart from spinal and radicular pain
   I. Visceral and other chest pain
   II. Chest pain of psychological origin
   III. Chest pain referred from abdomen or gastrointestinal tract
   IV. Abdominal pain of neurologic origin
   V. Abdominal pain of visceral origin
   VI. Abdominal pain syndromes of generalized diseases
   VII. Abdominal pain of psychological origin
   VIII. Diseases of the bladder, uterus, ovaries, and adnexa
   IX. Pain in the rectum, perineum, and external genitalia
G. Spinal pain—spinal and radicular pain syndromes of the lumbar, sacral, and coccygeal regions
   I. Lumbar spinal or radicular pain syndromes
   II. Sacral spinal or radicular pain syndromes
   III. Coccygeal pain syndromes
   IV. Diffuse or generalized spinal pain
   V. Low back pain or psychological origin with referral
This system establishes a five-digit code that assigns to each chronic pain diagnosis, a unique number. For example, the code for carpal tunnel syndrome is 204.X6. Thus,

- 200 = REGION: upper shoulder and upper limbs
- 00 = SYSTEM: the abnormal functioning is attributed to the nervous system
- 4 = TEMPORAL CHARACTERISTICS: symptoms occur irregularly
- X = PATIENT’S STATEMENT OF INTENSITY AND TIME SINCE ONSET: this will vary by patient
- 06 = ETIOLOGY: degenerative, mechanical

Table 2.3 contains the IASP scheme developed for the coding of chronic pain diagnoses.

The IASP classification is the most comprehensive approach to classification of chronic pain syndromes. By design, the IASP classification is a heuristic, multiaxial guide that emphasizes the consideration of both signs and symptoms. Unfortunately, it excludes
assessment of psychosocial or behavioral data. Moreover, to be useful, any classification system must be reliable and valid, but as yet little published research has evaluated the reliability, validity, or utility of the IASP classification. What little evidence is available indicates that, although Axis I (body region) demonstrated reliable coding across examiners, Axis V (etiology) failed to achieve acceptable interrater reliability. The consistency (test–retest reliability) of the IASP taxonomy has yet to be established. Further research is needed in order to evaluate the psychometric properties of the classification system and to facilitate refinements of the system. The classifications we have described are only a few examples and are definitely not exhaustive. Specialists can arrive at classification categories based on clinical experience, published data, and consensus. There is no single system for classifying pain patients that is universally accepted by clinicians or researchers. Furthermore, several problems associated with the current classification systems have generated debate and research concerning an alternative classification of pain. We provide several examples to illustrate different attempts to devise alternative taxonomies of pain and chronic pain patients.

Recently, IASP proposed a classification of chronic pain for inclusion in the ICD-11. The classification includes seven categories (i.e., “primary”, cancer, postsurgical/posttraumatic, neuropathic, headache and orofacial, visceral, and musculoskeletal). The primary category is somewhat of a mixed back pain that cannot be explained by other chronic pain conditions and includes back pain that is neither identified as musculoskeletal or neuropathic, chronic widespread pain, FM, or irritable bowel syndrome. The primary category is consistent with the lumping of this set of disorders in the category of AAPM’s diagnosis of maldynia and central sensitivity disorders advocated by Clauw and Yunus among others. There may be some concern that this poorly defined category may imply the discredited psychogenic classification; that is, an artificial dichotomy where either the condition has a physical basis (somatogenic) or in the absence is psychogenic.

**COMPREHENSIVE, MULTIDIMENSIONAL CLASSIFICATION OF PAIN: ACTTION-AMERICAN**
Recently, a consortium composed of ACTTION partnering with the American Pain Society to create chronic pain taxonomy (AAPT) and with the AAPM (AAAPT) to create an acute pain taxonomy.

AAPT and AAAPT are evidence-based pain taxonomy in which a multidimensional diagnostic framework has been applied to the most prevalent and important chronic and acute pain conditions. A major impetus for the AAPT/AAAPT initiative derived from observing the transformative impact of evidence-based diagnostic classifications in related medical specialties.

An essential characteristic of the AAPT multidimensional framework, taxonomy, and diagnostic criteria is that they are based on the best available evidence regarding symptoms, signs, mechanisms, and consequences rather than on expert opinion alone. This coordinated effort can be applied across all chronic pain conditions, and as has been true of other diagnostic criteria, AAPT will be revised periodically on the basis of accumulating evidence. Another critical aspect of the AAPT is that it reflects the multidimensional, biopsychosocial nature of chronic pain, in which psychological and social risk factors and consequences are integrated with neurobiologic mechanisms and outcomes. In addition, an essential characteristic is that the taxonomy is intended to be applicable for both research and clinical settings; it is recognized, however, that widespread clinical use is likely to develop gradually as the clinical utility of the criteria become apparent and as the evidence base increases. Finally, the initial version of AAPT is based on currently available evidence, and the goal is to systematically update the criteria on the basis of new evidence, especially the results of studies of reliability, validity, and neurobiologic mechanisms.

AAPT therefore categorizes chronic pain conditions by organ system and anatomic structure, distinguishing peripheral and central neuropathic pain, musculoskeletal pain, spine pain, orofacial and head pain, and abdominal/pelvic/urogenital pain (Table 2.4). Because certain types of chronic pain cannot be included in one of these groups, an additional category for disease-related pain not classified elsewhere includes pain
associated with cancer and pain associated with sickle cell disease (pain associated with Lyme disease and with leprosy, among other conditions, would also be included in this group). It is important to emphasize that all types of headache were intentionally excluded from AAPT because the International Classification of Headache Disorders (ICHD)\textsuperscript{20} provides systematic, valid, and widely used diagnostic criteria for these conditions.

**NOTE:** The specific chronic pain conditions listed within each of the seven categories are those for which diagnostic criteria are included within AAPT and are not all of the chronic pain conditions.
that occur within these categories. This table is updated from (Fillingim et al.\textsuperscript{21}).

The AAPT multidimensional framework comprises five dimensions that can be applied to all chronic pain conditions. This can be contrasted with the new IASP taxonomy where psychosocial factors are “optional specifiers” for each diagnoses beyond the classification of “chronic primary pain” where it is given a prominent role along with interference with activities and participation in social roles (somewhat of a departure from the original IASP taxonomy). An overview of these dimensions is presented in Table 2.4, and each is briefly summarized in this section (see also Fillingim et al.\textsuperscript{21}). Other than prioritizing core diagnostic criteria, which is the first AAPT dimension, the order of the dimensions does not reflect their importance. Indeed, as noted earlier, it is anticipated that AAPT diagnostic criteria will ultimately be based on the mechanisms of the specific chronic pain conditions, whereas in the current version of the taxonomy, these mechanisms constitute the final dimension.

Like the IASP classification, the AAPT also includes seven but somewhat different categories of chronic pain (i.e., peripheral nervous systems; central nervous system; spine; musculoskeletal; orofacial and head; visceral, pelvic, and urogenital; other [e.g., cancer, sickle cell]). Within the AAPT classification, psychological and behavioral factors are identified with all of the seven categories. Specifically, the AAPT classification incorporates five dimensions for each condition within the seven categories (Table 2.5). The AAAPT is being extended to acute pain, incorporating the same five dimensions, in this application for eight acute pain sets of conditions (i.e., acute surgical/procedural pain; acute trauma pain; acute musculoskeletal pain; acute visceral pain; cancer/immune-mediated acute pain; acute neuropathic pain; acute orofacial pain; acute pain in pediatric, geriatric, and special populations).

<table>
<thead>
<tr>
<th>Dimension Description</th>
</tr>
</thead>
</table>

22
1. Core diagnostic criteria
   Symptoms, signs, and diagnostic test findings required for the
diagnosis of the chronic pain condition. Includes differential
diagnosis considerations.

2. Common features
   Additional information regarding the disorder, including
common pain characteristics (e.g., location, temporal
qualities, descriptors), nonpain features (numbness, fatigue),
the epidemiology of the condition, and life span
considerations, including those specific to pediatric and
geriatric populations.
   These features are important in describing the disorder but are
not components of the core diagnostic criteria.

3. Common medical and
   psychiatric comorbidities
   Medical and psychiatric disorders that commonly occur with the
chronic pain condition. For example, major depression is
comorbid with many chronic pain conditions. Also includes
chronic overlapping pain conditions, that is, those chronic
pain conditions that are comorbid with each other.

4. Neurobiological,
   psychosocial, and
   functional consequences
   Neurobiological, psychosocial, and functional consequences of
chronic pain. Examples include sleep and mood disorders and
pain-related interference with daily activities.

5. Putative neurobiological
   and psychosocial
   mechanisms, risk factors,
   and protective factors
   Putative neurobiological and psychosocial mechanisms
contributing to the development and maintenance of the
chronic pain condition, including risk and protective factors.
Examples include central sensitization, decreased descending
inhibition, and somatosensory amplification.

INDUCTIVE EMPIRICALLY BASED
CLASSIFICATIONS OF PAIN

Those who advocate the use of empirically derived taxonomies maintain
that quantitative analysis should define the relationships of contiguity and
similarity among individuals. That is, the taxonomic system must reflect
clinically relevant characteristics that exist in nature, defined by empirical
methods rather than based on expert judgment and consensus.

The American College of Rheumatology (ACR) proposed the first
standard criteria that were empirically derived for the classification of FM
in 1990. In a multicenter study, a group of FM experts from several
medical centers collected FM-related variables and used those variables in
an attempt to differentiate FM patients from patients with other types of
chronic pain syndromes. The acceptable sensitivity and specificity were
achieved by two criteria: presence of widespread pain (i.e., above and below the waist, right and left side of the body, and along the midline) and at least 11 of 18 positive tender points upon palpation. Other symptoms commonly reported by FM patients, such as fatigue and stiffness, did not differentiate between FM and other types of chronic pain. Since publication, most subsequent research seems to conform to this classification system, making it a bit easier to compare results across studies. Nonetheless, debate remains about the extent that this classification contributes to clinical practice and the meaning of tender points and the necessity of the tender point criterion.\textsuperscript{50}

Although the criteria were well acknowledged as the important step to standardize the nature of FM population, they were criticized by many as not quite capturing the disease entity well. It is important to acknowledge that all relevant factors cannot be measured by a single classification system. The use of an inductive approach depends on what the investigator chooses to include within the statistical analysis. Thus, in practice, the inductive approach to classification is not a totally objective process that is completely atheoretical. Furthermore, there are significant difficulties in defining a “pure” syndrome that is distinct from all the relevant illnesses when the syndrome itself is a multisymptom disorder. In a case of FM, one of the major criticisms of the empirically driven 1990 ACR criteria is that they fail to incorporate main feature of FM, such as fatigue, cognitive problem, and sleep disturbance. These main features are common in other disorders and do not necessarily differentiate FM from others; nevertheless, not taking these features into account seemed to diminish the validity of the classification. Purely inductive approach to empirically delineate a clinical syndrome may benefit therefore from incorporating clinically and theoretically meaningful approaches.

**PSYCHOMETRIC CONSIDERATIONS**

The general utility of any proposed empirical taxonomy links closely to the psychometric properties (i.e., reliability, validity, and utility) of the measures, scales, or instruments used to derive the classification system. Because these are the building blocks used to generate profiles or clusters, the reliability and validity of the classification system depends, in part, on
the psychometric quality of the measures used. Because reliability and validity coefficients are generic terms, the specific psychometric techniques used to evaluate a measure’s “psychometric properties” require consideration. There are multiple ways to demonstrate the reliability and validity of measures. Therefore, the more psychometric support there is for a measure, the more likely it will perform well when used in taxometric identification and classification procedures. Additionally, replication of classification accuracy on new samples and demonstrating substantial, statistically significant differences across patient profiles for conceptually related measures external to the measures used to develop the profiles are some of the best ways to demonstrate the reliability and validity of empirically derived profiles. Evaluation of any classification should demonstrate reliability, validity, and utility prior to widespread adoption.

**Conclusion**

Pain management specialists have witnessed rapid advances in the basic sciences and clinical arenas of pain medicine over the past three decades. Many pain-related terms, once a major source of confusion, have received clear definitions, aiding efficient and productive communication among researchers and clinicians. The classification systems that direct our research and clinical practice need to reflect the progress in our understanding of mechanisms, multifactorial integration, and outcome predictability of classification criteria. In this chapter, we have reviewed several conventional classifications as well as emerging classification systems that can supplement the conventional ones. The review of various classification systems suggests that the comprehensive taxonomy of pain require multifactorial assessments including physical, psychosocial, and behavioral components (see Table 2.5).

The utility of any classification system depends on application. The important question is whether assignment of an individual to a class truly facilitates treatment decisions or predictions of future behavior. Several of the taxometric systems have demonstrated their utility to predict treatment outcome. The prognostic approach has some data supporting its use as an alternative to the traditional approach based on the acute–chronic duration
continuum. In support of this, the multiaxial RDC for Temporomandibular Disorders has acquired sufficient data to warrant it being adopted as Diagnostic Criteria for Temporomandibular Disorders.\textsuperscript{24} Research is needed to demonstrate the validity of the newer IASP\textsuperscript{4} and AAPT\textsuperscript{21}/AAAPT\textsuperscript{22} taxonomies.

\textsuperscript{†}The discussion describing the distinction between acute and chronic pain reflects on deliberations among the editors of the third edition of this volume.

References

38. Spitzer WO, LeBlanc FE, Dupuis M, et al. Scientific approach to the assessment and

Pain has been categorized by duration (acute vs. chronic), location (superficial or deep; cutaneous, bone/joint, muscle, or viscera), and cause or type (inflammatory, neuropathic, cancer). Generally, activation of and/or ongoing activity in specific subpopulations of primary afferent neurons underlies the experience of pain regardless of how it is categorized. Accordingly, primary afferents are key players in understanding mechanisms of, and managing, pain.

Sir Charles Sherrington anticipated by many decades the existence of sensory receptors that respond to noxious stimuli, that he called nociceptors and thereby provided for us the operational definition of stimuli that are noxious (i.e., stimuli that damage or threaten damage of tissue). Two considerations are important to this discussion. First, Sherrington functionally defines the nociceptor by its response to a noxious stimulus (e.g., a nociceptive withdrawal reflex, pain). Second, the definition of an applied stimulus as noxious is based on the response to the stimulus applied to skin and subcutaneous structures.

Sherrington’s definition of a nociceptor continues to the present day. However, the term has undergone change and challenge over the past 100 years and may be nearing the end of its utility in the face of the growing understanding of the heterogeneity in the neurons that may not fit so comfortably under this umbrella term. It is therefore important to consider, within the context of our current knowledge, how a nociceptor is defined, identified, and studied, as the interpretation of this information will directly affect the management of pain.

All would agree that a nociceptor is a sensory receptor which, when activated or active, can contribute to the experience of pain. Nociceptors
are present in skin, muscle, joints, and viscera, although the density of innervation (i.e., the number and distribution of sensory endings) varies between and within tissues. As originally described by Sherrington, a nociceptor is the peripheral sensory terminal (i.e., the site of energy transduction—see following section), although commonly the term is used to also include the cell body (in a dorsal root, trigeminal, or nodose ganglion) and its central termination in the spinal cord or brainstem. Beyond this, agreement about important features of nociceptors is less uniform. One of the best examples of why this definition is becoming problematic is the observation that injury-induced changes in the central nervous system underlie the emergence of allodynia, pain in response to normally innocuous stimuli. Allodynia is problematic for this definition of nociceptor because pain is mediated by activity in low-threshold afferents that in the absence of tissue injury would, if anything, contribute to the suppression of pain. That is, these afferents would not be considered nociceptors despite the fact that they contribute to the experience of pain.

Furthermore, because stimuli adequate for activation of nociceptors differ between tissues (e.g., tissue damage is not always required), defining a noxious stimulus has become a challenge. For example, some nociceptors in skin and joints and most nociceptors in the viscera have low thresholds for mechanical activation that do not conform to the condition that stimulus intensity must be either damaging or threaten damage. Further, so-called “silent” or “sleeping” nociceptors are unresponsive to intense mechanical stimulation (and are better denoted as mechanically insensitive nociceptors) but develop spontaneous activity and mechanosensitivity after exposure to inflammatory and other endogenous mediators. These types of nociceptors—low threshold and sleeping—as well as other subpopulations of sensory neurons that may contribute to the sensation of pain following tissue injury are considered further in the discussion of sensitization in the following section.

Functional Characterization of Nociceptors

As suggested earlier, there are many types of nociceptors, our knowledge of which has been advanced by human psychophysical studies while
recording from afferent fibers (Box 3.1). In human skin, for example, there exist nociceptors that respond only to mechanical, only to cold thermal, or only to hot thermal stimuli as well as those that are insensitive to both mechanical and heat stimuli (mechanically insensitive or sleeping nociceptors). The most abundant is the polymodal nociceptor, which responds to mechanical, thermal, and chemical stimuli. In general, nociceptors that innervate skin have the broadest range of modality selectivity, whereas nociceptors innervating deeper structures tend to be less modality-selective and more polymodal in character. For example, mechanical sensitivity is a prominent feature of visceral and joint nociceptors because stimuli adequate for their activation include hollow organ distension and overrotation, respectively. Many of these nociceptors also respond to chemical and/or thermal stimuli as well, although the functional significance of thermal sensitivity in deep tissues is uncertain.

An important characteristic of polymodal nociceptors, whether the modalities of stimulation to which they respond are two or all three, is that when sensitized (e.g., by an inflammatory insult), responses to the other modality or modalities of stimuli to which it responds are all increased. That is, it is not only the mechanosensitive modality, for example, that becomes sensitized, but other modalities to which it responds are sensitized as well.

**BOX 3.1 Microneurography**

The development of a method to record from human nerve fibers in situ, termed microneurography, provided an unparalleled opportunity to expand our knowledge about peripheral sensory receptors, including nociceptors. The method involves percutaneous insertion of the tip of a sharp, insulated metal microelectrode into a nerve (e.g., peroneal or radial nerve) and the application of search stimuli to sites distal to the electrode. In earlier work, mechanical search stimuli (e.g., von Frey filaments) were used, and accordingly, only mechanosensitive afferents were studied. An electrical search stimulus (surface electrode), however, has become favored because the electrical stimulus identifies afferent fibers independent of sensitivity to
natural stimulation. After an afferent fiber is isolated, the innervation territory can be drawn on the skin and the adequate, natural stimulus/stimuli determined.

Because microneurography can be easily coupled with a psychophysical approach, human subjects are able to describe stimulus-produced experiences (e.g., pain) while recording from single afferent fibers. Microneurography also has been expanded to include intraneural electrical stimulation of the fiber through the recording electrode, providing additional insight into the qualities of sensation produced, for example, by low- and high-frequency stimulation in addition to qualities associated with natural stimulation. Microneurography has confirmed in psychophysical experiments sensations associated with activation of rapidly adapting (flutter, vibration) and slowly adapting (pressure) cutaneous mechanoreceptors, Aδ-mechanonociceptors (AM\textsubscript{mechano}; sharp pain), C-polymodal nociceptors (CM\textsubscript{mechano}H\textsubscript{heat}; dull, burning [heat] pain), and group IV muscle nociceptors (cramping pain).

Electrical search strategies have revealed a wider range of nociceptors, including\textsuperscript{190} A-mechanoheat (AMH), which have similar heat thresholds as CMH (C-polymodal) fibers and also typically respond to chemical stimuli; C-mechanonociceptors (CM), C-heat (CH); C-mechano- and heat-insensitive (CM\textsubscript{iH}, or sleeping nociceptors); and C-mechanoinsensitive-histamine responsive (CM\textsubscript{iH}His+, or itch fibers\textsuperscript{193}). Microneurography has also been extended to psychophysical study of pathologic pain states in humans. In a study of patients suffering from erythromelalgia, a condition characterized by painful, red, and hot extremities, a proportion of CM\textsubscript{iH} fibers were found to be spontaneously active or sensitized to mechanical stimuli. Because CM\textsubscript{iH} fibers also mediate the axon flare reflex, their hyperexcitability was considered to contribute to the patients’ ongoing pain and tenderness as well as the redness and warming in this pain syndrome. In patients with painful peripheral neuropathy, Ochoa et al.\textsuperscript{194} reported hyperexcitability in CMH and CM\textsubscript{iH} fibers. Signs of hyperexcitability included reduced thresholds to mechanical and heat stimuli, spontaneous activity, and increased responses to stimulation. In
diabetic neuropathic pain patients, Ørstavik et al.\textsuperscript{195} found that the ratio of CMH to CM\textsubscript{1}H\textsubscript{1} fibers was reduced by about 50%, apparently due to loss of mechanical and heat responsiveness in CMH fibers.

These and future studies will help to understand which nociceptors (and non-nociceptors) in which conditions contribute to spontaneous, ongoing pain as well as stimulus-evoked pain and what therapeutic strategies are most effective.

With respect to mechanosensitivity, nociceptors at the opposite extremes of sensitivity are most illustrative of the limitations of even a functional definition of a nociceptor. Nociceptors with low mechanical thresholds for response and those with very high mechanical thresholds for response (i.e., sleeping nociceptors) are both clinically important. Mechansensitive sensory neurons with low thresholds for response have long been classified as non-nociceptors (because it was considered that nociceptors had to have response thresholds in the noxious range). Some mechansensitive skin, joint, and many visceral sensory neurons have low thresholds for response (i.e., in the nonnoxious range) but possess characteristics that suggest an important role in pain. First, they encode stimulus intensity well into the noxious range and, moreover, typically give greater responses to all intensities of stimulation than do nociceptors with high mechanical thresholds for response. Second, they sensitize after tissue insult. Unlike nociceptors with low mechanical thresholds, mechanically insensitive or sleeping nociceptors normally provide no information to the central nervous system but after tissue insult become spontaneously active and mechansensitive.\textsuperscript{5}

**Identification of Putative Nociceptors**

As indicated earlier, nociceptors are defined classically in a functional context. However, in experimental situations where function cannot be assessed, other criteria to classify a neuron as a nociceptor have been advanced. These include the presence or absence of axon myelination, cell size, and/or cell content (e.g., peptide or ion channel) as well as central termination pattern. Sensory neurons commonly identified as nociceptors
are those with unmyelinated (C-fiber) axons, small cell body diameters (<20 or 25 µm), that terminate in the superficial layers of the spinal cord dorsal horn. The presence or absence of certain markers (e.g., the tetrodotoxin (TTX)-resistant sodium channel NaV1.8, the transient receptor potential vanilloid receptor TRPV1) have been used to identify subsets of nociceptors. More recently, with the ability to analyze many genes expressed in a single cell, patterns of gene expression have been used to further define subpopulations of nociceptors. With respect to cell body size and myelination, it should be appreciated that there exist some large diameter cells with heavily myelinated and rapidly conducting axons that have been documented functionally to be nociceptors. Conversely, many non-nociceptors have unmyelinated axons, and thus, axon myelination or cell diameter cannot be applied as reliable criteria to define a nociceptor. Similarly, identifying nociceptors by content or by what genes they express has limitations. Two examples of this are that (1) cells other than nociceptors express TRPV1 and (2) the features of the subset of nociceptors in the mouse skin that stain positive for the isolectin B4 do not apply to the visceral innervation. And although patterns of gene expression may enable identification of additional subpopulations of nociceptive sensory neurons, the extent to which any particular pattern reliably reveals a neuron’s function remains to be established.

The fact that no single criterion can be used to identify all nociceptors combined with the growing number of examples to the ways in which these neurons are heterogeneous is at the core of a growing concern over the utility of the term. In addition to the anatomical, biochemical, and physiologic heterogeneity in the afferent population, generally referred to as nociceptors, there is functional heterogeneity. As will be discussed later, this functional heterogeneity is manifest both within the context of nociceptive signaling (i.e., subpopulations of nociceptors may underlie distinct “types” of pain such as cold allodynia or thermal hyperalgesia) and in the context of nonnociceptive function (i.e., such as the maintenance of tissue integrity).

Even the two functional properties that have been viewed as common to all nociceptors, that they encode stimulus intensity into the noxious range and they sensitize, are, at best, generalities. As noted earlier, the so-called
mechanically insensitive afferents shown to play such a prominent role in visceral pain\textsuperscript{11} and the burning pain associated with capsaicin\textsuperscript{12} do not appear to code stimulus intensity in the noxious range. Similarly, a variety of nociceptive afferents may be desensitized under the appropriate conditions.\textsuperscript{13–16} The link between the stimulus–response properties of a given subpopulation of afferents and the functional role of these neurons in the context of nociceptive signaling has been further complicated by results of selective ablation/silencing studies in mice, where modality specific deficits in nociceptive processing are associated with the silencing of specific subpopulations of afferents despite electrophysiologic data suggesting that the majority of the afferents silenced/ablated are polymodal. For example, the majority of cutaneous neurons in the mouse that express the Mas1-related G protein-coupled receptor D (MrgprD) are polymodal nociceptors,\textsuperscript{17} yet mice in which this subpopulation of neurons has been ablated respond normally to changes in temperature, demonstrating, instead, a relatively selective mechanosensitivity deficit.\textsuperscript{18} Conversely, the voltage-gated sodium channel (VGSC) NaV1.8 is enriched in nociceptive afferents that are responsive to both noxious thermal (TRPV1-expressing) and mechanical (MrgprD-expressing) stimuli, yet mice in which NaV1.8-expressing neurons have been ablated respond to noxious heat but not noxious mechanical pressure or cold stimuli.\textsuperscript{19} Minimally, these results suggest that the behavioral response to noxious stimulation involves a number of factors in addition to the types of afferents that are activated.

All of this heterogeneity does not bode well for the development of broadly acting novel analgesics. That is, given our current understanding of the complexity of peripheral pain mechanisms, it seems unlikely that the range of intensities within any one modality (thermal, mechanical) that is encoded by a nociceptor and initiates nociceptive transmission involves only a single voltage- or ligand-gated channel. Similarly, even if the ability to sensitize is one means of functionally defining a peripheral neuron as a nociceptor, the endogenous mediators and factors that contribute to an increase in the excitability of nociceptors (i.e., sensitization) are numerous and synergetic and differ in different pain conditions (e.g., inflammation, nerve injury). A sampling of the complexities and contributors to
sensitization are discussed in the following section.

Why include in a clinical textbook of pain management a chapter on peripheral pain mechanisms and nociceptors? There are many reasons. First, in most cases, blockage of peripheral nociceptor activity removes the “drive” for the experience of pain. Further, if a primary goal is to develop mechanism-based strategies for pain management, it is critical that characteristics of a key player—the nociceptor—are fully understood. Finally, nociceptor characteristics change as the local environment in which they reside changes (inflammation, nerve injury, etc.). I discuss in the following section how nociceptors are activated, differ in different tissues, and contribute to the experience of pain and how their behavior changes when they become sensitized. Where possible, we have added relevant clinical examples and have inserted text boxes to elaborate on key issues.

Nociceptor Characteristics

ANATOMY OF THE NOCICEPTOR

As stated earlier, nociceptors are sensory neurons with a cell body located in dorsal root, trigeminal, or nodose ganglia. All sensory neurons arising from these ganglia are pseudo-unipolar neurons with a central process terminating in the central nervous system (e.g., spinal dorsal horn) and a peripheral process terminating in a peripheral target such as the skin, muscle, or viscera. Both central and peripheral processes terminate in a branching pattern referred to as a terminal arbor. The extent of the peripheral arbor depends on the afferent type and site of innervation with the general rule that the higher the spatial resolution for sensory discrimination, the smaller the terminal arbor. In contrast to low-threshold afferents that are responsive to nonnoxious stimuli such as brush or vibration and which terminate in specialized structures, such as Ruffini endings or Merkel disks, nociceptors are said to have “free” (unencapsulated) nerve endings because peripheral terminals of these afferents do not appear to be associated with any specific cell type.

Both light and electron micrographic analyses of peripheral nociceptor terminals reveal complex anatomical structures. As suggested earlier, the
structure of the terminal arbor varies with target of innervation. There is also evidence that subpopulations of nociceptive afferents have distinct terminal arbor patterns within the same structure. For example, the terminal arbor morphology of cutaneous C fibers varies according to whether the C fiber is peptidergic (i.e., expresses substance P or calcitonin gene-relative peptide) or expresses the MrgprD. On the other hand, the terminal morphology of a subpopulation of high-threshold Aδ fibers that appear to mediate the pain associated with hair pull is similar to that of a subpopulation of low-threshold mechanosensitive Aβ fibers that appear to underlie the sensation of gentle stroking of the skin. Evidence also suggests that distinct but overlapping subpopulations of nociceptors may signal distinct aspects of the painful experience (i.e., sensory/discriminative vs. emotional/motivational), suggesting that it may someday be possible to selectively treat the suffering associated with chronic pain while still enabling patients to appropriately respond to noxious stimuli in their environment.

Four distinct events are necessary for a nociceptor to convey information to the central nervous system about noxious stimuli impinging on peripheral tissues (Fig. 3.1—the events are discussed fully in the following paragraphs). First, “energy” from the stimulus (mechanical, thermal, or chemical) must be converted into an electrical signal. This process, referred to as signal transduction, results in a generator potential or depolarization of the peripheral terminal. Second, the generator potential must initiate an action potential, the rapid “all or nothing” change in membrane potential that constitutes the basic unit of electrical activity in the nervous system. This process is sometimes referred to as transformation. Third, the action potential must be successfully propagated from the peripheral terminal to the central terminal. And fourth, the propagated action potential invading the central terminal must drive a sufficient increase in intracellular calcium ions to enable release of enough transmitter to initiate the whole process once again in the second-order neuron. Distinct sets of proteins underlie each of these processes and are, therefore, the targets of a wide variety of therapeutic interventions.
FIGURE 3.1 Nociceptive afferents terminate as free nerve endings in skin and other tissues. A: Their principal sensory functions consist of (1) transduction of external or internal chemical or physical stimuli into generator potentials, (2) transformation of a generator potential into an action potential, (3) propagation of the action potential toward the central nervous system, and (4) release of neurotransmitters and neuromodulators into the superficial dorsal horn of the spinal cord or brainstem. Nociceptive afferents also release transmitters in the periphery, a process that contributes a neurogenic component to inflammation (not shown). The sensory neuron cell body (soma, 5) appears to be a site critical for the integration of neural activity. Proteins and signaling molecules are delivered to the soma via axonal transport mechanisms (not shown) under normal conditions,
which may contribute to aberrant or ectopic activity under pathologic conditions. Many of the proteins responsible for each of these processes, both under normal and pathologic conditions, have been identified. Although not a complete list, several lines of data implicate each of the proteins and mediators illustrated in each subpanel. B: Transduction: In naive tissue, proteins thought to play a role in mechanotransduction include transient receptor potential vanilloid type 4 (TRPV4), acid-sensing ion channel type 3 (ASIC-3), and the low-threshold voltage-gated calcium channel (VGCC) CaV3.2. Several different classes of TRP channels are involved in transduction of changes in temperature from noxious cold (TRPA1, ankyrin type 1), cool (TRPM8, melastatin type 8), warm (TRPV4), and hot (TRPV1, vanilloid type 1). Many chemoreceptors are present in nociceptive afferents including those involved in the response to tissue acidosis (TRPV1 and ASIC-3), noxious organic compounds (e.g., aldehydes at TRPA1), and endogenous chemicals (e.g., ATP at P2X3, the ionotropic purine receptor type 3). A wide variety of other receptors for both pro- and anti-inflammatory (not shown) mediators are also present on the terminals of nociceptive afferents. These include G protein-coupled receptors (GPCRs) responsive to E-type prostaglandins (EP), bradykinin (B) types 1 and 2, and serotonin (5-HT) types 1A, 2, and 7. Tyrosine receptor kinases (TRK), responsive to trophic factors such as nerve growth factor (NGF) and artemin, are present as are receptors for cytokines such as TNF-α and interleukin 1-β. Also depicted are transmitters such as ATP stored in epithelial cells. Following tissue insult, there are changes in nociceptive terminals that result in both an increase in sensitivity to noxious stimuli as well as the emergence of membrane depolarization. There are increases in the density of several transducers as well as posttranslational modifications (depicted as phosphorylation, P) that increase channel activity or sensitivity such that the transducers are activated by lower intensity stimuli. These changes are brought about by actions of inflammatory mediators such as ATP, prostaglandin E2, NGF, and TNF-α that can directly depolarize nociceptive terminals, drive posttranslational changes via the activation of second messenger cascades, and/or alter the expression of transducers via influencing transcription and/or translation. All of these processes may be facilitated as a result of an increase in the release of mediators from epithelial cells, resident (mast) cells, and recruited (macrophages) immune cells. Several therapeutics currently in use or in development act via suppressing the actions of proinflammatory mediators. The specific pattern of changes and mediators depends on many factors, including the type and site of injury, time after injury, and previous history of the injured tissue as well as age and sex, which also influence the relative efficacy of the therapeutic intervention. C: Spike initiation: The appropriate anatomical distribution of ion channels is critical for normal function. A number of ion channels play an important role in determining the threshold for spike initiation and upstroke of the spike. Action potential threshold appears to be critically regulated by potassium (K+) channels, which include voltage-gated K+ channels (KV), inward rectifying K+ channels (KIR), two-pore K+ channels (K2P), large-conductance calcium-modulated K+ channels (BK), and small conductance calcium-dependent K+ channels (SK). The nonselective inward rectifying cation channel (HCN) also contributes to action potential threshold. In some cases, the low-threshold calcium channel (CaV3.2) may contribute to action potential threshold, but when present, CaV3.2 appears to play a more prominent role in mediating burst activity. The voltage-gated sodium channel (VGSC) NaV1.9 may also contribute to establishing action potential threshold. Finally, the channels responsible for the upstroke of the action potential include the VGSCs NaV1.7 and NaV1.8. As with transduction, there are a number of changes in ion channels that affect action potential threshold and spike initiation to increase in the excitability of nociceptive afferents in the presence of insult. These changes include a decrease in K+ channel density and/or current and an increase in CaV3.2, HCN, and NaV channel density and/or activity. These changes are the result of both posttranslational modifications and/or changes in transcription driven by the same inflammatory mediators that influence transduction. Thus, several of the therapeutics listed under transduction may also act by inhibiting changes in channels underlying spike initiation. Other
drugs may act via direct inhibition of the ion channels underlying spike initiation (which include local anesthetics, tricyclic antidepressants [TCAs], and several cyclooxygenase inhibitors). K+ channel openers such as retigabine may also have efficacy in increasing the threshold for spike initiation. **D:** Action potential propagation: The ion channels underlying action potential propagation are distinct from those underlying spike initiation. The channel most prominently implicated in action potential propagation is the VGSC NaV1.6. In myelinated axons, NaV1.6 is clustered at nodes of Ranvier, whereas in unmyelinated axons, the channel is distributed throughout the axon. Following insult, however, the pattern of channel expression can change, including redistribution of VGSCs NaV1.7 and/or NaV1.8 to the cell membrane. The dependence of action potential propagation on VGSCs confers the therapeutic efficacy of sodium channel blocking compounds such as local anesthetics, TCAs, and some cyclooxygenase (COX) inhibitors. **E:** Ectopic activity: As is true for all neurons in the absence of tissue insult, the soma serves as the supply depot for the rest of the neuron, synthesizing and packaging the proteins, transmitters, and lipids that will be used throughout the cell. Although the soma is capable of generating action potentials and is likely depolarized in response to neural activity in the axons, it is not necessary for action potentials to invade the soma for information to propagate from the periphery to the central nervous system. In nociceptive afferents, the VGSC NaV1.8 can be the primary, if not the only sodium channel in the cell underlying action potential generation. In the presence of nerve injury, however, changes in the soma and/or proximal axon can include an increase in transducer proteins that may make the soma responsive to mechanical, thermal, and chemical stimuli, an increase in sodium channels that may lead to membrane instability (manifesting as oscillatory behavior), and an increase in inflammatory mediators and their receptors. The result of such changes is that the soma and/or proximal axon may become a source of aberrant or ectopic activity. An important implication of this activity is that local administration of therapeutic agents to block activity arising from peripheral terminals may not provide pain relief. Given the source of much of this activity, therapeutic interventions designed to block sodium channels and/or inhibit the actions of inflammatory mediators are predicted to have the greatest efficacy. **F:** Transmitter release: The release of transmitter at the central terminals of nociceptive afferents is essential for transmission of nociceptive information to the central nervous system. This process is calcium-dependent—extracellular calcium enters the central terminal generally via high-threshold VGCCs that are activated following invasion of the action potential into the central terminals. N-type channels (CaV2.2) are the most abundant, but P/Q-type (CaV2.1) and L-type (CaV1.3) are also present. CaV2.2 is most readily modulated following activation of inhibitory GPCRs, serving as the primary mechanism for the therapeutic efficacy of intrathecal opioid receptor and alpha adrenergic receptor (α-AR) agonists. Transmitters present in nociceptive afferents are generally packaged in vesicles referred to as small clear vesicles, which generally contain the excitatory amino acid glutamate, and large dense-core vesicles, which contain, among other things, neuropeptides such as substance P and calcitonin gene-related peptide (CGRP). There are a number of excitatory ionotropic receptors, including P2X3 and TRPV1, that appear to facilitate transmitter release from the central terminals. Inhibition of the central terminal may involve activation of voltage-gated (KV) and calcium-modulated (BK) K+ channels. Under normal conditions, presynaptic ionotropic γ-aminobutyric acid (GABA) receptors (GABAA) play a major role in mediating presynaptic inhibition of the central terminals of nociceptive afferents. The VGSC that appears to play a major role in enabling spike invasion of the central terminals of nociceptive afferents is NaV1.8. Finally, excitatory GPCRs (e.g., EP and β1, β2 receptors) are also present. As with other steps in the process, a number of changes occur in the central terminals of nociceptive afferents after tissue insult that contribute to the transmission of nociceptive information. These include an increase in the α2δ1 subunit in VGSCs. This subunit is important for trafficking channels to the membrane and, importantly, is a
binding site for gabapentin and pregabalin. There is also an increase in neuropeptide expression, the emergence of additional excitatory receptors, modulation of ion channels such as NaV1.8, and a decrease in K+ currents that facilitate nociceptive signaling. Interestingly, there is a growing body of evidence suggesting that there may be changes in GABAA receptor signaling as well such that activation of these receptors may become excitatory secondary to changes in the regulation of intracellular chloride. This issue is complicated by the fact that benzodiazepine receptor agonists may have therapeutic efficacy in the presence of tissue insult which appears to involve, at least in part, activation of presynaptic receptors. From the therapeutic perspective, it is important to note that following tissue insult, in particular that associated with inflammation, there may be an increase in the expression of inhibitory receptors, ultimately facilitating the therapeutic efficacy of opioid and adrenergic receptor agonists. Additional therapeutic interventions may also involve inhibitors of VGCCs, K+ channel openers, and inhibitors to inflammatory mediators.

STIMULUS TRANSDUCTION

An important implication of the fact that nociceptive afferents terminate in “free nerve endings” is that they are not dependent on other cell types for the transduction of a noxious stimulus. That is, proteins responsible for transduction should be intrinsic to the nociceptor. Consistent with this suggestion, isolated sensory neurons are responsive to thermal (both heating\(^ {27,28} \) and cooling\(^ {29,30} \), mechanical,\(^ {31,32} \) and a wide variety of chemical stimuli, including both endogenous\(^ {33,34} \) and exogenous\(^ {35,36} \) compounds that activate nociceptors in vivo. Proteins involved in the transduction of each stimulus modality have been identified (see Gold\(^ {37} \) for review).

With the exception of transient receptor potential (TRP) channels (see the following discussion), two-pore potassium channels (K2P), and possibly the acid-sensing ion channels (ASICs), chemotransducers are, in general, only activated by chemical stimuli (and not also mechanical or thermal stimuli) and encompass various families of proteins that respond to specific molecules such as adenosine triphosphate (ATP)\(^ {38} \) and protons.\(^ {39} \) There is also compelling evidence to support the suggestion that different members of the TRP superfamily underlie thermal transduction of temperatures ranging from the very cold (TRPA1\(^ {40} \)) to the very hot (TRPV2\(^ {41} \)), with receptors for cool,\(^ {42} \) warm,\(^ {43,44} \) and hot\(^ {45} \) in between. Subsequent research, however, suggests that in contrast to traditional chemoreceptors, TRP family members are not modality-specific as all are activated by specific chemicals\(^ {46} \) and several contribute to mechanical transduction.\(^ {32,47,48} \)
Because the only sensation associated with TRPV1 activation is pain, this receptor has received considerable attention from pain researchers. Data from an array of studies paint a picture of TRPV1 as an excellent example of a polymodal receptor; it is activated by exogenous compounds such as capsaicin and resiniferatoxin, endogenous compounds ranging from protons to lipids, as well as noxious heat. TRPV1 is also present on the central terminals of nociceptive afferents where it also facilitates transmission of noxious mechanical stimuli. Furthermore, excessive activation of the receptor with compounds such as capsaicin results in desensitization of the nociceptive terminal to all modes of stimuli, a process that underlies the therapeutic efficacy of topical capsaicin application. More recently, intrathecal application of resiniferatoxin has been used to selectively ablate the central terminals of TRPV1 containing nerve terminals, resulting in a sustained block of nociceptive transmission. There is also evidence that TRPV1 receptor antagonists may have some analgesic efficacy, although their therapeutic potential may be limited by a small but significant hyperthermia associated with systemic administration of blood–brain barrier permeable analogs.

Of the three modalities of noxious stimuli, molecular mechanisms of mechanotransduction remain the most elusive. Many mechanically sensitive proteins have been identified, but none appears to be both necessary and sufficient for mechanotransduction in nociceptive afferents. Data from null mutant mice, where the deletion of a single putative mechanotransducer results in an increase in mechanosensitivity in one population of afferents and a decrease in others, suggests that several different proteins are likely to work together in specific subpopulations of afferents to enable responses to specific forms of mechanical stimuli (e.g., stretch or compression). This picture is complicated further by the observation that some mechanotransducers such as piezo2 contribute to mechanotransduction in specific subsets of sensory neurons. That even these more specialized forms of mechanosensitivity reflect intrinsic properties of afferents are suggested by the emergence of mechanosensitivity at the severed ends of a subpopulation of axons within hours of transection. Despite the slow progress in this area, identification of a nociceptor specific mechanotransducer blocker remains an active area.
of investigation because of its therapeutic potential in light of the fact that mechanical hypersensitivity is the primary complaint associated with the vast majority of chronic pain syndromes.\textsuperscript{62–64}

Whereas mechanotransduction is an intrinsic property of many nociceptors, there is evidence that epithelial cells may also be mechanosensitive.\textsuperscript{65–67} Because these cells may store and release transmitters such as ATP, it has been suggested that afferent activity evoked with mechanical stimulation of peripheral structures such as the bladder,\textsuperscript{65} gastrointestinal tract,\textsuperscript{68} and skin\textsuperscript{66,67,69} may be secondary to the transduction event that has occurred in the epithelial cell that subsequently releases a chemical mediator capable of activating nearby nociceptor terminals. The implication of this mechanism from a therapeutic perspective is that it may be possible to attenuate mechanical hypersensitivity in several peripheral tissues with the appropriate antagonist of the responsible chemoreceptors on nociceptive afferents.\textsuperscript{70} Consistent with this idea, there is evidence that mechanical hypersensitivity observed in several visceral structures can be attenuated with ATP receptor antagonists.\textsuperscript{71} That a similar mechanism may contribute to chemotransduction, at least in the intestine, was recently suggested by the observation that enterochromaffin cells are not only activated by a variety of chemicals but are electrically excitable and form synaptic connections with primary afferents.\textsuperscript{72} However, serotonin appears to be the primary transmitter underlying the signaling from these cells to primary afferents, possibly accounting for the therapeutic efficacy of inotropic serotonin receptor (i.e., 5-HT\textsubscript{3}) antagonists for the treatment of visceral pain.\textsuperscript{73}

Aberrant expression of transducers may play a significant role in chronic pain associated with tissue injury. The presence of a functional transducer at a site other than the peripheral terminal may underlie the emergence of ectopic activity and contribute to ongoing or spontaneous pain. Such changes have been most extensively detailed following nerve injury, where, as mentioned earlier, mechanical sensitivity is detectable in cut axons within hours of injury\textsuperscript{61} and may persist in neuromas indefinitely.\textsuperscript{74} Similarly, chemosensitivity, particularly to adrenergic agonists, develops at both the cut ends of nociceptive afferents\textsuperscript{75} as well as
within the ganglia itself,\textsuperscript{76} contributing to ectopic activity arising from both the site of injury and from the ganglia. The emergence of ectopic activity arising from sites distant to the site of injury may explain why interventions targeting the site of injury are unsuccessful.

**PASSIVE ELECTROPHYSIOLOGIC PROPERTIES AND THE SPREAD OF THE GENERATOR POTENTIAL**

A generator potential at a primary afferent terminal ending is not equivalent to an action potential propagated along that afferent’s axon. The generator potential decays over distance from the point of origin as a function of membrane resistance, membrane capacitance, and internal resistance of the nerve terminal and may or may not be propagated beyond the terminal ending. Generally considered stable properties, there is evidence for dynamic remodeling of the terminal arbor of central nervous system neurons\textsuperscript{77} which may influence both membrane capacitance and internal resistance; it remains to be determined whether such changes may also impact passive conduction of generator potentials in peripheral terminals. In contrast, a number of ion channels have been identified that may establish resting membrane resistance and therefore the spread of the generator potential within the terminal arbor.\textsuperscript{78} This issue is important to nociceptive signaling because action potential initiation does not always occur at the site of stimulus transduction.\textsuperscript{79} Consequently, the magnitude of the generator potential at the site of action potential initiation must be greater than or equal to action potential threshold. Thus, at least in some fiber types, it may be possible to block nociceptor signaling and therefore pain, with manipulations such as the local administration of potassium (K+) channels openers\textsuperscript{80,81} that decrease membrane resistance and therefore spread the generator potential.

Although ion channels have been the focus of research into mechanisms controlling neuronal excitability of peripheral neurons, recent evidence suggests that ion pumps and exchangers may contribute as well. Some pumps and exchangers, such as the sodium/potassium ATPase and the sodium/calcium exchanger, are electrogenic; that is, they generate net flux of ions when active and therefore may contribute directly to resting membrane potential and consequently neuronal excitability. They may also
contribute indirectly, via an influence on intracellular ion concentrations and consequently the activity and/or actions of other ion channels. For example, the sodium/calcium exchanger, and the calcium ATPase control intracellular calcium levels in sensory neurons, and intracellular calcium influences activity of calcium, potassium, and chloride channels in sensory neurons. Conversely, the sodium/potassium/chloride cotransporter and the bicarbonate/chloride exchangers in sensory neurons influence intracellular chloride concentrations, which, in turn, influence the impact of type A γ-aminobutyric acid (GABAA) on sensory neurons.

The results of several recent studies suggest that influencing the magnitude and/or spread of the generator potential may underlie the next generation of therapeutics. Because of the limitations of the nonspecific nerve block produced by local anesthetics, strategies that enable a more selective afferent block are an active area of investigation. In one such strategy, a viral vector was used to drive expression of an ionotropic glycine receptor, an inhibitory ligand-gated ion channel not normally present in sensory neurons. Sensory neurons innervating specific targets such as the skin or the bladder could be selectively infected by injecting the viral vector into the intended target tissue. This strategy enabled the reversal of hypersensitivity with the local administration of glycine. A similar approach involves the use of optogenetics, or light-activated proteins that can be selectively expressed in targeted cell types. Inhibitory light-activated ion pumps, such as halorhodopsin or archaerhodopsin, have been used to study the role of specific subpopulations of afferents in pain, where both viral vector-based and site-specific recombinase technology have been used. Expression of these light-activated proteins can be restricted to specific subpopulations of afferents via a variety of approaches including the site of infection, the virus serotype used, as well as cell-specific promoters. Given the spatial and temporal control of the afferent inhibition afforded by these strategies, combined with the ability to selectively target subpopulations of afferents, the therapeutic potential is tremendous.

**ACTION POTENTIAL GENERATION**

VGSCs are responsible for the upstroke of the action potential in virtually
all excitable tissue. As their name implies, these channels are gated (opened and closed) by changes in membrane potential. VGSCs are generally composed of an α subunit and up to two β subunits. The α subunit is a large molecule (~200 kD) that contains all features necessary for a functional channel including voltage sensor, ion selectivity filter, channel pore, and inactivation gate. Ten α subunits have been identified, nine of which form functional channels in heterologous expression systems. The channels encoded by each of these subunits can be distinguished by a combination of pharmacologic and biophysical properties. Eight of these nine α subunits are present in the nervous system, all eight of which are present in nociceptive afferents at one point during development, with six of these detectable in the adult. β Subunits influence channel gating properties as well as trafficking and localization in the plasma membrane. Four β subunits have been identified, at least three of which are present in nociceptive afferents.

The VGSC α subunit primarily responsible for action potential initiation in the majority of nociceptors is NaV1.8. This subunit is unique in several ways. First, it is normally only expressed in primary afferents where it is primarily expressed in nociceptors. This unique pattern of distribution, in combination with its primary function in spike initiation, makes it an ideal target for novel therapeutics. Although in no way mitigating the therapeutic potential of this channel, recent evidence suggests that it may contribute to action potential propagation in the distal peripheral axon in addition to its role in action potential initiation. Second, NaV1.8 has a relatively high threshold for activation. Whereas many other VGSCs begin to activate at membrane potentials between −50 and −40 mV, a depolarization to −30 mV or greater is necessary to activate NaV1.8. This feature may explain, at least in part, why greater intensity stimuli are generally needed for nociceptor activation. Third, NaV1.8 is relatively resistant to steady-state inactivation, a voltage-dependent process whereby channels residing in a closed or resting state transition to an inactive state before they ever get a chance to open. Recovery from the inactivated state requires membrane hyperpolarization; thus, inactivated channels cannot contribute to the upstroke of the action potential. Even a small sustained depolarization to −50 mV can inactivate virtually all other
VGSCs. However, NaV1.8 is still fully available for activation at this membrane potential. Fourth, NaV1.8 recovers from inactivation rapidly. These last two features enable the channel to underlie sustained activity in the face of a persistent depolarization that might be observed in the presence of inflammatory mediators. Fifth, NaV1.8 is resistant to cooling-induced inactivation. Other VGSCs are completely inactivated at temperatures at or below 18°C. However, NaV1.8 is still functional at temperatures down to 4°C, enabling the burning pain associated with noxious cold stimuli. Sixth, in contrast to all but one other VGSC α subunit (NaV1.9), NaV1.8 is resistant to TTX and is therefore referred to as a TTX-resistant channel.

Whereas NaV1.8 is critical for action potential initiation in nociceptors, data from the study of rodent sensory neurons suggests that in many of these afferents, NaV1.8 works in concert with another VGSC α subunit, NaV1.7. The NaV1.7 subunit has unique features enabling it to play a significant role in spike initiation. That this channel may play a critical role in nociceptor activity is suggested by the recent discovery of individuals possessing both gain-of-function and loss-of-function point mutations in this subunit. Strikingly, two distinct pain syndromes—primary erythermalgia (PE) and paroxysmal extreme pain disorder (PEPD)—reveal the specific impact of gain-of-function mutations. PE is associated with burning pain in the hands and feet, and PEPD is initially associated with pain in the rectum that ultimately progresses to include trigeminal structures including the eye and jaw. The unique distribution of these pain syndromes, in light of the widespread distribution of NaV1.7 in the peripheral nervous system as well as neuroendocrine tissues, highlights the importance of other channels in sculpting the response properties of sensory neurons. Furthermore, in contrast to the impact of the gain-of-function mutations, loss-of-function mutations that result in nonfunctional channels are associated with a complete insensitivity to pain. Although the data from patients with these rare genetic mutations is intriguing, recent evidence suggests the role of NaV1.7 in nociceptive processing may be more complicated than originally anticipated. That is, evidence from null mutant mice suggests that the loss of function phenotype may not only involve sympathetic postganglionic neurons but a compensatory
upregulation of the endogenous opioid enkephalin in primary afferents. Furthermore, electrophysiologic analysis of nociceptive afferents in patients with gain-of-function mutations in these channels suggests that at least at rest, the afferents are hypoexcitable. These observations raise the possibility that the pain phenotypes associated with mutations in NaV1.7 reflect developmental processes independent of any ongoing influence of the channel in controlling afferent excitability. Furthermore, in contrast to isolated sensory neurons from the rat, where NaV1.7 appears to contribute to action potential initiation, recent evidence suggests that this may not be the case in human sensory neurons.

Low voltage–activated, or T-type, calcium channels may also contribute to spike initiation in the periphery. Whereas there is compelling evidence that these channels are present in high density in low-threshold D-hair afferents, there is also evidence that they may be present in a subpopulation of nociceptors as well. The biophysical properties of these channels enable them to play a particularly important role in mediating bursting activity, as the channels underlie a sustained membrane depolarization after a single action potential that provides the driving force for the initiation of subsequent action potentials. This feature has led some to speculate that selective T-type channel blockers may be particularly effective for treating paroxysmal pain such as that associated with trigeminal neuralgia.

The focus on NaV1.8 has been on its role in action potential initiation in the periphery. Nevertheless, there is also evidence that the channels are present and functional at central nociceptor terminals. At the central terminal, the channel appears to facilitate the spread of the invading action potential throughout the terminal arbor and consequently the release of transmitter from the primary afferent. There is also a growing body of evidence suggesting that action potentials may also be initiated at the central terminals of nociceptors, where they are conducted antidromically to the periphery. This activity, referred to as the dorsal root reflex, appears to play a significant role in the neurogenic inflammation that develops following tissue injury.

**ACTION POTENTIAL PROPAGATION**
NaV1.8 and NaV1.7 underlie action potential generation and even propagation over the first 5 to 10 mm of peripheral axon. However, a different set of VGSCs underlies action potential propagation into the central nervous system in the absence of tissue injury. NaV1.6 appears to be the subunit primarily responsible for propagation in both myelinated and unmyelinated axons of both nociceptive and nonnociceptive afferents, although data from a small molecule inhibitor of NaV1.7 suggests this channel may contribute to action potential conduction as well (but see Zhang et al. for data suggesting this channel may not be as selective as originally thought). Unfortunately, the distribution of NaV1.6 in the peripheral nervous system in combination with its widespread expression in the central nervous system precludes selective block of propagation in nociceptors via a NaV1.6 specific mechanism. Nevertheless, block of these channels with local anesthetics and/or TTX, or more recently small interfering RNA knockdown, remains an effective means of blocking input into the central nervous system.

TRANSMITTER RELEASE
Voltage-gated calcium channels (VGCC) are primarily responsible for the initial influx of calcium necessary for initiation of machinery underlying the release of neurotransmitters. Like VGSCs, these multisubunit channels consist of a large α subunit that contains all of the features necessary for a functional channel as well as a β subunit. Ten α subunits have been identified, encoding channels that are commonly defined by their threshold for activation or pharmacologic properties. T-type channels (CaV3.1 to CaV3.3), as mentioned earlier, have a low threshold for activation, whereas all others have a high threshold for activation. The high-threshold channels are further subdivided based on their sensitivity to specific channel blockers: L-type channels (CaV1.1 to CaV1.4) are blocked by dihydropyridines such as nimodipine, N-type channels (CaV2.2) are blocked by the snail toxin ω-conotoxin GVIA, P/Q-type channels (CaV2.1) are blocked by the spider toxin ω-agatoxin IVA, and R-type channels (CaV2.3) are blocked by the spider toxin SNX-482. In contrast to VGSCs, VGCCs are not effectively targeted to the plasma membrane in the absence of the α2δ subunit complex. A single β subunit also appears
to be important for efficient gating.\textsuperscript{127} All VGCC subtypes are present in nociceptors. And whereas there is evidence that all high-threshold calcium channels may contribute to transmitter release, N-type channels appear to play a dominant role in the release of transmitter from nociceptors.\textsuperscript{128}

The dominant role N-type channels play in mediating transmitter release from nociceptive afferent terminals makes them an ideal target for both endogenous and exogenous analgesics. Opioid and adrenergic receptor agonists act through inhibitory G protein-coupled receptors which enable inhibition of VGCCs via two major intracellular pathways. The first is a rapid, membrane delimited pathway involving G protein βγ-subunit displacement of the VGCC β subunit, resulting in a “sleepy” or “unwilling” channel that requires a larger membrane depolarization for channel opening.\textsuperscript{127} The second pathway involves more traditional second messenger kinase dependent signaling with a slower onset and offset.\textsuperscript{129} Interestingly, neither pathway results in complete VGCC block, yet both result in a dramatic inhibition of transmitter release. This amplification effect reflects the fact that there is considerable cooperativity of calcium in mediating vesicle fusion to the cell membrane that is necessary for transmitter release; four to five calcium ions are needed to trigger vesicle fusion.\textsuperscript{130} This amplification effect is also likely to facilitate the use of relatively low concentrations of the N-type channel blocker SNX-111 (Prialt), enabling the block of transmitter release from nociceptive afferent terminals in the superficial dorsal horn while minimizing side effects associated with block of channels at more distant sites. Finally, although additional mechanisms likely contribute to the therapeutic efficacy of drugs like gabapentin and pregabalin, that have been shown to bind to the α\textsubscript{2}δ subunit, the most compelling model involves the inhibition of membrane trafficking of the α subunit. That is, following nerve injury, there is a dramatic increase in α\textsubscript{2}δ\textsubscript{1} subunit expression in nociceptive afferents.\textsuperscript{131} This increase in expression appears to facilitate the trafficking of VGCC α subunits to nociceptive afferent central terminals, which in turn, appears to facilitate transmitter release and consequently the increase in pain associated with nerve injury. These compounds block the increase in α subunit trafficking via an α\textsubscript{2}δ\textsubscript{1}-dependent mechanism.\textsuperscript{132}

Although VGCCs play a dominant, if not essential, role in the increase
in intracellular calcium needed for transmitter release, recent evidence suggests other calcium regulatory proteins contribute to the regulation of the amplitude and duration of the increase in intracellular calcium and, consequently, transmitter release. These include the sarco-endoplasmic reticulum ATPase/ryanodine receptor system,\textsuperscript{133,134} the plasma membrane calcium ATPase,\textsuperscript{135} mitochondria,\textsuperscript{135} and the sodium/calcium exchanger.\textsuperscript{83} Consistent with the suggestion, these calcium regulatory proteins influence nociception, selective genetic knockdown of the sodium/calcium exchanger, a regulatory protein that attenuates the calcium transient, in a subpopulation of nociceptive afferents decreases nociceptive threshold.\textsuperscript{83}

**Nociceptor Sensitization**

Sensitization is a characterizing feature of nociceptors; non-nociceptors do not sensitize following tissue insult. Sensitization represents an increase in nociceptor excitability, which is expressed and defined as an increase in response to a noxious stimulus. Sensitization is also typically accompanied by a reduction in the threshold for activation and occasionally by the development of ongoing, spontaneous activity. Nociceptor sensitization is the cause of primary hyperalgesia (i.e., increased pain produced by stimulation at the site of tissue insult) and is important because nociceptor sensitization is the trigger for initiation of an increase in excitability of central neurons in the nociceptive pathway, an event termed central sensitization.

An increase in nociceptor excitability is a reflection of changes in the behavior of nociceptor voltage- and/or ligand-gated ion channels produced by actions of endogenous substances either released or synthesized at the site of tissue insult or attracted there. Endogenous substances considered classically to contribute to sensitization include products of arachidonic acid metabolism (e.g., prostaglandin E2 [PGE\textsubscript{2}]), histamine, serotonin, protons and ATP, but the list has grown quite extensively and now also includes cytokines, chemokines, growth factors, peptides, etc., some of which are released from immune competent cells attracted to the site of insult (e.g., macrophages), from nearby cells (e.g., mast cells), or from nociceptor (and other) nerve terminals (e.g., peptides). Interestingly,
despite the variety of mediators capable of producing nociceptor sensitization, several appear to play particularly important roles. This list includes prostanoids, as evidenced by the antihyperalgesic efficacy of nonsteroidal anti-inflammatory drugs (NSAIDs) that act via inhibition of cyclooxygenase and thus prostanoid synthesis.\textsuperscript{136,137} More recently, the importance of tumor necrosis factor alpha (TNF-α) in chronic inflammatory conditions has been highlighted by the antinociceptive efficacy of compounds such as etanercept which are designed to bind and inactivate TNF-α released at sites of inflammation.\textsuperscript{138,139} Finally, nerve growth factor (NGF) appears to play a major role in orchestrating a variety of signaling cascades necessary for an inflammatory response and therefore has also been targeted with antibody-based strategies.\textsuperscript{140–144}

The mechanisms that trigger changes in nociceptor excitability are not fully known. A growing body of evidence suggests that despite what appears to be a bewildering assortment of mediators and membrane receptors, there are a relatively small number of intracellular pathways that underlie their actions. For example, both prostaglandins and bradykinin, which are among the most extensively studied inflammatory mediators, act at G protein-coupled receptors. Two major G protein-dependent pathways have been implicated. One involves a stimulatory G protein, Gs, which drives activation of adenylate cyclase, resulting in an increase in cyclic adenosine monophosphate (cAMP) and the activation of protein kinase A (PKA).\textsuperscript{145,146} The other involves a Gq-dependent pathway, resulting in the activation of phospholipase C, the liberation of diacylglycerol (DAG) and IP3, and the subsequent activation of protein kinase C (PKC).\textsuperscript{147,148} The PKC-ε isoform appears to play a particularly important role in nociceptor sensitization. Other mediators that appear to play important roles in nociceptor sensitization, such as TNF-α and interleukin (IL) 1β, utilize a mitogen-activated protein kinase (MAPK)-dependent pathway ultimately resulting in the activation of p38.\textsuperscript{149} Still other mediators directly activate ion channels. For example, protons (which increase in concentration during inflammation) act at TRPV1 and ASICs. ASIC-3 is important to pain associated with ischemia, such as that which occurs during angina, and deep muscle pain where protons and lactic acid accumulate. In contrast, ATP and its metabolites act at ionotropic P2X and metabotropic
P2Y receptors to modulate nociceptor excitability.

The relatively novel, if not paradoxical, mechanism of sensitization involving ionotropic GABAA receptors that we described in the action potential generation section serves as an example of the dynamic interplay between second messenger signaling cascades and the regulation of ion channels. Activation of these receptors are normally inhibitory, even in nociceptive afferents where they drive membrane depolarization, because of the relatively high intracellular chloride concentration maintained in these neurons. The GABAA-mediated depolarization in these neurons is inhibitory, as suggested earlier, because of the decrease in membrane resistance, referred to as shunting, as well as the depolarization-induced activation of low-threshold voltage-gated potassium channels. In the presence of persistent inflammation, there is a constitutive shift in the balance of tyrosine kinase to tyrosine phosphatase activity, such that there is a net increase in protein phosphorylation. This increase results in a net increase in functional GABAA receptors in the plasma membrane because of a decrease in receptor internalization. The result is an increase in GABA-evoked current and an increase in the magnitude of the GABA-evoked depolarization. These changes are further augmented by a decrease in the density of low-threshold potassium current. The result is a shift in GABA signaling, from inhibition to excitation.

This picture gets a little more complicated when one considers the ceramide/sphingosine 1-phosphate (S1P) system because ceramide, a potent proinflammatory sphingolipid-generated de novo from hydrolysis of sphingomyelin or synthesis from serine and palmityl CoA, can directly activate protein kinases and phosphatases as well as serve as a precursor to S1P, which acts via G protein-coupled receptors to sensitize nociceptive neurons. And although a common set of second messengers, including phosphatidylinositol 3-kinase, phospholipase Cγ, and extracellular signal-regulated kinase (ERK), underlie the acute sensitizing actions of trophic factors such as NGF, these mediators signal via a distinct class of receptors that contain intrinsic tyrosine kinase activity, referred to as tropomyosin receptor kinase, or Trk receptors. Channels underlying transduction and spike initiation, in particular TRPV1 and NaV1.8, respectively, appear to be final common targets for this diverse array of mediators and second
messenger pathways.\textsuperscript{155} Phosphorylation of specific residues on the channel or associated proteins results in increases in channel density and/or increases in channel function. Importantly, many inflammatory mediators including ceramide/SP1 and NGF drive long-term increases in nociceptor excitability via changes in gene expression, and mechanisms contributing to long-term changes in gene expression, such as alterations in DNA acetylation and methylation, have emerged as potential therapeutic targets.\textsuperscript{156,157}

Although mechanisms underlying changes in gene expression associated with the emergence of persistent pain have received considerable attention, there is a growing body of evidence suggesting that changes in protein translation are also important. One of the first studies to implicate a change in the regulation of protein translation per se in manifestation of persistent pain was focused on the role of TRPV1 in persistent inflammatory pain. The authors observed that inflammation is associated with an increase in TRPV1 protein in the absence of a detectable increase in messenger RNA.\textsuperscript{158} It was subsequently demonstrated that inflammatory mediators such as NGF and IL-6 could rapidly increase protein translation via the phosphorylation of proteins responsible for control over the rate-limiting step of protein translation, that of the initiation of protein synthesis.\textsuperscript{159} The protein initiation step involves the assembly of a complex of eukaryotic initiation factors (eIF) eIF4E and G among others, as well as the dissociation of the eIF4E binding protein (4EBP), from eIF4E. At least two distinct signaling pathways have been identified underlying the actions of NGF and IL-6. In addition to the activation of PI3K, NGF activation of TrkA drives the activation of PI3K which subsequently activates Akt (also known as protein kinase B). Akt then activates the mammalian target of rapamycin (mTOR), which facilitates the initiation of translation via facilitating the dissociation of 4EBP from eIF4E, as well as the activation of eIF4G, via the phosphorylation of both proteins. In contrast, IL-6 drives the activation of ERK, which subsequently activates MAP-kinase interacting kinase (MNK), which facilitates the initiation of translation via the phosphorylation of eIF4E (which facilitates the eIF4E/G complex formation).\textsuperscript{159} Interestingly, this rapid regulation of translation contributes not only to the magnitude and duration of both the mechanical
and thermal hypersensitivity associated with acute inflammation and the actions of inflammatory mediators like NGF and IL-6 but also the manifestation of more persistent changes in nociceptive processing, referred to as hyperalgesic priming.\textsuperscript{160}

Hyperalgesic priming is the term used to describe the changes in nociceptive processing associated with an initial inflammatory insult, such as that associated with the subcutaneous injection of carrageenan, or inflammatory mediators such as IL-6.\textsuperscript{148} These changes were manifest up to weeks after the complete resolution of hypersensitivity associated with the initiating stimulus and were most prominently manifest as a dramatic increase in the duration of the hypersensitivity associated with a subsequent challenge, although an increase in the magnitude of the hypersensitivity has also been described. That is, although the intradermal injection of PGE\textsubscript{2} into naive skin results in a relatively transient hypersensitivity lasting ~1 hour, the same injection into primed skin results in hypersensitivity detectable for more than 24 hours. This phenomenon has been proposed to contribute to the transition from acute to chronic pain.\textsuperscript{161}

In the context of a discussion of mechanisms underlying nociceptor sensitization, the mechanisms implicated in the manifestation of hyperalgesic priming are notable for several reasons. First, although there are data suggesting changes within the central nervous system, notably involving a descending dopaminergic input to the superficial dorsal horn, contribute to the manifestation of hyperalgesic priming,\textsuperscript{162} the bulk of data generated so far suggest that changes in nociceptive afferents may play a critical role in the emergence of chronic pain. Second, as further evidence of the differential role of distinct subpopulations of nociceptive afferents in nociceptive signaling, two distinct forms of hyperalgesic priming have been described, where type I depends on a subpopulation of neurons that do not express the neuropeptides calcitonin gene-related peptide (CGRP) or substance P and bind the plant lectin IB4,\textsuperscript{163} whereas type II depends on a subpopulation of neurons that do express these neuropeptides and do not bind IB4.\textsuperscript{164} Third, there appear to be sex differences in the mechanisms underlying both the initiation (type I)\textsuperscript{165} and maintenance (type II)\textsuperscript{164} of the primed state. And fourth, although a cAMP response element binding
protein (CREB)-dependent change in gene expression appears to be necessary for the establishment of the primed state, local translation appears to be critical for the manifestation of the more robust response observed in primed state, at least for type I priming. Given the length of some nociceptive afferents, in particular those innervating the distal appendages, local control of translation may prove to be an important therapeutic target for the treatment of pain.

Clinical Implications of Nociceptor Function

As researchers have begun to explore the basis for chronic pain syndromes generally associated with specific body regions and/or organs (e.g., temporomandibular joint disorder [TMJD], inflammatory bowel disease [IBD], irritable bowel syndrome [IBS], or painful bladder syndrome [formerly interstitial cystitis or IC]), a number of common themes have emerged that are likely to impact future treatment approaches. First, specific mechanisms underlying injury-induced sensitization of nociceptors vary as a function of target of innervation. For example, inflammation-induced sensitization of masseter muscle afferents appears to reflect a decrease in a specific subpopulation of voltage-gated potassium channels. The same channels do not appear to contribute to the sensitization of TMJ afferents. Similarly, inflammation-induced increases in the excitability of bladder sensory neurons appear to reflect one pattern of changes in voltage-gated ion channels, whereas the inflammation-induced increase in the excitability of sensory neurons innervating the stomach, ileum, or colon reflect other patterns. Although tissue-specific patterns of inflammation may contribute to these differences between subpopulations of afferents, differences persist when the response to inflammatory mediators is studied in vitro. These observations imply that it may be possible, if not necessary, to treat pain arising from a specific structure with a specific intervention. Second, specific mechanisms underlying insult-induced sensitization of nociceptors also vary as a function of the type of insult. For example, acute phosphorylation-dependent modulation of the voltage-gated sodium channel NaV1.8 results in an increase in current which
contributes to an inflammation-induced increase in nociceptor excitability.\textsuperscript{178,179} In contrast, following traumatic nerve injury, redistribution of NaV1.8 to the axons of uninjured afferents appears to be necessary for the expression of mechanical hypersensitivity associated with nerve injury.\textsuperscript{180} The dynamic allodynia that often develops after nerve injury, however, likely represents more than only a redistribution of NaV1.8 (Box 3.2).

**BOX 3.2 Afferent Contributions to Neuropathic Pain and Allodynia**

One of the most striking positive symptoms of neuropathic pain is dynamic mechanical allodynia, a term used to describe pain resulting from light tactile stimuli that would never be considered noxious in the absence of nervous system injury. This phenomena can be recapitulated with a subcutaneous injection of capsaicin.\textsuperscript{196} Data from detailed psychophysical analysis in combination with microneurography\textsuperscript{197} and dorsal horn recording in animal models\textsuperscript{198} all suggest that dynamic mechanical allodynia reflects activity in low-threshold afferents that signal pain as a result of changes in the central nervous system. The exact nature of these changes, generally referred to as central sensitization, is still debated (e.g., see Polgar and Todd\textsuperscript{199} and Schoffnegger et al.\textsuperscript{200}), but it is clear that they depend on activity in nociceptive afferents. Another possibility, however, is that low-threshold afferents undergo a phenotypic switch such that they begin to transmit information to the central nervous system as if they were nociceptive afferents. Consistent with this possibility, there is evidence following peripheral nerve injury that a subpopulation of putative nonnociceptive afferents begins to express the neuropeptide, substance P,\textsuperscript{201} although this change does not appear to be necessary for the expression of allodynia.\textsuperscript{202} Evidence of a third possibility, which would involve sprouting of nonnociceptive afferents into more superficial layers of the dorsal horn to enable low threshold drive of nociceptive dorsal horn neurons,\textsuperscript{203} remains largely unsubstantiated.\textsuperscript{204–206}
With respect to the viscera, because each organ receives innervation from two nerves, the effect of organ insult can be different in the two groups of sensory neurons that innervate the organ (e.g., Wang et al., Traub). These observations underscore the importance of developing diagnostic criteria that enable identification of the factors primarily responsible for ongoing pain. Third, as clearly indicated by the discussion of hyperalgesic priming, the history of the nociceptor influences the response to subsequent challenge. Furthermore, there is evidence of a developmental window within which injury may produce permanent changes in nociceptors. With the development of more specific therapeutic tools, patient history may become a critical factor in the identification of the most appropriate intervention. Fourth, there is evidence for sex differences in both the excitability of different groups of nociceptors as well as the response to tissue injury. These differences appear to be mediated, at least in part, through the actions of gonadal hormones and may contribute to sex differences in the manifestation of a number of chronic pain syndromes. There is also evidence for age-dependent changes in nociceptor function. Given the ever-growing proportion of aging adults, this particular issue is in need of further investigation. Finally, all of these factors interact with what are clearly genetic differences in pain and analgesic mechanisms.

As indicated earlier, the consequences of tissue insult are not limited only to changes in the excitability of nociceptors and the awakening of sleeping nociceptors. Because sensitization leads to an increased response to noxious stimuli and a decrease in response threshold, previously nonnoxious intensities of stimulation also are now able to activate nociceptors. In addition, spontaneous activity may develop. In the aggregate, central nervous system input from sensitized nociceptors, awakened sleeping nociceptors, and spontaneously active nociceptors is significantly increased. For example, approximately 24% of human cutaneous C fibers are sleeping nociceptors, comprising significant new input to the central nervous system if awakened. Consequently, the amount of neurotransmitters (as well as perhaps their relative proportions) released onto central neurons is increased, which in turn alters the excitability of central neurons. The increase in excitability of central neurons is manifest
as an increase in the size of the cutaneous receptive field (i.e., secondary hyperalgesia) or area of tenderness referred from deep structures, particularly the viscera. Although the principal focus of study of mechanisms of central sensitization has been the spinal cord, it should be appreciated that nociceptor-driven changes in central excitability extend throughout the central nervous system.

CHAPTER 4
Substrates of Spinal Cord Nociceptive Processing
JENNIFER J. DEBERRY, ALAN RANDICH, and TIMOTHY J. NESS

The spinal cord and brainstem nuclei are home to second-order neurons, the first step of central nervous system (CNS) processing. As the first site of sensory integration and modulation, second-order neurons are more than a simple relay, and any plan for the treatment of nociception must understand the critical role these neurons play in the formation of painful sensation. The second-order neuron encodes afferent input from multiple sites and often multiple modalities into a message that is sent to other parts of the CNS. Those other parts of the CNS, in turn, modify the second-order neuron through both excitatory and inhibitory mechanisms. These modifying influences are the subject of the next chapter, whereas the present chapter focuses on the neuroanatomical and neurochemical characteristics of these spinal substrates.

Although it seems like a simple statement that pain-related second-order neurons are the neurons which receive primary afferent input related to tissue damage (i.e., from nociceptors), it must be accepted that this statement may or may not be wholly true because in certain pathologic states, pain can be evoked by non–tissue-damaging stimuli (allodynia). It is unfortunate that there has been a tendency in pain-related research to turn common observations into overgeneralizations, and so an attempt will be made in this chapter to be precise when possible. Sometimes, “assumptions” related to neuronal substrates of sensation have been necessarily used as “premises” on which to build scientific logic. The primary premise on which this chapter is based is that all nociceptive second-order neurons receive nociceptive primary afferent input as one of their excitatory modalities. If one can accept that premise, then one can
identify where the neurons receiving such input are located and can further identify where these neurons send the information.

**Defining Nociceptive Systems**

**MODELS OF PAIN PROCESSING**

Pain is both a sensation and responses to that sensation. The sensory component of pain is described in terms of tissue damage (e.g., cutting, burning, rending) even when tissue damage is not occurring, and so the sensation of pain is defined as nociception. The sensory systems of our body which encode for nociception can be modeled in two main ways: (1) as a system which is specific for pain (specificity theory) or (2) as a system that requires a pattern of neuronal activation to occur for the experience of pain to be generated (pattern theory). The simplest and oldest of the pattern theories is that which suggests pain is due to high intensities of input that are independent of modality (intensity theory). Each of these theories (or the multiple variants thereof) has prominent proponents who can make persuasive arguments that focus on subsets of data that support their particular view. Each knowledgeable person must derive their own model system which is ideally based on characterized human phenomena and which must clearly go beyond simple models.

As is apparent from the preceding chapter, primary afferent neurons with sensory endings have been characterized using functional and neurochemical methods. A subset of these primary afferents with sensory endings in cutaneous tissues is only activated by (and so specific for) pain-producing stimuli. Although these afferents may be polymodal, that is, encode for multiple different stimuli, the stimuli that excite these primary afferents have in common the potential for producing tissue damage. They have therefore been defined as nociceptors. Primary afferent nociceptors are thinly myelinated or nonmyelinated and so fall into the Aδ- and C-fiber classes. Human psychophysical data support that when Aδ- and/or C-fiber function is disrupted by ischemia or pharmacologic agents, then cutaneous sensations associated with immediate (first) or briefly delayed (second) pains are similarly disrupted. Unfortunately (for the sake of easy logic), there are also many primary afferents that do not encode for tissue-
damaging stimuli (e.g., “warm” receptors) but which are also of the Aδ- and C-fiber classes. Hence, it is a flawed logic that interprets all Aδ- and C-fiber–related input to second-order neurons as nociceptive. Existent literature constrains further definition of specific nociceptor neurochemical and localization characteristics except on an anecdotal (single unit) basis. With that caveat, there are basic patterns that appear common to most Aδ and C fibers, and generalizations related to these fiber groups have some validity as being representative of nociceptor localization and neurochemical content.

METHODS OF NEURONAL CHARACTERIZATION
To definitively describe the structure and function of CNS structures is a daunting task. As with nociceptors, standard histologic, ultrastructural, and neurochemical methods used to examine CNS structure have allowed for precise definition of axons, dendrites, and neurotransmitter content, but, unfortunately, they do not allow for the precise definition of function. Studies of neuronal function typically utilize electrophysiologic techniques to measure the real-time electrochemical activity of single neuronal units (e.g., action potentials) which may be evoked by multiple manipulations. These neurophysiologic measures utilize electrodes placed either extracellularly or intracellularly. When the former technique is utilized, correlative anatomic localization is possible but little more. Electrophysiologic techniques such as retrograde activation of axonal extensions can define some of the neuronal anatomy, but true morphology is only certain with the intracellular injection of a dye. Immunohistochemical characterization of intracellularly labeled neurons is methodologically feasible, and so it is possible to quantitatively define sensory elements. However, such studies are sufficiently tedious and subject to interpretive concerns related to sampling error and preparation effects (i.e., anesthesia) that, to date, these types of experiments have only been performed at a rudimentary level. A compromise microscopic analysis technique is that which uses induction of the c-fos gene or phosphorylation of extra cellular signal-related kinase (pERK) in response to neuronal activation to functionally identify neurons excited by a noxious stimulus. A proto-oncogene, c-fos, is activated after potentially tissue-
damaging stimuli are applied to most tissues. The expressed product, Fos protein, is immunohistochemically identifiable within hours of stimulation. As a consequence, mapping of gene induction or Fos protein in the nucleus of activated neurons can be used to indirectly functionally define these neurons as “nociceptive.” However, a systematic comparison study of Fos and pERK as markers of spinal nociceptive activation revealed greater specificity for activity in nociceptive pathways (vs. nonnociceptive activation) using pERK. Labeled neurons can then be colabeled with antibodies against neurotransmitters or important cell proteins or specific histologic stains to further characterize the neurons. Analgesic pharmacologic manipulations such as systemic morphine reduce both the total number of labeled neurons and the total Fos or pERK content of the spinal cord following a noxious stimulus. Even newer technologies have been able to identify a changed form of receptors following neuronal activation by noxious stimuli. For example, the internalization of neurokinin 1 (NK1) receptors following activation by substance P or the phosphorylation of glutamate receptor subtypes has been used as surrogates for neuronal excitation. Macroscopic examination of CNS activation sites using magnetic resonance imaging technologies have allowed confirmation of microscopic techniques and further demonstrated the functional complexity of spinal and supraspinal connections. At a microscopic level, “tracer” dyes which are taken up by the terminal endings of axons of neurons and transported back to the neuron somata allow for a histologic identification of axonal projections of spinal neurons that is dependent on the site of dye injections (e.g., spinothalamic neurons are retrogradely labeled to the spinal cord by injections in the thalamus). Such labeling techniques, when coupled together with functional techniques, have made it possible to construct a quantitative but nonspecific “global” neuroanatomic view of spinal cord nociceptive processing that appears to agree with anecdotal, definitive evidence generated by single-unit studies.

DEFINING NOCICEPTIVE SECOND-ORDER NEURONS

Strict proponents of specificity theory state that all discussion related to pain should only involve CNS neurons excited exclusively by primary
afferent nociceptors. Such specific second-order neurons are a small but an obviously important minority of the total sample of spinal neurons receiving input from primary afferent nociceptors. One can also argue that the presence of primary afferent neurons with specificity for pain-producing stimuli does not necessitate that the second-order neurons responsible for pain sensation have a similar specificity. For purposes of the present discussion, the primary premise of the rest of this chapter is that such excitatory input is a necessary requirement of pain-related second-order neurons, but it is notable that most second-order neurons receiving such input receive other types of sensory input. Excitation of second-order neurons may come from primary afferent pathways or from segmental (interneurons), propriospinal (nonsegmental intraspinal), and supraspinal sources. Inhibition arises from the same CNS sources and can promote neuronal specificity by selectively reducing responsiveness to nonnociceptive inputs. It is for this reason that proponents of pattern theory argue that all second-order neurons receiving nociceptive inputs should be considered as candidates for inclusion in pain-processing pathways.

DEVELOPMENT OF SENSORY SYSTEMS

The embryologic development of the nervous system suggests reasons that differences can exist between peripheral and central phenomena because excitatory systems develop before inhibitory systems. The edges of the neural plate that come together to form the neural tube split off to become the migratory cells of the neural crest. These cells spread to form the sensory components of the peripheral nervous system. At a spinal cord level, substances from the ventrally located notochord induce the formation of motoneurons with axonal extensions extending to the periphery. The dorsal aspect of the spinal cord, lacking effects of the notochord, forms short connections (local connectivity) or develops axonal projections attracted to distant spinal cord and/or brainstem sites. Sensory structures that develop from the neural crest send axonal projections both to the periphery as well as into the dorsal aspect of the spinal cord and contain neurotransmitters that are predominantly excitatory. At birth, sensory systems have very little inhibitory connectivity. This changes
during development until inhibitory connections become the predominant form of CNS communication.

In humans, the precise timing of both excitatory and inhibitory system maturation is not fully known, but based on experiments in nonhuman animals, these systems appear highly plastic with cell death processes as important as cell growth processes in relation to the final product. Specific transcriptional factor expression has been used to track neuronal subgroup development and has demonstrated a profound role for pathologic modification of nociceptive circuitry. The general phenomenon of use-dependent growth (or preservation) appears to hold in multiple sensory systems ranging from taste to vision with the nociceptive systems notwithstanding. Ruda and colleagues have demonstrated that injury during critical periods of development, such as the neonatal period, can have profound effects on the subsequent development of nociceptive systems. In humans, critical periods of neuronal outgrowth and myelination occur in childhood, during puberty, and following events that injure nervous system structures.

**Targets of Primary Afferent Input**

**GROSS ANATOMY OF THE SPINAL CORD**

The spinal cord is segregated into areas that, on gross examination, appear as white and grey matter and consist of predominantly myelinated nerve fiber tracts and cell bodies, respectively. Wrapped in protective pial, arachnoid, and dural meninges, the spinal cord is continually being penetrated by centrally directed axons of primary afferent neurons whose cell bodies reside within the neighboring dorsal root ganglia. These axons enter as the dorsal roots and may traverse several spinal segments rostrally or caudally in the dorsolaterally located Lissauer’s tract before entering the grey matter for synaptic contact. The spinal cord white matter is divided into multiple subdivisions with component “tracts” consisting of ascending or descending axonal fibers of various origins and destinations. There is significant overlap of these tracts, such that any lesion of white matter is likely to interrupt fibers of passage with multiple origins and multiple sites of termination. The white matter gets larger as one ascends the spinal cord.
from sacral to cervical levels as additional ascending fibers to the brain add to the white matter and progressive numbers of descending fibers to spinal targets drop out to form synaptic connection. Grey matter is largest at the cervical and lumbar enlargements due to association with sensation and motor control of the limbs. The most notable divisions of the white matter that are important to pain sensation are the dorsal columns, the dorsolateral fasciculus, and the ventrolateral (anterolateral) fasciculus and their associated subdivision into tracts (Fig. 4.1).

FIGURE 4.1 Diagram of the white matter of the spinal cord. The ascending tracts are emphasized on the right side and the descending tracts on the left side. The anterolateral (ventrolateral) funiculus, which is composed of the anterolateral fasciculus (ALF), composed of the spinothalamic (STT), spinoreticular (SRT), and spinomesencephalic (SMT) tracts in the spinal cord. As it ascends, the ALF becomes progressively larger, the largest part being in the upper cervical region. This is
not only because the STT continues to add axons but also because there are more SRT cell bodies (and hence axons) in the cervical enlargement than in the lumbosacral enlargement. Throughout the course of the ALF in the spinal cord, the three nociceptive pathways are situated medial to the anterior (ventral) spinocerebellar tract, lateral to the ventrolateral and ventral horns, and posterolateral to the spino-olivary tract. The anterior spinothalamic tract (ASTT), which may be an alternate nociceptive pathway, is separate from the three tracts of the ALF. Because a cordotomy lesion in the upper thoracic or cervical segments usually extends from the dentate ligament medially, the ASTT and some of the descending tracts are likely to be interrupted with the operation. In the cervical region, the ALF is shaped as a somewhat flat triangle with the apex medial and the base lateral. At successively higher cervical levels, there is a gradual dorsolateral shift of the ALF.

**SPINAL LAMINAE**

The morphology of neurons in the grey matter of the spinal cord differs depending on location. Using Rexed’s cytoarchitecture-based classification system, there are at least 10 different layers or laminae of neurons—of which the first six (I to VI) are termed the dorsal horn of the spinal cord (Fig. 4.2). These laminae, plus the area around the central canal (lamina X), receive a bulk of primary afferent inputs. Spinal dorsal horn neurons receiving excitatory inputs from nociceptive afferents have been demonstrated to be present throughout the dorsal horn but with particular localization to laminae I, II, V, VI, and X. One must remember that laminar assignment is based on the central location of the neuronal soma. However, dendritic extensions of these neurons may extend throughout numerous laminae such that the immunohistochemical demonstration of primary afferent neuron terminations in specific laminae does not limit connectivity to just neurons of those laminae. Furthermore, although both myelinated and unmyelinated nociceptive afferent fibers project predominate to the laminae described earlier, there exist projections in those laminae from afferent fibers that transmit innocuous sensory information. Mapping of individual C-fiber primary afferents encoding for cutaneous nociception has demonstrated sites of connectivity that are highly localized into tight “baskets” typically located in superficial laminae of a single spinal segment. In contrast, single primary C-fiber afferents from deep, visceral structures have been demonstrated to travel via Lissauer’s tract to multiple spinal segments and multiple laminae (I, V, X, and even contralateral sites) (Fig. 4.3). Fine muscle afferents and articular afferents have sites of termination similar to those of visceral...
afferents. By using intracellular recording and labeling techniques, it has been possible to determine that nociceptive afferents connect with second-order neurons that have many different morphologies—some of which correlate with electrophysiologic characteristics (see Morris et al.\(^9\) and Grudt and Perl\(^\text{10}\)). The morphology and neurotransmitter content of each lamina will be briefly discussed.

**FIGURE 4.2** Diagrams showing Rexed’s laminar histologic organization of the cat spinal cord grey matter at three levels. The dorsal horn corresponds to laminae I through VI inclusive. (Redrawn after Rexed B. The cytoarchitectonic organization of the spinal cord in the cat. J Comp Neurol 1952;96(3):415–495. Copyright © 1952 The Wistar Institute of Anatomy and Biology. Reprinted by permission of John Wiley & Sons, Inc.)
FIGURE 4.3 The different extents of central terminal fields are shown here for an individual somatic C-fiber primary afferent (A) and a visceral C-fiber primary afferent (B) from guinea pigs that were injected with Phaseolus vulgaris leucoagglutinin after functional identification. The visceral C-fiber afferent had many more central branches and numerous arbors that include contralateral projections, whereas the somatic C-fiber afferent had a more limited terminal field. CC, central canal; DF, dorsal funiculus; LF, lateral funiculus. (Redrawn after Sugiura Y, Terui N, Hosoya Y. Difference in distribution of central terminals between visceral and somatic unmyelinated (C) primary afferent fibers. J Neurophysiol 1989;62[4]:834–840. **Lamina I:** Termed the marginal zone as it forms the outermost layer of the dorsal horn. This single lamina contains a heterogeneous population of neurons with morphologic studies identifying neurons with pyramidal, fusiform, and multipolar shapes, some with smooth and some with spiny dendrites. Morphology and function are correlated in at least a subset of these neurons. Lamina I and the adjoining lamina II are the predominant
location of excitatory neuropeptide input from primary afferent neurons with heavy immunohistochemical labeling for substance P and calcitonin gene-related peptide (CGRP). Axonal projections of a subset of lamina I neurons extend to supraspinal structures such as the medulla, midbrain, and/or thalamus. Fos and pERK induction in response to noxious stimuli have consistently been reported to occur in lamina I with double-labeling noted in association with antibodies to preproenkephalin, dynorphin, glutamate, N-methyl-D-aspartate (NMDA) receptors, γ-aminobutyric acid (GABA), glycine, GABA-B receptors, NK1 receptors, calbindin, glucocorticoid receptors, and estrogen receptor α.¹

**Lamina II:** Called the substantia gelatinosa due to its gross jellylike appearance in fresh cut tissue. The neurons of this lamina are generally small with five distinct morphologies, two of which are viewed as important to the local processing of nociceptive information: stalked and islet cells (using the terminology of Gobel¹¹). Stalked cells have soma at the outer edge of lamina II with centrally arborizing dendrites and axons that synapse with lamina I projection neurons. Islet cells have fusiform cell bodies with extensive dendritic and axonal arborizations containing inhibitory neurotransmitters such as GABA or enkephalin.¹²,¹³ Axodendritic, dendrodendritic, and axoaxonic synapses are manifest throughout lamina II on ultrastructural analysis demonstrating a profound potential for neuronal interaction and signal processing. Primary afferent input from both nociceptive and nonnociceptive neurons has been noted; particularly, input from a population of nonpeptidergic, nociceptive primary afferents, is received in a narrow band within lamina II. Descending axonal connections are also present with evidence of serotonergic and noradrenergic inputs to lamina II neurons. A distinction is frequently made between lamina II-outer (IIₐ) and lamina II-inner (IIᵢ) with IIₐ commonly combined with lamina I in discussions of the superficial dorsal horn.

**Lamina III and lamina IV:** Known as the nucleus proprius as both receive highly myelinated low-threshold primary afferent neuronal inputs that include proprioceptors. Whereas lamina III consists mainly of small neurons with morphologies similar to lamina II, lamina IV has a subpopulation of large cells with extensive dendritic extensions that reach
superficially. Laminae III and IV also have neurons with axonal projections extending up ascending pathways including the spinothalamic tract and the dorsal columns.

**Lamina V:** Neurons receive input from Aδ- and C-fiber nociceptors as well as myelinated afferents carrying low-threshold information. Cell bodies are frequently moderately sized pyramidal cells and may have dendritic extensions through the entire dorsal horn reaching to lamina I and II sites of synaptic contact as well as laterally. Neurons of this lamina have been demonstrated to receive input from all somatic, muscle, and visceral afferent types. Axonal projections of lamina V neurons to supraspinal sites are common.

**Lamina VI:** Neurons are small neurons present in the cervical and lumbar enlargements but largely missing in the rest of the spinal cord. Low-threshold muscle afferents and both low- and high-threshold cutaneous afferents reach to this lamina.

**Laminae VII to IX:** Represent neurons of the ventral horn.

**Lamina X:** Neurons are arranged around the central canal of the spinal cord. They receive bilateral inputs of unmyelinated, poorly myelinated, and highly myelinated afferents. Cell bodies are of moderate size with local dendritic arborizations. Some neurons in the dorsal aspects of lamina X have axonal projections extending up the dorsal columns to reach medullary targets. Peptidergic inputs are extensive and immunohistochemical localization of noradrenergic and serotonergic inputs have been identified. Inhibitory neurons with immunohistochemical identification of glycnergic and GABAergic enzymes are locally present.

**FUNCTIONAL CHARACTERIZATION OF NOCICEPTIVE NEURONS**

In addition to morphologic heterogeneity, the multiple laminae of the spinal cord also have functional heterogeneity. Second-order neurons have been characterized electrophysiologically according to their responsiveness to cutaneous and deep tissue stimuli. Most commonly, a distinction is made between excitatory responses that are produced by noxious (potentially tissue-damaging) stimuli such as high-intensity mechanical or thermal stimuli and those produced by innocuous stimuli.
such as hair movement or vibration. Using these two criteria, the simplest nomenclature defines neurons as Class 1 if excited only by innocuous stimuli, Class 2 if excited by both innocuous and noxious stimuli, and Class 3 if excited only by noxious stimuli. Similar nomenclatures, but with additional subtle meanings implied by their original descriptions, include the use of terms such as low threshold for Class 1 neurons, wide-dynamic-range\textsuperscript{14} or convergent\textsuperscript{15} for Class 2 neurons, and high threshold or nociceptive-specific for Class 3 neurons. A fourth nonresponder group also must be factored in for neurons that fail to be excited by any of the employed stimuli. Despite the “clean” nature of this categorization, there unfortunately appears to be a spectrum of responses to all afferent input modalities with varying overlap that is somewhat dependent on the precise stimuli and definitions employed. The definition of neurons according to excitatory stimuli also appears to be preparation-dependent, as extracellular dorsal horn recordings of spinal neurons in cats have demonstrated that the classification of an individual neuron may change with the administration of anesthesia.\textsuperscript{16}

The number of neuronal subgroups in any classification system is a function of the number of criteria employed for that classification. Despite this, it has been suggested that the use of inhibitory inputs as part of a classification criterion might actually simplify overall schema. Some neurons are inhibited following primary afferent activation. Inhibitory neurotransmitters are uncommon, if not absent, in primary afferents and so inhibition has generally been interpreted as due to a “modulatory” influence. One such modulatory inhibitory influence used in classification is known as diffuse noxious inhibitory controls (DNIC) which is proposed to be an endogenous inhibitory system activated by a nonsegmental noxious stimulus. DNIC produces inhibition of ongoing or evoked dorsal horn neuronal activity, and according to its original description,\textsuperscript{17,18} DNIC is specific for Class 2 (wide dynamic range [WDR], convergent) neurons and has no effect on Class 3 (nociceptive-specific [NS]) neurons. Subsequent studies of DNIC would support the general statement that DNIC effects are highly selective for Class 2 neurons with lesser effect on Class 3 neurons. Nomenclatures using a combination of responses to excitatory and inhibitory inputs have not been universally accepted.
CLASSIFICATION ACCORDING TO SITE OF PROJECTION

Second-order nociceptive spinal dorsal horn neurons frequently have axonal extensions projecting to rostral (and caudal) sites of termination. These sites include other segments of the spinal cord and supraspinal structures such as the thalamus, the hypothalamus, the midbrain, the pons, and the medulla. These axons travel predominantly within the white matter of the spinal cord in two main sites: the ventrolateral quadrants and the dorsal midline. Ascending fiber tracts in the dorsolateral funiculus have also been described. Decussation of fibers to the contralateral ventrolateral white matter occurs for axons projecting to the thalamus and most other brainstem sites, although many axons with sites of termination in “reticular” structures remain in the ipsilateral ventrolateral white matter. Dorsal column pathways have sites of termination in the gracile or cuneatus nucleus of the medulla. Intraspinal pathways that may stay within the grey matter have also been demonstrated as well as extensive collateralization of axons with multiple sites of termination at supraspinal and intraspinal sites.

Targets of Axonal Projections

INTRASPINAL PATHWAYS

Multiple interconnections occur between spinal neurons. On a segmental level, this is referred to as interneuron connectivity. When connections are more distant, the pathways of connection are termed propriospinal based on the initial demonstration of a coordinating connectivity between the cervical and lumbar enlargements of quadrupeds that allowed for coordinated motion. Intraspinal connectivity has also been demonstrated in the case of neurons receiving afferent input from pelvic structures with a dual innervation through thoracolumbar sympathetic and sacral pelvic nerves. These intraspinal connections appear to coordinate autonomic functions related to the pelvic organs. A precise white matter localization of the axonal extensions of propriospinal nociceptive neurons has not been performed, but they are presumed to follow the paths of other propriospinal neurons which include dorsally located white matter paths.
and some within grey matter extensions. Collateral intraspinal extensions of ascending axons located within the ventrolateral white matter have also been demonstrated.

A separate system of intraspinal connections, the multisynaptic ascending system, may have particular relevance to chronic pain. In concepts championed by Noordenbos but first proposed by Goldschneider, long chains or “webs” of neuronal connections extend through the length of the spinal cord and carry nociceptive information in a slow but progressive fashion to the brain by short “hops.” Support for this concept is given by animal experiments, in which opposing hemisections performed at differing spinal levels fail to block nociceptive behaviors, but total transections at a single level are effective. Traditionally described as an ascending pathway, bidirectionality of signaling is possible with a potential for the generation of “reverberatory” circuits.

**SPINOThALAMIC TRACT**

**Ventrolateral (Anterolateral) Axonal Pathways**
The most studied spinal projection pathway is the spinothalamic tract which is located within the ventrolateral white matter of the spinal cord. Both ipsilateral and contralateral localization of axon pathways have been demonstrated en route to supraspinal sites, but the predominant path for axonal projections traveling to the ventrobasal thalamus resides on the contralateral side. Experiments utilizing lesions of the ventrolateral spinal white matter have demonstrated reduction or abolition of ventrobasal thalamic neuronal responses to most somatic noxious stimuli. Consistent with this observation, surgical or traumatic interruption of ventrolateral fiber pathways results in the lack of sensation to noxious cutaneous stimuli (i.e., pinprick) applied to the contralateral side of the body at spinal segments below the level of the lesion. The second-order neurons which project to the thalamus have been identified in rodent, feline, and primate models using neuroanatomical (retrograde dye labeling or chromatolytic responses to axonal section) and electrophysiologic (antidromic activation) methods. Neurophysiologic experiments have not always proven that the neurons of study had axonal projections that actually reach the thalamus but have always demonstrated that neurons of interest have axons present.
within the ventrolateral spinal white matter and so the term spinothalamic tract (STT) neurons is generally employed to describe the neurons rather than the more specific term spinothalamic.

**Neospinothalamic versus Paleospinothalamic**

There exist two different components of the spinothalamic tract—the neospinothalamic tract (nSTT) and the paleospinothalamic tract (pSTT), the former of which forms a direct, dedicated relay to the ventrobasal group of the thalamus and the latter of which has many neurons with one or more axonal bifurcations that form dichotomizing fibers ending in synaptic contact with medullary, pontine, midbrain, and medial thalamic structures. Ascending information transmitted through the pSTT produces activation of numerous limbic structures and has therefore been viewed as important to affective and motivational aspects of pain, whereas the nSTT, through relays in the ventrobasal and posterior thalamus, activates the somatosensory cortex and so has been viewed as important to localization and intensity coding of pain-related sensations. Axonal collateral branchings of pSTT neurons have been identified that correspond to multiple areas of limbic and autonomic activation which include medullary, pontine, mesencephalic, hypothalamic, and medial thalamic targets.

**Laminar Distribution of Spinothalamic Tract Neurons**

The cells of origin of the STT reside within all laminae of the spinal cord except motoneuronal layers and therefore can have multiple different morphologies. At lumbar levels in primates, the greatest number of nSTT neurons not only reside in laminae I and V but also are highly represented in laminae IV, VI, IX, and X with additional representation in III, VII, and VIII. In contrast, the neurons of the pSTT have soma in deeper laminae (VI to VIII) with a lesser representation in I, IV, and V. The axons of STT neurons typically decussate to the contralateral side via the dorsal commissure within one to two spinal segments of the neuronal soma, but at sacral and upper cervical levels, a significant number (up to 26%) of axons of STT neurons may remain ipsilateral. A general somatotopic organization of the ascending fibers within the STT has been noted with an
inner-to-outer progression of layers of fibers to the white matter from cervical to sacral levels (Fig. 4.4). A similar somatotopy is noted at medullary levels. The STT splits into two parts through the rostral medulla and pons to merge again at mesencephalic regions where an anterior-to-posterior somatotopic distribution is noted. Differences in conduction velocity of subsets of STT neurons has been identified (lamina I STT neurons have slower conduction velocities than lamina V STT neurons) suggesting differences in axonal diameter and myelination processes. That, in turn, suggests a potential for temporally different delivery of sensory information to brain structures and differential susceptibility to pathologic processes.

**FIGURE 4.4** Schematic diagrams showing cross-section of the spinal cord, medulla, and midbrain, depicting the laminar arrangement of the ascending tracts in the ventrolateral funiculus in the upper part of the cervical spinal cord (A) and with the addition of the trigeminothalamic tract in the medulla (B) and midbrain (C). C, cervical; F, face; L, lumbar; S, sacral; T, thoracic.
Functional Characterization of Spinothalamic Tract Neurons
Quantitative electrophysiologic characterization of STT neurons has demonstrated a predominance for neurons processing nociceptive information. However, approximately 20% of STT neurons encode exclusively for nonnoxious light touch sensations, and a small subset encodes for proprioceptive information. Multiple subsets of nociceptive neurons have been identified that have selective laminar localization. NS STT neurons, with slow adapting responses to noxious pinch, heat, or chemical stimulation, are commonly located in lamina I but are also present in deeper laminae. Noxious cold has been used as an additional characterizing stimulus and allowed for the identification of additional subsets of lamina I NS STT neurons. WDR STT neurons, which demonstrate excitatory responses to multimodal sensory inputs (including both noxious and nonnoxious stimuli), are found extensively in lamina V but can also be found in all other laminae. Convergence of visceral, myofascial, articular, and cutaneous inputs is the rule rather than the exception when examining WDR STT neurons, but similar convergence has been noted in NS STT neurons. Overall, with the possible exception of noxious cold inputs, the presence or absence of a particular group of sensory inputs has been of limited value in identifying lamina-specific, morphologic, functional, or projection-related neuronal subsets. However, there are important generalities that are apparent in quantitative analyses of neuronal subsets: Lamina I STT neurons tend to be NS neurons, lamina V (and other deep laminae) STT neurons tend to be WDR neurons, STT neurons with projections to the medial thalamus (pSTT) are more likely to be NS rather than WDR neurons and frequently have large receptive fields, STT neurons with projections to the lateral thalamus (nSTT) are more likely to be WDR rather than NS neurons and often have smaller receptive fields, and STT neurons with projections to both medial and lateral thalamus appear similar to neurons with projections only to the lateral thalamus.

Dorsolateral and Ventromedial Axonal Pathways
Spinothalamic neurons with soma primarily located within lamina I have been demonstrated to send axonal projections to the contralateral posterior
nuclei of the thalamus via a contralateral dorsolateral pathway.\textsuperscript{27,28} Estimated to form up to a quarter of all spinothalamic neurons,\textsuperscript{29} these neurons have been identified electrophysiologically to be primarily NS neurons with small cutaneous receptive fields. Deeper laminae neurons and WDR neurons are also represented in this pathway. Many axons of spinothalamic neurons also travel within the ventromedial white matter of the spinal cord with soma located within laminae I, IV, V, VI, and VII.\textsuperscript{30} Functional characterization of spinothalamic neurons with axons in the ventromedial white matter suggest a mixture of nonnociceptive and nociceptive neurons with supraspinal targets in the mesencephalon and intralaminar nuclei of the thalamus.

**SPINORETICULAR AND SPINOMESENCEPHALIC TRACTS**

**Ventrolateral (Anterolateral) Axonal Pathways**

As noted previously, ascending axonal fibers of nociceptive second-order neurons traveling to the thalamus may frequently branch and send collaterals into brainstem structures including the medulla, pons, and mesencephalon. However, numerous ascending fibers travel to these brainstem structures without having collaterals to the thalamus and collectively are described as spinoreticular if they reach medullary and pontine sites or spinomesencephalic if they reach midbrain targets. Subsets of spinoreticular neurons, defined by known targets for the axons, include spinomedullary, spinopontine, spinoolivary, spinosolitary, spinoraphe, and spinoparabrachial neuronal groups. Identification of these subgroups has been possible using focal injections of retrogradely transported neuronal dyes at supraspinal sites or antidromic electrical activation of axonal extensions. Although the former technique has reasonable localization potential, the latter does not always discriminate axons of passage from final sites of termination. The presence of collateralization of axons to multiple targets has been identified but not quantitatively defined, and so the overlap between the sampling of groups is not known. The spinal localization of spinoreticular and spinomesencephalic ascending axons overlap with those of the ventrolateral STT except for a greater propensity for remaining ipsilateral within the spinal cord and a slightly more medial
line of passage upon entering the medulla. Spinomesencephalic neurons also utilize the dorsolateral funiculus for a subset of lamina I neurons in a fashion similar to that of similar spinothalamic neurons.

**Features of Spinoreticular Neurons**
The locations and functional characteristics of spinoreticular neurons in primates are virtually identical with the same features of STT neurons with projections to the medial thalamus. They demonstrate a predominant localization to deeper laminae of the spinal cord and tend to have large, sometimes whole-body, receptive fields of the NS and WDR types. Synaptic targets include many areas of the medulla and brainstem highly involved in autonomic regulation as well as the regulation of nociceptive systems. The potential for feedback control of nociceptive processing is therefore anatomically present. An important relay site is the parabrachial nucleus in the pons which has extensive projections to limbic subcortical structures such as the amygdala.

**Features of Spinomesencephalic Neurons**
In contrast to spinoreticular neurons, the locations and functional characteristics of spinomesencephalic neurons in primates are similar to STT neurons with projections to the lateral thalamus, although significant differences are present. They demonstrate a predominant localization of soma to laminae I and V of the spinal cord with a small scattering to other deep laminae. Electrophysiologic characterization of spinomesencephalic neurons suggests a predominance of NS neurons. Synaptic targets include the periaqueductal gray, a site with known importance to the regulation of nociception as well as the collicular and cuneiformis nuclei.

**POSTSYNAPTIC DORSAL COLUMN NEURONS**
Recently, there has been increasing evidence for the existence of a spinal pathway in the midline of the dorsal spinal cord that carries the rostral transmission of deep tissue nociception. Traditionally, the dorsal columns have been viewed as transmitting information related to nonnociceptive information such as vibration or other light touch sensations. However, discrete neurosurgical lesions of this portion of the spinal cord have been
demonstrated to relieve cancer-related pain in patients with pelvic visceral and deep muscle pathology.\textsuperscript{32,33} Parallel studies in nonhuman animals have demonstrated that in this area of spinal white matter, there exist axons of postsynaptic dorsal column (PSDC) neurons receiving noxious excitatory input from the colon, bladder, and/or uterus. Excitatory responses of neurons located in the ventrobasal thalamus to noxious deep tissue stimuli are attenuated/abolished with lesions of the dorsal midline region of the spinal cord\textsuperscript{32} but are only minimally affected by lesions of the traditional spinothalamic pathways (ventrolateral quadrant).

The soma of PSDC neurons are located predominantly in lamina III, IV, and X, and in a limited number of studies, the neurons have been demonstrated to be responsive to both somatic and visceral nociceptive inputs. Both NS and WDR neuronal types have been reported and their role in nociception is linked more to the secondary effects of dorsal column lesions than inherent neuronal characteristics. Targets for synaptic contact include the gracile and cuneatus nuclei of the medulla (dorsal column nuclei), but it is notable that the presence or absence of collaterals to other ascending tracts or other supraspinal targets has not been performed.

OTHER ASCENDING PATHWAYS
There exist other pathways to the brain apart from those noted. The spinocervicothalamic tract is important in other species but appears minimal or absent in humans. Direct projection pathways to the hypothalamus, amygdala,\textsuperscript{31} and cerebellum have also been identified with presumed roles in autonomic function, affective-emotional modulation, and motor coordination, respectively. Extraspinal pathways for peripheral primary afferents exist and can sometime lend confusion to studies of central pathways. Vagal afferents can reach the brainstem carrying extensive information from visceral and other deep tissue structures leaving brainstem-mediated responses intact despite the interruption of spinal pathways. Similarly, primary afferents from deep structures including the viscera and peripheral vasculature can travel via the sympathetic chain to enter the spinal cord at levels much higher than expected and so can “bypass” selective spinal lesions of ascending
pathways forming synaptic contact at levels above the lesions. Clinically, these other pathways sometimes prove important to consider, particularly in conditions of spinal cord injury.

**Neurochemistry of Second-order Neurons**

**NEUROTRANSMITTERS FROM PRIMARY AFFERENTS**

Excitatory neurotransmission of second-order spinal neurons is produced predominantly by the release of excitatory amino acids (EAAs), such as glutamate and aspartate, from primary afferent neurons. Various other neurotransmitters lead to neuroexcitatory effects by channel activation or sometimes via second messenger systems, but in most cases, these other neurotransmitters appear to have the augmentation of EAA-induced excitatory responses as their primary function. Most notable of these neurotransmitters are CGRP, substance P, and NK-A, but roles for serotonin, adenosine triphosphate (ATP), and cholecystokinin (CCK) have been identified. The inhibitory neuropeptides galanin and somatostatin are also released from primary afferents, but they are small in number and with limited effects on second-order neurons. A summary of spinal cord dorsal horn neurotransmitter location and associated receptors is given in Table 4.1.

**NOTE**: Pharmacologic systems thought to contribute to the transmission and modulation of second-order nociceptive neurons in the dorsal horn of the spinal cord. The various neurochemicals and receptors depicted each has its own pharmacologic profile and may represent independent populations of neurons and fibers but more commonly coexist and interact with each other at individual synapses. Interactions may take place at presynaptic terminals, dendrites, and somata.

x, origin of neurotransmitter; +, pronociceptive effect; −, antinociceptive effect; α1, α2, alpha adrenoceptors; A1, adenosine receptor 1; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; ARTN, artemin; ATP, adenosine triphosphate; B2, beta 2; BDNF, brain-derived neurotrophic factor; CB1, cannabinoid receptor 1; CCK, cholecystokinin; CGRP, calcitonin gene-related peptide; CRF, corticotropin-releasing factor; DOR, δ-opioid receptor; 5-HT, 5-hydroxytryptamine; GABA, γ-aminobutyric acid; Gal1, galanin receptors type 1; Gal2, galanin receptors type 2; GDNF, glial cell line-derived neurotrophic factor; GFR, GDNF family receptors; iGluR, ionotropic glutamate receptor; KA, kainate receptors; KOR, κ-opioid receptor; mACh, muscarinic acetylcholine; mGluR, metabotropic glutamate receptor; MOR, µ-opioid receptors; nACh, nicotinic acetylcholine; NFF, neuropeptide FF; NGF, nerve growth factor; NK1, neurokinin 1 receptor; NK2, neurokinin 2 receptor; NM, neuromedin receptor; NMDA, N-methyl-D-aspartate. Excitatory Amino Acids: Ionotropic Receptor/Channels

EAAs not only act on ligand-activated ion channels to produce immediate excitatory postsynaptic potentials (EPSPs) but also act at metabotropic receptors to alter intracellular second messenger systems (discussed in the following text). Three different EAA-activated ion channels have been characterized: α-amino-3-hydroxy-5-methyl-4-isozazolepropionic acid (AMPA) receptors, NMDA receptors, and kainate (KA) receptors. These receptors have differential functions despite frequent colocalization on the same neurons due to differences in their regulation by baseline membrane potentials. As different receptors/channels, they are also differentially affected by the presence of other agonists and ions such as magnesium.

Activation of AMPA receptors immediately allows selective sodium ion flow through the extracellular membrane and is responsible for a majority of the “fast” transmission in nociceptive systems. AMPA receptors are unaffected by the baseline depolarization state of the second-order neuron. In contrast, NMDA receptors are both voltage- and ligand-gated and allow permeability to both sodium and calcium ions. Magnesium ions act to block the channels of NMDA receptors, which are unblocked following a sustained depolarization of the extracellular membrane. Such a sustained alteration in membrane potential enables the magnesium ion to disengage intracellularly which then allows the opening and activation of the NMDA receptor/channel complex, which, in turn, results in a very sustained depolarization. Because the NMDA receptor/channel is permeable to calcium, its sustained activation can produce alterations in intracellular second messenger functions of calcium.

Two phenomena have been clearly linked to NMDA receptor activation: “wind-up” (increasing responses to repeated stimuli of equal intensity) and “central sensitization” (decreased thresholds for response and/or increased vigor of responses due to a sensitizing event). NMDA antagonists will block/blunt both phenomena, but these phenomena can also be stopped prior to their development by pharmacologic antagonists that block the initial event that led to the sustained depolarization that allowed the NMDA receptor activation. As a consequence, the antagonism of other
excitatory systems (i.e., AMPA receptors) or the activation of endogenous inhibitory systems may also blunt or block these “hyperalgesic” phenomena. Clinical use of NMDA receptor antagonists such as ketamine or dextromethorphan has been demonstrated to produce prolonged analgesic effects when coadministered with opioids or as part of a perioperative regimen.

The third ligand-activated ion channel, the KA channel, is not well-understood but is likely to affect nociceptive systems in a yet-to-be-defined fashion. Metabotropic effects (second messenger–mediated) of the KA receptor that are in addition to its primary ionotropic effects have been observed in CNS sites such as the hippocampus. Evidence of participation in intracellular signaling cascades and G protein activation that lead to the modulation of GABA release suggest that KA receptors could have a role in nociceptive processing.47

**Metabotropic Glutamate Receptors**

Acting via second messenger systems rather than channel activation, the eight different metabotropic glutamate receptors (mGluRs) can be classified into three groups on the basis of sequence similarity and whether they positively couple to the phospholipase C cascade or negatively couple to the adenyl cyclases.34 Group I (mGluR1 and mGluR5) has been linked to nociceptive processing as these receptors produce alterations in NMDA receptor/channel opening. As such, they have been implicated in processes of central sensitization and persistent pain. Group II (mGluR2 and mGluR3) has also been used to modify nociceptive behavioral responses in models of neuropathic and inflammatory pain. Group III (mGluR6, mGluR7, and mGluR8) has not yet had a clearly defined role in nociception.

**Substance P**

This neuropeptide has long been attributed a special role in pain processing as it is located in small diameter primary afferents and is released following cutaneous noxious stimuli.48,49 Substance P acts by binding to NK1 receptors on second-order neurons, thereby affecting intracellular G protein-related phosphorylation processes. It is often
colocalized with, and so coreleased with, glutamate from primary afferents and promotes membrane depolarization produced by glutamate. In this way, it modifies the gain of nociceptive transmission. It is important in conditions of inflammation, particularly neurogenic inflammation, where it is released from peripheral axons and produces a local tissue effect. However, substance P may not be necessary for acute nociceptive transmission because the pharmacologic or genetic “knock-out” of the NK1 receptor has minimal effect on acute responses to most nociceptive stimuli. Substance P is present in highest concentration in laminae I and II, as well as in laminae V and VI. Other neurokinin receptors also exist which bind other neuropeptides such as NK-A, which has physiologic effects similar to substance P. Neuropeptide antagonists such as the NK1 antagonists have proved to have disappointing results in clinical trials when pain was the clinical endpoint, although efficacy has been noted in association with nausea therapy.

**Calcitonin Gene-Related Peptide**

The most commonly located neuropeptide in afferent systems (CGRP) has a poorly defined role in nociceptive processing with mixed results from depletion, augmentation, and antagonism studies. At present, its most important effects appear to be related to peripheral vasodilation that is associated with the generation of headaches. Electrophysiologic studies of spinal WDR second-order neurons have demonstrated an augmentation of nociceptive responses due to direct application of CGRP in a neuromodulatory fashion similar to substance P and NK1 receptor activation. Like substance P, the knockout of CGRP synthesis has little effect on acute experimental models. CGRP localizes in primary afferent terminals in laminae I, II, and V. Human and nonhuman animal studies suggest that CGRP may be most important in relation to neurogenic inflammatory processes—particularly those associated with migraine headache. There is a clear association between headache symptomatology and the peripheral release of CGRP and antagonists to the CGRP receptor have been reported as efficacious for the relief of acute migraine attacks. For these reasons, CGRP may not be as important as a substrate for spinal cord processing as it is for the peripheral effects of nociceptor activation.
Cholecystokinin

A peptide present in primary afferent neurons, CCK has little effect in animals without pathology, but the neuropeptide increases in content and its receptors in number following nerve injury.\textsuperscript{35,55} Opioid receptor function and CCK receptor activation are also related in a complex fashion as CCK receptor antagonists may promote opioid analgesia and slow morphine tolerance development at spinal levels. Consistent with this, CCK receptor antagonists may be analgesic in neuropathic pain models, and this analgesia is antagonized by naloxone. CCK is localized predominantly to laminae I, II, IV, and X and is a neurotransmitter present in both primary afferents and interneurons.

Other Neuropeptides

Multiple other neuropeptides that are in primary afferent neurons or which have receptors on the central terminals of primary afferent receptors have been implicated in nociceptive spinal processing. These include vasoactive intestinal polypeptide (VIP), bombesin, gastrin-releasing peptide, neuromedin B, neuromedin C, neuropeptide YY, and thyrotropin-releasing hormone (TRH). Action of most of these neurotransmitters on nociceptive systems appears to be predominantly a facilitatory presynaptic action on primary afferent neurotransmitter release. VIP has a presence in the ventral horn of the spinal cord, but the predominant source of VIP to the dorsal horn is primary afferents with strong localization in lamina I and a sparse representation in lamina V. Two neuropeptides located in primary afferent terminals, galanin and somatostatin, have inhibitory influences on second-order neurons.\textsuperscript{35,36} Trophic factors such as nerve growth factor and brain-derived neurotrophic factor (BDNF) also act as influences to the second-order neurons, particularly in conditions of nerve injury or death.

Adenosine Triphosphate

Present in many primary afferents, ATP, as a neurotransmitter, is known to activate the ligand-gated ion channels of the P2X family as well as the metabotropic P2Y family of receptors. P2X receptor activation both potentiates glutamatergic transmission and produces fast transmission related to nociceptor activation.\textsuperscript{37,38} Ubiquitous as the compound used to
drive most energy-requiring processes of metabolism, ATP also has breakdown products that may serve as agonists to other purinergic receptors (A1, A2) located both extracellularly and intracellularly on second-order neurons.

**Colocalization of Neurotransmitters**
Corelease of neurotransmitters from primary afferent neurons is the typical rule rather than exception in relation to small diameter fibers. EAAs coexist with ATP, substance P, NK-A, CGRP, and other neuropeptides. These neuropeptides coexist in nerve terminals in varying combinations with each other with all possible mixtures described in overlap. CGRP is the most ubiquitous of the neuropeptides located within C fibers and so commonly colocalized with other neurotransmitters. The mechanisms of corelease are poorly understood and could involve selective release of one of the neurotransmitters.

**NEUROTRANSMITTERS FROM INTERNEURONS**
Whereas the predominant effect of primary afferent neurotransmitter release on second-order spinal neurons is excitation, the predominant effect of interneuron neurotransmitter release is inhibition. Second-order neurons may act as interneurons and at the same time may also be third, fourth, or higher order neurons responsible for excitatory and/or inhibitory effects on other second-order neurons. This is apparent in intermediate laminae neurons which have complex cutaneous receptive fields that represent the total body when both excitatory and inhibitory influences are considered. Interneurons utilize many of the same excitatory neurotransmitters as primary afferents but, in addition, utilize many other neurotransmitters to produce inhibitory influences. These fall mainly into the amino acid, neuropeptide, and small molecule groups. A listing of these neurotransmitters is also given in Table 4.1.

**Inhibitory Amino Acids**
GABA and glycine are the two main inhibitory amino acids of the CNS. GABAergic systems appear to be more predominant at supraspinal sites and glycine at spinal sites, but both are present throughout the CNS.
GABA acts through a “fast” ligand-activated ion channel that allows chloride ion flow, which in turn produces hyperpolarization of the neuronal membrane. Termed the \( \text{GABA}_A \) receptor, it has associated structures that allow benzodiazepine or barbiturate binding to alter the GABA affinity and channel activation characteristics of the receptor/channel complex. The “slow” metabotropic receptor for GABA, the \( \text{GABA}_B \) receptor is the binding site for baclofen and works via G protein-linked systems to alter potassium (promotes) and calcium (inhibits) ion channel flow. Via actions on motoneurons, \( \text{GABA}_B \) receptor activation leads to decreased spasticity and muscle tone. At brainstem levels, in association with cranial nerve function, \( \text{GABA}_B \) activation may be analgesic and so is indicated in the treatment of various cranial neuralgias. A putative \( \text{GABA}_C \) receptor which is ionotropic has been described but with an uncertain role in sensory systems.

Glycine acts through both strychnine-sensitive and strychnine-insensitive receptors. The former, a ligand-gated anion channel very similar to the \( \text{GABA}_A \) complex, is diffusely located but with particular effect in the ventral horn of the spinal cord such that the administration of strychnine can lead to spontaneous muscle contractions. Also present in spinal sensory systems, the antagonism of glycine effects with strychnine in animal models leads to motor and autonomic hyperreflexia. Paradoxically, glycine can also have excitatory effects via binding as a coagonist to a separate site of the NMDA receptor. Because of their multiple nonspecific effects, anti- or pro-glycinergic drugs have not been employed clinically, although theoretical uses are present. Selective delivery of agents to focused CNS sites might be able to overcome some of these nonspecific effects.

**Opioids**

Endogenous opioids form the most prominent family of inhibitory neuropeptides in the dorsal horn. Arising from intrinsic spinal interneurons, enkephalins, dynorphin, and \( \beta \)-endorphin bind to G protein-related receptor complexes that fall into three major classes: the \( \mu \)-opioid receptors (MOR), the \( \kappa \)-opioid receptors (KOR), and the \( \delta \)-opioid receptors (DOR). Exogenously administered MOR agonists are the mainstay of
analgesic therapy for severe pain today with actions at both spinal and supraspinal sites. Spinal effects arising from supraspinal actions of MOR agonists are via descending serotonergic and noradrenergic mechanisms. MOR agonists administered to spinal sites act both presynaptically on primary afferents to inhibit release of excitatory neurotransmitters and postsynaptically to directly inhibit second-order neurons. KOR agonists, such as the endogenous dynorphins, have been demonstrated to be neurotoxic when administered in high concentrations. Peripherally, these same agents appear to produce analgesia particularly in the realm of deep tissue afferents. DOR agonists hold great promise with many of the favorable characteristics of MOR agonists. However, to date, study of selective DOR agonists have been hampered by the lack of highly selective, nontoxic drugs for use.

An opioid receptor–related neurotransmitter is the substance nociceptin and its receptor, the nociceptin/orphanin FQ (N/OFQ) peptide receptor. Due to the technology of functional genomics, this receptor, formerly known as the opioid receptor like orphan receptor-1, was the first of hundreds of G protein-coupled receptors identified which had no known endogenous ligand or function. Subsequently, nociceptin (orphanin FQ) was identified and functional pharmacology performed with agonists to the N/OFQ peptide receptor showing some promise in relation to the treatment of anxiety, stress-induced anorexia, cough, neurogenic bladder, edema, drug dependence, cerebral ischemia, and epilepsy. The precise role of nociceptin in pain processing is still being determined with both antiopioid and opioid-potentiating modulatory properties demonstrated.

Acetylcholine
A rediscovered and so developing, novel pharmacology important to nociceptive processing is that involving the cholinergic systems. Numerous dorsal horn interneurons label positive for enzymes associated with acetylcholine synthesis and/or degradation and pharmacologic effects have been noted in relation to both nicotinic and muscarinic subtypes. Use of neuraxially delivered cholinesterase inhibitors, which leads to the increased activation of both nicotinic and muscarinic receptors, not only clearly produces analgesia in nonhuman animal models but also produces
intractable nausea in clinical studies (which reduces enthusiasm for their use). Cholinergic interneurons may act as intermediary steps for other analgesic treatments such as descending norepinephrine-related inhibitory systems.

Other Neurotransmitters within Interneurons
Numerous other neuropeptides and small molecules have been localized to interneurons which include thyroid-stimulating hormone (TSH), neurotensin, neuropeptide FF, neuropeptide Y, somatostatin, galanin, and CCK. All of these have been demonstrated to have dorsal horn localization, and all produce neuromodulatory effects, many with mixed excitatory/inhibitory interactions with opioid systems.

NEUROTRANSMITTERS FROM SUPRASPINAL SOURCES
Spinal transection leads to a depletion of the content of several neurotransmitters within the dorsal horn of the spinal cord. Most notable of these are the monoamines serotonin and norepinephrine. Spinal transection still leaves residual serotonin content within the ventral horn indicating some local production of neurotransmitter that may be in addition to that circulating in blood components. Any residual noradrenergic content appears to be of sympathetic origin. As will be discussed in the next chapter, descending noradrenergic and serotonergic fibers originating in the brainstem produce robust inhibitory effects on second-order spinal neurons. It has also been recently appreciated that these same neurotransmitters may also produce excitatory effects and may therefore serve as the mechanisms of descending facilitation, another topic of the next chapter.

Serotonin (5-Hydroxytryptamine)
The pharmacologic characterization of responses to the endogenous substance, serotonin, has identified a highly complex interaction of this substance with multiple receptors, some with multiple subtypes. At last count, seven main families of 5-hydroxytryptamine (5-HT) receptors (most families further subdivided) have been identified, some with inhibitory and
some with excitatory effects. The receptor of greatest relevance to pain production or excitatory phenomena is the 5-HT$_3$ receptor, the only one of the receptors which is a ligand-gated ion channel.\cite{56} Excitatory responses to serotonin administered peripherally suggest that it can directly activate nociceptive primary afferent neurons. Actions on the dorsal roots have been postulated to be pronociceptive, antinociceptive, and propruritic. An increasing role for 5-HT$_{1A}$ has also been demonstrated as well as other serotonergic subsets. Boutons with serotonin content have been noted throughout the dorsal horn, and cell bodies with serotonin have been identified in the ventral horn. A colocalization within synaptic boutons with the neuropeptide substance P has been commonly noted.

**Noradrenaline**

Adrenoceptors important to the spinal processing of pain appear to be of the $\alpha_1$ or $\alpha_2$ subtypes based on the use of agonists (i.e., clonidine) and antagonists administered spinally. Descending from brainstem noradrenergic neuronal nuclei (primarily A5, A6, and A7), known pharmacologic sites of action for norepinephrine include presynaptic terminals of nociceptive primary afferent neurons ($\alpha_2$ inhibitory), second-order neurons ($\alpha_2$ inhibitory), and interneurons ($\alpha_1$ excitatory) and, as such, has been implicated in both descending inhibition and descending facilitation of nociceptive transmission.\cite{41} Immunohistochemical localization of noradrenergic nerve fibers have found them widely dispersed throughout the dorsal horn and much of the release of neurotransmitter appears nonsynaptic in nature,\cite{57} such that the neurotransmitter has to diffuse from its site of release to its site of action which may be neuronal or glial.\cite{58} Extensive synaptic contact of noradrenergic nerve endings does occur within the ventral horn and intermediolateral grey.

**Other Neurotransmitters in Descending Systems**

Often colocalized with other neurotransmitters, certain neuropeptides and other monoamines are also in descending fibers that make contact with the spinal dorsal horn. These include substance P, CCK, corticotropin-releasing factor, urocortin 1, and TRH, which have excitatory
neuromodulatory effects and dopamine, oxytocin, GABA, glycine, and endogenous opioids, which have inhibitory neuromodulatory effects. These descending fibers modulate more than just nociceptive sensory information but when exogenously administered to the spinal cord can produce profound autonomic and motor effects. TSH has been noted to have effects that are like CCK in that it appears to inhibit opioid analgesia.

**NEUROTRANSMITTERS FROM GLIA OR UNKNOWN SOURCES**

Numerous substances alter the excitability of second-order neurons to nociceptive input that are not from neural structures. For example, bradykinin, which is normally known for its peripheral nervous system effects, activates B2 receptors in the dorsal horn with the subsequent induction of hyperalgesia phenomena. Destruction of primary afferents results in the loss of two-thirds of these receptors, but the source of the activating bradykinin is unknown. Likewise, other substances associated with inflammation, such as prostanoids and cytokines, have similar neuromodulatory effects and the spinal administration of prostaglandin receptor agonists such those associated with prostaglandin E2 (PGE$_2$), prostaglandin D2 (PGD$_2$), or prostaglandin I2 (PGI$_2$) leads to hypersensitivity. Prostaglandin receptor activation may require other receptors for full expression of sensory phenomena as appears to be the case for PGE$_2$ which needs an intact NMDA receptor and a PGD$_2$ which requires intact NK1 receptors. Cytokines such as interleukin 1 beta (IL-1$\beta$), interleukin 6 (IL-6), and tumor necrosis factor-$\alpha$, which are released by activated microglia and other neuroimmunologic cellular components of the CNS following nerve injury, have also been appreciated as having neurotoxicity effects on nociceptive neurons that involve purinergic mechanisms.$^{59,60}$ Second-order neurons are sensitive to neurotrophin and glial cell line-derived neurotrophic factor (GDNF) families of ligands, released locally from multiple sources, including neural structures. Neuron responsiveness to these ligands is dependent on expression of high-affinity receptor tyrosine kinases (TrkA-C), the low-affinity receptor p75, GDNF family coreceptors (GDNF family receptor $\alpha$ [GFR$\alpha$] 1 to 4), and the tyrosine kinase RET. The angiogenic growth factor, vascular endothelial
growth factor (VEGF), and its receptors also modulate dorsal horn pain transmission. Receptor expression patterns, and thus growth factor sensitivity, are cell type–specific and produce trophic and phenotypic changes, but the specifics are beyond the scope of this chapter due to complexities related to developmental regulation and altered expression following tissue injury. Of note, however, is evidence that BDNF plays a substantial role in pain transduction by decreasing inhibition in dorsal horn neurons and descending inputs and increasing dorsal horn neuronal excitation. In addition to its pronociceptive actions mediated by TrkB, BDNF modulates a subset of NMDA receptors involved in the development and maintenance of central sensitization (discussed in the following chapter).42,61,62

**OTHER IMPORTANT RECEPTORS/CHANNELS**

Consideration needs to be given to the presence of receptors or channels that are either “universal” in that their pharmacologic modulation seemingly affects all spinal cord neurons in a relatively nondiscriminutive fashion, or “selective” in that they are present in a subset and/or subsite of neurons such as the end terminals of primary afferent neurons. A particular group of ion channels that are in the selective group are the N-type calcium channels found on primary afferent neurons.43 Calcium influx into the intercellular space due to receptor activation (ligand-gated) or due to membrane depolarization (voltage-gated) results in both membrane depolarization effects and second messenger cascade activation. In primary afferents, this calcium influx is associated with the release of neurotransmitter at synapses. There exist at least five families of voltage-gated channels (L, N, P/Q, R, and T) with differing pharmacologies and localization within the spinal cord. Some of the families share auxiliary subunits such as the L- and N-type channels which both have an α2δ subunit. This subunit is the site to which the drugs gabapentin and pregabalin bind with a subsequent reduction but not abolition of membrane excitability. The N-type calcium channels are located throughout the CNS but, at a spinal cord level, have particular localization to the nerve terminals of small diameter primary afferents. The ω-conotoxin ziconotide binds to and blocks ion flow through this channel and has found clinical
utility in the control of pain when administered intrathecally.

Primary afferent sensory neurons also express voltage-gated sodium channels (VGSCs) that are fundamental to the generation and propagation of action potentials. Those VGSCs with subunits encoded by the genes for Nav1.8 and Nav1.9 are specific to sensory neurons, and Nav1.7 is expressed in nociceptive sensory neurons as well as other cell types. Changes in the expression of these channels or posttranslational modifications that alter their gating or trafficking impact nociceptive transmission, and thus, VGSCs expressed on sensory neurons have become targets for therapeutic strategies. Gain- and loss-of-function mutations that increase or decrease nociceptive transmission in animal models have been corroborated in humans; for example, gain-of-function mutations have been found in patients with painful neuropathy, erythermalgia, and paroxysmal extreme pain disorder, and loss-of-function mutations have been reported in families with congenital insensitivity to pain.

**What Is Important to the Clinician**

The substrates of nociception that exist at a spinal level are as complex as the phenomenon of pain itself. More than 30 different neurotransmitters acting at more than 50 different receptors have been identified as present in the spinal cord and associated with some pain-related phenomenon. Sensory pathways connecting the spinal cord to the brain have been identified that result in rapid transmission of information that is highly organized and site-specific, but similar pathways have also been identified which have slow transmission that is poorly organized and therefore resistant to attempts at ablation. The clinician must synthesize these diverse pieces of information into a general model of nociceptive processing and must accept that at this point in time, the model is incomplete. The effectiveness of therapeutic interventions intended to treat pain is dependent on the modulation of these substrates of nociception which forms the topic of the next chapter.

**ACKNOWLEDGMENTS**

The authors of this chapter are supported by DK51419, DK73218, and
Note: The present chapter is intended as a summary of information important to pain clinicians and as a presentation of new information coupled with a simplification of previous presentations of similar information in this text and other sources. As such, referencing has been lessened, although many of the primary sources of information may be found in the previous reviews.

CHAPTER 5
Modulation of Spinal Nociceptive Processing
TIMOTHY J. NESS, ALAN RANDICH, and JENNIFER J. DEBERRY

The preceding chapter addressed the neuroanatomy and neurochemistry of neurons located within the spinal cord that process information related to pain-related sensation. These neurons are highly regulated components of the central nervous system (CNS) with inhibitory and excitatory feedback mechanisms. Pain may be due to increased primary afferent input or may be the result of a failure of feedback regulation or a combination of the two. Too much “gain” or inadequate “braking” can both result in an excess of sensory transmission. In the normally functioning state, there are tonic influences present as well as evocable mechanisms whereby the responses of second-order neurons can be suppressed or facilitated dependent on other events important to the organism. Some modulatory effects are relatively “hardwired” occurring in a reliable and predictable fashion. Other modulators are less predictable and may be dependent on psychic/cognitive processes that vary from organism to organism and may involve learning, motivation, or emotional factors. In most cases, modulatory systems are adaptive in that they help an organism to function optimally. Unfortunately, with disease, some of these same modulatory systems have become maladaptive and serve to impede both physiologic and social processes of healing. The complex nature of these modulatory influences and the neurotransmitters involved are discussed in three parts beginning with a discussion of mechanisms based at spinal levels, followed by a discussion of mechanisms related to descending influences, and finally by a brief discussion of some “triggers” of spinal neuron hyperexcitability that may occur pathologically and/or iatrogenically which lead to hypersensitivity. These triggers are used as examples of the
interactive nature of these modulatory forces. There is value in understanding endogenous modulatory systems because they are the systems which the clinician activates or suppresses by using exogenous modulators, such as electrical stimulation or pharmacologic agents. Modulation occurs at each step of processing within the CNS, but the focus of the present discussion is the modulation of the spinal second-order nociceptive neuron.

**Spinal Cord–Based Modulatory Mechanisms**

**ACUTE SEGMENTAL MODULATORY EFFECTS**

Sensory inputs to the spinal cord and trigeminal nucleus begin to interact at the very first steps of transmission. Activation of large diameter afferents (Aβ) produces an inhibitory effect on the processing of signals from small diameter (Aδ and C-fiber) afferents. This effect has been documented since ancient times and is relearned by every child who rubs or massages injured parts of their bodies in order to achieve pain relief. The mechanism of this manipulation has been more difficult to explain than the time-honored efficacy of the effect.\(^1\) What is clear is that second-order neurons of the spinal cord have both excitatory and inhibitory “receptive fields.” Namely, stimulation of different parts of the body using one or more types of stimuli (e.g., noxious heat, low threshold mechanical, high threshold mechanical) results in the depolarization or hyperpolarization of individual second-order neurons. Inhibition of second-order neurons which is produced by noxious stimuli can be evoked from heterosegmental sites and so is discussed separately later. Inhibition of second-order neurons which is produced by nonnoxious stimulation appears to be predominantly segmentally organized. Theoretically formulated as the initial gate control theory of Melzack and Wall,\(^2\) this effect was hypothesized to occur because of a combination of presynaptic inhibition and the actions of inhibitory interneurons located in lamina II (substantia gelatinosa) of the spinal cord which are activated by large diameter afferents (Fig. 5.1). Although the specifics of this theory have evolved further to include nonsegmental effects, its general description has served as the theoretical underpinnings for the clinical effects of
neuromodulatory (electrostimulatory analgesic) techniques ranging from transcutaneous electrical nerve stimulation to spinal cord stimulation and aspects of acupuncture.\(^3\)

**FIGURE 5.1** Gate control theory as originally schematically described by Melzack and Wall\(^2\) where large-diameter (L) and small-diameter (S) primary afferent fibers project to substantia gelatinosa (SG) and second-order transmission (T) neurons in the spinal dorsal horn. The inhibitory effect of SG neuronal activity is increased by L and decreased by S fiber activity. T neurons transmit information to the brain and other action sites. Activation of peripheral or central projections of L fibers using transcutaneous nerve stimulation, peripheral nerve stimulators, or dorsal column stimulators would all be expected to produce inhibition of S fiber input to the T cells.

Numerous electrophysiologic studies of second-order neurons have observed that low-intensity, high-frequency electrical stimulation of nerves or somatic tissues located at the same segmental level as the neuron produces an inhibitory effect which is not reduced by naloxone (nonopioidergic) but which may involve GABAergic or glycinergic mechanisms. This phenomenon is present in both spinally transected and intact animals and so does not necessarily involve a brainstem mechanism. Dorsal column stimulation, which produces retrograde activation of Aβ fiber inputs to the spinal cord (but may also activate descending modulatory pathways), produces similar nonopioid, GABAergic, and/or glycinergic inhibition of spinal nociceptive processing.

**HETEROSEGMENTAL MODULATORY SYSTEMS**

Both excitatory and inhibitory effects can occur at one spinal level when stimuli are presented to distant portions of the body. Excitatory effects
have generally been described in imprecise terms as extended connectivity or as propriospinal pathways that are just one component of the systems that alter the “gain control” mechanisms of nociceptive systems. Some of these intraspinal networks serve to integrate both sensory and motor functions involving the upper and lower extremities with an example being crossed flexion–extension reflex responses to noxious stimuli. A coordination of pelvic organ function also relies on intraspinal excitatory and inhibitory connections that link processing of sensory information from afferents traveling in the pelvic nerve to the lumbosacral cord with that of afferents traveling in sympathetic nerves to the thoracolumbar spinal cord. Intraspinal networks of neurons, which form a reticular network in the deeper parts of the spinal dorsal horn, have been described in the context of the multisynaptic ascending system of Noordenbos. This same network could just as easily serve as the substrates for multisynaptic descending modulatory influences.

The most formally studied heterosegmental interaction related to nociception is the phenomenon known as diffuse noxious inhibitory controls (DNIC). This endogenous inhibitory system is activated by noxious stimuli presented to a distant nonsegmental site and results in the inhibition of ongoing or evoked dorsal horn neuronal activity. The mechanisms of DNIC are postulated to involve the activation of brainstem nuclei that subsequently produce inhibition of spinal dorsal horn neurons through a descending modulatory mechanism, but it is notable that the neurophysiologic phenomena associated with DNIC have been demonstrated in spinally transected preparations. These “propriospinal” phenomena represent a general inhibitory system activated by heterosegmental noxious conditioning stimuli which is either synonymous with or highly augmented by the presence of a brainstem and mechanisms of DNIC. According to its original description by Le Bars et al.,6,7 DNIC results in the inhibition of class II (wide dynamic range [WDR]; convergent) neurons and has no effect on class III (nociceptive specific) neurons. A consistency of many studies related to DNIC (and propriospinal heterosegmental inhibition) is that they have identified that most spinal neurons responsive to noxious stimuli effectively have “total body” receptive fields in that noxious stimuli will produce excitation or
inhibition that is dependent on precise body site. DNIC-sensitive neurons have a resultant “inhibitory surround” effect where all noxious inputs outside of a defined area are inhibitory to the individual neurons. Human studies of the similar, but more general, phenomenon of conditioned pain modulation have described the potential for complex interactions of heterosegmental stimuli in which one pain typically inhibits other pains (as in DNIC) except in case of pathologic pain disorders where the expected inhibition may be absent or facilitation may be noted instead.\(^8\)

**C-FIBER WIND-UP AND CENTRAL SENSITIZATION**

Changes in excitability occur in second-order neurons when repetitive or prolonged high-intensity input is received from primary afferent C-fibers. One of these changes in excitability is termed C-fiber wind-up. Noted by Mendell\(^9\) when recording from ascending axons of spinal dorsal horn neurons, wind-up is the phenomenon whereby repeated electrical C-fiber activation at certain rates (i.e., \(\geq\)1 Hz) leads to a sequential increase in the number of action potentials evoked by each stimulus (Fig. 5.2). Slower stimulus rates do not produce progressive increases in activation. Mechanical and thermal stimuli at intensities sufficient to activate C-fibers also produce similar wind-up. This sequential increase in response can be blunted through use of N-methyl-D-aspartate (NMDA) receptor antagonists and the effect disappears after a few seconds of nonstimulation.

![Wind-up responses of single dorsolateral column axon to repeated stimulation of the](image)

**FIGURE 5.2** Wind-up responses of single dorsolateral column axon to repeated stimulation of the
sural nerve at sufficient intensity to activate A and C fibers (no wind-up seen with A-fiber stimulation by itself). The vertical time markers on the far right represent 100 milliseconds. Each mark at the bottom of the time line represents the stimulation artifact and the burst of activity immediately above each of these stimulations is the response to A-fiber stimulation (each dot represents an action potential). The more delayed responses are to the more slowly conducting C-fiber inputs. Response to stimulation shows increasing C-fiber wind-up responses on to 1 per second stimulation (not to 1 every 2 or 1 every 4 second stimulation rates at right). Wind-up lasts for only several seconds following the stimulation as seen by transient increase in spontaneous activity. (Redrawn from Mendell LM. Physiological properties of unmyelinated fiber projections to the spinal cord. Exp Neurol 1966;16:316–332.)

Another general category of increased neuronal excitability is termed central sensitization. This term has been used in a focused manner to describe acute changes in the responsiveness of second-order neurons following high-intensity or prolonged stimuli such as those that occur with nonneuronal tissue injury and subsequent inflammation. The term has also been used to describe phenomena such as delayed-onset nerve injury–related hypersensitivity and, in that case, is more subacute or chronic in nature with a potential for morphologic as well as biochemical alteration of second-order neurons. For purposes of the present discussion, injury-induced central sensitization as described by Woolf is used as the archetype model of central sensitization (Fig. 5.3). Multiple studies have demonstrated that tissue injury produces an augmentation of nociceptive reflexes that is NMDA receptor–dependent. In preclinical models, pharmacologic treatment has the greatest effect if given prior to injury and a blocking of afferent input serves to delay the onset of development of hypersensitivity. Extrapolating from this data and coupling it with evidence of long-term potentiation (LTP) of synaptic efficacy in the spinal cord after even brief bouts of NMDA receptor activation and interaction with glia, some have further extrapolated these laboratory data to the clinical concept of “preemptive analgesia.” Treating pain before (and after) it begins has a clear potential for clinical benefit, although the true clinical significance of early intervention has proven difficult to define. On a neurophysiologic basis, an expansion of cutaneous excitatory receptive fields has been noted following tissue injury which follows a similar pharmacology, but specific results have been model- and species-dependent.
FIGURE 5.3 Raster dot displays of a single biceps femoris unit activated by stimulation of the sural nerve once every 2 seconds before an ipsilateral thermal injury (Control), 30 and 60 minutes postinjury, and 10 minutes after the injured foot has been completely anesthetized with local anesthetic (LA). Each dot represents a unit discharge. The vertical scale is the latency of the responses after sural nerve stimulation, and the stimulus artifact can be seen at time 0. Stimulation strengths were sufficient to activate Aβ, Aδ, and C fibers. Note the different time scales used in the three panels to record the activity evoked by the three different fiber populations. In the preinjury state, only Aβ input was evoked. Thirty minutes after injury, a C-fiber response begins to occur, whereas at 60 minutes, both Aδ and C-fiber evoked responses are present (the C-fiber responses with wind-up). Ten minutes after LA, the C-fiber evoked responses remain higher than before the injury suggesting a central component of the sensitization. (Redrawn from Woolf CJ. Evidence for a central component of post-injury pain hypersensitivity. Nature 1983;306:686–688.)

Supraspinal Modulatory Systems

TONIC DESCENDING INFLUENCES
A characteristic of spinal nociceptive systems is that they are under tonic descending inhibition such that a common effect of injury to spinal pathways is a release from this inhibition. Hyperreflexive states with secondary spasticity and autonomic lability can occur. The precise neurophysiologic circuits associated with this descending inhibition is of significant debate, but known inhibitory neurotransmitters such as norepinephrine (NE) and serotonin (5-hydroxy-tryptophan; 5-HT) are synthesized in the brainstem and transported to the spinal cord from multiple supraspinal sites. This role for supraspinal structures in providing descending influences on spinal reflexes has long been recognized. In 1915, Sherrington and Sowton\(^{12}\) demonstrated enhanced flexion reflexes following spinal transection. Later in 1926, Fulton\(^{13}\) suggested that this effect reflected removal of tonic descending inhibitory modulation of spinal interneurons mediating those reflexes. Descending control of flexion reflexes was extensively studied in ensuing years,\(^{14}\) but these studies did not target the issue of how the brain might specifically modulate incoming nociceptive signals from peripheral tissue.

A series of seminal events in the late 1960s and early 1970s led to a full-fledged appreciation and analysis of descending modulation of spinal nociceptive processing. These included a modification of the original gate control theory to include supraspinal systems (Fig. 5.4). This change was prompted by studies which showed that spinal dorsal horn neurons were subject to tonic descending inhibitory influences\(^{15}\) and Reynolds’s\(^{16}\) demonstration that electrical stimulation of the midbrain periaqueductal grey (PAG) produced analgesia sufficient to perform abdominal surgery in a rat. This last phenomenon was referred to as “stimulation-produced analgesia” (SPA).\(^{17,18}\) SPA can also be produced in humans\(^{19}\) in the form of deep brain stimulation, and it suggests the existence of endogenous systems that can selectively modulate pain. This served as the impetus for the extensive, formal analyses of supraspinal structures involved in descending modulation of spinal nociceptive processing that continues today. Later, a number of investigators found that electrical or chemical stimulation of other brain regions could also promote facilitation of nociceptive processing,\(^{20,21}\) suggesting the existence of similar descending facilitatory systems.
FIGURE 5.4  A modification of the gate control theory schematic models includes excitatory (white circle) and inhibitory (black circle) links from the substantia gelatinosa (SG) to the transmission (T) cells as well as descending inhibitory control from brainstem systems. The round knob at the end of the inhibitory link indicates that its actions may be presynaptic, postsynaptic, or both. All connections are excitatory except the inhibitory link from SG to T cells. (Redrawn after Melzack R, Wall PD. The Challenge of Pain. New York: Basic Books; 1983.)

SUPRASPINAL SUBSTRATES MEDIATING THE DESCENDING MODULATION OF PAIN
Periaqueductal Grey of the Mesencephalon and the Rostral Ventral Medulla
The midbrain PAG and the rostral ventral medulla (RVM), in particular the medullary nucleus raphe magnus (NRM) figured prominently in the original analyses of descending modulation of pain. Indeed, they are often viewed as the “backbone” of the pain modulatory system and have been more extensively studied than any other brain regions. Yet, other brainstem nuclei/cell groups also serve in this role and include the nucleus gigantocellularis (NGC), nucleus reticularis gigantocellularis pars alpha (NGCo), nucleus paragigantocellularis (NpGC), midbrain reticular formation, locus coeruleus/A6 cell group (LC/A6), the A5 cell group, the lateral reticular nucleus (LRN) and nearby A1 and C1 cell groups, the parabrachial nucleus/A7 cell group (PBN/A7) and the nucleus tractus solitarius (NTS). A limited amount of information is also available on cortical and limbic systems such as the anterior cingulate cortex (ACC),
the amygdala, and hypothalamus that contribute to descending modulation. It is the investigation of these structures that has led to our current understanding of how descending pain modulatory systems affect pain perception. This topic has been well reviewed.\textsuperscript{1,23–29} Table 5.1 summarizes results related to many of these areas separately along with the neurotransmitters associated with their putative inhibitory versus facilitatory effects on nociceptive transmission. A summary of the most important components is described in Figure 5.5.

NOTE: A1 to A7 designation are noradrenergic nuclei as defined by Dahlström and Fuxe. From Randich and Ness; Mendell; Le Bars et al.; Zhuo; Mason; Boadas-Vaello et al.; Lau and Vaughan; Ossipov et al.; Kwon et al.; Peirs and Seal; Basbaum and Fields; Taylor and Westlund; Tsuruoka et al.; Stevens et al.; Janss and Gebhart; Randich and Aicher; Ren et al.; Aimone and Gebhart; Neugebauer; Senapti et al.; Kuroda et al.; Zhang et al.; Zhang et al.; Hutchinson et al.; Millan; Gebhart and Randich; Thurston and Randich; Urban et al.; Schaible et al.; Ren and Dubner; Butler and Finn; Jennings et al.; Robbins and Ness; Suzuki et al.; Gao and Mason; Kaplan and Fields.
FIGURE 5.5  Schematic diagram of descending modulatory influences of spinal nociceptive processing. Multiple sites within the brain have been demonstrated to be of importance including the midbrain periaqueductal grey (PAG), locus coeruleus/A6 cell group (LC/A6), and the rostral ventromedial medulla (RVM). These sites are reciprocally interconnected, are activated by ascending nociceptive information, and serve as relays for other brain sites known to modulate spinal processing including the anterior cingulate cortex (ACC), other cortical sites (somatosensory, motor, insular, ventrolateral orbital), and the hypothalamus. Resultant modulatory effects on spinal dorsal horn processing can be inhibitory (−) or facilitatory (+) to nociceptive primary afferent input.

The PAG was the initial site of investigation for endogenous pain control systems and is still viewed as an integral component of these systems. Antinociception produced by electrical stimulation of the PAG (SPA) is profound and comparable to that produced by a high dose of morphine. It eliminates behavioral and spinal dorsal horn neuronal responses to noxious stimuli including electric shock applied to the tooth pulp or limbs, noxious heating of the tail and hind paws, noxious pinching of the limbs, and injection of irritants into the viscera. The effects of SPA are produced almost immediately after the onset of stimulation and may last from a few seconds to hours after termination of stimulation.
Microinjection of opiates into the PAG also produces behavioral antinociception and inhibition of spinal nociceptive transmission via disinhibition of inhibitory interneurons in the PAG. The subsequent discovery of endogenous opioid receptors and peptides and demonstration of the presence of opioid receptors throughout the brainstem further established a role for the PAG in pain modulation. Similarities were also observed between phenomena associated with PAG-derived inhibitory effects and opiate-induced analgesia, including tolerance and cross tolerance. SPA- and morphine-induced antinociception from the PAG also involve a spinal release of 5-HT and NE and mediation by both spinal 5-HT receptors and α₂ adrenoreceptors suggesting the need for a relay through serotonergic and noradrenergic brainstem sites. Anatomical studies reveal relatively few fibers that descend from the PAG directly to the spinal cord. However, the PAG does have strong projections to the NRM and adjacent areas of the RVM. Attention has therefore been focused on the NRM as the primary relay in mediating the antinociceptive effects of activation of PAG neurons. Studies of the NRM were performed in a manner analogous to those performed in the PAG and often with comparable results. Electrical stimulation of sites within the PAG or NRM produces inhibitory postsynaptic potentials (IPSPs) in dorsal horn neurons including those with ascending projections. Lesions of the dorsolateral funiculi (DLFs) of the spinal cord eliminate this inhibition and so this white matter pathway has been viewed as the primary spinal locus for descending fibers from the RVM. Ventrolateral funiculi (VLFs) have also been implicated as the spinal pathways by which descending systems access the spinal dorsal horn (e.g., from the LRN), but there is greater evidence for these descending paths to promote facilitatory influences as opposed to inhibitory influences.

Detailed electrical stimulation mapping and intensity studies of the RVM, and the NGC and NGCα in particular, reveal that these regions not only support inhibition of nociceptive reflexes but also facilitation or enhancement of those reflexes under certain conditions. In most cases, facilitatory effects were supplanted by inhibitory effects at a given site of stimulation when greater intensities of electrical stimulation were
examined. The results of behavioral studies were paralleled by in-depth analyses of the effects of either electrical stimulation or glutamate microinjection into the NGC and NGCα on spontaneous activity and noxious heat-evoked activity of spinal dorsal horn neurons. The results are generally comparable in nature. Facilitatory effects are observed as a leftward shift in the stimulus–response functions (SRFs) to graded heat, whereas inhibition is manifested as a rightward shift or a decrease in the slope of the SRF to noxious stimuli. Multiple electrophysiologic studies, in conjunction with the behavioral studies, reinforced the notion that that activation of cell bodies in the NGC/NGCα can produce direct descending inhibitory effects via pathways traveling in the DLFs but that the facilitatory effects required at least another relay prior to passage in the VLFs of the spinal cord.21

Other Deep Brain Sites
Using the nomenclature of Dahlström and Fuxe,64 the noradrenergic nuclei of the CNS are designated as “A” nuclei numbered in ascending order from the caudal medulla near the A1 to the lateral pons near the PBN (A7). One of the most important of these nuclei is the A6 nucleus which colocalizes with and is also ventral to the morphologic structure, the LC. This area has extensive direct axonal projections to the spinal cord. The effects of LC/A6 descending inhibition are independent of midbrain or medullary mediation, although the reverse is not necessarily true. The role of the LC/A6 in nociceptive modulation is complex, reminiscent of the role of the RVM with evidence of both inhibitory and facilitatory influences originating from the same site.30,31,65 The PBN and adjacent Kölliker-Fuse/A7 area has also been examined in relation to descending pain modulation. The Kölliker-Fuse nucleus, which is lateral and ventral to the LC, is the principal source of descending NE-containing fibers in the cat and may play a comparable role to that of the LC/A6 noted earlier for rat and primate.32 The PBN has long been known for its role in respiratory and cardiovascular function, taste and aversions, locomotion, and sleep. However, the PBN/A7 complex may have particular relevance to descending modulation of nociception as this site also receives extensive ascending nociceptive input directly from the spinal cord.
Occasional facilitation of nonnociceptive and nociceptive responses of trigeminal nociceptive neurons when stimulating in the PBN/A7 has also been observed. These facilitatory effects may bear on those described previously in the RVM but have not been systematically studied. The PBN/A7 has few direct projections to spinal cord but has multiple interconnections with PAG, NRM, NpGC, and the ventrolateral medulla. Electrical stimulation of the region of the A5 cell group in the ventrolateral pons produces antinociception that can be antagonized by intrathecal administration of NE receptor antagonists. The A5 cells project to the spinal cord, although their overall contribution to the total NE innervation of the spinal cord is relatively small, and A5 neurons may exert their effects primarily on lamina X neurons.

The LRN is a bilateral structure located in the ventrolateral medulla and lies in close proximity to the A1 (norepinephrine-containing) and C1 (epinephrine-containing) cell groups, although most of the effects of C1 activation appear to be associated with hemodynamic changes and not with nociception. Like the PBN/A7, the LRN is of particular interest because is also a major relay center for ascending nociceptive information. Electrical and glutamate stimulation of the LRN inhibits spinal nociceptive reflexes and responses of spinal dorsal horn neurons to noxious stimuli. These effects can be antagonized by spinal administration of \( \alpha_2 \) receptor antagonists. The involvement of spinal adrenoreceptors in these antinociceptive effects suggests that the LRN relays to an NE-containing cell group to produce these outcomes because little or no NE-containing fibers descend from the LRN. The LRN is also innervated by the PAG, PBN, LC, and RVM regions, suggesting complex reciprocal interactions exist between all these regions.

Several studies have demonstrated that the NTS is a region that is both capable of modulating pain and may serve as a relay site for peripheral cardiopulmonary afferent influences on nociception. Input from vagal nerve stimulation relays through the NTS and has been demonstrate to produce both inhibition and excitation dependent on stimulation parameters. The NTS has few direct spinal projections suggesting that changes in nociception derived from the NTS involved secondary relays including the RVM, LC/A6, PAG, A5 cell groups, and other forebrain...
Subcortical limbic structures have also been implicated in supraspinal modulation of nociception. Electrical stimulation of a variety of hypothalamic periventricular structures results in antinociception, although not necessarily with similar characteristics. The hypothalamus has connections with a variety of structures implicated in descending inhibitory influences including the PAG, NTS, and RVM, and these sites may be necessary for the effects of the hypothalamus on nociception.\(^{37,67,68}\)

The amygdala is another limbic structure highly implicated in both the receipt of nociceptive input and the activation of sensation modulating phenomena. Evidence has been found that the amygdala mediates both stress responsiveness and nociceptive processing.\(^{38,69}\) Pain-related plasticity within the amygdala has been demonstrated in rats in multiple systems including visceral, somatic, and neuropathic models of pain. Chemical stimulation of the central nucleus of the amygdala results in facilitation of nociceptive reflexes and dorsal horn neurons.\(^{70,71}\)

At the present time, the complex pharmacology and intricate connections that project to other brain sites such as the PBN/A7 and the PAG as well as the spinal cord itself preclude any definitive statements about pharmacologic mediators, except to say they include stress-related compounds such as oxytocin, corticotropin-releasing factor, urocortins, and adrenocorticoid receptors.\(^{38}\) Recent optogenetic studies by Sadler et al.\(^ {72}\) suggest even greater complexity in terms of right versus left central amygdala influences on nociceptive responses with both facilitatory and inhibitory effects originating from amygdalar site.

**Cortical Structures**

The previously discussed literature related to the effect of supraspinal modulation of nociception has as its translational therapeutic correlate, the technique of deep brain stimulation—where an electrode is surgically, stereotaxically placed via a craniotomy into a CNS location for purposes of electrically evoking an analgesic effect. More superficial structures such as the cortex have allowed the application of noninvasive brain stimulation techniques such as transcranial direct current stimulation (tDC) and
transcranial magnetic stimulation (TMS). Some of these techniques have clear and obvious benefit in association with effects on phenomena such as depression. Because they are also relatively noninvasive with limited adverse events,\textsuperscript{73,74} they have found increasing use in the treatment of pain.\textsuperscript{75}

Stimulation of both somatosensory cortex (SSC) and motor cortex (MC) have been used in the clinical treatment of neuropathic pain, central poststroke pain, and phantom limb pain. These have been achieved using either surgically implanted electrical stimulation methods or TMS. Although spinal influences of such treatments have been reported, there is reason to believe most of their effects are mediated at the supraspinal level.\textsuperscript{76} These factors notwithstanding, there is evidence for SSC and other cortical influences in producing descending inhibition of spinal nociceptive transmission via various brainstem sites. Senapati et al.\textsuperscript{39} provided one of the stronger demonstrations of cortical influences on spinal nociceptive transmission. They showed that electrical stimulation of either the ipsilateral or contralateral primary SSC of rats inhibited responses of L5–L6 WDR neurons to noxious pressure and pinch but not brush. In contrast, electrical stimulation of the secondary SSC has been reported to produce only a weak behavioral antinociception in the second phase of the formalin test and was without effect on responses to noxious thermal or mechanical stimuli.\textsuperscript{40} There are reports that electrical stimulation of or glutamate microinjections into the ventrolateral orbital cortex (VLO) can inhibit nociceptive reflexes via the PAG,\textsuperscript{41,42} but others have found pronociceptive effects of similar treatments.\textsuperscript{43} Morphine administration in the VLO also has been reported to inhibit both the hot plate and paw withdrawal responses to noxious heat in intact rats, and the tactile allodynia, hot plate, and paw withdrawal responses in rats with peripheral mononeuropathy. The antinociceptive effects produced by VLO stimulation observed in neuropathic rats were reversed by naloxone, whereas those observed in intact rats were not affected by naloxone. However, it cannot be ascertained from these studies whether descending inhibitory systems were activated by morphine because all of the response measures were organized at the supraspinal level.\textsuperscript{77} Morphine microinjection in the rostral agranular insular cortex (RAIC), a structure
immediately caudal to the VLO, also has been reported to inhibit nociceptive responses in the formalin test, reduce c-Fos expression in the spinal cord ipsilateral to a formalin stimulus, and produce a naloxone-reversible inhibition of spinal dorsal horn neuronal responses to a noxious thermal stimulus.\textsuperscript{78} The influence on the RAIC on descending inhibitory influences may critically depend on dopamine acting on neurons in this region.\textsuperscript{79}

There is also strong evidence that some cortical regions can provide descending facilitatory influences. Electrical, chemical, or optogenetic activation of the ACC produced significant facilitation of nociceptive reflexes with components both dependent and independent of a relay in the RVM.\textsuperscript{21} It is notable that the ACC is one of the cortical sites reliably activated by ascending nociceptive inputs.

**SUMMARY OF SUPRASPINAL INFLUENCES**

There is overwhelming support for the structures discussed in the previous sections in mediating descending inhibitory and facilitatory influences on spinal nociceptive transmission. A striking feature of these systems is the Janus-like dual nature of almost all of the identified CNS sites. Those which receive ascending nociceptive information almost invariably are associated with a dual function of both inhibition and facilitation. There is also overwhelming support that activation of most of these structures involves spinal release of both 5-HT and NE in producing inhibitory phenomena but many other neurotransmitters including acetylcholine, \( \gamma \)-aminobutyric acid (GABA), glycine, substance P, corticotropin-releasing factor, urocortins, thyroid-stimulating hormone, and oxytocin, which have been described as part of both excitatory and inhibitory mechanisms.\textsuperscript{44} Thus, “coactivation” or “recruitment” of more than a single system appears to be the rule rather than the exception.\textsuperscript{45} It is quite surprising, therefore, that although the discovery of endogenous opioids prompted the intense study of descending modulatory systems, endogenous opioids per se have not figured prominently in the “system” side of the analyses. Rather, they appear far more critical in the local circuitries of specific brainstem or spinal regions that allow these systems to function. Furthermore, although the structures supplying these transmitters affecting
spinal nociceptive transmission have been identified, for the most part, our
general knowledge about how those structures interact in producing
inhibitory and facilitatory effects is still not well understood.

**ON, OFF, AND NEUTRAL CELLS**

With the identification of CNS sites that could be stimulated to produce
inhibitory and/or facilitatory effects at the spinal cord level came theories
related to the neuronal constituents of those sites. Seminal studies
performed by Fields and colleagues\(^{80,81}\) demonstrated the existence of
three types of neurons in the RVM that can be classified based on the
neuron’s response to noxious heat applied to the tail of a lightly
anesthetized rat that elicited the tail flick reflex. ON cells were shown to
increase their firing rate just before the occurrence of the tail flick, OFF
cells decreased their firing rate just before the occurrence of the tail flick,
and NEUTRAL cells showed no change in activity throughout the
application of noxious heat. Importantly, the activity of ON and OFF cells,
but not NEUTRAL cells, was shown to be affected by systemic
administration of morphine. At doses of systemic morphine that inhibit the
tail flick reflex, OFF cells became continuously active and failed to pause
before reflex movements, whereas ON cell activity decreased.\(^{81}\) These and
other findings led to the proposition that OFF cells exert descending
inhibitory effects on spinal nociceptive transmission. ON cells were
hypothesized to exert a pronociceptive or facilitatory influence.
NEUTRAL cells were purported to have no role in nociception.

Extensive studies have examined the role of ON and OFF cells in
relation to other descending modulation-related phenomena such as spinal
cord stimulation,\(^{82}\) diffuse noxious inhibitory controls,\(^{83}\) or the pain
associated with diabetic neuropathy\(^{84}\) with a mixture of results, but the
role of a subpopulation of these neurons in pain modulation is firmly
established. Neurons with the same characteristics as RVM ON and OFF
cells have been identified in other CNS sites such as the PAG such that an
exclusive role of the ON and OFF cells located in the RVM is unlikely. An
exclusive association of ON and OFF cells with nociception is similarly
unlikely. Mason\(^{22}\) has argued using data that there is substantial evidence
that these cells are involved in a variety of homeostatic control functions
including micturition and arterial blood pressure control, and that they should be viewed as modulating a much broader spectrum of somatosensory inputs than nociception. Indeed, correlative data supporting a role of ON and OFF cells in control of arterial blood pressure is equally as compelling as for pain modulation. Whether different subsets of ON and OFF cells serve different functions, or whether individual ON and OFF cells can subserve or coordinate many different functions, remains to be determined.

Triggers of Clinical Hypersensitivity

ALLODYNIA AND HYPERALGESIA

Clinically, there are at least four general etiologies producing hypersensitivity or sudden “flares” in pain experience. These include inflammation, stress, altered neurologic function (typically secondary to previous injury), and drug-related effects. Each of these etiologies is associated with mechanisms that include altered modulation of spinal dorsal horn processing. The terms allodynia and hyperalgesia are clinical terms that represent different forms of hypersensitivity. Defined using clinical terms, allodynia has been defined as “pain produced by a stimulus that does not normally cause pain.” Similarly defined, hyperalgesia is “an increased response to a stimulus that is normally painful,” which may mean either a lower threshold for evoking pain or a higher intensity of pain perception produced by a given intensity of a suprathreshold painful stimulus. Based on psychophysical experiments, hyperalgesia may be either “primary” when it is located at a site of injury such as a burn or “secondary” when altered sensations are evoked from uninjured tissue that typically surrounds the site of injury but, in some cases, could be physically distant. Primary hyperalgesia has generally been relegated to mechanisms involving the primary afferents and secondary hyperalgesia to spinal second-order neuron effects.

Notably, when studying hypersensitivity in nonhuman animal models, interpretive issues can be problematic, particularly when studying phenomena that have clinical definitions. For purposes of the present discussion, hyperalgesia is defined as augmented responses and/or lowered
stimulus thresholds for response to a nociceptive stimulus. Alldynia is
defined as the evocation of responses that would have been called
nociceptive (e.g., flexion-withdrawal responses) to clearly nonnociceptive
stimuli (e.g., light brushing).

INFLAMMATION-INDUCED HYPERSENSITIVITY AND
INHIBITORY SYSTEMS
Tissue-damaging events can result in both the peripheral sensitization of
primary afferent nociceptors and the central sensitization of spinal dorsal
horn neurons. Historically, these two phenomena have played a
fundamental role in accounting for primary and secondary hyperalgesia,
respectively. These phenomena were viewed as either increased input to or
increased responsiveness of second-order neurons with an emphasis on
local spinal mechanisms. However, a role for brainstem descending
control systems in both primary and secondary hyperalgesia phenomena
are now receiving increasing attention and have led to a much better
understanding of persistent pain states. There is now evidence that the
RVM and the LC/A6 sites are responsible for exerting primarily
descending inhibitory influences under conditions of primary hyperalgesia
associated with either somatic or visceral tissue damage and primarily
descending facilitatory influences under conditions of secondary
hyperalgesia. These processes are not well understood, but
spinobulbospinal loops are now being proposed to recognize that enhanced
afferent input from the spinal dorsal horn ascends either directly or
indirectly to the brainstem, which in turn, changes this balance and,
ultimately, the perception of pain.

There is substantial evidence that RVM ON cells, originally
hypothesized to exert a pronociceptive effect, may be responsible for
contributing to the descending facilitatory influences that result in
secondary hyperalgesia in persistent pain states. Acute inflammation
produced by ipsilateral topical application of mustard oil above the knee of
a rat increases ongoing ON cell discharge and decreases ongoing discharge
of OFF cells. These changes correlate with a decrease in the withdrawal
latency of the ipsilateral but not contralateral paw. This hyperalgesic effect
could be blocked by either lidocaine infusion or a local infusion of an
NMDA-receptor antagonist\textsuperscript{86} into the RVM suggesting the NMDA-receptor activation induced by inflammation contributes to the secondary hyperalgesia. The spinobulbospinal loop engaged by peripheral cutaneous inflammation and mediating secondary hyperalgesia may involve spinal release of cholecystokinin (CCK) because spinal intrathecal administration of CCK antagonists block these effects.\textsuperscript{47}

Whereas secondary hyperalgesia may be augmented by descending facilitatory systems, primary hyperalgesia (increased primary afferent activity) associated with either acute or persistent inflammation may actively engage descending inhibitory influences. Schaible et al.\textsuperscript{48} showed that a mixture of kaolin and carrageenan injected into the knee joint of the cat resulted in a progressive increase in both spontaneous activity and evoked activity of spinal dorsal horn neurons to innocuous and noxious stimuli. Reversible interruption of descending modulatory influences using spinal “cold block” further increased activity in a progressive fashion demonstrating that spinal descending inhibitory influences were being progressively engaged by inflammation. Ren and Dubner\textsuperscript{49} showed that primary thermal hyperalgesia produced by carrageenan administration into the hind paw of the rat was increased by prior transections of the DLFs and that lidocaine microinjection in the RVM increased the spontaneous activity of nociceptive dorsal horn neurons and their responses to mechanical and thermal stimulation of the inflamed hind paw.

In the RVM, this enhancement of descending inhibitory influences may reflect inflammation-induced increases in the synthesis of enkephalins and/or enhanced efficacy of endogenous opioids acting at µ- and δ-opioid receptors such that the effectiveness of opioids is increased.\textsuperscript{87,88} Mechanistically, these changes would be consistent with opioid inhibition of pronociceptive ON cells and disinhibition of pro-inhibitory OFF cells; the net outcome of which should be enhanced descending inhibition. They also depend on RVM glutaminergic influences and increased sensitivity to both NE and opioidergic spinal inhibitory mechanisms.

The LC/A6 region may play a comparable role to the RVM in attenuating the development of primary hyperalgesia induced by acute inflammatory pain but not necessarily persistent inflammatory pain. Upregulation of spinal α\textsubscript{2} adrenoreceptors under conditions of
inflammation may also enhances the potency of this descending inhibitory influence.

That descending inhibitory influences are recruited from both the RVM and LC/A6 under conditions of inflammation are supported by studies of spinal cord lesions. Wei et al. observed that the c-Fos expression observed in the L4–L5 spinal segments 24 hours after hind paw injection of complete Freund’s adjuvant (CFA) was significantly increased on the side ipsilateral, but not contralateral, to the injection by either bilateral DLF or VLF lesions. The increases occurred in both superficial and deep laminae, as well as lamina III to IV, region of termination of mechanoreceptor afferents. Presumably, descending facilitatory influences accompanying the CFA-induced inflammatory state, and which should have been eliminated by these lesions, were masked by the descending inhibitory influences.

Following a common theme, these multiple examples illustrate that inflammation activates both inhibitory and facilitatory influences on spinal cord sensory processing with identical sites in the CNS responsible for the differing phenomena.

**STRESS-INDUCED ANALGESIA AND HYPERALGESIA**

Exposure to psychological stressors can produce bidirectional modulation of nociceptive responses, secondary to presumed mechanisms of descending inhibition and descending facilitation. These modulatory phenomena are termed stress-induced analgesia (SIA) and stress-induced hyperalgesia (SIH), respectively, and are viewed as classic examples of descending modulation because they are thought to originate from supraspinal psychological processes. From a translational standpoint, SIA is relatively uncommon except when associated with acute injuries and the need for uninhibited motor activity (i.e. escape). It has been identified as having both opioid-related and opioid-independent components. SIH, on the other hand, is the more typical phenomenon when discussing clinical pain, as psychologically stressful events are commonly associated with increases in pain. Animal models of both stress and nociception have allowed a better understanding of the mechanisms underlying the pathophysiologic processes that produce and exacerbate chronic pain. SIH
appears to be the result of a combination of intrinsic and extrinsic factors, including dysfunction in the hypothalamic-pituitary-adrenocortical (HPA) axis and activation of various neurotransmitter systems and anatomical sites, genes, and environment. Hyperalgesia following the experience of stress appears to occur particularly (but not exclusively) when exposure to a stressor is prolonged or exaggerated. Chronic stress can result in long-term and maladaptive physiologic changes. Interestingly, the two seemingly mutually exclusive phenomena of SIA and SIH can occur concomitantly (e.g., Robbins and Ness\textsuperscript{52}). Particular vulnerability factors, such as genetics and perinatal environment, may play a predominant role in SIH. Known CNS sites of importance to HPA axis activation, SIA, and SIH are the amygdala, the hypothalamus, the PAG, and the RVM. Neurotransmitters of interest at a spinal level include oxytocin, endocannabinoids, corticotropin receptor agonists, 5-HT, and NE as well as the more typical opioids.

**NEUROPATHIC PAIN**

The injury of peripheral nerves has many consequences, one of which is an alteration in spinal dorsal horn neuron excitability. One of the recently identified mechanisms important to this is the activation of spinal microglia in male rats by substances such as fractalkine released by the central processes of the injured nerves. In female rats, similar astrocytic mechanisms appear to be ongoing. Subsequent release of cytokines, purines, and growth factors results in the sensitization of second-order nociceptive neurons\textsuperscript{90} and subsequent increased excitability reflected as hyperalgesia and allodynia. These spinal mechanisms are not the whole phenomenon as there is clear evidence that supraspinal modulatory systems are also important to the development of hypersensitivity following nerve injury. The RVM is now believed to significantly contribute to neuropathic pain produced by such experimental treatments such as loose ligation of L5–L6 spinal and chronic sciatic nerve transection. For example, inactivation of the RVM with lidocaine injections enhanced both the withdrawal response and the thermal and tactile hypersensitivity produced by peripheral nerve injury.\textsuperscript{91,92} Various lines of evidence suggest that RVM ON cells may be critical for sustaining
neuropathic pain. Selective lesions of ON cells block the thermal hyperalgesia and tactile allodynia produced by peripheral nerve injury.\textsuperscript{92} Other evidence suggests that the effect of ON cells in contributing to neuropathic pain may reside in spinal release of 5-HT and a presynaptic action on 5-HT\textsubscript{3} receptors located on substance P–containing terminals.\textsuperscript{53} The precise details relating ON cell activation to spinal 5-HT release remain to be worked out because some studies have reported that neither ON nor OFF cells contain 5-HT.\textsuperscript{54} In neuropathic pain, the influence of the LC/A6 may be reduced leading to increased pain. For example, following rhizotomy, the antinociceptive effect produced by LC/A6 stimulation is reduced.\textsuperscript{93}

**OPIOID-INDUCED HYPERALGESIA**

Opiates remain the primary treatment for a wide variety of pain disorders in both acute and chronic clinical pain disorders. Prolonged administration of opiates can be associated with significant reactive processes including the development of tolerance to the analgesic effects of the drugs such that greater doses of drug are required to achieve adequate pain relief. Recently, it has been recognized that exposure to opioids can also result in paradoxical pain including regions not described in the initial pain complaint,\textsuperscript{94} a phenomenon commonly referred to as “opioid-induced hyperalgesia.”\textsuperscript{94,95} Many substances delivered spinally can reverse or block antinociceptive tolerance as well as opioid-induced hyperalgesia, which include NMDA receptor antagonists, phosphokinase C inhibitors, cyclo-oxygenase inhibitors, and use of differing opioid receptor subtype agonists/antagonists.\textsuperscript{94,95} It is also clear that there is an effect of chronic opioids on descending pain modulatory systems that is critical to the development of the spinal cord changes mediating paradoxical pain and antinociceptive tolerance. These drugs have known neuroexcitatory effects arising within the RVM and PAG when the effects of opioids are rapidly reversed by naloxone or other substances interacting with opioid systems. Additional evidence that supraspinal modulatory systems are involved in the mechanisms of opioid-induced hyperalgesia includes the demonstration that animals with lesions of the DLF of the spinal cord do not appear to develop abnormal pain or antinociceptive tolerance that are
normally a consequence of prolonged opiate administration.\textsuperscript{96,97} Furthermore, the effects of both acute and prolonged exposure to morphine (tactile hyperesthesia, thermal hyperalgesia, and antinociceptive tolerance) are abolished by local anesthesia blockade of the RVM.\textsuperscript{55,96,97} Thus, opioid-induced pain and tolerance in these circumstances may be mediated in part by activation of descending facilitatory mechanisms arising in the RVM. This, in turn, has been suggested to act as a trigger for the upregulation of spinal dynorphin that serves to promote enhanced input from nociceptors.\textsuperscript{98} An underlying assumption related to these studies has been that opioid-induced hyperalgesia requires the activation of opioid receptors. However, it is possible that opioid drugs may also be acting by nonopioid mechanisms to produce their physiologic effects. The demonstration that opioid-induced hyperalgesia can be elicited in mice without functional $\mu$-, $\kappa$-, or $\delta$-opioid receptors supports this possibility.\textsuperscript{99} At this point in time, it is clear that the use of opioids for the treatment of pain leads to a series of complicated interactions in spinal pain processing systems such that the resultant physiologic effects may be at times beneficial (analgesic) and at other times detrimental to the function of the organism.

**Conclusion**

The original proposition of gate control theory of Melzack and Wall\textsuperscript{2} that nociceptive input to spinal dorsal horn neurons could be modulated by a number of systems prompted investigations of the systems that modulate our perception of pain. One could hardly have envisioned both the diversity and complexity of the systems that have been identified with evidence of positive feedback loops, negative feedback loops, and tonic effects that may be either inhibitory or facilitatory. As a consequence, the original notions of systems descending from supraspinal sites to the spinal cord to inhibit pain have been expanded to include descending systems that also enhance our perception of pain. At the present time, our analyses indicate these two systems are functionally and anatomically intertwined and appear to operate as a unit rather than as separate entities. The ultimate perception we develop following exposure to noxious events represents
some balance between these two systems. It is possible that these systems attenuate or amplify responses to noxious stimuli in order to enhance our ability to localize and attend to peripheral stimuli that threaten us. Studies of stress, inflammation, neuropathic pain, drug-induced hypersensitivity, or other mechanisms leading to chronic pain states have begun to demonstrate that deficits in descending inhibition and/or activation of descending facilitation-related systems may also serve as mechanisms of pain generation or amplification.

Studies related to the neurotransmitters of modulation have consistently identified NE, 5-HT, GABA, and endogenous opioids to be key substances involved in the balance of inhibitory and excitatory influences. It should come as no small wonder then, that the drugs clinicians find useful in the treatment of hypersensitivity and pain are associated with noradrenergic, serotonergic, GABAergic, and opioidergic function within the CNS. It is the subtleties of the pharmacology that will define future refinements in therapeutics and many of these subtleties are only now being defined.

The preceding chapters addressed the peripheral and spinal mechanisms of nociceptive processing. Neither normal nor pathologic pain can be understood without knowledge about supraspinal mechanisms. The multidimensionality of pain with mainly sensory-discriminative and emotional-affective components has its anatomic counterparts in a variety of supraspinal areas, which are involved in pain processing. Hence, the experience of pain is formed in a distributed network which gates the transformation of peripheral nociceptive input to conscious pain.¹

Supraspinal structures include the hindbrain (lower and upper brainstem and cerebellum) and the forebrain. The forebrain has two major divisions, the lower diencephalon involving hypothalamus and thalamus and the cerebrum involving the cortex, basal ganglia, and the limbic system (cingulate cortex, amygdala, hippocampus, Fig. 6.1). In humans, the forebrain anatomically dominates and physiologically controls much more than in other species nociceptive processing. Because of the large proportion of the human forebrain of the entire central nervous system (CNS) volume (85%) when compared to that of the spinal cord (2%), descending modulatory influences assume much greater importance than for example in the rat in which the forebrain comprises 44% and the spinal cord 35% of CNS volume.²³ Thus, the great variety of psychological phenomena characterizing normal and abnormal pain in humans can only be studied in humans, although anatomic tracing and electrophysiologic techniques and behavioral studies in rodents and primates contributed significantly to our current knowledge about the pathways connecting the dorsal horn with supraspinal structures.
Functional Imaging of Pain in Humans

Since release of the early editions of this handbook, functional brain imaging in human volunteers and patients addressed many questions pertaining to brain structures involved in pain processing. Before going into the details of supraspinal regions engaged in pain processing and perception, we will therefore briefly describe the methodologic basis of these technologies.

METHODOLOGIES OF NONINVASIVE AND INVASIVE FUNCTIONAL BRAIN IMAGING IN PAIN

Functional imaging techniques applied for the study of pain are positron emission tomography (PET), functional magnetic resonance imaging (fMRI), near-infrared spectroscopy (NIRS), multi-channel electroencephalography (EEG) and magnetoencephalography (MEG), and intracranial recordings. PET measures cerebral blood flow, glucose metabolism, or neurotransmitter kinetics. A very small amount of a labeled compound (called the radiotracer) is intravenously injected into the patient or volunteer. During its uptake and decay in the brain, the radionuclide emits a positron, which, after traveling a short distance, “annihilates” with an electron from the surrounding environment. In case of the most common use of O$^{15}$-water injection, counting and spatial reconstruction of these occurrences within the brain anatomy allow visualization of the regional cerebral blood flow response (rCBF) as an indicator of neuronal...
activity. Radio-labeled fluorodeoxyglucose (FDG) is applied to measure regional energy consumption as a function of metabolic rate. An interesting refinement of PET technology represents the use of neurotransmitters as tracers to investigate binding mechanisms and kinetics, for example, in the opioidergic system.

One method of fMRI images blood oxygenation, a technique called blood oxygen level-dependent (BOLD), which exploits the phenomenon that oxygenated and deoxygenated hemoglobin possess different magnetic properties resulting in different relaxation behavior following radiofrequency pulses inside the magnet. An additional fMRI technique called arterial spin labeling (ASL) uses a radio pulse to magnetically “label” hydrogen atoms ascending through the vasculature and then determines alterations in paramagnetic characteristics as the labeled blood perfuses the brain. The rCBF measures using O\textsuperscript{15}-water PET, the BOLD technique, and the ASL technique rely on neurovascular coupling mechanisms that are not yet fully understood, but which overcompensate local oxygen consumption, thus causing a flow of oxygenated blood into neuronally active brain areas in excess of that used.\textsuperscript{4}

NIRS is an optical approach that also analyses changes in hemoglobin oxygenation levels by using light in the near infrared range (650 to 950 nm). Shortly, NIRS measures the attenuation of light over the cortex and can be applied noninvasively through the skull. Another advantage is the portability of NIRS systems and the possibility to measure in different environments. However, the spatial and temporal resolution in noninvasive measurements is low for NIRS.\textsuperscript{5}

EEG and MEG are noninvasive neurophysiologic techniques that measure the respective electrical potentials and magnetic fields generated by neuronal activity of the brain and propagated to the surface of the skull where they are picked up with EEG electrodes or, in the case of its magnetic counterpart, received by supra conducting quantum interference device (SQUID) sensors located outside the skull. Compared with PET and fMRI, EEG and MEG are direct indicators of neuronal activity and yield a higher temporal resolution of investigated brain function. The spatial distributions of EEG potentials and MEG fields at characteristic time points following noxious stimulation are analyzed using an inverse
mathematical modeling and spatial filtering to estimate the anatomic origin of the recorded pain-related activity. The spatial acuity of MEG is higher than that of EEG because the latter measures the extracellular volume currents that are distorted by the differentially conducting tissues such as gray and white matter, cerebrospinal fluid, durae, and bone. In contrast, MEG measures the magnetic field perpendicular to the intracellular currents undistorted by the surrounding tissue.

Invasive recordings, which are assessed during neurosurgical interventions in patients ongoing epileptic surgery, or deep brain stimulation (DBS) procedures (most common in Parkinson disease), are extremely helpful to directly measure supraspinal pain signals. Different invasive recording techniques, namely, depth electrodes, subdural grids, subdural strips, and stereoencephalography, are used today. Advantage of all these invasive recordings is that the neuronal activity is picked up directly from the neurons and not being distorted by the cerebrospinal fluid, durae, and bone as in EEG or MEG. Disadvantage lies in the invasive nature of the procedure and the only limited area that can be investigated using invasive recordings.

Brainstem

The brainstem represents the connection of the spinal cord with the diencephalon (hypothalamus and thalamus). It comprises the rhombencephalon (pons and medulla) and the mesencephalon (midbrain, see Fig. 6.1). A major rhombencephalic structure is the reticular formation (RF) which encompasses a distributed network of small and large nerve fibers and extends from the medulla up to the level of the thalamus. It has manifold local interneuronal connections within the brainstem and contains both ascending and descending projecting systems. It is divided into three vertical zones. The medial magnocellular zone contains the ascending reticular activating system (ARAS), a major pathway to the thalamus, hypothalamus, and basal forebrain (a group of structures at the base of the frontal lobe, including the nucleus basalis, diagonal band, medial septum, and substantia innominata). The median and paramedian zones contain the raphe nuclei of serotonergic projection neurons. The
lateral parvocellular zone receives afferents from amygdala and hypothalamus. RF and basal forebrain have reciprocal connection with virtually all cortical and subcortical structures through cholinergic (from the basal forebrain), noradrenergic (from the locus coeruleus), dopaminergic (from the substantia nigra [SN] and ventral tegmentum [VTA]), and serotoninergic (from the raphe) pathways. Reciprocal connections with the spinal cord mediate motor, respiratory, and cardiovascular functions and pain modulation.

The RF is an important mediator of consciousness and arousal. The stream of information about the outer world that reaches specific nuclei of the thalamus and cortex through the sensory pathways of vision, audition, gustation, and somatosensation is blocked when the activity of the mesencephalic RF, which drives nonspecific thalamic sites, drops below a critical level, such as, for example, during slow wave sleep or certain types of absence epilepsies. Wakefulness and arousal are thus closely coupled to the RF, which act as the “energetic supplier” of conscious perception and behavior. Widespread areas of the RF are responsive to noxious stimuli. The gigantocellular and magnocellular fields of the medullar RF, that is, the bulboreticular region, mediate escape behavior following acute painful stimuli and respond neurochemically during persistent pain. The close relationship of nociception and pain with arousal and consciousness guarantees optimal alertness and readiness to avoid bodily harm. Sleep is therefore disrupted by the awakening nature of pain through its influence on the RF. Similarly, opioid-induced sedation is antagonized by residual pain. These aspects will be discussed in more detail later.

A view of the RF as a “diffuse arousal network” has been replaced by the acknowledgement of localized reticular cell groups with highly specific functions and connections in the coordination of head and eye movements, postural orientation, and autonomic visceral control. Also, the understanding of RF in pain has become more differentiated. The subnucleus reticularis dorsalis (SRD) represents a homogenous population of neurons in the caudal-dorsal medulla whose axons form both ascending and descending collaterals to the thalamus and spinal cord, respectively. SRD neurons are strongly activated by noxious cutaneous and visceral stimuli from any part of the body. It is regarded a medullary substrate of
the link between nociceptive and motor activities. SRD has also been suggested as major supraspinal site mediating the “pain-inhibits-pain,” or counterirritation, phenomenon as formulated in the concept of diffuse noxious inhibitory controls (DNIC). As part of a spinal-bulbospinal feedback loop, SRD is proposed to facilitate the extraction of nociceptive information by increasing the signal-to-noise ratio between a pool of deep dorsal horn neurons activated by a tonic painful focus and the remaining population of such neurons, which are inhibited for simultaneous phasic noxious input. Youssef et al. used fMRI in healthy test participants and observed that the magnitude of signal reduction in SRD following repetitive phasic heat stimuli applied to the right lip correlated with magnitude of analgesia produced by a conditioning pain exerted by injection of hypertonic saline into the tibialis anterior muscle.

**PERIAQUEDUCTAL GRAY MATTER—A KEY STRUCTURE OF ENDOGENOUS ANALGESIA**

The periaqueductal gray (PAG) is a midbrain territory located medially adjacent to the RF surrounding the cerebral aqueduct in a horse shoe–shaped manner by sparing ventral regions subserving distinct ocular-motor functions unrelated to pain. The PAG plays a critical role in the expression of a variety of emotion-related behaviors including pain. It represents a key structure in relaying descending pathways from the limbic system (prefrontal cortex, amygdala, and hypothalamus) to midbrain (e.g., inferior and superior colliculi), pons (e.g., locus coeruleus, lateral parabrachial nucleus, dorsolateral pontine tegmentum), the raphe nuclei of the rostroventral medulla (RVM) and the deeper layers of the spinal cord (Rexed layers V, VII, VIII). Midbrain, pontine, medullar, and spinal connections are all reciprocal, such that the PAG is connecting afferents from these origins to medial thalamic nuclei and hypothalamus. Early systematic studies identified PAG and RVM as brainstem sites that elicit powerful surgical levels of analgesia through focal brain stimulation, subsequently more elaborated and referred to as stimulus-induced analgesia. A milestone contribution to the understanding of the interaction between PAG and RVM and its role in opioid analgesia was delivered by Fields and colleagues working group who identified two
classes of pain modulatory cells in the RVM exerting inhibitory and facilitatory actions through respective off- and on-cells. Off-cells are activated by local infusion of µ-opioid agonists, and their activity inhibits nociceptive transmission. In contrast, on-cells facilitate nociceptive transmission, are inhibited by local µ-opioids, and are activated by naloxone and morphine abstinence. Approximately 15% of RVM neurons are serotonergic and are neither on- nor off-cells and do not respond to opioids. Some respond to baroreceptor input integrating cardiovascular and nociceptive function. Descending serotonergic fibers from the RVM project to dorsal horn neurons via the dorsolateral funiculus and mediate the analgesic effect of opioid receptor activation. Also noradrenergic structures in the brainstem, namely, the locus coeruleus, are regarded to be pain inhibitory through activation of α\textsubscript{2}-adrenoceptors on central terminals of primary afferent nociceptors (presynaptic inhibition), by direct α\textsubscript{2}-adrenergic action on spinal pain-relay neurons (postsynaptic inhibition), and by α\textsubscript{2}-adrenergic activation of inhibitory interneurons. However, the central as well as the peripheral efficacy of pain inhibition can vary depending on neuroplastic changes following inflammation and injury. Taylor and Westlund recently reviewed evidences that argue for a pain facilitatory action of locus coeruleus neurons under conditions of neuropathic pain, especially at later stages after the traumatic lesion.

The biologic significance of endogenous pain control is generally seen in the context of behavioral conflicts in which the subject needs to disengage from pain in order to fight or escape at the presence of body injury. Analogous human life situations are sporting competition or combat, during which a subject may fail to be aware of even severe tissue damage, which becomes painful when the victim releases engagement in these activities. Thus, forebrain input to the PAG mediates contextual information, from the prefrontal cortex, the amygdala, the anterior cingulate cortex (ACC), and the hypothalamus about momentary behavioral goals, past experience, and bodily needs. Evidence furthermore indicates that injury and inflammation causing increased sensitivity toward painful stimuli (primary hyperalgesia) triggers the RVM as key structure of a feedback pain inhibiting circuitry. There is solid evidence by fMRI that PAG and RVM are also mediating the placebo response in
Using the expression of the immediate early gene, c-fos, as a marker of neuronal activation, an interesting regional distinction for deep versus cutaneous pain had been demonstrated within the midbrain PAG. Noxious stimulation of a range of deep somatic and visceral structures evoked a selective increase in Fos expression in the ventrolateral PAG column (vlPAG), whereas, noxious cutaneous stimulation evoked Fos expression predominately in the lateral PAG column (lPAG). vlPAG and lPAG areas are suggested to represent different modes of behavioral adaptation characterizing inescapable and escapable types of pain, respectively. Earlier studies showed that both deep pain as well as microinjection of excitatory amino acids (EAA) into the vlPAG of freely moving animals evoked a response of quiescence, decreased vigilance, decreased reactivity, hypotension, and bradycardia. In contrast, cutaneous pain as well as activation of the lPAG-evoked fight-and-flight behavior, increased vigilance, hyperreactivity, hypertension, and tachycardia. Lumb et al. presented evidence that differential representation of escapable and inescapable pain in the PAG extends to distinct representations of “first” and “second” pain, as indicated by the columnar distribution of neurones activated by inputs from respective Aδ and C nociceptors. Furthermore, the functional organization of projections from circumscribed regions of the hypothalamus to the different columns of the PAG indicates that the behavioral significance of the pain signal is also represented in brain regions other than the PAG. Such specificity may coordinate antinociception with adequate behavioral and autonomic responses to prevent damage, in case of an imminent threat, or promote healing when an injury is already manifest.

Finally, the PAG is a promising target in invasive DBS to treat chronic pain, first applied by Hosobuchi et al. and Richardson and Akil in humans. However, its use is limited due to loss of efficacy over time and intolerable side effects. It remains to be cleared whether more precise electrode positioning and simultaneous stimulation of distinct locations or a better understanding of pain mechanisms that are sensitive or insensitive to DBS will help to achieve better outcome. In chronic neuropathic and central pain syndromes, DBS of the PAG appears less
effective than nociceptive pain.\textsuperscript{38}

**MESOLIMBIC DOPAMINE SYSTEM**

The mesolimbic system comprises dopaminergic brainstem sites, that is, the VTA and the SN projecting to the striatum. Neurons originating in the SN pars compacta innervate D1- and D2-receptors of the dorsal striatum (putamen and caudate nucleus) that are functionally integrated into the motor loop of the basal ganglia (see the following text). The nucleus accumbens of the ventral striatum is regarded the key structure of a mesolimbic circuitry receiving input from SN and VTA mediating motivational salience and valence of painful stimuli to drive pain avoidance and pain endurance depending on the situational context.\textsuperscript{39} The mesolimbic circuitry is furthermore regarded important for the encoding of the rewarding effect of pain relief.\textsuperscript{40} Chronic fibromyalgia and low back pain have been observed to be associated with reduced responses of the mesolimbic circuitry to salient stimuli\textsuperscript{41,42} that could account for the depressive comorbidity in these patients.\textsuperscript{39}

**Hypothalamus**

The hypothalamus occupies the ventral half of the diencephalon below the thalamus on either side of the third ventricle. It lies just above the pituitary gland with which it is intimately coupled for various neuroendocrine secretions subserving autonomic functions. Neurosecretory neurons are mainly located in periventricular and supraoptic nuclei. Fiber tracts to the pituitary gland are subdivided into two parts: (1) magnocellular secretory cells expressing vasopressin and oxytocin innervate the posterior pituitary gland and (2) parvocellular secretory cells expressing gonadotropins, releasing and inhibiting hormones that innervate the anterior pituitary gland. The hypothalamus receives nociceptive inputs from the midbrain parabrachial nucleus, the ventrolateral medulla, and the spinal and trigeminal dorsal horn.\textsuperscript{43,44} The nucleus of the solitary tract (NTS), a major relay of cardiorespiratory, visceral, and gustatory information, is also connected with the hypothalamus. Its role in nociception is not quite clear, but the convergence of autonomic, visceral, and nociceptive information in
the hypothalamus underpins the importance of it for the control of homeostasis as part of the brain’s defense system. More recent research points to a pain inhibitory role of hypothalamic orexin neurons (orexin-A and orexin-B), similar to opioidergic neurons, acting on the PAG as the most important supraspinal site.\textsuperscript{45,46} Interestingly, hypothalamic orexin neurons mediate analgesia induced by odorants in mice.\textsuperscript{47}

**Thalamus**

The thalamus is the major structure of the diencephalon, which additionally contains, in relation to thalamus, basally the hypothalamus, laterally the globus pallidus and nucleus subthalamicus, and medially the third ventricle. With the exception of the olfactory system, all sensory systems send afferent input to the thalamus from where it is projected into the specific cortical representation areas. This is why the thalamus is often referred to as the gate to consciousness. The intralaminar and ventral motor nuclei are the main targets of thalamic inputs from the striatum (putamen and caudate nucleus). Corticostriatal and striatothalamicocortical connections form the sensory-motor loop of the basal ganglia which is under control of dopaminergic input from the midbrain SN pars compacta (see earlier discussion). The thalamic extension of the ARAS contributes to arousal and wakefulness driven by the midbrain RF (see earlier discussion). The multidimensional nature of pain as composed of sensory-discriminative and affective-motivational determinants first introduced by Melzack and Casey\textsuperscript{48} four decades ago formed a conceptual framework that guided many research groups studying supraspinal pain mechanisms. One of their postulates was that sensory and affective pain dimensions are anatomically represented by spinal pathways that differentially target respective lateral and medial nuclei of the dorsal thalamus.

**THE LATERAL PAIN SYSTEM—THE SENSORY-DISCRIMINATIVE PATHWAY**

The cell bodies of spinothalamic tract (STT) fibers are located in the most superficial layers, lamina I, the outer region of lamina II, and deeper laminae V to VI\textsuperscript{49} according to the Rexed scheme. STT axons cross via the
anterior commissure to the anterolateral portion of the contralateral hemisphere and have their main thalamic targets in lateral nuclei, namely, ventral posterolateral (VPL; from the body) and posteromedial (VPM; from the face) nuclei and the ventral posterior inferior (VPI) nucleus. These fibers contribute to thermal and pain sensation. The lateral thalamic nuclei have small receptive fields and mostly gradual stimulus response functions over nonnoxious and noxious intensities, representing the “wide-dynamic-range,” or to a lesser extent, over noxious range only, representing the “nociceptive-specific” type of cells. These features render lateral thalamic targets of spinal nociceptive afferents ideally suited for the encoding of spatial localization and intensity of painful stimuli, similar to the properties of touch. The sensory-discriminative determinant of pain is thus governed by a spinal afferent pathway that mainly reaches lateral thalamic nuclei, from where neuronal activity is projected into the contralateral primary (SI) and bilateral secondary (SII) somatosensory cortices and mid and posterior sections of the insula (see the following text). Invasive DBS of the VPL demonstrated improvement of chronic neuropathic and central pain.\textsuperscript{50}

**SPINAL CONNECTIONS TO BRAINSTEM AND MEDIAL THALAMUS—THE AFFECTIVE PATHWAY**

Although direct connections of lamina I STT cells exist with medial thalamic nuclei, namely, the central lateral nucleus and intralaminar complex,\textsuperscript{51–53} the major source of nociceptive input to the medial thalamus is likely indirect through the brainstem that relays spinoreticular, spinomesencephalic, and spinoparabrachial input from both superficial and deeper dorsal horn. Medial thalamic nuclei project densely into key structures of the limbic system, such as the ACC, the amygdala, the hippocampus, the anterior insula, and prefrontal cortex, which represent the perceived intrusion and threat by pain, referred to as affective-motivational and cognitive-evaluative determinants of pain.\textsuperscript{48}

The contention that slowly and rapidly conducting nociceptors project differentially to respective medial and lateral thalamic nuclei had been recently challenged. Using intracerebral recordings of laser-evoked potentials in patients receiving neurosurgery due to refractory partial
epilepsy, Bastuji et al.\textsuperscript{54} identified three major thalamic regions, namely, the centrolateral (CL), VPL, and anterior pulvinar responding equally and simultaneously to phasic nociceptive laser input. The authors conclude that at least part of the nociceptive input driven by rapidly conducting Aδ fibers reaches both lateral and medial thalamic regions arguing for rapid medial thalamic projection to cingulate structures to subserve rapid orienting reactions to, and withdrawal from, the noxious stimulus. This suggests that both medial and lateral thalamic sites contribute to the exteroceptive function of escapable pain.

In contrast, Craig\textsuperscript{55} hypothesized that pain is a purely interoceptive perception such as hunger, thirst, or itch. It originates in specific lamina I neurons which impinge on specific thalamic nuclei, such as the posterior part of the ventral medial nucleus (VMpo) and the ventral caudal part of the mediodorsal nucleus (MDvc). These distinct thalamic nuclei relay afferent input to the dorsal posterior insula and caudal ACC, respectively, and form separate pathways regarded as important elements of a hierarchical system subserving homeostasis, linking thermal sensation and pain contributing to the sense of the physiologic condition of the body (interoception) with subjective feelings and emotion.

**Cortex**

The human cortex is divided according to functional and anatomic criteria. The German neuroanatomist and psychiatrist Brodmann\textsuperscript{56} introduced a systematic classification of the human cortex based on cytoarchitectonic properties, which, in refined modification, is still often referred to in the neuroimaging literature. Functional classifications consider the specific relevance of different cortical structures for motor, sensory, cognitive, emotional, or autonomic information processing. These functional areas can be divided into hierarchically organized subregions, for example, primary and secondary projection areas or network systems consisting of distributed areas. The current view is that higher order projection areas and distributed networks rather than a unique “pain center” represent the cortical substrate of pain perception. This view is consistent with the multidimensional definition of pain\textsuperscript{48,57} which postulates differential
projection of lateral and medial thalamic pathways to respective sensory and limbic cortical structures in addition to cortico-cortical as well as cortico-subcortical interactions for the composition of sensory-discriminative, affective-motivational, and cognitive-evaluative determinants (see earlier discussion). According to this concept, the primary (SI) and secondary somatosensory (SII) cortices receiving input from lateral thalamic nuclei are responsible for sensory-discriminative processing. Emotional content and aversive quality to noxious stimuli motivating escape and avoidance behavior are linked to limbic areas. The limbic system involves cortical and subcortical areas from the frontal, parietal, and temporal lobe that from a ring (limbus) around the upper brainstem and diencephalon, first regarded by Papez as important for emotion. It includes the cingulate cortex, the insula, the prefrontal cortex, and, as subcortical structures, amygdala, hippocampus, medial thalamus, and hypothalamus. Taken together, it is important to highlight that the multidimensionality of pain is neuroanatomically reflected in multiple cortical sites being involved in pain processing.

**SENSORY AREAS**

**Primary Somatosensory Cortex**

The primary somatosensory cortex (SI) is located in the parietal lobe within the postcentral gyrus (Fig. 6.2). It includes the Brodmann areas 1, 2, 3a, and 3b, the latter two occupying the depth and the posterior wall of the central sulcus and generally considered to be the major recipient of cutaneous somatosensory input. Early studies of patients with cortical lesions reported controversial results. Whereas Head and Holmes did not find deficits in pain sensitivity following cortical lesions, studies on World War I and II injury victims with lesion of SI (area 3a) reported loss of cutaneous pain sensibility. Experimental data using single-cell recordings in awake monkeys revealed a strong correlation between SI firing rate and stimulus intensity and duration of painful stimuli. Patients with subdural electrodes implanted for surgical treatment of intractable epilepsy showed encoding of intensity of painful stimuli within SI. Direct intracerebral electrical stimulation of SI in awake patients, however, failed to elicit painful sensations. Thus, it appears that SI processes
nociceptive input, but it is not sufficient to cause a pain sensation. Due to its spatial and intensity-encoding properties, SI is regarded to contribute to discriminative analysis of painful stimuli but does obviously not cause the aversive nature of pain perception.

**FIGURE 6.2** Schematic anatomic localization of cortical areas, which are regarded as important for pain processing. Somatosensory areas, which are responsible for sensory-discriminative pain processing such as intensity and stimulus decoding, are the primary (SI) and secondary somatosensory cortex (SII). Adjacent to SII is the insula (Ins), which belongs to the limbic system and is involved in emotional-affective pain processing. Other limbic structures include the cingulate gyrus (CI) with its subdivisions anterior cingulate cortex (ACC), midcingulate cortex (MCC), and posterior cingulate gyrus (PCC). Finally, the prefrontal cortex (PFC) plays an important role in cognitive-evaluative pain processing especially for the organization of context-dependent pain behavior.

Consistent evidence for SI involvement in pain processing is derived from other functional neuroimaging studies in humans. SI is organized somatotopically; that is, neighboring peripheral skin areas are also represented by neighboring cortical sites. Human imaging studies established a somatotopic organization of SI for painful laser stimuli (Fig. 6.3). Accordingly, laser stimuli at the foot and hand activated SI regions medially, near the interhemispheric gap, or more laterally, respectively. Ploner et al. and Tran et al. showed that laser-evoked MEG responses to Aδ- and C-fiber activation, respectively, appeared simultaneously in SI and SII, a finding which contrasts with the sequential activation of SI and SII following tactile stimuli. Kanda et al. confirmed these results by using implanted subdural electrodes. Yet, not all functional imaging studies revealed SI activation related to pain. PET and fMRI studies exhibited robust SI activity following painful stimuli when using contact heat, laser radiant heat, or electrical pain but less consistently during spontaneous or provoked clinical pain states. Casey et al.
noted a clear temporal dynamic of SI activity following painful contact heat using PET. Notably, hypnotic suggestion of sensory pain quality enhanced SI activity following thermal stimulation, whereas that of the affective pain quality did not. This latter result with experimental pain stimuli fits with clinical observation that SI lesions alter sensory qualities but leave affective or cognitive aspects of pain, especially chronic pain largely unchanged. Furthermore, pain-induced BOLD activations in SI are more likely correlated with stimulus intensity than perceived pain, although other authors showed that gamma oscillations in SI reflect pain perception and not the stimulus intensity. Collective evidence thus indicates that noninvasive imaging methods strongly support the participation of SI in sensory-discriminative aspects of pain perception, although temporal aspects of the applied stimulus method and imaging technique and attentional and cognitive factors can significantly modify SI activity.

FIGURE 6.3 Somatotopic organization of somatosensory areas. Experimental pain was induced using an infrared laser, which elicits a short burning and pinprick-like pain sensation. Laser stimuli were given at both hands and feet, before pain-induced activation of the primary (SI) and secondary somatosensory (SII) areas were localized using functional magnetic resonance imaging (fMRI) technique. Pain-induced activation after hand stimulation (red) was found in SI near the interhemispheric gap, whereas foot stimulation (green) elicits more lateral activation of SI. Pain-induced localization in SII is less spatially separated between hand and foot stimulation. The center of the colored circles is the mean coordinate of the subjects, whereas the radius of the circle is the standard deviation. L, left; R, right. (Reprinted from Bingel U, Lorenz J, Glauche V, et al. Somatotopic organization of human somatosensory cortices for pain: a single trial fMRI study. Neuroimage 2004;23[1]:224–232. Copyright © 2004 Elsevier. With permission.)

Secondary Somatosensory Cortex
The existence of a secondary somatosensory cortex (SII) was introduced
for the first time by Adrian\textsuperscript{87} in the cat. SII is situated lateral and posterior to SI and occupies the posterior parietal operculum at the upper bank of the Sylvian fissure (see Fig. 6.1), encompassing Brodmann areas 40 and 43.\textsuperscript{88} Because SII receives input from the thalamus via the spinothalamic projection into lateral nuclei (VPI, VPL, VPM) and sends output to the adjacent insula, SII is in a position to link nociceptive information to limbic cortical regions, such as the ACC and medial prefrontal cortex. Because of the robust generation of dipolar electric activity following noxious laser stimuli in SII that is oriented tangentially to the skull convexity, multichannel MEG recordings became an important functional brain imaging method to study pain-related SII activity in humans at high temporal resolution. The activity starts between 90 and 150 ms after the painful laser stimulus, depending on the body site and activated nerve fiber spectrum\textsuperscript{89–91} and coincides with parallel SI activation.\textsuperscript{68} Selective C-fiber activation also activates SII.\textsuperscript{92} PET and fMRI revealed SII as one of the most consistent structure activated by pain.\textsuperscript{82,93,94} Notably, the origin of painful somatosensory seizures could be assigned to the operculo-insular cortex including SII by intracerebral recordings.\textsuperscript{95} Although less precise than SI, SII is also organized somatotopically (see also Fig. 6.3).\textsuperscript{66,67,96} Patients with lesions within the SII cortex have been reported to exhibit elevated pain thresholds contralaterally,\textsuperscript{97} sometimes associated with a central (neuropathic) pain syndrome.\textsuperscript{98,99} Several authors point to the problem of differentiating SII from the adjacent posterior insula.\textsuperscript{93} Recent evidence from intracerebral recording and stimulations in patients, however, indicates separate representations of nociceptive processing in SII and insula.\textsuperscript{66,100} The functional role of SII is not clear. Given its coarse somatotopy, it unlikely represents a critical site for spatial discrimination but rather supplements SI in the organization of spatially guided defensive and protective behavior against bodily threat. Accordingly, SII seems to be involved in recognition, memory, and learning of painful events\textsuperscript{101} in that it links a primordial sensory representation of pain with further cognitive evaluation and affective appraisal.

\textbf{LIMBIC AREAS}

\textit{Insular Cortex}
As stated, the insula belongs to the limbic system and is located adjacent to SII and can be divided cytoarchitectonically into Brodmann areas 13 (anterior insula) and 41 (posterior insula). Functionally, the anterior insula, which lies rostral to the most lateral point of the central sulcus, mainly processes viscero-autonomic (intrapersonal) functions and is closely linked to gustation and olfaction, thus proximal senses. In contrast, the posterior part is related to distal senses such as audition, vision, and somatosensation and extrapersonal functions. Craig\textsuperscript{55} attributes a key role to the insular cortex in the integration of thermosensation and pain for homeostatic feelings and behavior. Despite the already cited evidence of distinct representations of pain in SII and posterior insula (see the following text), there is not enough data to clearly delineate SII and posterior insula functionally. However, the anterior part appears to represent separate functions from posterior insula and SII, from where it receives input. Further input comes from the amygdala and brainstem nuclei. Projections from the anterior insula go to various limbic structures such as the ACC and the entorhinal cortex of the temporal lobe (amygdala and hippocampus).

Lesion studies from patients are rare. Isolated anterior insula lesions without damage of the posterior insula and SII yield normal heat pain thresholds.\textsuperscript{97} Others reported that damage of the anterior insula reduces pain affect and appropriate behavioral reactions to pain.\textsuperscript{102} Functional imaging studies strongly confirmed the engagement of the anterior insula in pain and the ability to manipulate anterior and posterior insula differentially.\textsuperscript{103} Using PET, Casey et al.\textsuperscript{79} demonstrated that anterior insula responds early, whereas posterior insula is activated late following painful contact heat stimuli. This result is consistent with the dissociation of anterior and posterior insula according to respective anticipatory and real pain sensations.\textsuperscript{104} Lorenz et al.\textsuperscript{105} found stronger anterior insula activation with PET following heat stimuli applied on sensitized skin (heat alldynia) in comparison with equally intense heat stimuli applied on normal skin, whereas posterior insula and SII exhibited same activation across skin conditions. Thus, although both portions of the insula vary with pain intensity, anterior insula additionally represents subjective relevance and meaning of the pain in terms of its relation to an
exteroceptive or interoceptive threat. This is also consistent with the role of the anterior insula in processing stimulus novelty.\textsuperscript{106} On the other hand, besides multifactorial influences of pain such as pain-related anxiety, altered attention, and other nonspecific features, the posterior insula plays a major role in pain processing and can be regarded as pure nociceptive region in human pain processing (Fig. 6.4).\textsuperscript{107} The insula also plays an important role in chronic pain processing because evidence exists that chronic pain disrupts functional connectivity of the insula cortex characteristic for resting state brain activity.\textsuperscript{1}

**FIGURE 6.4** Involvement of the insula in human pain studies. Activation clusters in purple and blue represent activation clusters triggered by acute painful stimulation of subjects’ feet using heat or a laser. The activation clusters in red and yellow represent surgical coordinates at which direct electrical stimulation resulted in the perception of pain at a particular body site (red = face pain, yellow = lower limb pain). The activation clusters in green were derived by a newly developed stimulation procedure to identify true nociceptive input using contact heat stimulation with topical capsaicin treatment. Radiologic convention is used. L, left; R, right. (Reprinted by permission from Nature: Segerdahl AR, Mezue M, Okell TW, et al. The dorsal posterior insula subserves a fundamental role in human pain. Nat Neurosci 2015;18[4]:499–500. Copyright © 2015 Springer Nature.)

**Cingulate Cortex**

The cingulate cortex represents a key structure of the limbic system. Anatomically, it is located in the medial portion of both hemispheres above the corpus callosum. Cytoarchitectonically, it is divided into distinct areas, the ACC (areas 24 and 25) and the posterior cingulate cortex (PCC, area 23). A more recent view additionally separates the midcingulate
cortex (MCC, area 24) and the retrosplenial cortex (RSC). A major input to ACC comes from medial and intralaminar thalamic nuclei,\textsuperscript{108} which places the ACC into the center of the medial pain system subserving affective-motivational and cognitive-evaluative pain determinants.\textsuperscript{47} Anatomically distinct regions are thought to relate to different functions, some more specifically related to pain, and others to motor, autonomic, and cognitive functions (Fig. 6.5).\textsuperscript{108} Whereas cingulotomy for intractable pain yielded only a modest relief from pain, it appeared that the degree to which pain interfered with other cognitive activities, behaviors, and social functions was significantly reduced.\textsuperscript{109} Also cingulate lesions in animals revealed minimal deficits in discriminative pain function but robust changes in pain-related behavior and learning.\textsuperscript{110,111} A multimodal integrative rather than a specific nociceptive role of the ACC is also underlined by its large receptive fields and the absence of somatotopy.\textsuperscript{108} MEG activity following laser radiant heat pain demonstrates a preferential response of the ACC to C-fiber input, regarded as important for the sustained “suffering” component of pain associated with C- rather than Aδ-fiber activity.\textsuperscript{112} Together with SII and insula, ACC is the most consistent region activated by pain.\textsuperscript{90,94,103} However, imaging of subjects engaged in a variety of cognitive, affective, and motor tasks also revealed ACC as the most consistent brain area.\textsuperscript{113} The MCC is involved in response selection, fear avoidance, and motor function. Despite the diversity of perceptual, emotional, cognitive, motor, and autonomic processes harbored within distinct or overlapping cingulate cortex structures as revealed from numerous functional imaging studies, a common function to which all these processes converge may be seen in the awareness and monitoring of bodily threat or behavioral conflict demanding for executive control. Such view would explain why both the detrimental effects of pain on cognition as well as the beneficial effects of cognitive distraction on pain are represented in the ACC.\textsuperscript{114,115} Thus, the reciprocity of pain and cognitive processes at the level of the ACC might significantly determine the degree by which pain interrupts cognitive performance and is intrinsically difficult to ignore.\textsuperscript{116}
FIGURE 6.5  Region borders of the cingulate cortex according to Vogt. Subregions are marked with arrows and were determined based on postmortem cases that were coregistered to a stereotaxic atlas with the vertical plane at the anterior commissure (VCA) and the anteroposterior commissural line. A functional overview, derived from the analysis of a large volume of literature, is provided. This illustrates general regional function and, where known, subregional specializations. aMCC, anterior midcingulate cortex; cas, callosal sulcus; cgs, cingulate sulcus; dPCC, dorsal posterior cingulate cortex; irs, inferior rostral sulcus; mr, marginal ramus of cingulate sulcus; pACC, pregenual anterior cingulate cortex; pcgs, paracingulate sulcus; pMCC, posterior midcingulate cortex; RSC, retrosplenial cortex; sACC, subgenual anterior cingulate cortex; spls, splenial sulci; vPCC, ventral posterior cingulate cortex. Prefrontal Cortex
The prefrontal cortex (PFC) is the anterior part of the frontal lobe and contains numerous neurons and a large volume (30% of brain mass) and is farthest developed in humans compared to nonhuman species.\textsuperscript{117} It can be divided into different subdivisions:\textsuperscript{113} the mid-dorsal (area 9), dorsolateral (BA 46), ventrolateral, orbitofrontal, and medial frontal parts (BA 10, 11, 13, 14). All these frontal areas receive convergent input from different sensory modalities and again project to different associative sensory areas, motor areas, and limbic structures. The PFC is considered to be important for higher cortical functions that characterize the flexibility of human behavior, the ability to control attention, and the richness of intellectual and emotional competence. With respect to pain, PFC plays a major role in cognitive, attentional, and emotional processing of painful stimuli and recruitment of endogenous pain control. A particular part of the PFC, the dorsolateral prefrontal cortex (DLPFC), is important for continuous monitoring of the external world, maintenance of information in short-term memory, and governing efficient performance control in the presence of distracting or conflicting stimuli.\textsuperscript{118,119} In turn, orbital and medial portions
of the PFC are known to be important for mood and emotional behavior, for example, when guided by cues of reward or punishment as well as for visceral and autonomic homeostasis related to eating and drinking behavior.\textsuperscript{120} The famous case of Phineas Gage demonstrated that lesions of the PFC can strongly interfere with the maintenance of an individual’s personality, socially appropriate behavior, and learning capabilities.\textsuperscript{121,122} There is evidence of elevated pain thresholds in patients with frontal lobe lesions.\textsuperscript{123}

The PFC is activated in several, yet not all, functional imaging studies using experimental painful stimuli or clinical pain states. Older studies using blood flow–related analysis failed to show a clear pain-related stimulus–response function,\textsuperscript{74,124} which led to the assumption that PFC activity mainly relates to the engagement of attention during pain processing.\textsuperscript{93} On the other side, prefrontal gamma oscillations have shown to encode ongoing tonic pain,\textsuperscript{125} which differed from the encoding of brief experimental pain. Further evidence indicates that the PFC, irrespective of pain intensity, integrates information about the psychological and bodily context of pain in order to allow disengagement from pain through activating endogenous pain control. Lorenz et al.\textsuperscript{105,126} confirmed strong responses of dorsolateral PFC and orbitofrontal and medial PFC (OMPFC) during inflammatory pain (Fig. 6.6). They used O\textsuperscript{15}-water injections in healthy volunteers to compare cerebral blood flow responses by PET following contact heat stimuli applied on normal skin with those following warm stimuli but equally painful on capsaicin-treated skins of the volar forearm. They found strong activation of the bilateral DLPFC and OMPFC during capsaicin-induced heat alldynia. Whereas DLPFC exhibited a negative, OMPFC yielded a positive relationship to the unpleasantness of perceived pain. Furthermore, the interregional correlation of activity between midbrain and medial thalamus was significantly reduced during high, compared to low, left DLPFC activity which could indicate a top–down mode of inhibition of effective synaptic connectivity between brainstem and medial thalamus as cause for the inverse relationship of DLPFC activity to pain unpleasantness. A role of the DLPFC in the initiation of endogenous pain control is further supported by its participation in placebo analgesia. Wager et al.\textsuperscript{127} demonstrated that
DLPFC responds to cues that inform test participants about an expected analgesic effect in a placebo experiment. The analgesic effect itself, however, goes along with stronger rostral ACC activation\textsuperscript{127,128} being stronger coupled with the brainstem PAG\textsuperscript{30}.

\textbf{FIGURE 6.6} Regional brain activity during equally intense pains across normal and capsaicin-treated skin conditions. \textbf{Top:} Stimulation of the normal skin with the high-intensity stimulus yields the same pain intensity as stimulation with the low-intensity stimulus on capsaicin-treated skin. However, the O\textsuperscript{15}-water positron emission tomography (PET) images during heat pain (left) and
equally intense heat allodynia (middle) are different when compared against normal rest condition. Similar magnitudes of activity in the dorsal striatum, lateral thalamus (lat tha), and posterior insula (post ins) are removed in the image subtraction of heat allodynia minus heat pain (right) contrasting activity in the ventral striatum, medial thalamus (med tha), anterior insula (ant ins), midbrain, dorsolateral prefrontal cortex (DLPFC), medial prefrontal cortex (MPFC) and ventral/orbitofrontal cortex (VOFC), and perigenual anterior cingulate cortex (ACC) during heat allodynia. (Reproduced from Lorenz J, Minoshima S, Casey KL. Keeping pain out of mind: the role of the dorsolateral prefrontal cortex in pain modulation. Brain 2003;126:1079–1091. Reproduced by permission of Guarantors of Brain.)

Other clinical studies lend further support for the association of the DLPFC with pain suppression. Apkarian et al.\textsuperscript{129} observed a reduction of the gray matter density determined by morphometry of magnetic resonance scans in bilateral DLPFC and right thalamus in chronic back pain patients that was strongly related to pain characteristics. In agreement with the suggested role of DLPFC in pain control high-frequency transcranial magnetic stimulation (rTMS) over left DLPFC was able to ameliorate chronic migraine.\textsuperscript{130} This is consistent with earlier studies in animals where electrical stimulation of fiber connections of the PFC to the midbrain mediates antinociceptive effects in rodents.\textsuperscript{131} In summary, collective evidence suggests that the PFC represents an important brain substrate for the human ability to actively disengage from pain. Seminowicz and Moayedi\textsuperscript{132} recently reviewed the neuroimaging literature regarding the role of the DLPFC as a therapeutic target for chronic pain conditions. Evidence indicates functional and structural abnormalities of the DLPFC and their reversal after successful interventions for chronic pain.

**Amygdala**

The amygdala is an almond-shaped structure deep in the midtemporal lobe (see Fig. 6.1) and belongs to the limbic system. The amygdala complex comprises about 13 nuclei, which are further divided into subregions.\textsuperscript{133} These nuclei can also be grouped by functional properties in frontotemporal, autonomic, main, and accessory olfactory systems.\textsuperscript{134} Tracer studies revealed that the amygdala gets multiple inputs from different cortical and subcortical structures and all sensory modalities. Cortical somatosensory and pain input arises directly from SI, SII, and the insula,\textsuperscript{135} whereas subcortical pain signals arise among others from the
thalamus and the brainstem parabrachial nucleus. In addition, numerous projections from the amygdala go back to the brainstem, the hippocampus, and cortical areas such as the PFC, whereas output connections to sensory areas are rare.\textsuperscript{133} Numerous, but not all, imaging studies have revealed amygdala activation during pain perception. Furthermore, the amygdala is involved in the pathophysiology of migraine-related pain.\textsuperscript{136} There is no steady increase of activity in the amygdala with stimulus intensity but rather a stepwise increase once stimulus intensity transits into pain.\textsuperscript{74} This finding may point to learning following painful stimuli or to processing the emotional valence of pain stimuli. Amygdala activation during pain might also reflect activation of a “defensive behavioral system,” which controls transmission of nociceptive experience to the brain through descending modulatory circuits.\textsuperscript{137} Furthermore, the central nucleus of the amygdala is involved in emotional-affective behaviors and the modulation of defense behavior.\textsuperscript{138} There are projections of the amygdala to the PAG that might initiate antinociceptive function during emotional stress or pain expectation.\textsuperscript{139–141} Lesions in the amygdala, also known as Klüver-Bucy syndrome, lead to flattened emotional reactivity and loss of fear conditioning but, similar to ACC lesions, do not impair pain discrimination but change the behavioral response to pain. It is conceivable that the amygdala is important for the memory storage of past pain experiences and their context in terms of the processes underlying fear conditioning to facilitate defensive autonomic reactions and behavior.

**Hippocampus**

The hippocampus forms, relative to the amygdala, the caudal extension of the deep medial temporal lobe. It can be subdivided into the dentate gyrus and the cornu ammonis (CA1 and CA2). Its major input comes from the entorhinal cortex, a network including the DLPFC and parietal association cortex. Reports of Patient H.M.\textsuperscript{142,143} highlight the role of the hippocampus in learning and explicit memory. Moreover, the importance for the involvement in pain processing and learning pain related behavior is evident because associations between pain and predictive cues have fundamental adaptive value.\textsuperscript{144} Furthermore, learning adverse effects can play an important role in chronic pain and chronic pain–related avoidance.
behavior. Functional imaging revealed hippocampus activity during mild and moderate heat pain,\textsuperscript{137,145} in a pain-learning paradigm when pain was not expected and when pain stimuli were manipulated as to induce anxiety.\textsuperscript{144} Together with the assumed role of the amygdala in pain, these findings show that medial temporal lobe structures participate in elaborating the experience of pain based on emotional state, expectation, and past experience.\textsuperscript{82}

\section*{Vigilance, Arousal, and Attention in Pain Processing}

Attention is not a single neurophysiologic entity. Among many authors, Parasuraman et al.\textsuperscript{146} describe different major components of attention that rely on a finite set of brain processes being hierarchically organized and interacting with each other. A basic component serves the maintenance of behavioral goals over time and is largely synonymous to arousal, vigilance, alertness, or sustained attention. It also involves the regulation of the sleep–wakefulness cycle. Cholinergic and noradrenergic ascending systems originating in the RF (see the earlier text) and the locus coeruleus and dopaminergic projections into the striatum are regarded as important for this function referred to as “the vigilance network” by Posner and Petersen.\textsuperscript{147} Another component concerns the bias or filtering of task-relevant against irrelevant information. It serves to cope with capacity limits of central information processing which cannot deal with the huge amount of input from a large variety of sensors in different modalities at the same time. This component is often referred to as selective or focused attention and, according to Posner and Petersen,\textsuperscript{147} depends on the posterior attention network that includes brain structures such as the superior colliculus, thalamic pulvinar, and the posterior parietal cortex. Selective attention is often metaphorically described by a “spotlight” or “cocktail party” effect, which emphasizes the phenomenon that the focus of awareness can momentarily fluctuate between sensory objects, features, or locations sometimes without overt orientation in the form of eye or head movements. It is believed that the gating of the afferent flow of information within attentional channels (i.e., the set of stimuli benefiting from selective attention) optimizes functional efficiency even at very early
stages of modality-specific cortical processes. Closely linked to this function is a supervisory component of attention that temporarily intervenes into ongoing performance when called for by new relevant, unfamiliar, or potentially dangerous information, the detection of performance errors, or when internal representations need to be continuously updated, that is, during working memory operations. This component is often referred to as executive attention, largely governed by the anterior attention network sensu\textsuperscript{147} that comprises the anterior cingulate, medial, and lateral PFC areas and the supplementary motor area. Long-duration mental tasks yield a characteristic vigilance decrement that can be measured subjectively or by behavioral indicators such as reaction time.\textsuperscript{146} Similarly, amplitudes of pain-related, evoked potentials after electrical stimuli, painful chemical stimulation of the nasal mucosa, and laser stimulation are strongly attenuated by habituation and decreases of vigilance over time.\textsuperscript{148} Although pain generally enhances arousal, the laser-evoked potential (LEP) test situation is characterized by short durations of single laser stimuli, presented at long interstimulus intervals in quite monotonous long stimulus blocks, which contribute to the vigilance decrement in LEP amplitudes. Experimental pain studies therefore use study designs to avoid or control for habituation. Pain habituation can be observed not only during short-term pain experience but also during longer lasting pain after several days. fMRI experiments on the mechanisms of habituation revealed decreases of activation in major pain areas including the thalamus, insula, SII, and the putamen. Notably, an increase of activation was observed in the ACC.\textsuperscript{149} One possible mechanism could be the involvement of the endogenous opioidergic pain control system (see earlier text). In an animal model of habituation, naloxone sufficiently prevents habituation to repeated electrical pain stimuli.\textsuperscript{150} There are important interindividual differences regarding the strength of habituation that are not well understood. However, it is described that especially chronic pain patients show an impairment of habituation.\textsuperscript{151–154} Beydoun et al.\textsuperscript{155} examined subjects who they allowed to fall asleep after 1 day of sleep deprivation to look for LEP during different sleep stages compared to normal wakefulness. They demonstrated the abolition
of the N2 to P2 component at the vertex position during sleep stage II, defined by the appearance of sleep spindles, and its strong amplitude attenuation during sleep stage I, defined by dropout of α activity and appearance of lateral eye movements. It appears evident that there is a reciprocal relationship between sleep and pain allowing not only sleep to reduce pain but also pain to reduce or disturb sleep. Furthermore, decreases of pain sensitivity also accompany sedation and drowsiness when induced pharmacologically using benzodiazepines, clonidine, or subanesthetic isoflurane. It is therefore often difficult to differentiate drowsiness or sedation from analgesia.

Given the profound role of attention in conscious perception, it is clear that attention significantly impacts on behavior and pain experience. Pain is a salient stimulus and draws attention for extended periods. The manipulation of attention by distraction or focused attention has been used as a therapeutic intervention for several years and reflects everyday life experience such as when a mother tries to distract her child when it is injured. Clinical evidence suggests that attentional mechanisms may be also involved in the amplification of some chronic clinical pain stages. Patients with chronic pain problems seem to selectively attend to pain and the degree by which pain distracts attention from concurrent tasks appears to depend on the evaluation of pain stimuli as threatening or worrying. In tasks where attentional shifts are required, anxious patients exhibit difficulties disengaging from painful stimuli.

The neural mechanisms underlying attentional modulation of pain are not fully understood, but various areas of the pain matrix appear to be involved. More recent studies using EEG and MEG have focused on cortical synchronization processes as indicators of attentional modulation of sensory input. Mainly derived from experiments with nonpainful stimuli, it is proposed that selective attention may act by modulating subthreshold oscillations in sensory assemblies and by enhancing the gain of oscillatory responses to stimuli that match stored contextual information. A recent study indicates that during selective attention, enhanced oscillatory activity in the γ bandwidth of EEG (60 Hz rhythms), which was localized in the insula, which suggests a key role of γ-band oscillations in the integration of nociceptive input into the
multidimensional experience of pain (Fig. 6.7)\textsuperscript{167} One possible neuronal correlate of abnormal attentional amplification may therefore be suspected in an “oversynchronization” among pain-related cortical areas, leading to an uncontrolled spread of signals even in the case of weak or absent nociceptive inputs. Thus, the dynamic control of neuronal signal flow might be disturbed, preventing an appropriate context-dependent modulation of the gain of neural signals and reducing the capacity for descending control of nociceptive afferent inputs. As assumed for states of chronic pain, such an oversynchronization might be viewed as the result of central neuroplastic changes underlying a learning process.\textsuperscript{168}

**Pain Plasticity**

The brain is an adaptive system, which has a high plasticity such that it can change excitability of its networks according to a variety of external and internal processes. The uniqueness of pain compared with other human senses is characterized by its enormous plasticity to adapt according to both the bodily and the psychological context in which pain occurs. Studies on acute pain models in animals and humans had long made clear that clinically important pains exhibit distinct neurophysiologic and pharmacologic properties due to alteration of impulse generation at the site
of an injury and propagation into and through the CNS. Once tissue damage and inflammation occur, the production and release of chemical mediators excite and sensitize nociceptors rendering their axons much more responsive and giving rise to tenderness and hyperalgesia as well as spontaneous pain. Hyperexcitability also occurs at the level of the dorsal horn in the spinal cord following tissue damage and inflammation, further aggravating sensitization and even rendering innocuous tactile stimuli outside the lesion capable of producing pain through an increase of synaptic efficacy of local interneurons, a phenomenon called allodynia. Thus, the bodily context of normal versus damaged tissue dramatically determines the perception of pain.

Several pain states such as chronic pain or phantom pain can induce central cortical changes in the pain matrix. Patients suffering from cancer with intractable unilateral pain developed a decrease in metabolism within the contralateral thalamus, which was abolished after blocking nociceptive input by surgical hemicordotomy. A smaller representation of the affected hand was found in somatosensory areas (SI and SII) for nonpainful stimulation that correlated with symptom severity in patients suffering from complex regional pain syndrome (CRPS), whereas representation for nociceptive input is extended in somatosensory areas in these patients. Similarly, other chronic pain states yielded exaggerated activation and occupied larger areas in somatosensory cortex as demonstrated for low back pain, fibromyalgia, and neuropathic pain. Anatomic changes in gray matter density can be observed for chronic pain patients as well. Using MRI scans with voxel-based morphometry analysis, changes in white and gray matter can be compared between groups and within subject during different time points. Changes in different cortical areas were found for different pain syndromes. In chronic back pain patients, atrophy in the thalamus and the PFC were observed (Fig. 6.8). Others describe atrophy in the hippocampus, the MCC, the frontal cortex, and the insula in fibromyalgia. Similar findings have been observed in chronic headache. Interestingly, these gray matter density changes occur in pain-related regions such as the PFC, thalamus (Fig. 6.8), the insula, and the cingulate cortex. However, it is still under debate if the brain atrophy is the reason or a consequence of ongoing
pain. Another possible explanation for the decreased gray matter density in these disorders might be atrophy secondary to excitotoxicity and/or exposure to inflammation-related agents, such as cytokines.¹²⁹

**FIGURE 6.8** Regional gray matter density decreases in patients suffering from chronic back pain (CBP). A nonparametric comparison of voxel-based morphometry (VBM) between CBP and control subjects is shown. **A:** Gray matter density is bilaterally reduced in the dorsolateral prefrontal cortex (DLPFC). The result is from a VBM permutation-based pseudo–T-test and voxel-level contrasts when all brain gray matter voxels were compared between controls and CBP subjects. Pseudocolor highly positive values indicate regions where gray matter density was reduced in CBP subjects (controls, CBP). **B:** A nonparametric comparison spatially limited to the thalami revealed a significant decrease in gray matter density in the right anterior thalamus. A slice at the peak of decreased thalamic gray matter is shown. Pseudo–T-values are color-coded; range is 3 to 6. (Republished with permission of Society for Neuroscience from Apkarian AV, Sosa Y, Sonty S, et al. Chronic back pain is associated with decreased prefrontal and thalamic gray matter density. **Summary and Conclusion**

Noninvasive functional neuroimaging and invasive recordings of pain in human volunteers and patients has attracted an enormous interest and activity in pain research and significantly enriched our knowledge about the contribution of the brain in processing and modifying peripheral and spinal nociceptive signals. Supraspinal mechanisms of nociception and pain rely on a multilevel organization of brain structures involving the brainstem (medulla, pons, midbrain), diencephalon (thalamus, hypothalamus), primary (SI) and secondary (SII) somatosensory cortices, and frontolimbic circuits (PFC, ACC, insula, amygdala, hippocampus). Spinal nociceptive afferents that reach predominantly lateral thalamic nuclei convey nociceptive signals into the sensory cortex (SI, SII) and provide the individual with the capability to recognize intensity, location,
and duration of noxious stimuli. This lateral pain system is therefore commonly referred to as the major brain anatomic substrate of the sensory-discriminative determinant of pain. Direct and multisynaptic projections from the dorsal horn and brainstem into medial thalamic nuclei transmit nociceptive signals into the limbic system (insula, ACC, PFC). This medial pain system predominantly comprises the affective-motivational determinant of pain. A pivotal role of the DLPFC in pain is its ability to coordinate nociceptive signals with momentary bodily needs and behavioral goals to account for the significance and threat value of pain. The multimodal connectivity of the DLPFC with sensory and motor systems allows the individual not only to maintain attention on pain but also to release it in favor of superior behavioral goals or in expectation of positive outcome through recruitment of endogenous pain control systems. A predominant feature of pain in comparison with other human senses is its enormous ability to adapt its response properties according to both the bodily and psychologic context. This plasticity implies fundamental changes in the course of pathologic processes underlying tissue damage and inflammation or in the course of memory processes and learning from past pain experiences. Supraspinal mechanisms thus contribute to such plasticity by integrating information about the nature and behavioral significance of pain by recruiting unique pathways during normal or sensitized conditions and by facilitating learned pain behaviors. Although in most instances such plasticity is adaptive to avoid actual bodily damage or promote the healing process, it also forms the basis for maladaptive consequences underlying chronic pain and neuropathic pain.

CHAPTER 7
Psychological Aspects of Pain

DENNIS C. TURK, KIMBERLY SHAWN SWANSON, and HILARY D. WILSON

Advances in the knowledge of the neurophysiology of pain have resulted in the development of new pharmacologic agents, sophisticated surgical interventions, and the use of innovative technologies (e.g., spinal cord stimulation, implantable drug delivery systems) for the treatment of patients with chronic pain. Despite these advances, the cure of pain remains elusive. Regardless of the treatment, the amount of pain reduction averages only about 35%, and fewer than 50% of persons treated with these interventions obtain this result. The extent of improvement in emotional, physical, and social functioning is often below these dissatisfying levels.¹

Notwithstanding the relatively modest track record for even “newer” chronic pain treatments, patients are often given an expectation, directly or indirectly, that they should expect significant improvements if not elimination of their pain. Although individuals with acute pain can often receive good relief from over-the-counter medications and treatments from their primary health care providers, people with persistent pain become enmeshed in the medical-legal system as they shuttle from doctor to doctor, diagnostic test to diagnostic test, in a frustrating quest to receive successful treatment. This experience of “medical limbo”—the presence of a painful condition that, in the absence of acceptable pathology, is either attributed to psychiatric causation or malingering on the one hand, or an undiagnosed but potentially progressive and untreatable disease on the other—is itself a source of significant and ongoing stress that can initiate high levels of emotional distress or aggravate a premorbid psychiatric condition.²

The person who has a chronic pain condition resides in a complex and costly world that is populated not only by themselves but also by their
significant others, including health care providers, employers, and third-party payers. Family members feel increasingly hopeless and distressed as medical costs, disability, and emotional suffering mount while income and available treatment options decline. Health care providers grow increasingly frustrated and feel defeated and ineffective as available treatment options are exhausted while the pain condition remains a mystery and may worsen. They may come to question the veracity of their patients and their complaints. Employers, who are already resentful of growing worker’s compensation benefits, pay higher costs while productivity suffers because the employee frequently calls out sick or is unable to perform at his or her usual level (“presenteeism”), often with coworkers having to pick up the slack. Third-party payers watch as health care expenditures soar with repeated diagnostic testing, often with inconclusive results. In time, the legitimacy of the individual’s report of pain may be questioned because oftentimes, a medical etiology fails to substantiate the cause of the symptoms.

People with chronic pain may begin to feel that their health care providers, employers, and even family members are blaming them when their condition fails to respond to treatment as expected. Some may suggest that the individual is complaining excessively in an attempt to obtain prescriptions for centrally acting and reinforcing medications (e.g., opioids), to receive attention, to avoid undesirable activities, or to be relieved from onerous obligations (e.g., gainful employment, household chores). Others may suggest that the pain reported is not real, they are feigning or exaggerating their symptoms, and is “all in their head”—“psychogenic.” Third-party payers may even suggest that the claimant is intentionally exaggerating his or her pain in order to obtain financial gain, whereas others may attribute reported symptoms to the desire to obtain mood-altering drugs. In this way, people with chronic pain may come to be viewed as “wimps,” “crock,” or “fakes.” Those experiencing persistent pain may in turn come to view health care providers and claims adjustors as “quacks,” “hacks,” or “thieves.” Often, the ensuing result is an unfortunate, inappropriate, and detrimental adversarial relationship.

As a result of the attitudes, and in the absence of cure or even
substantial relief described, individuals experiencing chronic pain may withdraw from contacts; lose their sources of income; alienate family, friends, and coworkers; and become more and more isolated, despondent, depressed, and, in general, demoralized. They become angry, and frustration increases as their bodies, the health care system, legal system, and their significant other have all let them down. They may feel they have even let themselves down as they relinquish their usual activities and responsibilities due to symptoms that are intractable, yet often inscrutable, when not validated by objective pathologic findings. This emotional distress, however, can be exacerbated by a variety of other factors, including fear of disease progression and their vulnerability to escalating sets of symptoms and disability, inadequate or maladaptive support systems, inadequate personal and material coping resources, treatment-induced (iatrogenic) complications, overuse of potent drugs with significant adverse effects, inability to work, financial difficulties, prolonged litigation, disruption of usual activities, and sleep disturbance. In short, living with persistent pain conditions requires considerable emotional resilience and tends to deplete people’s emotional reserves, taxing not only the individual sufferer but also the capacity of family, friends, coworkers, employers, and society to provide support.

Based on what we described earlier about the plight of the person with chronic pain, two conclusions are obvious: (1) Psychosocial and behavioral factors play a significant role in the experience, maintenance, and exacerbation of pain and potentially even the cause\(^3\) and (2) because some level of pain persists in the majority of people with chronic pain regardless of treatment, self-management is an important complement to biomedical approaches.\(^4\) In this chapter, we emphasize a set of important psychological constructs including dispositional, cognitive, affective, and behavioral factors. We discuss them individually for ease of explication. It is important to note, however, that although we describe these separately, there is considerable overlap and integration among them. We conclude with a discussion of integrative models and treatments of chronic pain.

**Cognitive Factors: Predispositions, Appraisals,**
Beliefs, Perceived Control, and Self-efficacy

PREDISPOSITIONS

Temperament is, at least partly, putatively heritable and may show continuity throughout the entire life span. Personality in adulthood reflects the molding of underlying temperament by life experiences. Temperament and personality may predispose individuals toward misinterpretation of pain sensations and maladaptive pain beliefs, or they can have a protective role contributing to resilience in the face of adversity.

Among the potential vulnerability factors that have been proposed are negative affectivity, anxiety sensitivity (AS), and illness/injury sensitivity. Negative affectivity may be considered as heritable, stable, and promoting a tendency to experience a broad range of negative emotions and to view the world as threatening and distressing. Negative affectivity has been associated with heightened vigilance to bodily sensations and interpretational biases toward ambiguous internal signals. Studies in nonclinical populations have reported negative affectivity to predict lower pain tolerance. However, studies in chronic pain populations have, to date, not provided consistent evidence for a role of trait negative affectivity. Thus, although negative affectivity has often been implicated as a vulnerability factor in chronic pain, convincing evidence is lacking.

More convincing has been the research on another potential vulnerability factor: AS. AS is defined as the fear of anxiety-related sensations and is conceived as a partly heritable personality trait. Individuals with high AS interpret unpleasant physical sensations (such as rapid heart beating, feeling faint) more often as a sign of danger than individuals with low AS. There is growing evidence that AS may also be a risk factor for the maintenance and exacerbation of chronic pain and disability. AS has been shown to correlate with measures of fear-avoidance (described in the following text) and is associated with distress, analgesic use, and impairment of physical and social functioning in patients across a wide range of different pain-related conditions. Moreover, path analyses and mediation models suggest that AS exacerbates fear-avoidance beliefs and the negative interpretation of bodily sensations, which in turn leads to enhanced pain experience and pain
avoidance. Studies examining the predictive value of AS in relation to cognitive and behavioral reactions to experimentally induced pain support a causal, negative biasing role of AS in maladaptive cognitive and behavioral pain response.

In contrast to the extensive search after negative predisposing factors described, there has been relatively little research on protective factors for chronic pain and disability. Traditionally, research on resilience has focused on adaptive responses in the wake of significant adversity or challenge (e.g., developmental resilience, posttraumatic growth). In the context of pain, resilience might mean effective recovery from an injury, infection, or other painful experience, both from a physical and psychosocial standpoint (e.g., effective resilience in the wake of an injury might ideally mean total resolution of pain and resumption of normal functioning). However, in patients for whom resolution of pain is unlikely, behavioral, and cognitive responses to pain may have very different implications in terms of their adaptiveness. When a new and unfamiliar painful condition develops, a fearful and avoidant response may be protective; consistent with an evolutionary view of pain, new painful sensations may signal significant danger to the organism, such that mobilization of individual resources to escape pain and threat may prolong survival. However, prolongation of this fearful avoidant response tends to yield fewer benefits in cases of chronic pain and, instead, increase the risk of protracted physical disability, deconditioning, and psychosocial dysfunction. Chronic pain resilience is a construct that has garnered a great deal of attention in recent years (e.g., Friborg et al., Hassett and Finan, Ruiz-Parraga et al., Sturgeon and Zautra).

Several investigators have proposed a model of resilience in chronic pain that follows a “temporal” order of adaptation, manifesting in three interrelated factors: sustainability, or prolonged and positive functioning despite the immediate presence of pain; recovery, or expedient and effective recovery from the negative consequences of pain; and growth, or long-term learning or personal development that may result in new strengths, protective attitudes, or skills as a result of chronic pain.

Three potential resilience factors are particularly relevant in chronic pain: optimism, hope, and psychological flexibility. Review of the
literature suggests that optimism may be one of the most important personality traits in relation to adjustment to chronic pain. Dispositional optimism is defined as “the tendency to believe that one will generally experience good outcomes in life” and is distinguishable from neuroticism and trait anxiety. In cross-sectional and prospective studies, optimism was found to be associated with better general health, adaptation to chronic disease, and recovery after various surgical procedures.

Only a few studies have explored the role of dispositional optimism or hope in adaptation to chronic pain. Novy found that optimism was related to less catastrophizing and more use of active coping strategies in chronic pain patients. Affleck and Tennen reported that dispositional optimism predicts pleasant daily mood in fibromyalgia but that it is not related to daily pain. Finally, in studying rheumatoid arthritis patients, Treharne and colleagues found that optimism was associated with less depression and pain and higher life satisfaction for patients in the early and intermediate stages of disease.

The primary mechanism of the beneficial effect of optimism may be differences in coping behavior between optimistic and pessimistic people. In general, pessimists turn to avoidant coping strategies and denial more often, where optimists employ more problem-focused coping strategies. When problem-focused coping is not possible, they turn to coping strategies such as acceptance, use of humor, and positive reframing of the situation. Thus, it may not be the use of specific coping strategies but flexibility of coping that protects against disability and distress.

Snyder has described a similar pathway for hope, with people with low hope showing a tendency to catastrophize, whereas people with high hope seek means to encounter future challenges and show flexibility in finding alternative life goals when their original goals are blocked.

Psychological flexibility manifests as an ability to effectively and flexibly adjust behavioral efforts at goal pursuit in a way that is consistent with one’s own values despite the presence of pain and associated problems. Psychological flexibility may act independently of reductions in rumination about symptoms and impact on life and other negative patterns of thinking.

Individuals with chronic pain who better sustain their optimism, hope,
and flexibility appear to be more able to persist in painful behavioral
tasks and to be less susceptible to other pain-related difficulties, such as
fatigue and problematic opioid use. Similarly, positive emotional states
have been found to be predictors of better social and physical
functioning in some individuals with chronic pain.

APPRAISAL AND BELIEFS
Specific appraisal and beliefs are largely shaped by an individual’s
learning history through direct experience, observational learning, or
information acquired from others. These experiences may interact with an
individual’s enduring traits, sociocultural background, prior learning and
experiences, and the current context in which they reside. That is,
personality factors may predispose some people to make certain kinds of
appraisals and to be more susceptible to some idiosyncratic beliefs than to
others.

Pain appraisal refers specifically to the meaning ascribed to pain by
each individual. In accordance with the transactional stress model, a
distinction can be made between primary appraisal (evaluation of the
significance of pain as threatening, benign, or irrelevant) and secondary
appraisal (evaluation of the controllability of pain and one’s coping
resources). Beliefs refer to assumptions about reality that shape how one
interprets events and can thus be considered as determinants of appraisal.
Pain beliefs develop throughout the lifetime as a result of an individual’s
learning history and cover all aspects of the pain experience (e.g., the
causes of pain, its prognosis, appropriate treatments).

Appraisal and beliefs about pain can have a strong impact on an
individual’s response to pain. If a pain signal is interpreted as harmful
(threat), it may be perceived as more intense, more unpleasant and evoke
more escape or avoidance behavior. For instance, Smith and colleagues
demonstrated that cancer patients who attributed pain sensations after
physiotherapy directly to cancer reported more intense pain than patients
who attributed this pain to other causes. Perception of danger of an
experimental pain stimulus may also lead to avoidance of this stimulus.
Arntz and Claassens experimentally manipulated the appraisal of a
mildly painful stimulus (a very cold metal bar placed against the neck) by
suggesting that it was either very hot or very cold. As expected, participants rated the stimulus as more painful in the condition where they were informed that it was hot. The effect appeared to be mediated by the belief that the stimulus would be harmful. These studies demonstrate the important role of people’s interpretations regarding the meaning of the pain.

Pain appraisal and pain beliefs are also prominent determinants of adjustment to chronic pain. Pain that is viewed as a signal of damage, leads to disability, is uncontrollable, and is a permanent condition has been shown to affect individuals’ responses, and these beliefs are widespread.

CATASTROPHIZING AND FEAR-AVOIDANCE BELIEFS

Pain catastrophizing can be defined as an exaggerated, negative cognitive and emotional orientation toward actual or anticipated pain experiences. Current conceptualizations most often describe it in terms of appraisal or as a set of maladaptive beliefs. Pain-related catastrophizing thought patterns are fairly common in both acute and chronic pain and show significant relationship to pain intensity and functional disability. For example, prospective studies indicated that catastrophizing might be predictive of the inception of chronic musculoskeletal pain in the general population. For patients undergoing surgery, catastrophizing has been shown to predict postoperative pain severity, length of hospital stay, poor quality of life, greater postsurgical opioid use, opioid misuse, as well as later development of chronic pain and disability (e.g., Khan et al., Theunissen et al.). Catastrophizing has been associated with increased perceptions of pain severity in both acute and chronic pain severity and disability among groups with diverse pain diagnoses. Catastrophizing also alters perception of noxious stimulation. In addition, catastrophizing is related to greater sensitivity to experimentally induced pain in pain-free volunteers and pain patients. The relationship has been observed in healthy adults as well as children. In a systematic review, Wertli et al. reported that catastrophizing was a prognostic factor predicting outcomes of patients with low back pain. Conversely, following treatment,
reductions in catastrophizing were related to reduction in pain intensity and physical impairment and maintenance of treatment benefits. 61

Imaging studies have shown how catastrophizing is associated with specific brain regions. 62–64 Several studies 65,66 used the diffuse noxious inhibitory control/conditioned pain modulation (DNIC/CPM) paradigm demonstrated that catastrophizing may influence the pain modulatory process in pain-free individuals and predict pain following surgery. 67 Catastrophizing has also been associated with immune function (i.e., interleukin-6) responses to acute pain 68 and stress hormones in response to laboratory-induced pain in individuals with chronic pain and pain-free individuals. 69

People with chronic pain often anticipate that certain activities will increase their pain or induce further injury. These fears may contribute to avoidance of activity and subsequently greater physical deconditioning, emotional distress, and, ultimately, greater disability. 14 Their failure to engage in activities prevents them from obtaining any corrective feedback about the associations among activity, pain, and injury.

In addition to fear of movement, people with persistent pain may be anxious about the meaning of their symptoms for the future—will their pain increase, will their physical capacity diminish, will they have progressive disability where they ultimately end up in a wheelchair or bedridden? In addition to these sources of fear, people experiencing persistent pain may fear that on the one hand, people will not believe that they are suffering, and on the other, they may be told that they are beyond help and will “just have to learn to live with it.” Such fears can contribute to additional emotional distress and to increased muscle tension and physiologic arousal that may directly exacerbate and maintain pain.

The role of catastrophizing and the belief that pain means harm and activity should be avoided has been most articulated in fear-avoidance models (FAMs) of chronic pain. 14,70 Although FAMs are multifaceted and include affective (fear) and behavioral (avoidance) components, cognitions are identified as the core determinants of entering into a negative pain cycle. The tenets of contemporary FAMs can be summarized as follows: When pain is perceived following injury, an individual’s idiosyncratic beliefs will determine the extent to which pain is catastrophically
interpreted. A catastrophic interpretation of pain gives rise to physiologic (arousal), behavioral (avoidance), and cognitive fear responses. The cognitive shift that takes place during fear enhances threat perception (e.g., by narrowing of attention) and further feeds the catastrophic appraisal of pain.\textsuperscript{49,70}

There is substantial evidence that fear-avoidance beliefs are associated with disability and impaired physical performance in chronic pain.\textsuperscript{14,37} A systematic review of the literature on psychological risk factors in back and neck pain indicated that the evidence for the association between fear-avoidance beliefs and increased pain and disability was of the highest level.\textsuperscript{14,37} In addition, prospective studies have shown that fear-avoidance beliefs in patients seeking care for acute pain may be predictive of pain persistence, disability, and long-term sick leave.\textsuperscript{71–73} A number of treatment approaches have been developed and implemented to address pain-related fear and anxiety in chronic pain patients (e.g., Bailey et al.\textsuperscript{74}).

Fear-avoidance beliefs of health care providers have also been found to be related to their treatment behavior and their recommendation for engaging in physical activities.\textsuperscript{75–77} The beliefs of patients and health care providers may further interact with each other in a mutually reinforcing way because a patient’s beliefs may guide the choice of which health care provider is visited.\textsuperscript{78}

**PERCEIVED CONTROL AND SELF-EFFICACY**

Perceived control over pain refers to the belief that one can exert influence on the duration, frequency, intensity, or unpleasantness of pain. Perceived controllability of a pain stimulus may modify the meaning of this stimulus and directly affect threat appraisal.\textsuperscript{79} As a consequence, pain may be rated as less intense or less unpleasant, and pain tolerance may increase.

The belief that one has control over pain has a strong influence on disability in patients with chronic pain\textsuperscript{40,80} and an increase in this belief after multidisciplinary pain treatment may predict pain reduction and decreases in disability.\textsuperscript{81–83} demonstrated that perceived control over the effects of pain was more strongly related to better adjustment and less disability than perceived control over pain itself.

Related to perceived control is the construct of self-efficacy. Self-
efficacy is the conviction that one can successfully perform a certain task or produce a desirable outcome.\textsuperscript{84} A major determinant of self-efficacy is prior mastery experience. In laboratory experiments, self-efficacy beliefs predict pain tolerance.\textsuperscript{85,86} In chronic pain patients, self-efficacy positively affects physical and psychological functioning,\textsuperscript{87,88} and improvements in self-efficacy after self-management and cognitive-behavioral interventions are associated with improvements in pain, functional status, and psychological adjustment. Recent reviews of psychological factors in chronic pain have concluded that the evidence for the role of self-efficacy across a broad range of pain populations is impressive (e.g., Jackson et al.,\textsuperscript{39} Riddle et al.\textsuperscript{89}). Moreover, self-efficacy also influences the prognosis after acute physical interventions like surgery.\textsuperscript{89,90} Prospective studies in patients who underwent surgery demonstrated that high self-efficacy before the start of rehabilitation and larger increases over the course of rehabilitation speed recovery and predict better long-term outcome.\textsuperscript{91,92} A preoperative intervention (an instruction video demonstrating movement and breathing skills) in hysterectomy patients was able to enhance preoperative self-efficacy and decrease pain associated with postoperative activities and promote earlier mobilization.\textsuperscript{93} Perceived self-efficacy has been shown to have a direct effect on the body’s opioid and immune systems\textsuperscript{94} confirming the important association between psychological constructs and physiology.

**Coping**

Self-regulation of pain and its impact depend on people’s specific ways of dealing with pain, adjusting to pain, and reducing or minimizing distress caused by pain; in other words, their coping strategies. Coping is assumed to involve spontaneously employed purposeful and intentional acts, and it can be assessed in terms of overt and covert behaviors. Overt behavioral coping strategies include rest, use of relaxation techniques, or medication. Covert coping strategies include various means of distracting oneself from pain, reassuring oneself that the pain will diminish, seeking information, and problem solving. Coping strategies are thought to act to alter both the perception of pain intensity and the ability to manage or tolerate pain, and to continue everyday activities (e.g., Skinner et al.,\textsuperscript{4} Flor and Turk\textsuperscript{95}).
Some studies have found active coping strategies (efforts to function in spite of pain or to distract oneself from pain, such as engaging in activity or ignoring pain) to be associated with adaptive functioning, and passive coping strategies (such as depending on others for help in pain control and restricting one’s activities) to be related to greater pain and depression (e.g., Benyon et al., Ip et al., Samwel et al.). However, beyond this, there is no evidence supporting the greater effectiveness of any one active coping strategy compared to any other. It seems more likely that different strategies will be more effective than others for some people at some times but not necessarily for all people all the time.

**Stress and Autonomic Responses: Hypothalamic-Pituitary-Adrenal Axis Dysregulation**

It is becoming clear that the pain experience is determined by a multitude of factors. Although the focus has historically been directed at sensory mechanisms, more attention is being placed on factors related to cognitive and homeostatic factors. The primary basis for including discussions of homeostatic factors is that chronic pain threatens the organism and produces a cascade of events that eventually contributes to the maintenance of such conditions. If one views pain as a primary threat to the organism, then mechanisms should be present to engage and motivate the organism to restore basic homeostatic function. The major consequence of homeostatic imbalance is stress. Regardless of the source, stressors activate numerous systems such as the autonomic nervous system and the hypothalamic-pituitary-adrenal (HPA) axis. Prolonged activation of the stress system has disastrous effects on the body and sets up a condition of a feedback loop between pain and stress reactivity.

During periods of short-term stress and homeostatic imbalance, the hypothalamus activates the pituitary gland to secrete adrenocorticotropic hormone, which acts on the adrenal cortex to secrete cortisol. Secretion of cortisol elevates blood sugar levels and enhances metabolism, an adaptive response that allows the organism to mobilize energy resources to deal with the threat and restore homeostatic balance (i.e., fight or flight response). The situation is much more serious during prolonged periods of
stress and homeostatic imbalance that is associated with long-term psychological stress, chronic pain, and other pathologic conditions. Prolonged, elevated levels of cortisol are related to the exhaustion phase of Selye’s general adaptation syndrome. The negative effects of this stage of the adaptation syndrome include atrophy of muscle tissue, impairment of growth and tissue repair, and immune system suppression, which together might set up conditions for the development and maintenance of a variety of chronic pain conditions. According to Melzack, psychological stress, as well as sensory and cognitive events, modulates the neurosignature of the body–self neuromatrix which, as a consequence of altered neuromatrix output, is associated with chronic pain conditions. The concept of the neuromatrix has potentially important explanatory implications for brain function in general and also provides a theoretical framework for the biopsychosocial perspective of chronic pain. As will be discussed later, there is a growing literature demonstrating the importance of psychosocial factors (emotion and cognition) in this neuromatrix conceptualization.

Emotion

Pain is ultimately a subjective, private experience, but it is invariably described in terms of sensory and affective properties. As defined by the International Association for the Study of Pain, “[Pain] is unquestionably a sensation in a part or parts of the body but it is also always unpleasant and therefore also an emotional experience [emphasis added].” The central and interactive roles of sensory information and affective state are supported by an overwhelming amount of evidence. The affective component of pain incorporates many different emotions. Depression and anxiety have received the greatest amount of attention in chronic pain patients; however, anger and hostility have received considerable interest as a significant emotion in chronic pain patients (e.g., Burns et al., Burns et al., Burns et al.). Additionally, the ability to maintain positive affect during times of stress has been investigated in relationship to pain.

In addition to affect being one of the three interconnected components
of pain, emotions and pain interact in a number of ways. Emotional distress may predispose people to experience pain, be a precipitant of symptoms, be a modulating factor amplifying or inhibiting the severity of pain, be a consequence of persistent pain, or a perpetuating factor. Moreover, these potential roles are not mutually exclusive, and any number of them may be involved in a particular circumstance interacting with cognitive appraisals. For example, the literature is replete with studies demonstrating that current mood state modulates reports of pain as well as tolerance for acute pain. Levels of anxiety have been shown to influence not only pain severity but also complications following surgery and number of days of hospitalization. Individual difference variables, such as AS, have also been shown to play an important predisposing and augmenting role in the experience of pain. Level of depression has been observed to play a significant role in premature termination from pain rehabilitation programs.

Emotional distress is commonly observed in people with chronic pain. As described previously, people with chronic pain often feel rejected by the medical system, believing that they are blamed or labeled as symptom magnifiers and complainers by their physicians, family members, friends, and employers when their pain condition does not respond to treatment. Although most of the literature has focused on the relationship between negative affect and pain, research has indicated the ability to maintain positive affect during stress is an important factor contributing to ongoing adaptation to chronic illness. Positive affect serves to decrease distress in chronic pain patients by broadening the individual’s range of affective and cognitive responses permitting a wider range of experiences. Positive affect can serve as psychological immunity in that chronic pain patients may experience more optimal functioning and improved quality of life while living with ongoing pain. Although we provide an overview of research on the predominant emotions—anxiety, depression, and anger—associated with pain individually, it is important to acknowledge that these emotions are not as distinct when it comes to the experience of pain. They interact and augment each other over time.

ANXIETY
It is common for patients with symptoms of pain to be anxious and worried. This is especially true when the symptoms are unexplained, as is often the case for chronic pain syndromes. For example, in a large-scale, multicenter study of fibromyalgia patients, between 44% and 51% of patients acknowledged that they were anxious.\(^1\) In addition, up to 45% of patients with chronic pain will screen positive for an anxiety disorder.\(^2\) Chronic pain patients with comorbid anxiety may have a lower pain tolerance, be more prone to medication side effects or fearful of having side effects, and be more fearful of pain itself.\(^3\) One study indicated 40% of patients with panic disorder also had chronic pain, particularly head, shoulder, and lower back pain.\(^4\) Panic disorder involves a hyperfocus on somatic sensations that might increase subjective pain sensations. Patients with both chronic pain and panic may engage in more “illness behaviors.”\(^5\)

Fear and anxiety will also relate to activities that people with pain anticipate will increase their pain or exacerbate whatever physical factors might be contributing to the pain. As noted in the discussion of the FAM previously, these fears may contribute to avoidance, motivate inactivity, and, ultimately, greater disability.\(^6\) Continual vigilance and monitoring of noxious stimulation and the belief that it signifies disease progression may render even low-intensity aversive sensations less bearable. In addition, such fears will contribute to increased muscle tension and physiologic arousal that may exacerbate and maintain pain.

Threat of intense pain captures attention from which it is difficult to disengage. The experience of pain may initiate a set of extremely negative thoughts, as noted previously, and arouse fears—fears of inciting more pain and injury, fear of future impact.\(^6\) Fear and anticipation of pain are cognitive-perceptual processes that are not driven exclusively by the actual sensory experience of pain and can exert a significant impact on the level of function and pain tolerance.\(^7,8\) People are motivated to avoid and escape from unpleasant consequences; they learn that avoidance of situations and activities in which they have experienced acute episodes of pain will reduce the likelihood of reexperiencing pain or causing further physical damage. They may become hypervigilant to their environment as a way of preventing the occurrence of pain.
Investigators\textsuperscript{122,123} have suggested that fear of pain, driven by the anticipation of pain and not by the sensory experience of pain itself, produces strong negative reinforcement for the persistence of avoidance behavior and the putative functional disability in pain patients. Avoidance behavior is reinforced in the short-term through the reduction of suffering associated with noxious stimulation.\textsuperscript{124} Avoidance, however, can be a maladaptive response if it persists and leads to increased fear, limited activity, and other physical and psychological consequences that contribute to disability and persistence of pain.

Studies have demonstrated that fear of movement and fear of (re)injury are better predictors of functional limitations than biomedical parameters or even pain severity and duration.\textsuperscript{125,126} For example, Crombez and colleagues\textsuperscript{125} showed that pain-related fear was the best predictor of behavioral performance in trunk extension, flexion, and weight lifting tasks, even after partitioning out the effects of pain intensity. Moreover, Vlaeyen and colleagues\textsuperscript{127} found that fear of movement/(re)injury was the best predictor of self-reported disability among chronic back pain patients and that physiologic sensory perception of pain and biomedical findings did not add any predictive value. The importance of fear of activity appears to generalize to daily activities as well as in the clinical experimental context. Approximately two-thirds of individuals with chronic nonspecific low back pain avoid back-straining activities because of fear of (re)injury.\textsuperscript{125} For example, fear-avoidance beliefs about physical demands of a job are strongly related to disability and work lost during the previous year, even more so than pain severity or other pain variables.\textsuperscript{128,129} Interestingly, reduction in pain-related anxiety predicts improvement in functioning, affective distress, pain, and pain-related interference with activity.\textsuperscript{83} Clearly, fear, pain-related anxiety, and concerns about harm avoidance all play important roles in chronic pain and need to be assessed and addressed in treatment.

Pain-related fear and concerns about harm avoidance all appear to exacerbate symptoms.\textsuperscript{123} Anxiety is an affective state that is greatly influenced by appraisal processes; to cite the stoic philosopher Epictetus, “there is nothing either bad or good but thinking makes it so.” Thus, there is a reciprocal relationship between affective state and cognitive-
interpretive processes. Thinking affects mood, and mood influences appraisals and, ultimately, the experience of pain.

**DEPRESSION**

Research suggests that 40% to 50% of chronic pain patients experience depressive symptoms. Conversely, on average, 65% of depressed individuals also report pain symptoms. Epidemiologic studies provide solid evidence for a strong association between chronic pain and depression but do not address whether chronic pain causes depression or depression causes chronic pain. Prospective studies of patients with chronic musculoskeletal pain have suggested that chronic pain can cause depression, that depression can cause chronic pain, and that they exist in a mutually reinforcing relationship. A neuroanatomic link between depression and chronic pain via the hypothalamus, amygdala, and anterior cingulate gyrus pathway has been described. Reduced serotonin and norepinephrine are associated with both depression and increased pain sensation.

One fact often raised to support the idea that pain causes depression is that the current depressive episode often began after the onset of the pain problem. The majority of studies appear to support this contention. However, several studies have documented that many patients with chronic pain have often had prior episodes of depression that predated their pain problem by years. One important prospective study demonstrated that levels of depression predicted the development of low back pain 3 years following the initial assessment. Patients with depression were 2.3 times more likely to report back pain compared to those who did not report depression. Depression was a much stronger predictor of incident back pain than any clinical or anatomic risk factors. This has led some investigators to propose that there may exist a common trait of susceptibility to dysphoric physical symptoms (including pain) and negative psychological symptoms (including anxiety as well as depression). They conclude that “pain and psychological illness should be viewed as having reciprocal psychological and behavioral effects involving both processes of illness expression and adaptation.” For example, those who experience both depression and chronic pain report
more intense pain, less control of their lives, more unhealthy coping strategies, and reduced analgesic response to opiate medications. In addition, negative thinking is a common feature of depression and chronic pain. Commonalities in thinking patterns between chronic pain and depression include catastrophic thinking, helplessness-hopelessness, and negative expectations regarding treatment outcome. These thinking patterns negatively impact how a person might respond to pain treatment interventions in that they lead to a reverse placebo/nocebo effect where the patient concludes “nothing works for me.”

Given the scenario of chronic pain just described, it is hardly surprising that chronic pain patients are depressed. It is interesting, however, to ponder the flip side of the coin—why are not all chronic pain patients depressed? Turk and colleagues examined this question and determined that two factors appear to mediate the pain–depression relationship: patients’ appraisals of the effects of the pain on their lives and appraisals of their ability to exert any control over their pain and lives. That is, those patients who believed that they could continue to function and that they could maintain some control despite their pain were less likely to become depressed. Here, we see the interdependence of cognition and affect.

As noted previously, in the majority of cases, depression appears to be reactive, although some have suggested that chronic pain is a form of “masked depression,” whereby patients use pain to express their depressed mood because they feel it is more acceptable to complain of pain than to acknowledge that one is depressed. Once a person has a chronic pain diagnosis, it no longer matters which is the cause and which is the consequence—pain or depression. Both need to be treated.

**ANGER AND HOSTILITY**

Anger has been widely observed in people with chronic pain. Even though chronic pain patients might present an image of themselves as even-tempered, Corbishley and colleagues found that 88% acknowledged their feelings of anger when these were explicitly sought. Approximately 98% of the patients referred to a multidisciplinary pain rehabilitation center reported that they were feeling some degree of anger.
at the time of the assessment. We must be cautious in interpreting data from patients recruited at pain centers, however, as there may be a referral bias such that the most distressed patients are sent to these facilities, and they do not represent the large number of people with persistent pain who are never evaluated in treatment facilities that specialize in pain management.

Because anger is frequently considered as socially undesirable, some patients in the studies cited previously may have found it difficult to admit that they were angry to the health care professionals. Thus, it is possible that the anger rates may actually be an underestimate. The high prevalence of anger observed is perhaps not surprising, given the frustrations related to persistence of symptoms, limited information on etiology, and repeated treatment failures along with anger toward others (employers, insurance companies, the health care system, family members) and anger toward themselves, perhaps, for their inability to alleviate their symptoms and to move on with their lives. Several empirical studies provide preliminary support for the association between anger and pain intensity, unpleasantness of pain, affective component of pain, and emotional distress in chronic pain patients as well as families of chronic pain patients.

Anger in chronic pain has been considered by some to be attributable to enduring personality dispositions associated with unconscious conflicts, whereas others have suggested that anger may be a reaction to the presence of recalcitrant symptoms that have been unsubstantiated by objective medical findings and unrelieved by medical treatments. There is some evidence supporting the latter hypothesis. For example, a laboratory study demonstrated that the mere anticipation of pain was sufficient to provoke angry behavioral responses in healthy individuals. Using the cross-lagged design with a clinical sample, Arena et al. found that an increase in pain tends to precede anger, directly contradicting the anger–somatization association. Inhibition of anger seems to contribute to aversion of the chronic pain experience. Inhibition of anger has been found to be related to pain severity and overt pain behaviors as well as to increased emotional distress.

Denial of anger appears to be common among chronic pain patients.
However, awareness of anger should not be confused with anger expression. For example, Corbishley et al.\textsuperscript{142} observed that chronic pain patients tend to show strong reservations about expressing socially undesirable emotions that could create interpersonal conflict. For these individuals, it seems that expression of the emotion is under conscious control. They are aware of their anger but choose not to express it. On the other hand, some chronic pain patients may lack awareness of their angry feelings and have increased difficulties in recognizing and reporting these feelings.\textsuperscript{154}

Fernandez and Turk\textsuperscript{149} proposed that the specificity of targets toward which patients experience angry feelings may be important in understanding of the relationship between pain and anger. When a pain sufferer is angry, there are a range of possible targets (e.g., employer, insurance company, health care providers). The presence or intensity of anger toward different targets may be differentially related to chronic pain experience. That is, there may be some targets of anger that are more relevant to the chronic pain experience than others. As discussed later, Okifuji et al.\textsuperscript{143} found that anger directed toward oneself was particularly common among chronic pain patients evaluated at a pain rehabilitation facility.

Although the effects of anger, hostility, and frustration on amplification of pain and treatment acceptance has not received as much attention as anxiety and depression, Kerns et al.\textsuperscript{152} found that the suppressed feelings of anger accounted for a significant portion of the variance in pain intensity, perceived interference, and frequency of pain behaviors. Furthermore, Summers et al.\textsuperscript{155} found that anger and hostility were powerful predictors of pain severity in people with spinal cord injuries.

It is thus reasonable to expect that the presence of anger may serve as a complicating factor, increasing autonomic arousal and blocking motivation and acceptance of treatments oriented toward rehabilitation and disability management rather than cure, which are often the only treatments available for chronic pain.\textsuperscript{110} It would be reasonable to expect that the presence of anger may serve as a complicating factor, increasing autonomic arousal and blocking motivation and acceptance of treatments oriented toward rehabilitation and disability management rather than cure.
Frustrations related to persistence of symptoms, unknown etiology, and repeated treatment failures, along with anger toward employers, insurers, the health care system, family, and themselves, all contribute to the general dysphoric mood of patients. Okifuji et al. reported that 60% of patients expressed anger toward health care providers, 39% toward significant others, 30% toward insurance companies, 26% toward employers, and 20% toward attorneys. The target of anger most commonly acknowledged, however, was anger toward themselves (endorsed by approximately 70% of the sample). Internalization of angry feelings is strongly related to measures of pain intensity, perceived interference, and frequency of pain behaviors. Overall, correlations between anger and pain severity have been shown to be statistically significant, ranging from 0.17 to 0.35. Okifuji et al. reported that anger was significantly correlated with pain intensity (correlations = .30 to .35). They also reported that anger was significantly correlated with disability (r = .26) and was highly associated with depression (r = .52).

The precise mechanisms by which anger and frustration exacerbate pain are not known. One reasonable possibility is that anger exacerbates pain by increasing autonomic arousal. Anger and hostility may also interact with depression to modulate perceived severity of pain. In addition, anger may block motivation for, and acceptance of, treatments oriented toward rehabilitation and disability management rather than cure. Yet, rehabilitation and disability management are often the only treatments available for these patients.

In summary, it is important to be aware of the significant role of negative mood in chronic pain patients because it is likely to influence treatment motivation and compliance with treatment recommendations. For example, individuals experiencing pain who are anxious may fear engaging in what they perceive as demanding activities; patients who are depressed and who feel helpless may have little initiative or motivation to comply; and patients who are angry with the health care system are not likely to be motivated to respond to recommendations from yet another health care professional. Thus, clinicians who are treating people with persistent pain must focus on their mood states as well as physical pathology and somatic factors. Pain cannot be treated successfully without
attending to the patient’s emotional state. This is true for acute pain, such as pain associated with surgery, as well as persistent pain states.

**Psychogenic Conceptualizations of Chronic Pain**

As a result of the multiple psychosocial factors involved in the onset and maintenance of chronic pain, a number of different psychological perspectives on chronic pain have evolved. Many of the psychological treatments for chronic pain are based on different psychological principles that at times compete and differ from one another. Thus, it is important to consider the varying perspectives.

**PSYCHOGENIC VIEW**

Frequently in medicine, when physical explanations seem inadequate or when the results of treatment are inconsistent, reports of pain are attributed to a psychological etiology (and thus are “psychogenic”). Although psychogenic views of pain have been discussed since the formulation of psychodynamic theory, a psychodynamic perspective on chronic pain was first described systematically in the 1960s. During this time, people with pain were viewed as having compulsive and masochistic tendencies, inhibited aggressive needs, and feelings of guilt—“pain-prone personalities.”

It was commonly held that people with pain had childhood histories fraught with emotional abuse, family dysfunction (e.g., parental quarrels, separation, divorce), illness or death of a parent, early responsibilities, and high orientation toward achievement. Some current research has reported associations between chronic pain and childhood trauma, although the research is not consistent. Based on the psychogenic perspective, assessment of persons with chronic pain is directed toward identifying the psychopathologic tendencies that instigate and maintain pain. It is assumed that reports of pain will cease once the psychogenic mechanisms are resolved. Treatment is geared toward helping patients gain “insight” into the underlying maladaptive psychological contributors.

Empirical evidence supporting the psychogenic view is scarce. A number of people with chronic pain do not exhibit significant
psychopathology. Furthermore, insight-oriented psychotherapy has not been shown to be effective in reducing symptoms for the majority of patients with chronic pain. Studies suggest that the emotional distress observed in patients with chronic pain more typically occurs in response to the persistence of pain and not as a causal agent and may resolve once pain is adequately treated. The psychogenic model has thus come under scrutiny and may be flawed in its view of chronic pain.

Behavioral Formulations

CLASSICAL CONDITIONING
According to the classical or respondent conditioning model, if a painful stimulus is repeatedly paired with a neutral stimulus, the neutral stimulus will elicit a pain response. For example, a person who experienced pain after performing a treadmill exercise may become conditioned to experience a negative emotional response to the presence of the treadmill and to any stimulus associated with it (e.g., physical therapist, gym). The negative emotional reaction may instigate muscle tensing, thereby exacerbating pain, and further reinforcing the association between the stimulus and pain. Based on this, people with chronic pain may avoid activities previously associated with pain onset or exacerbation.

OPERANT CONDITIONING
In 1976, Fordyce (for an update, see Main et al.) introduced an extension of operant conditioning to chronic pain. This view proposes that acute pain behaviors (such as avoidance of activity to protect a painful area from additional pain) may come under the control of external contingencies of reinforcement (responses increase or decrease as a function of their reinforcing consequences) and thus develop into a chronic pain problem. Fordyce underscored the fact that because there is no objective way to measure pain—no pain thermometer—the only way we can know of anyone’s pain is by their behavior, whether verbal or nonverbal expressions. Overt pain behaviors include verbal reports, paralinguistic vocalizations (sighs, moans), motor activity, facial expressions, body postures and gesturing (limping, rubbing a painful body
part, grimacing), functional limitations (reclining for extensive periods of time, inactivity), and behaviors designed to reduce pain (taking medication, use of the health care system).

The central features of pain behaviors are that they are (1) sources of communication and (2) observable. Observable behaviors are capable of eliciting a response and the consequences of behavior will influence subsequent behavior. Through a process of learning, responses that receive positive consequences, especially repeated desirable consequences, will more likely be maintained; behaviors that fail to activate positive consequences, or that receive negative consequences, will be less likely to occur (i.e., extinguished). Pain behaviors may be positively reinforced directly (e.g., attention from a spouse or health care provider, monetary compensation, avoidance of undesirable activity). Pain behaviors may also be maintained by the escape from noxious stimulation through the use of drugs or rest or the avoidance of undesirable activities such as work. In addition, “well behaviors” (e.g., activity, working) may not be positively reinforcing, and the more rewarding pain behaviors may, therefore, be maintained.

The operant conditioning model considers pain an internal subjective experience that can be directly assessed and may be maintained even after an initial physical basis of pain has resolved rather than the initial causes. The pain behavior originally elicited by organic factors caused by injury or disease may later occur, totally or in part, in response to reinforcing environmental events.

It is important, however, not to make the mistake of viewing pain behaviors as being synonymous with malingering. Malingering involves consciously and purposely faking a symptom such as pain for some gain, usually financial or to gain attention. Contrary to the beliefs of many third-party payers, there is little support for the contention that outright faking of pain for financial gain is prevalent.

There is some support for the operant model (e.g., Becker et al., Block et al., Doleys et al., Lousberg et al.). For example, Romano et al. videotaped patients and spouses in a series of cooperative household activities and recorded patients’ pain behaviors. Sequential analyses showed that spouses’ solicitous responses more frequently
preceded and followed pain behaviors in patients than pain-free controls. At least a subset of patients do demonstrate high levels of pain behaviors and benefit from treatment targeting these behaviors (e.g., Thieme et al., \textsuperscript{174} Thieme et al.\textsuperscript{175}).

**SOCIAL (OBSERVATIONAL) LEARNING**

The social (observational) learning model emphasizes the point that behavior can be learned not only by actual reinforcement of the individual’s behavior but also by observation of how others respond and the consequences following responses. This is a powerful way of learning especially when the others being observed are judged to be similar to the observer. For example, a middle-aged man might learn what to expect by observing how other middle-aged men with similar medical problems are treated. People can acquire responses that were not previously in their behavioral repertoire by the observation of others performing these activities. Expectancies and actual behavioral responses to nociceptive stimulation are based, at least partially, on prior social learning history.

Another example of social learning occurs in children. Children develop attitudes about health and health care and the perception and interpretation of symptoms and physiologic processes from their parents and others they confront in their social environment. They learn how others respond to injury and disease and thus may be more or less likely to ignore or overrespond to symptoms they experience based on behaviors modeled in childhood. For example, children of chronic pain patients may make more pain-related responses during stressful times or exhibit greater illness behaviors (e.g., complaining, days absent, visit to school nurse) than children of healthy parents based on what they observed and learned at home.\textsuperscript{176} Models can influence the expression, localization, and methods of coping with pain. Even physiologic responses may be conditioned during observation of others in pain.\textsuperscript{177}

A central construct of the social learning perspective is that of self-efficacy.\textsuperscript{84} Self-efficacy as described previously is a personal expectation that is important in patients with chronic pain. A self-efficacy belief is defined as a personal conviction that one can successfully execute a course of action (perform required behaviors) to produce a desired outcome in a
Given sufficient motivation to engage in a behavior, it is a person’s self-efficacy beliefs that determine the choice of activities that he or she will initiate, the amount of effort that will be expended, and how long the individual will persist in the face of obstacles and aversive experiences. In this way, self-efficacy plays an important role in therapeutic change and compliance to psychological and medical regimes.

Efficacy judgments are based on four sources of information regarding one’s capabilities, listed in descending order of importance: one’s own past performance at the task or similar tasks; the performance accomplishments of others who are perceived to be similar to oneself; verbal persuasion by others that one is capable; and perception of one’s own state of physiologic arousal, which is, in turn, partly determined by prior efficacy estimation. Performance mastery can then be created by encouraging people to undertake subtasks that are initially attainable but become increasingly difficult and subsequently approaching the desired level of performance. It is important to remember that coping behaviors are influenced by the person’s beliefs that the demands of a situation do not exceed their coping resources.

How people interpret, respond to, and cope with illness is determined by cultural norms and perceptions of self-efficacy. These two sets of factors contribute to the marked variability in response to objectively similar degrees of physical pathology noted by health care providers.

GATE CONTROL THEORY
Although not a psychological formulation itself, the gate control theory (GCT) was the first to popularize the importance of central, psychological factors in pain perception. Perhaps the most important contribution of the GCT is the way it changed thinking about pain perception. Melzack and Casey differentiate three systems related to the processing of nociceptive stimulation—sensory-discriminative, motivational-affective, and cognitive-evaluative—all thought to contribute to the subjective experience of pain. Thus, the GCT specifically includes psychological factors as an integral aspect of the pain experience. It emphasizes the central nervous system (CNS) mechanisms and provides a
physiologic basis for the role of psychological factors in chronic pain. The GCT contradicts the notion that pain is either somatic or psychogenic. Instead, it postulates that both factors have potentiating and moderating effects. According to this theory, both the central and peripheral nervous systems interact to contribute to the experience of pain. It is not only these physical factors that guide the brain’s interpretation of painful stimuli that is at the center of this model; psychological factors (e.g., thoughts, beliefs, emotions) are also painful stimuli.

Prior to the Melzack and Wall\textsuperscript{179} formulation of the GCT, psychological processes were largely dismissed as reactions to pain. Although the physiologic details of the GCT have been challenged,\textsuperscript{181} it has had a substantial impact on basic research and can be credited as a source of inspiration for diverse clinical applications to control or manage pain, including neurophysiologically based procedures (e.g., neural stimulation techniques from peripheral nerves and collateral processes in the dorsal columns of the spinal cord, pharmacologic advances, behavioral treatments, and those interventions that target modification of attentional and perceptual processes involved in the pain experience).

**Cognitive-Behavioral Perspective**

The cognitive-behavioral perspective, perhaps the most commonly accepted model for the psychological treatment of individuals with chronic pain,\textsuperscript{182,183} incorporates many of the psychological variables previously described—namely, anticipation, avoidance, and contingencies of reinforcement—but suggests that cognitive factors rather than conditioning factors are of central importance. The model suggests that conditioned reactions are largely self-activated on the basis of learned expectations rather than automatically evoked. The model proposes that behaviors and emotions are influenced by interpretations of events, and emphasis is placed on how peoples’ beliefs and attitudes interact with physical, affective, and behavioral factors. It proposes that conditioned reactions are largely activated by learned expectations rather than automatically evoked. In other words, it is the person’s information processing that results in anticipatory anxiety and avoidance. The critical factor, therefore, is that
people learn to anticipate and predict events and to express appropriate reactions. From the cognitive-behavioral perspective, people with pain are viewed as having negative expectations about their own ability to control certain motor skills without pain. Moreover, people with chronic pain tend to believe they have limited ability to exert any control over their pain. Such negative, maladaptive appraisals about the situation and personal efficacy may reinforce the experience of demoralization, inactivity, and overreaction to nociceptive stimulation. These cognitive appraisals and expectations are postulated as having an effect on behavior leading to reduced efforts and activity, which may contribute to increased psychological distress (helplessness) and subsequent physical limitations. If one accepts that pain is a complex, subjective phenomenon that is uniquely experienced by each person, then knowledge about idiosyncratic beliefs, appraisals, and coping repertoires becomes critical for optimal treatment planning and for accurately evaluating treatment outcome.

People with chronic pain’s beliefs, appraisals, and expectations about pain; their ability to cope; social supports; their disorder; the medicolegal system; the health care system; and their employers are all important because they may facilitate or disrupt the individuals sense of control. These factors also influence patients’ investment in treatment, acceptance of responsibility, perceptions of disability, adherence to treatment recommendations, support from significant others, expectancies for treatment, and acceptance of treatment rationale.

Cognitive interpretations also affect how individuals with pain present symptoms to others, including health care providers. Overt communication of pain, suffering, and distress will enlist responses that may reinforce pain behaviors and impressions about the seriousness, severity, and uncontrollability of pain. That is, complaining of pain may induce physicians to prescribe more potent medications, order additional diagnostic tests, and, in some cases, perform surgery. Significant others may express sympathy, excuse the person with chronic pain from responsibilities, and encourage passivity, thereby fostering further physical deconditioning. It should be obvious that the cognitive-behavioral perspective integrates the operant conditioning emphasis on external
reinforcement and respondent view of conditioned avoidance within the framework of information processing.

People with persistent pain often have negative expectations about their own ability and responsibility to exert any control over their pain. Moreover, they often view themselves as helpless. Such negative, maladaptive appraisals about their condition, situation, and their personal efficacy in controlling their pain and problems associated with pain reinforce their experience of demoralization, inactivity, and overreaction to nociceptive stimulation. These cognitive appraisals are posited as having an effect on behavior, leading to reduced effort, reduced perseverance in the face of difficulty, reduced activity, and increased psychological distress.

The cognitive-behavioral perspective on pain management focuses on providing the patient with techniques to gain a sense of control over the effects of pain on his or her life as well as actually modifying the affective, behavioral, cognitive, and sensory facets of the experience. Behavioral experiences help to show individuals with pain that they are capable of more than they assumed, increasing their sense of personal competence. Cognitive techniques (e.g., self-monitoring to identify relationships among thoughts, mood, and behavior, distraction using imagery, and problem solving) help to place affective, behavioral, cognitive, and sensory responses under the person’s control.

The assumption is that long-term maintenance of behavioral changes will occur only if the person with pain has learned to attribute success to his or her own efforts. There are suggestions that these treatments can result in changes of beliefs about pain, coping style, and reported pain severity as well as direct behavior changes. Treatment that results in increases in perceived control over pain and decreased catastrophizing also results in decreases in pain severity and functional disability. When successful rehabilitation occurs, there is a major shift from beliefs about helplessness and passivity to resourcefulness and ability to function regardless of pain and from an illness conviction to a rehabilitation conviction.

A number of studies have attempted to identify cognitive factors that contribute to pain and disability. These studies have consistently
demonstrated that a person’s attitudes, beliefs, and expectancies about his or her plight, own self, coping resources, and the health care system affect reports of pain, activity, disability, and response to treatment. For example, people respond to medical conditions in part based on their subjective ideas about illness and their symptoms. When pain is interpreted as signifying ongoing tissue damage or a progressive disease, it is likely to produce considerably more suffering and behavioral dysfunction than if it is viewed as being the result of a stable problem that is expected to improve.

Once beliefs and expectancies are formed, they become stable and rigid and relatively impervious to modification. Pain sufferers tend to avoid experiences that could invalidate their beliefs (disconfirmations) and guide their behavior in accordance with these beliefs, even in situations where these beliefs are no longer valid. It is thus essential for people with chronic pain to develop adaptive beliefs about the relationships among impairment, pain, suffering, and disability and to deemphasize the role of experienced pain in their regulation of functioning.

Distorted thinking can also contribute to the maintenance and exacerbation of pain. A particularly potent and pernicious thinking style that has been observed among people with chronic pain is catastrophizing (holding negative thoughts about one’s situation and interpreting even minor problems as major catastrophes). Research has indicated that people who spontaneously use more catastrophizing thoughts report more pain than those who do not catastrophize.

Coping strategies, or a person’s specific ways of adjusting to or minimizing pain and distress, act to alter both the perception of pain intensity and one’s ability to manage or tolerate pain and continue everyday activities. Overt behavioral coping strategies include rest, medication, and use of relaxation, among others. Covert coping strategies include various means of distracting oneself from pain, reassuring oneself that the pain will diminish, seeking information, and problem solving to list some of the most prominent.

Studies have found active coping strategies (efforts to function in spite of pain or to distract oneself from pain) to be associated with adaptive functioning and passive coping strategies (depending on others for help...
with pain control, avoiding activities because of fear of pain/injury, self-medication, alcohol) to be related to greater pain and depression. \(^{187}\) Regardless of the type of coping strategy, if people with chronic pain are instructed in the use of adaptive coping strategies, their rating of intensity of pain decreases and tolerance of pain increases. \(^{187}\) Thus, the perspective on how people function and the emphasis on facilitating self-management are more important than any specific cognitive or behavioral techniques that are used to bring about change in thinking and changes in behavior.

**TREATMENTS BASED ON THE COGNITIVE-BEHAVIORAL PERSPECTIVE**

A detailed description of treatments based on the cognitive-behavioral perspective is beyond the scope of this chapter and can be found in many recent publications (e.g., Turk \(^{188}\)). There are a number of reports supporting the efficacy of cognitive-behavioral therapy (CBT) for treating various chronic pain conditions and with children \(^{189}\) as well as adults (e.g., Ehde et al. \(^{190}\)). A systematic review on CBT for chronic pain based on 35 randomized clinical trials (\(n = 4,788\) patients) suggests that the treatment had modest benefits for pain and disability and a small to moderate range of benefit for mood and catastrophizing. \(^{191}\)

**Biopsychosocial, Contextual Model**

Although Melzack and Wall’s GCT described previously introduced the role of psychological factors in the maintenance of pain symptoms, it focused primarily on the basic anatomy and neurophysiology of pain. The biopsychosocial, contextual model, which expands the cognitive-behavioral perspective of pain, views illness as a dynamic and reciprocal interaction between biologic, psychological, sociocultural, and contextual variables that shape the person’s response to pain. \(^{95,192,193}\) What is unique about the perspective is that it takes into consideration the influence of higher order cognitions, including perception and appraisal and the environmental context in which these appraisals take place. It accepts that people are active processors of information and that behavior, emotions, and even physiology are influenced by interpretations of events rather than
solely by physiologic factors. People with chronic pain may therefore have negative expectations about their own ability and responsibility to exert any control over their pain. Moreover, behaviors of people with pain elicit responses from significant others that can reinforce both adaptive and maladaptive modes of thinking, feeling, and behaving.

Loeser originally formulated a general model that delineated four dimensions associated with the concept of pain: nociception, the stimulation of nerves that convey information about possible tissue damage to the brain; pain, the subjective perception that is the result of transduction, transmission, and modulation of sensory information; suffering, the emotional responses that are triggered by nociception or some other aversive event associated with it, such as fear or depression; and pain behavior, those things that people do when they are suffering or in pain, such as avoiding activities or exercise for fear of (re)injury. Subsequently, Waddell emphasized that pain cannot be comprehensively evaluated without an understanding of the individual who is exposed to the nociception. Waddell also made a comparison between Loeser’s model of pain and the earlier discussed call by Engel of the need for a new, more biopsychosocial model in medicine. Engel proposed the important dimensions of the physical problem, distress, illness behavior, and the sick role, which correspond to Loeser’s dimensions of nociception, pain, suffering, and pain behavior, respectively. Thus, with this general perspective, a diversity of pain or illness can be expected (including its severity, duration, and psychosocial consequences). In order to fully understand a person’s perception and response to pain and illness, the interrelationships among biologic changes, psychological status, and the sociocultural context all need to be considered. Any model that focuses on only one of these dimensions will be incomplete.

Families and Family Systems Perspective

In family systems (and this could be expanded to significant others and not only traditional conceptualizations of nuclear families), the family is viewed as an interactional unit, and family members profoundly impact
each other’s emotions, thoughts, and behaviors. Thus, the functioning of family members is interdependent, and family relationships are an important factor not only in psychological but also physical health.\textsuperscript{197,198}

Increasingly, evidence supports family members contribute to behavioral risk factors to the development of numerous chronic illnesses such as smoking, lack of exercise, and poor diet.\textsuperscript{198} Additionally, families influence the development and maintenance of chronic pain (e.g., Cano et al.\textsuperscript{199}). One mechanisms that has been shown to be important is chronic pain is based on operant theory.\textsuperscript{131,200} For example, expressions of acute pain (reporting pain, grimacing, avoidance of activity, and use of pain medication), because they are overt and observable, may be reinforced through expressions of concern from family members. Furthermore, in support of this idea, a number of investigators (e.g., Thieme et al.\textsuperscript{174}) have found that spousal attentiveness to expressions of pain was positively correlated with higher levels of reported pain, pain behavior frequency, and disability. However, social interaction may not always be viewed negatively and may be important in building intimacy serving as a positive support for a person with pain who is distressed.\textsuperscript{201} Marital satisfaction has also been identified as an important mediator of disability associated with chronic pain.\textsuperscript{202}

The experience of chronic stress within the family has also been hypothesized to contribute to the development of chronic illness.\textsuperscript{203} Specifically, chronic stress within the family may play an important role in sympathetic nervous system and endocrine dysregulation often found in chronic pain patients.

As noted previously, pain does not take place in isolation but in a social context. Pain does not occur solely in people’s bodies, nor does it occur solely in their brains, but, rather, it occurs in their lives. The emphasis on the role of significant others is important, as it reminds us that to successfully treat chronic pain patients requires that we not only assess and treat the patient but must also target significant others that can either impede or facilitate rehabilitation.\textsuperscript{204}

\textbf{Conclusion}
For the person experiencing chronic pain, there is a continuing quest for relief that often remains elusive, leading to feelings of helplessness, hopelessness, and outright depression. Emotional distress may be attributed to a variety of factors, including inadequate or maladaptive coping resources, iatrogenic complications, overuse of medication, disability, financial difficulties, litigation, disruption of usual activities, lack of social support, and sleep disturbance. Thus, chronic pain is a demoralizing situation that confronts the person not only with the stress created by pain but also with a cascade of ongoing stressors that compromise all aspects of the life of the sufferer. Living with chronic pain requires considerable emotional resilience and tends to deplete emotional reserve and taxes not only the individual experiencing chronic pain but also the capacity of significant others to provide support.

There is a large body of evidence to demonstrate that psychological factors can interfere with or hinder a person’s ability to cope with the pain experience. As a result, psychological intervention in the assessment and treatment of chronic pain is becoming standard practice. Psychological treatments can focus on the emotional distress that accompanies chronic pain and provide education and training in the use of cognitive and behavioral techniques that may reduce perceptions of pain and related disability. Psychologists and psychological principles have played a major role in the understanding and treatment of people with pain, and psychologists have an important function in interdisciplinary pain rehabilitation programs (IPRPs) as clinicians and researchers.

None of the psychological treatments described are successful in eliminating pain completely; in fact, the same statement can be made in reference to the most commonly used pharmacologic, medical, and surgical interventions. Consequently, the majority of people have to adapt to the presence of chronic pain and learn self-management in the face of persistent pain and accompanying symptoms. The various psychological interventions described in this chapter provide a general overview of different treatment strategies. By far, however, treatment with CBT alone or within the context of an IPRP holds the greatest empirical evidence for success. There is a substantial and overwhelming body of research supporting the effectiveness of various psychological approaches. At point,
it seems prudent to consider the use of psychological treatments in combination with traditional medical interventions.

The experience of pain is characterized by tremendous interindividual variability. Indeed, similar injuries, disease states, or noxious stimuli are often accompanied by pain responses that differ dramatically across people. Although it is inarguable that such individual differences in pain responses exist, their contributing factors and clinical importance remain important topics of study. This chapter aims to review the nature of individual differences in responses to pain and its treatment. After briefly highlighting several examples of individual differences, several individual difference factors are reviewed, emphasizing demographic variables (e.g., sex/gender and race/ethnicity) and genetic contributions to individual differences in pain. This chapter concludes by considering the interactions among different individual difference variables and discusses the clinical relevance of individual differences, including implications for treatment tailoring.

In the clinical setting, providers are well acquainted with individual differences in pain, as patients with the same pain condition often vary markedly in their self-reported pain and related symptoms. This variability is often attributed to differences in disease severity, based on the misguided assumption that the noxious stimulus itself is the primary determinant of the pain experience, despite considerable evidence suggesting otherwise. For example, the majority of individuals who show radiographic evidence of osteoarthritis (OA) are asymptomatic, and even in symptomatic patients, radiographic measures of disease severity in OA account for a limited proportion of the interindividual variability in pain and disability. Likewise, physical and diagnostic findings have limited
value in predicting the occurrence or severity of low back pain.\textsuperscript{5,6} Moreover, in the acute pain setting, patients undergoing similar surgical procedures report widely varying amounts of pain.\textsuperscript{7–11} Thus, for many forms of clinical pain, the nature or magnitude of the noxious clinical stimulus appears to be a poor predictor of the degree of pain experienced.

Studying individual differences in the clinical setting is challenging because it is often difficult to quantify with any accuracy the noxious stimulus thought to be responsible for the patient’s pain. Moreover, clinical pain reports are commonly influenced by previous or current therapies, creating additional sources of interindividual variability. In order to circumvent some of these issues, investigators have turned to the application of quantifiable and controllable painful stimuli in the laboratory setting. Interestingly, responses to experimentally induced pain are also marked by robust individual differences. For example, in a previous study of healthy adults undergoing an identical cold water stimulus, pain intensity ratings ranged from 0 to 100.\textsuperscript{12} In subsequent analyses, the authors found that the intensity of the noxious stimulus accounted for only 40\% of the variance in pain ratings, with the remaining 60\% accounted for by true individual differences. More recently, findings from 321 healthy young adults revealed that pain ratings in response to a 48° C heat stimulus ranged from 4 to 100.\textsuperscript{1} Similarly, a prior study assessed 16 different experimental pain measures using identical methods in more than 200 healthy young females.\textsuperscript{13} They subsequently combined these measures into overall index scores by summing standardized (z scores) scores for each of the individual pain tests. This yielded a normal distribution of summary scores with a mean of 0, where positive and negative values indicated higher and lower pain sensitivity, respectively. They observed a range of summary scores from −20 to greater than 30 across the sample. These findings clearly demonstrate that even under experimental conditions in which stimulus intensity is carefully controlled, pain responses are marked by robust individual differences.

It is important to recognize that in addition to interindividual variability in pain responses, pain treatment outcomes are characterized by substantial individual differences. For example, a study of more than 3,000 patients undergoing different surgical procedures revealed that the number of
morphine boluses required to produce adequate postoperative pain relief (Visual Analog Scale rating <30) ranged from 1 to 20. A clinical trial of opioid therapy for chronic neuropathic pain showed that following treatment, patients reported changes in pain ranging from a 100% decrease to a nearly 70% increase in pain. Likewise, even in laboratory pain studies, analgesic responses to opioids differ considerably across individuals. In addition to variability in responses to medications, responses to nonpharmacologic pain treatments also vary widely from person to person. For example, a long-term (8 to 10 years) follow-up study of outcomes from surgical and nonsurgical management of spinal stenosis showed that approximately half of the patients in both treatment groups reported improvement in their symptoms over the follow-up period, whereas 20% to 25% reported no change and 20% to 25% reported that their symptoms had worsened. Several other nonpharmacologic treatments have also been shown to confer widely varying amounts of pain relief across individuals, including acupuncture and psychological interventions for pain.

This brief overview of individual differences demonstrates that responses to pain and its treatment vary substantially from person to person. Although the study of this variability in pain responses has a long history, recent years have witnessed substantially increased interest in individual differences, motivated in large part by the contemporaneous explosion of research on genetic determinants of health and disease. Although genetic factors contribute importantly to pain and analgesia, it is critical to remember that responses to pain and its treatment result from complex and dynamic interactions among numerous biologic, psychological, and social factors. Thus, before discussing findings regarding the contribution of various demographic, genetic, and psychosocial factors to individual differences in pain, I provide a brief overview of the biopsychosocial model (Fig. 8.1), which represents the optimal model for conceptualizing individual differences in pain.
FIGURE 8.1 Biopsychosocial model of pain. The figure shows that pain experiences are influenced by the combined effects of biologic, psychological, and social factors. Although variables from each of the three domains can impact pain individually (as shown by small bidirectional arrows), biologic, psychological, and social factors also interact to produce complex and important influences on pain, as illustrated by the large three-way arrows. These interactions across numerous biopsychosocial factors produce myriad possible pain-modulating combinations of variables, resulting in tremendous interindividual variability of pain experiences. (Modified with permission from Fillingim RB. Individual differences in pain: understanding the mosaic that makes pain personal. Pain 2017;158[suppl 1]:S11–S18.)

The biopsychosocial model emerged as an alternative to the unsatisfactory medical model, which reductionistically viewed health and symptoms as products of biologic disease. In its application to pain, the model posits that the experience of and response to pain are determined by multiple biologic, psychological, and social factors. In addition to their individual contributions, an important tenet of the biopsychosocial model is that these factors interact dynamically to drive the pain experience. Of particular relevance to individual differences, this mosaic of pain-related biopsychosocial influences varies considerably from person to person. Hence, for each individual at a given point in time, a unique combination of biologic and psychosocial factors operates to sculpt the experience of pain.

Next, I discuss sex/gender and race/ethnicity as potentially important individual difference variables. I emphasize these demographic variables for several reasons. First, sex and ethnic differences in pain have tremendous public health implications, as they may contribute to
differences in pain prevalence or severity that impact large population groups. Second, such demographic variables represent important proxies for a variety of other biopsychosocial factors that can influence pain, and the observation of group differences in pain is often the impetus for further exploration of these other pain-related factors. Finally, these demographic variables may be important moderators of the influence of other individual difference factors on pain, as discussed in the following text.

Sex and Gender Differences in Pain

CLINICAL PAIN

Although research addressing sex and gender differences in pain has a long history, interest in this topic has increased dramatically in the last two decades. Several recent reviews have addressed the topic from different perspectives and in varying levels of detail. The importance of the topic is dictated by the abundance of epidemiologic and clinical research demonstrating that, compared to men, women are at greater risk for pain, tend to have higher levels of pain, and are more likely to seek treatment for pain. Findings from myriad population-based studies demonstrate greater prevalence of chronic pain among females versus males. In a Canadian household survey, women reported higher rates of both temporary and persistent pain, and a mail survey of more than 3600 adults in Scotland found that women were significantly more likely than men to report chronic pain. Two Scandinavian studies found that multisite body pain was more common among women than men. Similarly, in a survey of health maintenance organization enrollees in Seattle, Von Korff and colleagues found that women were significantly more likely than men to report at least three of the following five pain conditions: headache, back pain, chest pain, abdominal pain, and facial pain. In our 2009 review article, we summarized the findings of 10 population-based studies of general pain prevalence that were conducted in different geographical regions. These studies reported widely varying prevalences of pain for both women (11% to 59%) and men (10% to 49%). Every study reported higher pain prevalence among women, although the magnitude of the excess female prevalence varied considerably across studies, ranging from
1% to 14%. Subsequently, findings from the National Health Interview Survey (NHIS) revealed significantly higher frequency of persistent pain (i.e., pain on most days or every day for the past 3 months) among women (21.6%) than men (16.2%). A recent meta-analytic review of epidemiologic studies reported an overall female-to-male prevalence ratio of 1.27, indicating that 27% more females than males reported chronic pain. Overall, these findings from numerous population-based studies conducted in varied geographic regions across the world reveal a consistent pattern of higher prevalence of general chronic pain among women than men, although the magnitude of the sex difference varies across studies.

In addition to these data on general pain symptoms, considerable research suggests that specific pain conditions show sex differences in their prevalence. More than 30 years ago, the NUPRIN Pain Report, based on a telephone survey of 1,254 US adults, found that women were more likely to report headaches, stomach pain, joint pain, and back pain than men. An abundance of epidemiologic evidence shows that several common chronic pain conditions are more common among women, including fibromyalgia (FM), chronic widespread pain (CWP), migraine headache, temporomandibular disorder (TMD), irritable bowel syndrome, and low back pain. Sex differences in the prevalence of specific pain conditions were recently summarized by examining findings from 47 studies that reported on sex differences in pain prevalence across the following pain conditions: back pain, migraine, musculoskeletal pain, neuropathic pain, oral pain, OA pain, and widespread pain. For each comparison, the excess female prevalence was computed by subtracting the prevalence in men from that in women. Prevalence in females was greater than in males in 45 of 47 comparisons, and the average excess female prevalence across all of the pain conditions was 5.5%. Sex differences in back pain prevalence were examined in a more recent study of adults aged 50 years and older from six low- and middle-income countries conducted by the World Health Organization. These authors reported that back pain during the past month was significantly more frequent for women (34.9%) than men (24.2%), and women also had more severe pain. Also, in a Canadian study, both knee
and hip OA were more prevalent among women versus men. A recent meta-analysis of 14 studies that reported sex-specific prevalence of CWP found that prevalence was approximately twice as great in women as men. Also, Jones and colleagues compared the prevalence of FM in females and males using three different diagnostic criteria. Prevalence was substantially higher in women, but the magnitude of the sex difference varied dramatically across diagnostic criteria. It is worth noting that these epidemiologic findings reflect the frequency of pain in the general population. The disproportionate impact of pain among women is even greater in the clinical setting due to their increased health care use for pain. Taken together, these findings demonstrate that the frequency of pain is higher for women than men, particularly for pain conditions that are both common and associated with substantial societal costs.

These findings of greater pain prevalence among adults are somewhat mirrored by studies of children and adolescents. For example, a systematic review found that pain prevalence for most pain types was higher for girls than for boys, including headaches, abdominal pain, musculoskeletal pain, combined pain types, and general chronic pain. Also, a recent study of children and adolescents (aged 10 to 17 years) found that females were more likely than males to transition from acute to persistent musculoskeletal pain. However, several studies of acute pain report no sex differences in children, and age appears to be an important moderating factor, as sex differences generally become more pronounced as children age. For example, LeResche and colleagues reported increasing excess female prevalence of pain conditions as children progressed through pubertal development, implicating potential hormonal contributions.

The aforementioned findings speak to the frequency of pain but not to its impact or severity, which has been addressed in a number of clinical studies. Regarding acute pain, sex differences in postoperative pain have been inconsistent. In cohorts of patients undergoing mixed surgical procedures, results have shown greater pain among women as well as greater pain among men. Other studies have evaluated sex differences in pain after specific types of surgery. More severe pain has been observed for women after dental surgery in some but not other studies.
Women have also been found to report higher pain levels following orthopedic and cardiothoracic surgery and after laparoscopic cholecystectomy. A recent review of this literature concluded that women generally experience more severe postoperative pain, but the observed sex differences are often small and of limited clinical significance. It should also be noted that persistent pain after surgery represents an important clinical concern, and several studies have shown that females are at greater risk for pain persistence than males.

In addition to these findings addressing acute pain, sex differences in the severity of chronic pain have also been investigated. Women with arthritis have been found to report higher levels of pain and disability than their male counterparts. In addition, in a cohort of people with mixed chronic pain conditions seeking treatment in a multidisciplinary pain clinic, women reported higher pain severity than men. In a sample of patients with chronic musculoskeletal pain, pain ratings did not differ by sex; however, women’s pain drawings showed a greater area of pain compared to men. In contrast to these findings of sex differences in chronic pain severity and impact, many other studies have found little evidence for sex differences in the severity of chronic pain. Moreover, in a treatment-seeking sample of patients composed largely of individuals with myofascial pain conditions, men reported more frequent and severe pain and greater disability compared to women. Thus, the available evidence regarding sex differences in chronic pain severity is inconsistent and precludes firm conclusions. Perhaps, this should not be surprising because most of the evidence regarding chronic pain derives from patients whose pain was severe enough to motivate treatment seeking, thereby increasing the likelihood of sampling bias. A handful of studies have examined sex differences in chronic pain severity in community-based samples, providing a less biased approach to the issue. A population-based study in Australia reported that among people reporting chronic pain, a greater proportion of females than males characterized their pain as moderate to severe. Among people reporting activity-limiting pain, pain frequency, pain-related negative affect, and disability were all greater for women compared to men. In a community-based study of knee OA, Glass and colleagues found that women reported higher pain levels that
men across all grades of radiographic knee OA severity, but these differences were small in magnitude, and some became nonsignificant after controlling for confounders. Similarly, we recently reported no differences in clinical pain severity in women and men with knee OA; however, women reported pain in more body sites than did men. A Scandinavian study revealed higher pain levels among women with musculoskeletal conditions compared to their male counterparts. In a study of individuals with painful TMD, multiple comorbid pain conditions (e.g., headache/migraine, neck pain, low back pain, joint pain) were significantly more prevalent among women than men. Recently, findings from a telephone survey showed that compared to men, women using chronic opioid therapy reported poorer pain-related adjustment. Thus, when considering these findings from community-based studies of individuals with existing chronic pain, women appear to have higher impact pain than men.

**EXPERIMENTAL PAIN**

Although sex differences in clinical pain prevalence and severity are inevitably driven by multiple factors, one possible contributor could be sex differences in the functioning of pain processing systems. Indeed, altered nociceptive processing characterizes many of the female-predominant pain disorders, which adds further credibility to this argument. Several reviews have examined the literature regarding sex differences in experimental pain sensitivity. Overall, the findings reveal lower pain thresholds (i.e., the minimum stimulus intensity required to produce pain) and tolerances (i.e., the maximum stimulus intensity that the individual is willing to tolerate) among women relative to men, across multiple stimulus modalities. The direction of the findings has been highly consistent across studies; however, the magnitude of the sex difference has been quite variable. Some 20 years ago, our meta-analysis reported that the average effect size was moderate. Over the past two decades, multiple review articles have summarized existing findings related to sex differences in responses to laboratory pain stimuli. For example, in a 2009 review paper, we concluded that “current human findings regarding sex differences in experimental pain indicate
greater pain sensitivity among females compared with males for most pain modalities, including more recently implemented clinically relevant pain models such as temporal summation of pain and intramuscular injection of algesic substances.\textsuperscript{98} Shortly thereafter, based on examination of largely the same literature, Racine and colleagues\textsuperscript{99} came to the contrasting conclusion that “10 years of laboratory research have not been successful in producing a clear and consistent pattern of sex differences in human pain sensitivity, even with the use of deep, tonic, long-lasting stimuli, which are known to better mimic clinical pain.” In an effort to reconcile these discrepant conclusions, Mogil\textsuperscript{27} conducted a careful analysis of the studies reviewed by Racine and colleagues, and his findings provided strong evidence of higher pain sensitivity among females. In another recent review article, the authors state that existing findings from laboratory pain studies of sex differences “represent trends, but, in most cases, the findings are more nuanced than the conclusions.” So what is one to conclude from these widely varying views of the same literature?

The answer is both simple and complex. Regarding the former, the existing literature shows that sex differences in responses experimental pain stimuli are undeniably consistent in their direction in that females are consistently found to be more pain-sensitive than men. This pattern has been observed for multiple stimulus modalities, numerous body regions, and across all common pain sensitivity measures (i.e., pain threshold, pain tolerance, and suprathreshold pain ratings). In addition, more sophisticated measures of pain modulatory processes have demonstrated greater temporal summation of pain among women versus men, in response to different stimuli, including heat,\textsuperscript{100} cutaneous mechanical,\textsuperscript{101} and pressure stimuli.\textsuperscript{102} Laboratory measures of pain inhibitory function seem to vary somewhat across assessment methods, with men showing greater conditioned pain modulation (CPM),\textsuperscript{103} but sex differences have been less consistent using other assays of pain inhibition.\textsuperscript{98} Findings from studies of children and adolescents reveal a pattern of results that is similar those observed in adults, but the differences in children are generally of lesser magnitude, and sex differences in pain responses are influenced by age, likely reflecting the influence of developmental stage.\textsuperscript{104} Thus, the simple answer regarding sex differences in experimental pain sensitivity is that
women are consistently more sensitive than men. However, the complexity of the issue is reflected in the highly variable magnitude of the sex difference, which suggests important influences of methodologic and contextual factors. For example, brief, repeated thermal stimuli evoke greater temporal summation of pain among females than males, whereas, in response to sustained heat stimuli, females show greater attenuation of pain over time. The study sample can also impact sex differences in pain sensitivity because in addition to sex, multiple individual difference factors are known to influence pain responses, including other demographic factors. For example, race/ethnicity and age are known to affect experimental pain responses; therefore, the age and ethnic diversity of the study sample could influence the magnitude of the sex differences observed. Moreover, a variety of other biopsychosocial variables can impact pain responses, sometimes in a sex-dependent manner, which could modulate the magnitude of observed sex differences in pain sensitivity. Regarding contextual factors, some evidence suggests that experimenter sex/gender may affect pain responses in the laboratory setting, and this could certainly contribute to the inconsistent magnitude of sex differences that have been reported.

Thus, studies of experimental pain reveal a consistent pattern of sex differences, with women showing more robust perceptual responses to painful stimuli than men. However, the magnitude of these differences varies considerably across studies, and the underlying mechanisms remain poorly understood.

RESPONSES TO PAIN TREATMENT
In addition to sex differences in clinical and experimental pain responses, whether women and men respond differently to pain treatment represents a topic of substantial interest. Before reviewing sex differences in treatment efficacy, it is important to consider whether there are differences in the provision of treatment to male and female patients. A gender bias in pain treatment has been previously described, although the patterns of gender differences in pain treatment are complex. Indeed, a systematic review noted that although different pain treatments are often provided to women and men, the evidence does not demonstrate a consistent bias in
A study of veterans typifies this pattern, as the authors found that compared to males, females received pain care that was more consistent with clinical practice guidelines; however, sedatives were prescribed more often for females than males, which is not supported by guidelines. When biases in pain treatment do occur, they emerge from a complex mosaic of factors, including characteristics of both the patient and the provider. In a recent study, after viewing a patient video, specialist physicians and medical students concluded that female patients had less pain and were more likely to exaggerate their pain, and providers were less likely to prescribe analgesics and more likely to recommend psychological treatment for female patients. Using computerized avatars to depict patients with chronic low back pain, Hirsh and colleagues reported that female but not male health care providers and trainees were more likely to prescribe antidepressants and mental health treatments for female versus male patients. Thus, there appear to be some gender-related biases in pain treatment, but these biases are influenced by interactions among multiple contextual factors, including but not limited to the gender of both the patient and the provider.

Another important issue regarding pain treatment is whether the effectiveness of treatments differs for women versus men. The treatment that has been most extensively studied in this regard is opioid therapy. In their meta-analysis, Niesters and colleagues examined whether responses to opioids differed across sex for both acute clinical pain and for experimental pain. Postoperatively, females consumed lower amounts of μ-opioid agonists than males, particularly for morphine administered via patient-controlled analgesia (PCA). The authors speculated that this pattern of results may have emerged because PCA studies often assess opioid use for a longer duration, which may increase detection of sex differences because morphine has a longer duration of action for women. Interestingly, a recent study reported sex differences in the daily rhythmicity of postoperative morphine consumption, with men using more morphine during the night. It should be mentioned that because these findings are based on opioid consumption rather than analgesic efficacy, it is possible that other factors may have contributed to lower consumption.
in women. Indeed, increased side effects, including nausea and vomiting, and unpleasant cognitive-affective effects have been reported for females. However, in experimental studies that directly measure analgesic responses, females showed greater analgesia in response to μ-opioids, with moderate effect sizes, which were larger than those observed for acute clinical pain. The authors also reviewed studies of mixed action opioids (e.g., pentazocine, nalbuphine, butorphanol), and in acute clinical pain, these agents produced considerably more robust analgesia in women. In contrast, studies of these medications tested against experimental pain models showed a striking absence of sex differences in analgesia. The most obvious explanation for these conflicting results lies in the characteristics of the pain models. Specifically, greater analgesic responses in women were observed for acute postoperative pain, which includes a strong inflammatory component, whereas the experimental pain models were decidedly noninflammatory. Taken together, the existing evidence suggests that women exhibit greater analgesic responses to μ-opioid agonists analgesia, whereas mixed-action opioid medications produce greater analgesia in females for postoperative but not experimental pain.

In the last 20 years, prescriptions of opioids for chronic pain have increased dramatically, resulting in a major public health crisis of opioid misuse and overdose in the United States. Very little research has addressed whether males and females with chronic pain respond differently to opioid therapy; however, there is evidence that the opioid crisis is differentially impacting women versus men. Opioids are prescribed more often for women than men, in part due to the excess female prevalence of chronic pain. Although even among individuals with chronic pain, women are more likely than men to use prescription opioids. Also, among people with chronic pain using long-term opioids, women showed poorer overall chronic pain status. However, nonmedical use of opioids is higher for males, as are risks for dose escalation and opioid-related death. Thus, despite more frequent opioid use in women with chronic pain, adverse outcomes are more common among males.

Scant research has addressed sex differences in responses to nonopioid therapies, and the inconsistent results of these studies defies general
conclusions. For example, males exhibited greater analgesic responses to ibuprofen tested against experimental but not postoperative pain. Analgesic responses tested with electrical pain were more robust for males who expected to receive ibuprofen regardless of whether they received ibuprofen or placebo. These findings suggesting that expectations induce greater analgesia in males are paralleled by other laboratory pain studies in which placebo analgesia has been found to be higher among males than females. In contrast, women displayed greater placebo responses in another study, and consistent findings were observed in a pediatric study that demonstrated increased placebo analgesia in girls compared to boys. Additional research elucidating sex differences in placebo analgesia is warranted not only because such information influences clinical trial design and interpretation but also because sex differences in placebo analgesia could reflect sex differences in the engagement of endogenous analgesic mechanisms.

Research investigating sex differences in outcomes from nonpharmacologic pain treatments is even more limited, with variable results. As described in our previous review, some evidence suggests more positive treatment effects in men, others show greater improvements among women; yet, others show similar outcomes across sex. A recent meta-analysis of sex differences in responses to psychological pain therapies in children and adolescents reported that boys and girls generally showed similar treatment responses. Clearly, more research is needed to determine the extent to which nonpharmacologic pain treatments impact males and females differently and whether the mechanisms underlying treatment response differ by sex.

BIOPSYCHOSOCIAL MECHANISMS
The mechanisms responsible for sex differences in pain are complex and incompletely understood. Multiple biologic and psychosocial factors contribute to sex differences in pain, as previously reviewed by multiple authors. Considerable evidence suggests that sex hormones may importantly influence pain responses and the effects of pain medications. For example, both clinical pain severity and experimental pain sensitivity have been found to fluctuate across the
female menstrual cycle. Moreover, use of exogenous hormones, particularly estrogen replacement in postmenopausal women, is associated with greater risk for clinical pain in some studies but not others. However, the association of gonadal hormones with pain appears complex and bidirectional. In contrast to the earlier findings suggesting pain promoting effects of estrogen, other findings imply an antinociceptive role for estrogen. For example, pain-evoked brain responses were attenuated during menstrual phases characterized by high estrogen levels, particularly in brain regions subserving the affective dimension of pain. Moreover, in healthy women, administration of exogenous estrogen reduced muscle pain sensitivity and increased pain-related brain µ-opioid receptor binding. Thus, sex hormones clearly can influence pain responses; yet, the pattern and direction of hormonal effects on pain are complex and remain poorly understood.

Sex differences in pain responses are also influenced by psychosocial variables. Indeed, pain coping has been found to differ by sex, which may contribute to sex differences in both clinical and experimental pain responses. Furthermore, females and males have been found to differ in emotional processes, and affective variables may relate to pain in a sex-dependent manner. Also, traditional masculine versus feminine gender roles may influence pain responses, as the former may promote stoicism, whereas the latter may encourage increased reporting of pain. Experimental studies suggest that both females and males report that willingness to report pain is higher for women than men, and adjustment for willingness to report pain has rendered sex differences in experimental pain responses nonsignificant in some studies. Moreover, traditional gender role measures assessing masculinity and femininity predict lower and higher pain sensitivity, respectively, and men who identified strongly with masculine gender norms had higher pain tolerance than men with low masculine identification. The extent to which such gender roles contribute to sex differences in clinical pain has received little empirical attention.

Ethnic Group Differences in Pain
Racial and ethnic background is another important pain-relevant demographic factor, and there is an increasing need to understand its contribution to individual differences in pain given the growing ethnic diversity of the US population. Indeed, racial and ethnic disparities across multiple health conditions have been well documented, which represents an urgent public health concern.\textsuperscript{156,157} That these ethnic/racial group differences extend to chronic pain conditions is increasingly appreciated.\textsuperscript{158,159} Progress in research addressing racial and ethnic disparities in pain has been impeded by inconsistent definitional and conceptual approaches to studying health and disease across population groups.\textsuperscript{160} Moreover, in contrast to sex differences, where individuals are relatively easily classified into one of two largely mutually exclusive groups, racial and ethnic categories are greater in number and overlap.

**CLINICAL PAIN**

The epidemiology of chronic pain across ethnic and racial groups has not been well characterized. Population-based studies in the United States generally show limited evidence suggesting consistent racial and ethnic differences in prevalence of general chronic pain.\textsuperscript{161} Plesh and colleagues\textsuperscript{162} reported lower incidence of common chronic pain conditions among African American young women compared to non-Hispanic white women. National Health and Nutrition Examination Survey (NHANES) data indicate lower prevalence of chronic pain among Mexican Americans compared to non-Hispanic black and white Americans.\textsuperscript{163} Likewise, findings from the Health and Retirement Study revealed similar prevalence of high-impact chronic pain among Hispanic, non-Hispanic white, and non-Hispanic black adults older than age 50 years.\textsuperscript{164} Using data from the NHIS, Nahin\textsuperscript{165} found that non-Hispanic whites had somewhat higher prevalence of pain, particularly when compared to Asians and Hispanic whites, but group differences were also influenced by language preference. A recent review noted that chronic pain prevalence is generally lower among Hispanic Americans compared to non-Hispanic white and black individuals.\textsuperscript{159} Thus, epidemiologic studies in the United States suggest that chronic pain prevalence may be slightly lower among individuals from minority ethnic and racial groups compared to non-Hispanic whites.
Other studies have moved beyond pain prevalence to examine whether racial and ethnic groups differ in the severity and impact of chronic pain. Studies in several clinical populations have reported greater pain among African Americans compared to non-Hispanic whites, including cancer\textsuperscript{166} and back pain,\textsuperscript{167,168} and in heterogeneous samples of people with chronic pain.\textsuperscript{169–172} Similarly, higher pain levels have been observed among Hispanic patients with chronic pain.\textsuperscript{159,173} Also, higher levels of pain-related disability have been observed among African Americans with back pain.\textsuperscript{174} The most consistent evidence of racial and ethnic differences comes from studies of OA, where African American and Hispanic adults with OA consistently show greater pain and disability than their non-Hispanic white counterparts.\textsuperscript{159,175–177} In addition to these findings derived from clinical samples, community-based research suggests that chronic pain may be more severe among African American and Hispanic individuals compared to non-Hispanic whites.\textsuperscript{178} For example, the prevalence of severe joint pain is higher among these minority groups than in whites.\textsuperscript{179} Not surprisingly, most of the available data have addressed the largest minority groups in the United States (African American and Hispanic); however, some investigators have also reported greater pain severity in other minority groups, including Asian Americans\textsuperscript{180} and Native Americans.\textsuperscript{181} In contrast to these findings, some population-based studies have observed minimal racial and ethnic group differences in chronic pain severity.\textsuperscript{182,183} Most recently, Grol-Prokopczyk\textsuperscript{184} examined data from the Health and Retirement Study and found that after adjusting for confounders, black older adults had lower pain severity than other racial or ethnic groups. Thus, the overall findings are variable, but the evidence suggests that among individuals with chronic pain, African American and Hispanic adults are at risk for more severe pain compared to non-Hispanic whites, with the strongest evidence emerging from studies of OA.

**EXPERIMENTAL PAIN**

Racial and ethnic group differences in clinical pain are influenced by multiple biologic and psychosocial factors. For example, socioeconomic variables (e.g., education and income) are associated with pain and its
impact, and these factors may well contribute to the observed racial and ethnic disparities in pain.\textsuperscript{184–186} Also, undertreatment of pain among African American and Hispanic patients represents another potential contributor to more severe pain in these individuals.\textsuperscript{187} However, patient-level factors, such as group differences in pain perception, could potentially play a role in the observed differences in clinical pain severity. In this regard, numerous studies have investigated racial and ethnic differences in pain responses using quantitative sensory testing. These findings have been summarized in two relatively recent meta-analyses. Rahim-Williams and colleagues\textsuperscript{188} reviewed findings from studies examining experimental pain responses in African Americans versus non-Hispanic whites. They concluded that African Americans displayed lower pain thresholds and tolerances, suggesting greater pain sensitivity. Effect sizes were generally small to moderate for group differences in pain threshold, but moderate to large for pain tolerance. A subsequent meta-analysis corroborated and extended these findings, concluding that African American, Hispanic, and Asian adults showed greater experimental pain sensitivity compared to non-Hispanic whites.\textsuperscript{189} These findings demonstrate group differences in pain sensitivity; however, whether these experimental findings contribute to group differences in clinical pain remains unknown. Interestingly, we previously observed that African Americans reported higher levels of OA-related pain and disability as well as greater experimental pain sensitivity than non-Hispanic whites.\textsuperscript{190} We also found that the relationship of pain sensitivity to clinical pain differed across race groups. Specifically, thermal pain sensitivity was related to clinical pain among non-Hispanic whites, whereas mechanical pain responses were associated with clinical pain among African Americans.

**RESPONSES TO PAIN TREATMENT**

Racial and ethnic group differences in clinical pain could in part be driven by differences in the provision or effectiveness of pain treatments. Several lines of evidence suggest that analgesic interventions are provided at lower doses and lower frequency for African American and Hispanic patients compared to non-Hispanic whites,\textsuperscript{158,191–193} although some studies have shown no such disparity.\textsuperscript{194–198} One recent emergency department study
reported no race group differences in administration of any analgesic treatment; however, African Americans were less likely than whites to receive an opioid for low back pain but not long bone fracture. Regarding opioid prescriptions for chronic pain, North Carolina Medicare claims data revealed that black patients were significantly less likely to have filled an opioid prescription. In contrast, data from the National Ambulatory Medical Care Survey showed that among patients with chronic pain, non-white individuals were more likely to have been prescribed an opioid. Potential race differences in opioid treatment may be influenced by other factors. For example, Burgess and colleagues found that among veterans with chronic pain, younger blacks were less likely to receive opioids, whereas older blacks were more likely to receive opioids, compared to whites. These clinical findings have been corroborated by experimental studies demonstrating that patient race influences decisions about analgesic treatments for chronic pain.

Limited research has addressed whether effectiveness of analgesics differs across racial or ethnic groups. More than 30 years ago, Kaiko and colleagues reported greater analgesic responses to morphine among African American patients with cancer-related chronic pain compared to white patients. Similarly, we found that African Americans exhibited more robust analgesia in response to both morphine and butorphanol using experimental pain stimuli to test analgesic efficacy. Regarding opioid side effects, white patients showed greater opioid-induced nausea and vomiting than black patients.

Given increasing concerns about opioid misuse and adverse outcomes, the possible importance of patient race and ethnicity in use of prescription opioids warrants some discussion. Among high school seniors, whites were significantly more likely to report both medical and nonmedical use of opioids compared to African Americans and Hispanics. In the primary care setting, opioid risk reduction strategies were more often implemented for black than for white patients. In contrast, white patients were more likely to be on a pain treatment agreement in one study but not another. Also, in this Veteran Affairs study, black veterans underwent significantly more urine drug tests than whites and were less likely to be referred to a pain specialist and more likely to be
referred to a substance abuse specialist. These findings suggest that race and ethnicity may impact the efficacy of opioids, as well as providers’ behaviors related to opioid prescription, which could influence patterns of medical and nonmedical use in the general population. More research is needed to elucidate these issues.

**BIOPSYCHOSOCIAL MECHANISMS**

Consistent with sex differences, multiple biologic, psychological, and social factors contribute to racial and ethnic group differences in pain. The limited information related to biologic mediators of racial and ethnic differences in pain derives primarily from laboratory studies. For example, several biologic markers of stress reactivity appear to be more strongly associated with lower pain sensitivity among white versus African American individuals, implicating neuroendocrine responses in racial and ethnic differences in pain perception. In a study of patients with knee OA, African Americans had lower vitamin D levels than non-Hispanic whites, and vitamin D mediated the greater mechanical and heat pain sensitivity observed in African Americans. Genetic factors represent another potential biologic contributor to racial and ethnic group differences in pain, as discussed further in text. Thus, although limited, some evidence implicates biologic factors in racial and ethnic group differences in pain.

Several psychological and social factors also may contribute to race group differences in the experience of pain. For example, differences in pain coping have been observed across racial and ethnic groups. A recent meta-analysis found that black individuals used pain coping strategies more frequently overall compared to whites, particularly praying and catastrophizing, whereas white individuals engaged in higher levels of task persistence. These authors subsequently conducted a study of experimental pain responses and found that the rumination component of pain catastrophizing mediated the lower pain tolerance of black participants. Social factors also represent important drivers of variation in pain responses both within and between racial and ethnic groups. Lower socioeconomic status has been associated with increased risk for pain, and some findings suggest that race differences in pain are accounted for by
the lower SES of certain minority groups.\textsuperscript{164,184} Also, experiences of discrimination are a source of chronic stress that occurs more frequently among minority groups, and discrimination has been associated with increased pain severity.\textsuperscript{218–221} In a sample of adults with knee OA, we found that African Americans reported more experiences of discrimination compared to whites, and discrimination mediated the lower heat pain tolerance observed among African American individuals.\textsuperscript{222} Additional research is needed to further characterize the influence of social factors on pain responses and ethnic group differences therein.

**Genetic Contributions to Pain**

The genomic revolution spurred substantially increased interest in understanding how individual differences influence health, including pain, such that considerable research has addressed genetic contributions to individual differences in pain. The following discussion text highlights several examples of genetic associations with pain, including interactions between genetics and other individual differences factors, such as sex and racial or ethnic group. For more detailed reviews of this literature, the reader is referred elsewhere.\textsuperscript{223–228}

**CLINICAL PAIN**

Increasing evidence from human research documents the importance of genetic influences in numerous clinical pain conditions. Twin studies, which estimate genetic contributions by comparing disease concordance rates for monozygotic versus dizygotic twins, demonstrate significant heritability for several common chronic pain conditions, including back pain, neck pain, headache, arthritis, CWP, and abdominal pain.\textsuperscript{229–233} Numerous candidate gene studies and an increasing number of genome-wide association studies have identified specific genes that are associated with certain pain conditions\textsuperscript{228}, however, these findings are often marked by small effect sizes and nonreplication.\textsuperscript{234,235} Genetic associations could reflect the pathophysiologic processes of specific diseases that produce pain. For example, genes involved in cartilage biology could be associated with OA pain. Alternatively, genetic influences on pain perception or
endogenous pain modulation could potentially underlie genetic associations with chronic pain conditions. This possibility is bolstered by findings that many of these heritable pain syndromes are characterized by enhanced pain sensitivity and/or altered endogenous pain modulation.\textsuperscript{223,236} Indeed, a recent review identified several genes that have been associated with multiple chronic overlapping pain conditions across multiple studies. These genes primarily reflect biologic systems involved in pain processing, including catecholaminergic, serotonergic, and opioidergic function.\textsuperscript{95}

**EXPERIMENTAL PAIN**

Abundant preclinical research implicates genetic factors in both nociceptive sensitivity and responses to analgesic drugs, and growing evidence from studies of experimental pain indicates important genetic contributions to human pain sensitivity.\textsuperscript{27,227,237} The first twin study of experimental pain response estimated the heritability of pressure pain threshold to be 10%, suggesting minimal genetic contribution.\textsuperscript{238} However, statistical power in twin studies is often insufficient for multifactorial traits like pain sensitivity, and twin pairs were tested together in unblinded fashion in this study, likely increasing the effect of nongenetic factors. Subsequent twin studies of experimental pain responses reported heritability estimates ranging from 22\% to 60\% across different pain modalities, including heat pain, cold pain, and chemically induced pain.\textsuperscript{12,15,239} Candidate gene approaches have identified several genes associated with experimental pain responses across multiple studies. The following discussion highlights three genes that have been associated with pain in numerous cohorts and across several pain phenotypes. It is important to note that although these genes have been associated with pain in multiple studies, numerous investigators have failed to find associations, as is common in genetic research, due to relatively small effect sizes and differences in methodology and study samples. Interested readers can find additional information in several recent reviews.\textsuperscript{223–225,227}

The gene that encodes catechol-O-methyl-transferase (COMT), an enzyme that metabolizes catecholamines, has been the most frequently examined gene in pain studies. A commonly studied COMT single
nucleotide polymorphism (SNP) involves the substitution of valine by methionine at codon 158 (val158met). This SNP produces a thermally unstable enzyme resulting in lower enzymatic activity. Zubieta and colleagues\textsuperscript{240} investigated this SNP using a model of facial pain produced by injection of hypertonic saline into the masseter muscle. Individuals carrying the val/val genotype required a larger dose of hypertonic saline to produce moderate pain, suggesting that the val/val genotype confers lower pain sensitivity. Moreover, using positron emission tomography, the investigators found that the val/val genotype group showed significantly greater pain-related brain µ-opioid receptor activation, which indicates more robust endogenous opioid-mediated pain inhibition. Subsequently, Diatchenko and colleagues\textsuperscript{13} identified three COMT haplotypes which were associated with experimental pain sensitivity in healthy young women. Interestingly, the haplotype that predicted lower pain sensitivity also was protective against future development of painful TMD. COMT has been associated with experimental pain sensitivity in several other studies\textsuperscript{241–243} as well as with risk for or severity of clinical pain.\textsuperscript{244,245}

Another frequently studied candidate gene is OPRM1, which encodes the µ-opioid receptor. The A118G SNP produces an amino acid substitution whose functional effects include altered binding affinity for β-endorphin\textsuperscript{246} and changes in messenger RNA expression and protein yield.\textsuperscript{247} The G allele has been associated with lower pressure pain sensitivity,\textsuperscript{248} lower heat pain sensitivity,\textsuperscript{249} and reduced pain-related evoked potential responses.\textsuperscript{250} Regarding clinical pain, the G allele has shown lower frequency among patients with chronic pain compared to controls.\textsuperscript{251,252} Also, patients homozygous for the A allele showed greater day-to-day pain variability compared to those with at least one G allele.\textsuperscript{253} In addition to associations with experimental and clinical pain phenotypes, OPRM1 may influence opioid analgesic responses. Recent meta-analytic reviews have found that carriers of the G allele of A118G require significantly higher postoperative opioid doses compared to patients homozygous for the A allele.\textsuperscript{254,255} Also, the G allele was protective against morphine-induced respiratory depression following spine surgery.\textsuperscript{256} G allele carriers also showed higher morphine requirements for management of cancer pain.\textsuperscript{257} Thus, the A118G SNP of OPRM1 has been
consistently associated with basal pain sensitivity and opioid requirements.

The GCH1 gene has also been associated with pain responses in multiple studies. GCH1 encodes an enzyme (GTP cyclohydrolase or GCH) which is involved in production of tetrahydrobiopterin (BH4). BH4 is a cofactor involved in biosynthesis of several neurotransmitters, including serotonin, dopamine, and norepinephrine. Tegeder and colleagues\textsuperscript{258} observed that upregulation of GCH and BH4 contributed to neuropathic and inflammatory pain in rodents. In a translational effort, these findings were extended to humans when a haplotype of the GCH1 gene was found to be associated with lower levels of persistent pain following lumbar surgery for disk herniation and with reduced experimental pain sensitivity among healthy adults. Since this original paper, several studies have reported associations of GCH1 with various pain phenotypes, including capsaicin-induced pain\textsuperscript{259} and hyperalgesia,\textsuperscript{260} HIV-associated neuropathic pain,\textsuperscript{261} and outcomes following surgery for lumbar disk disease.\textsuperscript{262}

### Interactions among Individual Difference Factors

The earlier discussion addresses each individual difference factor independently; however, it is important to recognize that these and many other individual difference variables interact to influence pain responses. Unfortunately, such interactions are often not considered in research design and analysis. Indeed, although pain responses have been shown to differ markedly by sex and race, whether these two demographic factors interact to influence pain remains largely unexplored. On the other hand, interactions between genetic factors and sex have been examined in several studies. For example, a previous twin study reported that the heritability of neck pain was significantly higher among females (51%) compared to males (33%).\textsuperscript{263} In a study of experimentally induced pain, the OPRM1 gene interacted with sex to predict ratings of heat pain, such that the G allele was associated with lower pain ratings for men but higher ratings among women.\textsuperscript{248} Interestingly, these findings were subsequently replicated in a clinical cohort in which the G allele predicted improved 12-month outcomes from lumbar disk herniation among men but worse
outcomes among women.\textsuperscript{264} Sex-dependent genetic associations have also been reported for both COMT and GCH1,\textsuperscript{242,265} which further reinforces the importance of incorporating both males and females into study samples and considering potential interactions in the analytic approach.

Interactions between genes and racial or ethnic background have received far less attention, which is somewhat surprising given that allele frequencies for many SNPs are known to differ notably based on racial and ethnic background.\textsuperscript{266–269} Regarding genes relevant to pain research, it has been reported that allele frequencies for the A118G SNP of OPRM1 differ across ethnic groups, such that minor (G) allele frequency is substantially lower among African Americans compared to other racial and ethnic groups.\textsuperscript{270,271} Because the G allele has been associated with lower pain sensitivity\textsuperscript{248,249} and higher morphine requirements,\textsuperscript{254,255} it is plausible that the previously reported increased pain sensitivity\textsuperscript{188,189} and reduced morphine requirements\textsuperscript{17,206} among African Americans could be due in part to the lower frequency of this minor allele of OPRM1. However, this speculation requires empirical confirmation. Beyond ethnic group differences in allele frequencies, an interaction could emerge if the strength or direction of a genetic association with a pain phenotypic differed across racial or ethnic groups. One such example emerged from a study examining associations of the A118G SNP of OPRM1 with experimental pain responses.\textsuperscript{271} The investigators report that Hispanic and non-Hispanic whites show similar minor allele frequencies; however, a gene by ethnic group interaction emerged. Specifically, the G allele was associated with lower pain sensitivity among non-Hispanic whites but with higher sensitivity among Hispanic participants. These findings highlight the importance of increasing the racial and ethnic diversity of samples used for genetic association studies and exploring potential race/ethnicity by genetic interactions in these designs.

Although psychological contributions to pain are beyond the scope of this chapter, it is important to consider interactions between psychological factors and other individual difference variables. For example, the COMT gene has been found to interact with pain catastrophizing to explain variability in both clinical and experimental models of shoulder pain. Specifically, among individuals with a high pain sensitivity COMT
haplotype, catastrophizing is associated with greater pain severity or duration.\textsuperscript{272–276} Another COMT by psychology interaction emerged from the Orofacial Pain Prospective Evaluation and Risk Assessment (OPPERA) study. Using a prospective design that included repeated measurements of perceived stress, these investigators found that increasing stress over time predicted development of TMD but only among people with a COMT haplotype that conferred low COMT activity.\textsuperscript{277} Thus, stress-related increases in risk for TMD were observed only among those individuals whose COMT genotype would result in greater catecholaminergic drive.

\section*{Conclusion}

Pain and analgesic responses are characterized by tremendous individual differences, which are driven by a complex mosaic of biologic and psychosocial factors. This chapter highlights the contributions of sex, racial and ethnic group, and genetic factors and their interactions. Females are at greater risk for clinical pain and show higher sensitivity to experimental pain compared to males. Some evidence also suggest that women show greater analgesic responses to µ-opioids. Racial and ethnic group differences in pain are more nuanced. Pain prevalence does not appear to differ greatly by racial or ethnic group, although some evidence suggests lower prevalence in minority groups compared to whites. However, among individuals experiencing chronic pain, African Americans and Hispanics generally reported greater pain and disability compared to their non-Hispanic white counterparts. African American and Hispanic individuals also display greater experimental pain sensitivity. These sex and racial/ethnic group differences are driven by multiple biologic and psychosocial mechanisms, and it is important to recognize that within-group differences are always greater than differences between groups. Additional research is needed to explain within-group variability in pain responses, especially considering that the mechanisms contributing to pain responses may differ substantially from one group to another. Thus, in addition to their role as individual differences factors, demographic group variables (e.g., sex, race group) may also moderate the
effects of other pain-related individual difference factors. An important goal of research on individual differences in responses to pain and its treatment is to enable a priori predictions of an individual’s projected pain experience or treatment response, which would inform personalized pain management. Ultimately, greater appreciation of the importance of individual differences in pain and continued research to elucidate the underlying biopsychosocial mechanisms will propel advancement toward improved diagnosis and treatment of pain.

From the standpoint of the physician, there are two perspectives from which to view pain. One is as a symptom of a disease process that will inform about the underlying pathophysiology. The other is as the primary cause for suffering that requires treatment in its own right. These two views of pain often coexist when the pain reveals pathology whose treatment will not resolve the pain rapidly enough for the patient to tolerate. For example, in acute myocardial ischemia, the pain is the cardinal symptom of the underlying illness but in itself can provide an ongoing stimulus for a catecholaminergic state that will increase myocardial demand and potentially worsen the ischemic state. Both of these perspectives, either using the pain as a clue or addressing it as the primary aim of treatment, are enhanced by considering the patient’s report of their pain in light of the specific anatomic structures that collect information about noxious stimuli and communicate this information to the central nervous system (CNS) where pain is perceived and behavioral responses are generated.

Pain may be grouped according to several different parameters including acute versus chronic, physiologic versus pathologic, and somatic versus visceral. Full understanding of the nature of any pain complaint requires knowledge of the anatomic structures involved and the functional status of these structures. Chronicity of pain is determined by the duration of the irritating stimulus and by the plastic response of the peripheral and CNS to injury or ongoing stimulus. Pain may be either nociceptive, induced by high-threshold sensory stimuli required for activation of peripheral nociceptors, or pathologic, induced by low-threshold stimuli
due to a heightened state of nervous system excitability brought on by either inflammatory cell–cell signaling (i.e., inflammatory pain) and signal transduction or by the extensive anatomic and physiologic alterations brought on by nerve injury (i.e., neuropathic pain). Finally, pain may be somatic, transmitted by the somatosensory nervous system, or visceral, transmitted by splanchnic sympathetic and pelvic nerve afferent fibers (or by specific cranial nerves in the case of the head and neck). This chapter touches on the specific anatomic structures that are involved in the transduction of physical stimuli into sensory responses, the conduction of sensory information to the CNS, and the processing and relay of this sensory information within the spinal cord and brain and discusses some of the major perturbations in these structures as related to clinical pain phenomena.

**Organization of the Peripheral Nociceptive System**

There are several major anatomic units involved in pain sensation. First, primary sensory neurons whose peripheral terminals respond to physical energy conduct action potentials along long axons bundled into peripheral nerves from the site of sensory stimulus to the CNS. Next, nociceptive synaptic relay occurs at the dorsal horn of the spinal cord, where substantial sensory processing occurs. Ascending fiber tracts carry this information to the brainstem and, from there, diverse brain regions. Descending fiber tracts project from the brainstem and brain to the dorsal horn of the spinal cord and regulate the processing of incoming sensory information.

The peripheral nerves that carry sensory information from visceral organs, bone, muscle, joint, or skin to the CNS may be either cranial nerves or spinal nerves. Cranial nerves carry sensory information to the brainstem, whereas spinal nerves carry sensory information to the spinal cord and may bear axons for neurons that synapse within the spinal cord or brainstem. Spinal nerves are mixed nerves that carry general somatic afferent fibers, general visceral afferent fibers, general somatic efferent fibers, and general visceral efferent fibers. Somatic afferents primarily carry information from skin, muscle, tendon, and joint, whereas visceral
afferents carry information from the other tissues. The cell bodies of both
the somatic and the visceral afferent fibers carried by spinal nerves reside
in the dorsal root ganglia (DRG) of the spinal cord, whereas those carried
by cranial nerves reside in the brainstem cranial nerve nuclei.\textsuperscript{12}

The ability to localize painful stimuli depends on the topographic
organization of the nervous system. The somatic afferent system and the
visceral afferent system are strikingly different in this regard, with precise
stimulus position detected and encoded by the somatic nervous system but
only relatively diffuse information coming to conscious awareness from
the visceral afferent system.\textsuperscript{4} In the clinical setting, precise localization of
pain is often considered as evidence that the pain is detected by somatic
afferents rather than visceral afferents. For example, knifelike well-
localized pain associated with inspiration is likely detected by somatic
fibers innervating the parietal pleura.\textsuperscript{13} In the abdomen, well-localized
lower right quadrant pain occurring late in the course of acute appendicitis
is likely due to spread of the periappendiceal inflammation that irritates the
somatic nerves innervating the abdominal wall overlying the appendix.\textsuperscript{14}

In the somatic system, the spinal cord is segmentally organized, such
that each spinal segment receives afferent information about a specific
cutaneous band or dermatome (Fig. 9.1).\textsuperscript{15} This organization arises during
embryonic development when the embryonic neural tube and adjacent
mesodermal tissues segment into a series of rostrocaudally adjacent
somites.\textsuperscript{16} Each spinal nerve innervates tissue developing from a single
somite.\textsuperscript{17} Spinal nerves from several different spinal segments, such as
axons from neurons with cell bodies located in several different DRG, join
to give rise to peripheral nerves with cutaneous fields of innervation that
span multiple dermatomes (Fig. 9.2).\textsuperscript{18} The innervation of specific
 peripheral cutaneous nerves, as compared to the organization of the
cutaneous dermatomes, is illustrated (Fig. 9.3).
FIGURE 9.1 The dermatomes developed by Bonica on basis of personal observation and data published by others. See text for description.
FIGURE 9.2 Simple diagrams to illustrate the overlap of cutaneous fields of segmental and peripheral nerves. In the upper figure, three intercostal (segmental) nerves extending from the periphery to the spinal cord are represented. The lower figure illustrates a somewhat analogous but less extensive overlap in the peripheral nerves.
Although there are many anatomic similarities between the somatic and autonomic afferent fibers, there are significant differences in the clinical presentation of visceral pain and somatic pain. Visceral pain is perceived as deep and is typically not well spatially localized. The clinical features of visceral as compared to somatic pain are summarized in Table 9.1. Pain symptoms resulting from visceral afferents are felt in a location different than the organ itself, such as the experience of arm pain with myocardial infarction. A possible explanation for the clinical symptoms of referred pain is that peripheral nociceptors from somatic and visceral origin converge on a single projection neuron in the dorsal horn. As a result, higher levels of the CNS cannot distinguish the source of the signal input and attribute the sensation to somatic structures by default because somatic sensory representation predominates in the CNS. Convergence occurs in the dorsal horn neurons in laminae I, IV, and V as well as in the intermediate gray matter in lamina X (Fig. 9.4) as well as other areas of the CNS including the brainstem, basal forebrain, thalamus, and cerebral cortex. Functional neuroimaging studies have shown that regions of the cortex that are activated by noxious stimuli can also be activated by visceral stimuli. In the thorax, substernal chest pain may be due to any of the visceral sensory afferents from the T1 to T6 spinal segments and may arise from the heart and great vessels, esophagus, lungs, or chest wall. Visceral pain in the abdomen tends to follow the structure of endodermal embryonic development with pain due to foregut structures (stomach, proximal duodenum, liver, biliary system, and pancreas) perceived in the epigastrium or upper abdomen, pain due to midgut structures (distal duodenum, small bowel, cecum, appendix, ascending colon, and proximal transverse colon) perceived in the periumbilical region, and pain due to hindgut structures (distal transverse colon, descending colon, sigmoid, rectum, and urinary bladder) perceived in the lower abdomen.

The central processes of the visceral fibers synapse extensively above and below the segment where they entered, thus activating spinothalamic cells at multiple levels. Clinically, noxious stimulation of the viscera elicits an autonomic spinal reflex reaction, with sympathetic activation that causes symptoms such as excessive sweating and pronounced changes in circulatory system resulting in increased blood pressure. This reflex
reaction tends to be more pronounced than what is seen with noxious stimulation of the skin. Noxious visceral stimulation can also result in hypotension and bradycardia by either reflex inhibition of sympathetic outflow or activation of the parasympathetic nervous system. These reactions may be mediated by the periaqueductal gray matter (PAG) and the nucleus of the solitary tract. There are also protective reflexes that are directed toward reducing pain, such as the inhibition of visceral motility. Deregulation of this reflex as well as aberrant response by vagal afferents in the enteric system is thought to contribute to the pathophysiology of irritable bowel syndrome. Coordination centers at higher levels of the CNS, such as the PAG, also mediate nausea and vomiting as well as complex somatic responses in the context of visceral pain.

Peripheral Nervous System Structures of Pain Sensation

Among the primary afferent neurons of the peripheral nervous system, there are several neuronal populations classified primarily according to caliber and myelination and secondarily according to the expression of chemical markers. Large myelinated fibers comprise the A-beta (Aβ) population, which respond predominantly to low-energy, nonpainful mechanical stimuli and conduct action potentials rapidly. Small, thinly myelinated fibers make up the A-delta (Aδ) population, which respond to high-energy mechanical stimuli and have intermediate conduction velocity. Small, unmyelinated fibers are classified as the C-fiber population and have slow conduction velocity. In general, C fibers can respond to chemical, thermal, and high-threshold mechanical stimuli, with several subclasses of C fibers exhibiting responses to various combinations of these stimulus categories. Typical of electrically excitable cells, the conduction of action potentials along the axons of primary afferent sensory neurons depends on voltage-gated ion channels. The inward current of the action potential is carried by voltage-gated sodium ion channels. There are six types of these in the DRG neurons of which two, Nav1.8 and Nav1.9, have expression pattern limited to sensory neurons, with Nav1.8 limited to nociceptors.
C-fiber neurons are further subdivided into two groups. One group expresses the nerve growth factor (NGF) receptor TrkA, as well as the neuropeptides substance P and calcitonin gene-related peptide (CGRP), whereas the other group of C fibers expresses the glial derived neurotrophic factor receptor c-ret and binds to the isolectin B4 (IB4).\textsuperscript{33,34} Interestingly, recent data has demonstrated that the free nerve endings in the epidermis are anatomically structured such that the peptidergic fibers terminate in the stratum spinosum, whereas the nonpeptidergic fibers terminate in the more superficial stratum granulosum.\textsuperscript{35} This topographic separation is maintained at the level of the dorsal horn of the spinal cord, where the peptidergic and nonpeptidergic afferents terminate in distinct Rexed laminae.

The peripheral terminals of DRG neurons are specialized to respond to thermal, mechanical, or chemical energy. Briefly, thermosensation depends on thermosensitive ion channels in the transient receptor potential (TRP) family, with TRPV1 and TRPV2 responsive to heat that is usually perceived as painful.\textsuperscript{36,37} Recently, a specific inhibitor of TRPV1 has been identified that may eventually prove to have a role as a pain-specific local anesthetic agent.\textsuperscript{38} Mechanosensation likely also depends on a set of mechanosensitive ion channels; however, the receptors responsible for transducing this information have yet to be unequivocally identified.\textsuperscript{39–41} A wide range of chemical mediators can also act on the peripheral terminals of DRG neurons, acting either directly to activate nociceptors or indirectly by sensitizing the peripheral terminals to be activated at a lower stimulus threshold. Chemical mediators may be either exogenous (e.g., capsaicin, mustard oil, chemical acids, bee venom) or endogenous (e.g., many of the myriad inflammatory mediators). Endogenously released chemical mediators that cause pain directly are typically associated with tissue destruction that alters the chemical microenvironment, for example, H+ ions and adenosine triphosphate, or causes an inflammatory response, such as bradykinin.\textsuperscript{42,43}

**Functional Anatomy of the Central Nervous System**

Pain is defined by not only the physiologic perception of nociception but
also the affective and emotional response to that perception. Pain is a highly individual and subjective experience to the extent that the same stimulus can produce different responses in different individuals under the same conditions. The CNS is both the processing center for the perception of noxious stimulation and the primary regulator of adaptive and modulatory mechanisms to produce a pain behavior. Pain is primarily categorized by duration of symptoms (acute vs. chronic) and the origin of the pain signal (visceral vs. somatic and nociceptive vs. neuropathic). Understanding the anatomy and function of the pain structures and pathways in the CNS is essential to understanding and managing the different categories of pain.

**DORSAL HORN**

The dorsal horn represents the termination point of the dorsal root in the CNS. There is a correspondence between the functional and anatomic organization of the dorsal horn. It is arranged into 10 laminae, and distinct sensory modalities from the periphery terminate in distinct laminae (see Fig. 9.4). Signals conducting nociceptive signals (Aδ and C fibers) terminate in the superficially located laminae I (also called the marginal layer) and II (also called the substantia gelatinosa). Many neurons from lamina I respond exclusively to noxious stimulation and project to higher levels of the CNS. Some neurons called wide dynamic range neurons respond in a stepwise fashion to peripheral stimulation. The neurons of lamina II are mostly interneurons and modulate nociceptive responses at the level of the dorsal horn. The Aδ fibers also terminate in lamina V which contains wide dynamic range neurons that project to higher levels of the CNS including the thalamus. There is some convergence of somatic and visceral nociceptive input into lamina V, which may explain referred pain from visceral structures. Single axons of all receptors give off ascending and descending branches after entering the spinal cord. In addition to synapsing at the level they enter, these branches give off multiple collaterals that end in the gray matter of the dorsal horns at one to two levels above and below where the axon entered the spinal cord. Integration of signals from the periphery and higher levels of the CNS occur at the level of the dorsal horn through the dense network of dendrites.
Synaptic transmission by nociceptive afferent neurons at the level of the dorsal horn is mediated primarily by the excitatory neurotransmitter glutamate. Both ionotropic and metabotropic glutamate receptors are located in high concentration in the substantia gelatinosa. Many neuropeptides (e.g., substance P, vasoactive intestinal polypeptide, cholecystokinin, and CGRP), which are theorized to modulate synaptic action, are present in the neurons in the dorsal horn. The receptors for most of these neuropeptides are concentrated in the substantia gelatinosa, which suggests that they are involved in the transmission of pain. Among the neuropeptides, substance P and its receptor, neurokinin 1, are likely to be involved in the processing and modulating of pain signals in the dorsal horn. Substance P may increase the excitation from incoming sensory fibers by enhancing and prolonging the actions of glutamate. This has been demonstrated experimentally: Substance P and CGRP have been found to increase the release of glutamate; substance P induces the N-methyl-D-aspartate (NMDA) receptors to become more sensitive to glutamate. This unmasks normally silent interneurons and sensitizes second-order spinal neurons. Blocking the neurokinin 1 receptors can prevent many of these effects. Substance P can also extend long distances within the spinal cord and sensitize dorsal horn neurons several segments away from the initial nociceptive signal. This results in an expansion of receptive fields and the activation of wide dynamic neurons by nonnociceptive afferent impulses.

Sustained noxious stimulation or high-intensity nociceptive signals to the dorsal horn neurons may lead to increased neuronal responsiveness or central sensitization. Hyperalgesia, which is an exaggerated perception of painful stimuli, is at least partially mediated through low-threshold mechanoreceptors (Aβ afferents) in the dorsal horn. Allodynia, which is a perception of innocuous stimuli as painful, is mediated through high-threshold nociceptors (Aδ or C fibers) in the dorsal horn. The factors that contribute to these hyperexcitable states include altered function of neurochemical and electrophysiologic systems as well as changes in the anatomy in the dorsal horn.

“Wind-up” refers to a central spinal mechanism in which repetitive noxious stimulation results in a slow summation of these signals that is
experienced as increased pain. The amplification of the pain signal occurs in the spinal cord when nociceptive C fibers synapse on the dorsal horn nociceptive neurons activating the NMDA receptors. A cascade of events ensues with the activation of nitric oxide synthase. This ultimately leads to enhance the release of sensory neuropeptides, including substance P, from presynaptic neurons, contributing to the development of hyperalgesia and maintenance of central sensitization. Wind-up can be elicited if identical nociceptive stimuli are applied at a frequency of 3 seconds or less.

**SPINOThALAMIC TRACT**

Prior to synapsing in the dorsal horn of the spinal cord, C and Aδ fibers may ascend or descend one to two spinal levels, forming a tract dorsal to the dorsal horn called the tract of Lissauer (Fig. 9.5); Lissauer’s tract also contains axons of interneurons that may travel for several spinal segments. Following synapsing of the central projections of C and Aδ afferents, the axons of many of the second-order neurons cross the midline, forming the lateral spinothalamic tract which ascends without interruption from the dorsal horn through the brainstem to the thalamus. This somatotopically organized tract carries information from neurons about the location, intensity, and duration of nociceptive stimuli. This tract is also responsible for relaying the sensation of temperature and, to a lesser extent, it transmits touch and pressure sensation. A large proportion of the neurons that contribute fibers to the lateral spinothalamic tract originate in lamina I. There is also a dorsally located spinothalamic tract arising ipsilaterally from lamina I neurons, although this projection of second-order nociceptive neurons is less well described.
FIGURE 9.5 Simple diagram of the course and termination of the spinothalamic tract. Most of the fibers cross to the opposite side and ascend to the brainstem and brain, although some ascend ipsilaterally. The neospinothalamic part of the tract has cell bodies located primarily in laminae I and V of the dorsal horn, whereas the paleospinothalamic tract has its cell bodies in deeper laminae. The neospinothalamic fibers ascend in a more superficial part of the tract and project without interruption to the caudal part of the ventroposterolateral thalamic nucleus (VPL), the oral part of this nucleus, and the medial part of the posterior thalamus (PO). In these structures, they synapse with a third relay of neurons, which project to the somatosensory cortex (SI, SII, and retrosensory cortex) (solid lines). Some of the fibers of the paleospinothalamic tract pass directly to the medial/intralaminar thalamic nuclei, and others project to the nuclei and the reticular formation of the brainstem and thence to the periaqueductal gray matter (PAG), hypothalamus (H), nucleus submedius, and medial/intralaminar thalamic (MIT) nuclei. Once there, these axons synapse with neurons that connect with the limbic forebrain structure (LFS) via complex circuits and also send diffuse projections to various parts of the brain (dashed lines).

Lamina V also contributes a large group of neurons to the spinothalamic
tract mostly composed of Aδ fibers. The anterior spinothalamic tract, which conveys information about the location of nociception, is largely composed of fibers from laminae VII and VIII. Conversely, lamina II sends very few fibers to the spinothalamic tracts despite being the destination for many C fibers. The fibers from lamina II modulate the spinothalamic cells in laminae I, V, VII, and VIII at the level of the nociceptive input as well as at spinal segments above and below via spinal interneurons that travel in the tract of Lissauer. This complex mesh of interneurons plays a significant role in determining whether signals from nociceptors will be propagated to higher levels of the nervous system or be inhibited. Spinal interneurons modulate the intensity of a stimulus and also establish connections with other spinal neurons to form somatic and autonomic reflex arcs at the level of the spinal cord. Whereas interruption of the spinothalamic tract results in immediate loss of pain and temperature perception in the contralateral side of the body, injuries of the spinothalamic tract can develop into central pain (CP) syndromes.

Nociceptive afferents from visceral organs and somatic structures terminate in the same population of spinothalamic cells in the spinal cord, which in turn synapse in the thalamus. The convergence of nociceptive signals in the spinal cord is segmentally arranged and may account for pain from visceral organs being referred to somatic structures; this topic is discussed in more detail later in the chapter. There are several other ascending tracts that supply nociceptive signals to higher levels of the CNS. The spinoreticular tract transmits nociceptive signals on the ipsilateral side of the spinal cord. This tract is clinically important as it may explain the persistence of pain after an anterior cordotomy.

**THALAMUS**

The majority of the second-order lateral spinothalamic tract fibers terminate in the lateral nuclear group of the thalamus which contains both the ventroposterior lateral (VPL) nucleus and the ventroposterior medial (VPM) nucleus. The VPL nucleus of the thalamus receives information from the lateral spinothalamic tract, whereas the VPM nucleus receives sensory information from the spinal trigeminal nucleus, which transmits sensory information from the face (Fig. 9.6). Spinothalamic fibers also
terminate in areas of the intralaminar nuclei and in the mediodorsal nucleus. These fibers transmit signals to the limbic system which integrates autonomic and arousal responses and attention to the perception of pain. Many of the fibers originating in lamina I terminate in the ventromedial (VM) nucleus. Most of the neurons in VM are activated by nociceptors. Lesions of the thalamus, such as stroke, can result in severe CP syndromes on the contralateral side of the body.

FIGURE 9.6  Schematic diagram of the human thalamus. A: Superior view. B: Lateral view shows the locations of the most important nuclei. C: Frontal section of the anterior part of the thalamus depicts the relationships of various nuclei. D: Frontal section of the middle part of the thalamus. Note that the spinothalamic tract and medial lemniscus terminate in nucleus (N.) ventralis posterolateralis, whereas the trigeminothalamic tract terminates in N. ventralis posteromedialis.

With the exception of olfaction, all sensory pathways traveling from the periphery to the cerebral cortex synapse in the thalamus. The spinothalamic fibers terminate in multiple areas of the thalamus and subsequently are relayed to different areas of the cortex. VPL/VPM supplies the primary and secondary somatosensory cortex (S1, S2) with nociceptive signals. Spinothalamic fibers terminating in other areas of the thalamus influence other cortical areas, such as the insular cortex.

SENSORY CORTEX
Nociceptive signals from the thalamus terminate in multiple areas of the
cerebral cortex and subcortical regions. The thalamic fibers project primarily to layer IV of the primary somatosensory cortex (S1) to transmit information about limb position, sense of touch, and discriminative aspects of sensation. This area of the cortex makes a limited contribution to the perception of nociception. The cortical association areas and secondary somatic sensory cortex are connected with S1 and help further process tactile information necessary for object recognition and spatial relationships.

Functional imaging has demonstrated that the insula and anterior cingulate gyrus are the areas most consistently linked with nociceptive stimulation. The insular cortex receives direct projections from the medial thalamic nuclei as well as from the lateral nuclear group. This area of the cortex processes nociceptive information on the internal state of the body and regulates the autonomic component of the pain response. Patients with lesions of the insular cortex do not display appropriate emotional responses to pain as part of a syndrome termed pain asymbolia. The anterior cingulate gyrus integrates the affective component of pain. To a lesser extent, S1, the premotor cortex, the prefrontal cortex, and posterior parietal cortex are activated with nociception. In the subcortical region, the amygdala, hypothalamus, PAG, basal ganglia, and cerebellum are all activated with nociception. Although there are multiple cortical regions that play significant roles in the perception of nociception, there is enough variability in the patterns of activation that, as of yet, there is not a defined area considered to be specific for nociceptive perception.

DESCENDING PATHWAYS OF THE CENTRAL NERVOUS SYSTEM

There are descending pathways from the cortex that modulate sensory impulses. For example, somatotopically organized fibers from the primary somatosensory cortex terminate in the thalamus, brainstem, and spinal cord. Descending pathways may modulate sensory signals from specific receptors and/or areas of the body. The inhibitory effects are most common and are usually transmitted through inhibitory interneurons. The sensory system is designed to react to the dynamic nature of the
environment. As a result, sensory signals are regulated at multiple levels of the nervous system. Collateral fibers from the periaqueductal gray, matter modulate both descending and ascending pain pathways. The PAG has been experimentally demonstrated to produce analgesia when stimulated and is felt to play a major role in modulating nociception at the level of the dorsal horn as well as at higher levels of the CNS. The PAG receives signals from limbic and cortical centers involved in the affective component of pain. The descending signal from the PAG travels through the nucleus raphe magnus (NRM) in the medulla as well as the medullary reticular formation. The serotonergic NRM fibers descend to inhibit peripheral nociceptors in the dorsal horn in laminae I and II. Clinically, this descending system blocks the spinal withdrawal reflex at the level of the dorsal horn. The PAG has ascending connections which may modulate sensory signals at the level of the thalamus. The PAG also supplies the reticular activating system responsible for arousal to painful stimuli.

**CENTRAL PAIN**

CP is a term that includes dysesthesias, paresthesias, and even pruritus initiated by a lesion that interferes with the pathway of nociceptive signals within the CNS from the spinothalamic tract to the parietal somatosensory areas. CP remains an underdiagnosed condition that occurs with damage to the CNS. Studies suggest that up to 10% of all individuals who experience strokes (more correctly, cerebrovascular accidents), up to two-thirds of spinal cord injury (SCI) patients, 18% of patients with multiple sclerosis, and an undefined number of patients with other neurologic conditions suffer CP.

CP is a complex complaint with several subtypes of pain that can be moderate to severe in intensity. Patients may complain of a constant pain often described as aching, burning, pricking, dysesthesias, paresthesias, or pruritus in isolation or in combination. Most of these patients also complain of stimulus-evoked pain. Patients may complain of spontaneous episodic pain superimposed on their chronic symptoms that is most commonly characterized as lancinating. These uncomfortable sensations are difficult to treat and are often poorly tolerated, which leads to a
Central poststroke pain was first described by Dejerine and Roussy\textsuperscript{66} in 1906 who found that thalamic stroke on one side of the brain can cause a pain syndrome affecting the contralateral half of the body. This syndrome may occur after a stroke in any location in the CNS. There are several theories as to the mechanism of central poststroke pain. Interruption of the descending inhibitory pathway, hyperexcitability of the affected afferent sensory pathways, denervation hypersensitivity, as well as loss of balance between excitatory (glutamatergic) and inhibitory (GABAergic) neurotransmitters are all possible contributors.

**CENTRAL PAIN AFTER SPINAL CORD INJURY**

Chronic pain is a major complication of SCI, with approximately two-thirds of all SCI patients experiencing some type of chronic pain and up to one-third complaining of that their pain is severe.\textsuperscript{67} The prevalence of pain after SCI often increases with time after injury.\textsuperscript{67} There are an estimated 40 cases per million population in the United States, or approximately 11,000 new individuals with SCI pain each year.\textsuperscript{68} Research suggests that chronic pain in SCI patients significantly interferes with their rehabilitation and activities of daily living and therefore reduces quality of life. Attempts to manage these pain symptoms are costly, and success is often limited.\textsuperscript{69}

In addition to CP, there are multiple types of pain that develop after SCI including musculoskeletal, visceral, and peripheral neuropathic pain. The etiology of pain in SCI is multifaceted and the various types of SCI pain differ with regard to clinical findings, pathophysiology, and therapy. The mechanisms involved in the development of CP after SCI are not fully elucidated, but continuing research has identified possible mechanisms for pain generation. CP has been reported with injury to all levels of the spinal cord.\textsuperscript{70}

CP is a common sequelae of SCI. It has many descriptors; it is often characterized by patients as a continuous burning, shooting, aching, and tingling. The distribution of pain is usually bilateral and can involve multiple adjacent dermatomes or be regional in nature. In addition, many patients with SCI report feeling the phantom phenomenon of their body.
below the lesion, and it is described in a distorted fashion. This occurs despite most patients having no conscious appreciation of sensory input below the spinal cord lesion. Central neuropathic pain after SCI has been categorized based on the location of the complaint as either at the level of the injury or below the level of the injury. Although it may be difficult to distinguish the two clinically (and both may be present in the same patient), CP that occurs at the level of injury is due to segmental spinal cord damage, not nerve root damage. CP that occurs at the level of injury can be within two dermatomal levels either above or below the level of injury. CP associated with SCI may also be caused by syringomyelia.

Physiologic changes occur to the nociceptive neurons in the dorsal horn following SCI, including an increase in abnormal spontaneous and evoked discharges from dorsal horn cells. Noxious stimulation causes primary afferent C fibers to release excitatory amino acid neurotransmitters in the dorsal horn. Prolonged high-intensity noxious stimulation activates the NMDA receptors, which induces a cascade that may result in central sensitization. The cascade includes upregulation of neurokinin receptors and activation of the intracellular cyclo-oxygenase-2, nitric oxide synthase, and protein kinase C enzymes. Other neuroanatomic and neurochemical changes thought to impact CP in SCI include alteration in the activity of the neurotransmitter glutamate, interruption of descending inhibitory pathways, and dysfunction of the inhibitory GABAergic interneurons, all at the level of the dorsal horn. On a molecular level, abnormal sodium channel expression within the dorsal horn (laminae I to VI) bilaterally has been implicated as a major contributor to hyperexcitability.

Thalamic neurons appear to undergo changes after SCI in both human and animal models. In the animal model, enhanced neuronal excitability in the VPL has been demonstrated directly as well as indirectly; enhanced regional blood flow has been found in the rat VPL after SCI, suggesting increased neuronal activity. Magnetic resonance spectroscopy studies have demonstrated changes in metabolism of the neurons in human thalamus associated with pain in SCI. Much like the neurons in the dorsal horn, the thalamic neurons after SCI show increased activity with noxious and nonnoxious stimuli. VPL neurons are spontaneously hyperexcitable following SCI without receiving input from the spinal cord.
neurons suggesting that the thalamus may act as a pain signal generator in CP accompanying SCI.\(^7\)

There is emerging evidence that cortical reorganization may play a role in the development of phantom symptoms after loss of limbs, but little evidence of the cortical mechanisms at work with the development of phantom phenomena after SCI.\(^8\) The full spectrum of anatomic, chemical, and physiologic changes contributing to central neuropathic pain after SCI is still being elucidated.

### Autonomic Nervous System

At the turn of the 20th century, the Cambridge physiologist John Newport Langley\(^8\) coined the term “autonomic nervous system” (ANS) to describe the portion of the nervous system that mediated the unconscious function of the internal organs. Soon afterward, the concept of two distinct components of the ANS, the sympathetic and parasympathetic systems, which antagonize each other to maintain homeostasis, was developed. The enteric system is also recognized as being a distinct part of the ANS. In addition to regulating the activity of visceral organs, vessels, and glands, the ANS has been found to play an active role in many pain states. Understanding the complexity of the pain–ANS interaction is essential to physicians managing all types of pain. The anatomy of the ANS with the current understanding of the interrelationship between these structures is shown in Figure 9.7. The ANS is composed of peripheral and central portions.

**Figure 9.7** Ganglia of the peripheral autonomic nervous system.

**PERIPHERAL AUTONOMIC NERVOUS SYSTEM**

The peripheral efferent pathways of both the sympathetic and
parasympathetic nervous system have two components: a primary presynaptic or preganglionic neuron and a secondary postsynaptic or postganglionic neuron. Unlike the somatic motor system which has its motor neurons in the CNS, the motor neurons of the ANS are located in the periphery. As such, the transmission of autonomic signals from the CNS synapses at ganglia in the periphery prior to reaching the target organ (Fig. 9.8). The different locations of the cell bodies of the primary preganglionic neurons of the different divisions of the ANS are discussed later.

The cell bodies of the postganglionic neurons are arranged in aggregates known as ganglia, wherein the synapses between pre- and postganglionic neurons are located. As shown in Figure 9.7, there are four general groups of these ganglia, two within the sympathetic division and two within the parasympathetic division.

A typical feature of the ANS is that postganglionic fibers form nerve plexuses around their target organs composed of both sympathetic and parasympathetic fibers. Unlike their somatic efferent counterparts, the postganglionic fibers branch extensively, forming a network in the vicinity of their effector cells allowing one fiber to act on several effector cells.

**PARASYMPATHETIC DIVISION**
The parasympathetic preganglionic fibers travel from the CNS to synapse in ganglia located close to their target organs. In most areas, parasympathetic innervation tends to be more precise than sympathetic innervation. Parasympathetic fibers generally innervate visceral organs. Table 9.2 summarizes parasympathetic nerve supply to essential body structures.

CRANIAL PARASYMPATHETICS

The preganglionic parasympathetic neurons have their cell bodies in the gray matter of the brainstem, and their fibers travel with the oculomotor, facial, glossopharyngeal, and vagus nerves (Fig. 9.9). The preganglionic fibers from the oculomotor, facial, and glossopharyngeal nerves synapse in the ciliary, sphenopalatine, otic, and submaxillary ganglia, all of which are located in the head. From these ganglia, the postganglionic fibers travel to the target organs (e.g., the lacrimal and salivary glands).
FIGURE 9.9 Schematic representation of autonomic pathways in the neuraxis and the efferent peripheral pathways. Note the connection among the various hypothalamic nuclei and between these structures and the nuclei and important autonomic centers in the brainstem and spinal cord. The dorsal longitudinal fasciculus (DLF) passes from the hypothalamus caudad through the central and tegmental portion of the mesencephalon and the tegmental portion of the pons to terminate in the reticular formation, the autonomic centers and cranial nerve nuclei in the brainstem, and in the intermediolateral cell column of the spinal cord. The DLF is composed of both crossed and uncrossed fibers, including some long ones and an extensive system of short fibers, which are arranged in the gray matter in frequent relays. Note also that the cell bodies of preganglionic sympathetic neurons are located only in spinal cord segments T1–L2, whereas the parasympathetic neurons are located in cranial nerves and in S2, S3, and S4. The solid lines represent preganglionic fibers, the dashed lines represent postganglionic fibers, and the dotted lines are afferent (sensory) fibers. Not shown are the sensory fibers contained in the facial, glossopharyngeal, and vagus nerves, which transmit nociceptive and other somatosensory information from the head.

The preganglionic parasympathetic fibers in the vagus nerve descend
from the brainstem to terminate in visceral organs. In the abdomen, many of these fibers synapse in a diffuse network of postganglionic neurons to form a plexus within the wall of the gastrointestinal tract. The postganglionic neurons within this plexus send short processes to innervate the smooth muscles and glands in the gastrointestinal tract. In the thorax, the vagus nerve supplies parasympathetic innervation to the heart (via the cardiac plexus) and airways. In the heart, the sinus node and atrioventricular node have significant parasympathetic innervation. This is in contrast to the ventricles, which are supplied with dense sympathetic innervation.\textsuperscript{85}

**SACRAL PARASYMPATHETICS**

The sacral portion of the parasympathetic system consists of preganglionic neurons which have their cell bodies in the intermediolateral column of the gray matter of the S2–S4 spinal segments (see Figs. 9.9 and 9.10). The preganglionic fibers travel via the ventral roots to the corresponding spinal nerves for a short distance and then form the pelvic splanchnic nerves. These nerves form the pelvic plexuses which are in close proximity to the target organs (rectum, bladder, prostate gland in the male, cervix in the female). Many of these preganglionic fibers synapse in the plexus, whereas other fibers pass through the plexus without interruption and terminate in intramural ganglia of their target organs (e.g., urinary bladder, descending colon, sigmoid colon and rectum, and genital organs). All of the pelvic organs are innervated by postganglionic parasympathetic fibers. These fibers play an essential role in eliminating waste products from the bladder and rectum.\textsuperscript{86}
FIGURE 9.10  Distribution of peripheral autonomic nervous system to various structures of the body. On the reader’s right are shown (from above downward) the four cranial nerves which contain preganglionic parasympathetic fibers, the axons of preganglionic sympathetic fibers (which pass from the anterior root to the paravertebral sympathetic chain), and the parasympathetic preganglionic axons in S2, S3, and S4. Note that the axons of all of the preganglionic sympathetic neurons pass via the white rami communicantes into the paravertebral chain, in which some synapse with postganglionic neurons, whereas others pass to the prevertebral sympathetic ganglia, in which they synapse with postganglionic fibers. On the reader’s left are depicted the gray rami communicantes, containing postganglionic sympathetic fibers, which originate in the paravertebral chain and then pass to each of the spinal nerves to innervate blood vessels, hair follicles, and sweat glands in various parts of the body.

SYMPATHETIC (THORACOLUMBAR) DIVISION
The peripheral sympathetic nervous system is composed of efferent and afferent fibers. The efferent portion of the sympathetic division of the ANS
consists of preganglionic neurons, the two paravertebral (lateral) sympathetic chains, prevertebral and terminal ganglia, and postganglionic neurons (see Figs. 9.9 and 9.10).\textsuperscript{87,88}

**Sympathetic Preganglionic Neurons**

The cell bodies of the efferent preganglionic neurons are located in the intermediolateral column in the spinal cord from T1 to L2. The efferent fibers of these preganglionic neurons travel from the spinal cord into the periphery through the ventral roots accompanying the somatic fibers at these levels at the thoracolumbar spine. From this point, the preganglionic neurons diverge to provide inputs to ganglia in multiple locations. Each preganglionic fiber synapses on multiple postganglionic cells, thus serving to amplify the sympathetic outflow from the CNS.\textsuperscript{89} Some of the sympathetic fibers leave the spinal nerve immediately after the ventral and dorsal roots fuse to form the white communicating ramus which synapses with postganglionic neurons in the sympathetic ganglia outside the neuraxis (see Fig. 9.10). The white rami are usually present only in the thoracic and upper two or three lumbar segments corresponding to the location of the intermediolateral column in the spinal cord (see Fig. 9.10). The white color of the rami is a result of the sympathetic fibers being myelinated.

The peripheral ganglia of the sympathetic nervous system are located close to the CNS. These paravertebral ganglia are segmentally arranged in two sympathetic trunks, each of which is a vertical row along the anterior margin of the vertebral column. Each trunk is composed of a longitudinal network of ganglia connected to each other by ascending and descending nerve fibers that extend the entire length of the spinal column. As each spinal segment develops in the embryo, one sympathetic ganglion is formed for every level on each side. Some of these ganglia fuse, so the final number of ganglia is usually less than the number of spinal segments.\textsuperscript{90} This is most prominent in the cervical region where only the superior, middle, intermediate, and inferior cervical ganglia are present for seven cervical vertebrae. The middle cervical ganglion is often not present, and the inferior cervical ganglion commonly fuses with the upper thoracic ganglion forming the stellate ganglion. The cephalic end of the
paravertebral ganglia continues beyond the cervical spine, traveling along the carotid nerve to eventually distribute sympathetic fibers within the head. The caudal end of the two trunks converges and terminates in front of the coccyx as the ganglion impar.\textsuperscript{87} The paravertebral sympathetic ganglia are connected by interganglionic fibers forming the lateral sympathetic chain, which extends from the skull to the coccyx. On entering the sympathetic chain, some preganglionic axons synapse in the ganglia at the spinal level they exited the neuraxis. Other preganglionic fibers pass uninterrupted cephalad or caudad within the sympathetic trunk before they synapse to ensure that preganglionic fibers synapse at all levels of the sympathetic trunk.

Some preganglionic sympathetic fibers pass uninterrupted through the sympathetic chain to form splanchnic nerves that synapse within one of the prevertebral ganglia that are found at the junction of the celiac and mesenteric arteries and the abdominal aorta. The postganglionic fibers that travel from the prevertebral ganglion tend to follow arteries within the abdomen to their target organs. The greater and lesser splanchnic nerves are formed from preganglionic fibers from the T6 to T10 levels, pass through the sympathetic chain without synapsing, and terminate in ganglia that innervate the abdominal viscera in the upper and middle part of the abdomen. Splanchnic nerves also contribute preganglionic fibers to the adrenal medulla. These fibers synapse within chromaffin cells, which are homologous to postganglionic neurons but release epinephrine into the bloodstream with sympathetic stimulation.\textsuperscript{91}

**Sympathetic Postganglionic Neurons**
The axons of the postganglionic neurons travel via multiple pathways into the periphery. Some of the postganglionic neurons which have their cell bodies in the paravertebral chain reenter the spinal nerves via the gray communicating ramus, which, in distinction to the white rami, has a gray color because most of these postganglionic fibers are unmyelinated. Postganglionic sympathetic neurons from gray rami communicans travel in all spinal nerves. These postganglionic sympathetic fibers follow the spinal nerves into somatic areas innervating various somatic, sudomotor, and pilomotor structures, such as the sweat glands and smooth muscle fibers in
hair follicles in the skin. The axons of other postganglionic neurons, which have their cell bodies in the paravertebral chain, travel largely along arteries to pass to the thoracic and pelvic viscera. This is in contrast to the preganglionic neurons that pass uninterrupted to the prevertebral ganglia via the greater and lesser splanchnic nerves and are distributed to the viscera in the upper and middle part of the abdomen. The visceral organs in the lower abdomen receive their sympathetic innervation from the lumbar splanchnic nerve which also synapses in prevertebral ganglia. The celiac ganglia is usually the largest of the prevertebral ganglia, and it surrounds the celiac artery at its juncture with the aorta. The sympathetic innervation of the heart originates in the cervical and thoracic ganglia and travels via the cardiac nerves to the heart. Table 9.3 summarizes the autonomic and nociceptive pathways to various body structures.

In addition to the gray rami, the sympathetic trunks give off postganglionic rami that supply the viscera of the head, chest, and abdomen. These rami include the carotid nerve; the superior, middle, and inferior cardiac nerves; the superior, middle, and inferior thoracic splanchnic nerves; and the lumbar and sacral splanchnic nerves.

Some preganglionic fibers synapse in the intermediary ganglia in the white communicating rami, ventral nerve roots, or the spinal nerves outside of the sympathetic chain. These anomalous sympathetic pathways are most commonly found in the sympathetic trunk at the cervicothoracic juncture and the thoracolumbar juncture. These pathways explain why surgical interruption of the sympathetic chain may not completely block sympathetic outflow. Conversely, these anatomic variations often respond to sympathetic blockade with a local anesthetic solution because it diffuses locally to affect these pathways. A sympathetic block can therefore be a poor predictor of the efficacy of surgical sympathectomy. In cases of incomplete sympathectomy, a postsurgical sympathetic block that produces complete interruption of sympathetic outflow and pain relief in sympathetically dependent pain syndromes may suggest the presence of anomalous sympathetic ganglia.

Sympathetic postganglionic neurons may be involved in the generation of pain, hyperalgesia, and inflammation in disease. Depending on the extent of the peripheral nerve lesion, plastic changes can occur at multiple levels of the ANS. Release of mediators (e.g., epinephrine, norepinephrine) from efferent sympathetic nerves both locally and systemically and upregulation of adrenoreceptors in nociceptive afferents contribute to the increased excitability of nociceptors and changes in local...
vasomotor and sudomotor activity. This reorganization of the peripheral neurons may lead to chemical coupling between sympathetic and afferent neurons. This may be responsible for sensitization and/or activation of primary afferent neurons by the sympathetic neurons.

**SENSATION IN VISCERAL ORGANS**

Visceral afferent fibers convey sensory information from the internal organs to the CNS. Sensory fibers from viscera follow autonomic nerves as they travel centrally; the majority of the fibers conducting nociceptive information travel along sympathetic nerves. The neurons of visceral afferent fibers are structurally similar to somatic afferent fibers and, like their somatic counterparts, have cell bodies in the DRG of spinal nerves. Their central processes pass to the spinal dorsal horn, primarily in laminae I and V, and from there, visceral information travel centrally via dorsal column pathways as well as by the spinothalamic and spinoreticular tracts. At the level of the dorsal horn, some primary afferents make synaptic connections with somatic motor neurons, whereas others synapse with preganglionic neurons in the intermediolateral cell column, thus mediating complex visceral reflexes. These reflexes usually involve alteration of the function of the viscera, increase in skeletal muscle tension, and increase in sympathetic activity.

Visceral afferent fibers mediate reflexes such as coughing, cardiopulmonary reflexes, and emptying of the bladder. Most of the visceral receptors are free nerve endings with large receptive fields that are able to respond to varied stimuli. The receptors responsible for transmitting nociceptive signals are largely chemoreceptors that are sensitive to changes that disrupt the internal milieu such as ischemia, inflammation, or the presence of an irritant (e.g., bile, blood). Indeed, in inflammatory diseases of the viscera, such as Crohn’s disease or ulcerative colitis, the peripheral nerve endings may become essentially engulfed in the inflammatory infiltrate that invades the mucosa. The visceral afferent fibers are sensitive to distention and contraction, not cutting or tearing of tissue like the somatic afferents. Although visceral sensations are for the most part not consciously perceived, nociceptive information is transmitted. These fibers also transmit information about the immune
system and contribute to the development of fever in the presence of infection.\textsuperscript{89,97}

Cervical spinothalamic cells receive input from cardiothoracic afferent fibers and transmit the information to autonomic and nociceptive centers higher in the CNS; these afferent fibers also activate propriospinal pathways in the cervical spine that modulate visceral input from lower levels of the spine.\textsuperscript{98}

\textbf{AUTONOMIC CENTERS IN THE CENTRAL NERVOUS SYSTEM}

Unlike the peripheral ANS, distinctions between the somatic and autonomic structures and pathways are often difficult in the CNS. The cortex is the central integration center for both somatic and vegetative functions. Multiple cortical structures have been identified as playing a role in the pain–ANS interaction. The insula, in addition to being associated with the limbic system, is the primary cortex for the viscerosensory system and is involved in the discriminative aspect of pain sensation. It plays a role in the subjective experience of pain and has connections with multiple centers (amygdala, lateral hypothalamus, etc.) involved with autonomic outflow.\textsuperscript{99,100} The anterior cingulate cortex receives nociceptive inputs and maintains broad connections with multiple areas of the central autonomic network. In addition to being included as part of the limbic system and being involved in goal related behavior, it plays an essential role in affective and motivational components of pain.\textsuperscript{101} Surgical stimulation of this region elicits a range of autonomic responses.\textsuperscript{102} The amygdala is composed of several nuclei with distinct functional properties. It plays an essential role in modulating the ANS and is closely linked to the hypothalamus. The amygdala plays a role in the subjective perception of pain as well as expression of emotional response to pain.\textsuperscript{103} The PAG is a complex region of the CNS that has distinct anatomic and functional regions. Different areas of the PAG receive sensory information and help integrate and regulate autonomic responses to these signals and modulate the sympathetic nervous system in analgesia.\textsuperscript{104} The PAG receives sensory signals from laminae I and V of the dorsal horn and helps regulate responses to cardiovascular and
nociceptive input.

There are several autonomic centers in the brainstem that have been physiologically delineated. In addition to regulating vital functions such as breathing and circulation, aggregates of neurons in the medullary and pontine reticular formation regulate the ANS through ascending and descending tracts. In the medulla, the nucleus of the solitary tract is a control center of vegetative functions and also appears to contribute antinociceptive input to the dorsal horn. The parabrachial nucleus integrates nociceptive and visceral information through its extensive connections with the medulla, hypothalamus, and amygdala to maintain homeostasis. The autonomic centers in the brainstem give rise to the parasympathetic visceral efferent fibers of the cranial nerves.

The spinal cord is a central area of integrating the somatic and autonomic functions. Through spinal reflexes, somatic nociception can exert a major impact on the autonomic system. Noxious stimulation to the skin induces a cascade of sympathetic responses, including increased sweat production and skin vasomotor responses.

The location of the preganglionic neurons for the sympathetic and parasympathetic nervous systems in the CNS differ. The sympathetic preganglionic neurons are located in the T1–L2 spinal segments of the spinal cord. The parasympathetic preganglionic neurons are located in the brainstem and the S2–S4 spinal segments (see Figs. 9.9 and 9.10). The locations of the cell bodies of preganglionic sympathetic and parasympathetic neurons, which mediate their function in various parts of the body, are listed in Table 9.4. There are essential differences between the ganglia these neurons form. The sympathetic ganglia are distributed widely throughout the body, are located close to the CNS, and use epinephrine as the primary neurotransmitter. In contrast, the parasympathetic ganglia largely innervate visceral organs, which they are in close proximity to, and use acetylcholine as a neurotransmitter. Figure 9.9 depicts the autonomic pathways that connect the preganglionic neurons in the intermediolateral horn of the spinal cord with the hypothalamus and other brainstem structures.

| TABLE 9.4 Autonomic Centers (AC) in Spinal Cord | 536 |
Structure | Location of AC in Spinal Cord
---|---
Head and neck | T1–T4
Upper limb | T2–T8/T9
Upper trunk | T2–T8
Lower trunk | T9–L2
Lower limb | T10–L2
Viscera | 
  Thoracic (sympathetic) | T1–T5
  Abdominal (sympathetic) | T5–L2
  Pelvic (parasympathetic) | S2–T4

TRANSMISSION IN THE PERIPHERAL AUTONOMIC NERVOUS SYSTEM

The majority of preganglionic neurons in the ANS are cholinergic, as are some sympathetic postganglionic neurons, such as sweat glands. Acetylcholine binds nicotinic receptors in the membrane of postganglionic neurons. Postganglionic parasympathetic neurons also release acetylcholine, which binds to muscarinic receptors in effector organs (e.g., cardiac and smooth muscle, glandular cells). There are drugs that selectively block each of these receptors (see Fig. 9.8).

Norepinephrine is the transmitter substance in the majority of sympathetic postganglionic nerve endings. The response of the effector cells is mediated by two types of receptors: the α- and β-adrenergic receptors. These receptors have different effects at different organs. For example, in the heart, norepinephrine binding to a β receptor causes an increase in heart rate, whereas in the bladder and airways, this same process causes a relaxation of smooth muscle cells. A variety of pharmacologic agents can either enhance or block the action of these receptor subtypes.

The cells in the adrenal medulla, which are homologues of the postganglionic neurons, mainly release epinephrine into the bloodstream with sympathetic stimulation. Although it has many of the same effects as norepinephrine, epinephrine stimulates the β receptors in the fat and liver cells accelerating metabolism of fat and glucose.

There are other neurotransmitters in the ANS. Most preganglionic neurons contain neuropeptides (enkephalin, somatostatin) of unclear functional purpose in addition to acetylcholine. Some autonomic neurons
do not contain either acetylcholine or norepinephrine. These are primarily located in the gastrointestinal tract.

**PHYSIOLOGY OF THE AUTONOMIC NERVOUS SYSTEM**

The ANS regulates activities that are required for maintenance of the internal environment of an organism but which are not normally under voluntary or conscious control. This includes modulating functions such as metabolism, circulation, respiration, body temperature, digestion, sweating, circadian rhythm, and endocrine secretion. The ANS coordinates these physiologic processes to maintain homeostasis,\(^{107}\) such as the constancy of the internal environment.

The effects of stimulating either portion of the ANS and its impact on various organs, visceral structures, and effector cells are summarized in Table 9.5. The sympathetic nervous system is focused on catabolic function and mobilizing the body’s resources. In contrast to the sympathetic nervous system, the parasympathetic function is anabolic and dedicated to regulating functions that maintain an organism over the long term. Through regulation of the enteric system, it conserves and stores energy, it plays a central role in coordinating the muscular contraction of the bladder and rectum to eliminate waste products, and it maintains the basal heart rate and respiration under normal conditions.\(^{90}\)

<sup>a</sup>By circulating epinephrine only.

The functional balance that is normally maintained by the two divisions of the ANS can be disturbed in disease. Linkages exist between the autonomic and immune systems that may be important in the production of disease states and the response to neoplasia and other chronic disease that may lead to pain. Pain itself may alter the immune response and thereby alter the progression of a disease. Animal and human physiologic and pharmacologic studies of visceral as well as somatic pain have demonstrated both plasticity and functional characteristics that are far more complex than the basic anatomy described in this chapter; entire books have been written, for example, on visceral pain.

**ENTERIC NERVOUS SYSTEM**

The enteric nervous system (ENS) is a highly dynamic division of the ANS often referred to as the “little brain” of the gut and contains as many neurons as the spinal cord. It controls gastrointestinal motility and secretion and is involved in visceral sensation. The digestive tract consists of two plexuses, the myenteric and submucous plexuses, formed from sympathetic and parasympathetic postganglionic neurons and a significant number of enteric neurons (Fig. 9.11). Although these plexuses interact with the ANS ganglia in the periphery as well as the spinal cord, brainstem, and cortex, the ENS can function autonomously without input from the sympathetic and parasympathetic systems or the CNS. Enteric neurons were once felt to be postganglionic parasympathetic fibers but are now felt to comprise an independent system in the ANS. The ENS regulates the gastrointestinal system to maintain homeostasis through
control of peristalsis, blood vessels, and glandular activity. The ENS also
has extensive interaction with the immune system. Disruption of this
delicate relationship may be the cause of functional bowel disorders such
as irritable bowel syndrome. Enteric neurons appear able to change their
function and phenotype, a phenomenon called neuronal plasticity, which
contributes to the pathogenesis of visceral hypersensitivity.

![Figure 9.11](image)

**Figure 9.11** Arrangement of nerve cells and nerve fibers in the intramural plexuses in the intestine. The axonal endings of the parasympathetic preganglionic neurons synapse in the wall of the intestine, whereas the axonal endings of postganglionic sympathetic neurons are largely distributed to the intramural ganglia and the blood vessels. (Modified from Kuntz A. Autonomic Nervous System. 4th ed. Philadelphia: Lea & Febiger; 1953:215.)

**Conclusion**

Complete evaluation of individuals with persistent pain includes anatomic localization of the lesion or lesions responsible for both the initiation and maintenance of pain. It is necessary to distinguish between pain that is of peripheral, central, and mixed origin; it is necessary to determine whether pain is somatic or visceral. Thus, optimal evaluation and care of patients with persistent pain is dependent on a thorough knowledge of the anatomy of nociceptive systems. Future advances in our understanding of the
anatomy and physiology of pain in conjunction with improvements in evaluative and diagnostic technologies (e.g., imaging, genetic) will no doubt enhance the care of individual patients.

Controversies abound in the clinical management of pain, and there are enormous geographic variations in care. Lumbar spine surgery rates historically vary fivefold among developed countries, with rates in the United States being highest and rates in the United Kingdom being among the lowest\(^1\)—yet, patient outcomes appear to be broadly similar across countries. In smaller geographic areas, variations are also striking. Within the United States, rates of lumbar fusion surgery among Medicare enrollees vary more than 20-fold between regions, from 4.6 per 1,000 enrollees in Idaho Falls, Idaho, to 0.2 per 1,000 in Bangor, Maine.\(^2\) Within Washington State, county back surgery rates vary more than sevenfold, even after excluding the smallest counties.\(^3\)

Another problem in pain management is the successive uptake of a series of fads in treatment. Research has eventually discredited many of these, but they enjoyed widespread use, with substantial costs and side effects, before they were found to be ineffective. Examples include sacroiliac joint fusion for the treatment of low back pain, coccygectomy for coccydynia, bed rest and traction for back pain, and many others.\(^4\) This phenomenon is prominent in the field of pain medicine but not unique to it. Examples of abandoned therapies from other areas of medicine include internal mammary artery ligation for treating angina pectoris, gastric freezing for duodenal ulcers, and vitamin E and hormone therapy for prevention of cardiovascular events.\(^5-7\) Promoting such ineffective treatments drains resources from more useful interventions, produces side effects, and eventually damages professional credibility.

Despite welcome breakthroughs in basic science research on pain, increases in knowledge regarding optimal ergonomics of work tasks, and the development and use of more technologically advanced medical therapies, evidence indicates an increasing prevalence of chronic back pain and disability. In the state of North Carolina, the prevalence of chronic,
impairing back pain more than doubled from 3.9% in 1992 to 10.2% in 2006.\textsuperscript{8} A large and steady rise in use of opioids, surgery, and interventional therapies for low back pain has not been associated with improved health status but appears to be an important factor contributing to increases in health care expenditures associated with back pain.\textsuperscript{9–11} Thus, despite impressive gains in our understanding of the molecular and cellular origins of pain, there is an important gap in translating this knowledge into effective clinical management. One reason may be the widespread reliance on inadequate research designs that lead to conflicting, confusing, or misinterpreted results. Biostatistical and epidemiologic methods make it possible to substantially improve this situation, but many key principles are not widely appreciated.

\textbf{Uncontrolled Studies Paradigm}

Historically, much of pain treatment research consisted simply of uncontrolled studies in which clinicians treated a group of patients and then reported mean pain scores or the proportion who improved. Such studies are often referred to as case series, although the alternative term before-after study or treatment series may help distinguish them from studies that identify “cases” based on an outcome (such as an adverse event) rather than an exposure (such as a medical intervention) and only assesses patients at one point in time.\textsuperscript{12} The before-after study design remains popular in part because it usually does not require extensive resources but is vulnerable to many pitfalls.\textsuperscript{13}

First, many uncontrolled studies are retrospectively reported. After treating a certain number of patients, the clinician looks back at his or her experience and tries to summarize the characteristics, treatments, and outcomes of the patients studied. Unfortunately, in this retrospective approach, there is often incomplete baseline information on patient characteristics. For example, factors such as age, sex, previous surgery, disability compensation, neurologic deficits, psychological comorbidities, and pain duration often have a major influence on the outcomes of back surgery. Yet, in a systematic review of outcome studies on surgery for spinal stenosis, 74 relevant articles were found, but less than 10%
mentioned all these patient characteristics.7

Another problem with the retrospective approach is that it can be difficult to identify an “inception cohort” of all patients (or a random sample) who met specified criteria and received the intervention. A systematic review of 72 uncontrolled studies of spinal cord stimulation for chronic low back pain or failed back surgery syndrome found that less than one-quarter clearly described evaluation of a consecutive or representative sample of patients.14 In such studies, it is impossible to know if patients with poorer results were excluded for arbitrary reasons, or how many patients received the treatment but were lost to follow-up. If patients excluded from analysis or lost to follow-up were more likely to experience poor outcomes than those who were followed, this could result in serious overestimates of benefits.

A third problem with uncontrolled studies is that even if the researcher collects data prospectively, there is typically no blinding of patient, therapist, or outcome assessor to the nature of the treatment provided. This allows important unconscious—or conscious—biases to affect assessments. This is particularly important for outcomes related to pain, which by nature are subjective. Most of us would question the reliability of outcomes rated by a surgeon evaluating his or her own patients, and yet, this is the norm in much of the literature.

By definition, uncontrolled studies do not include control groups for comparison. The assumption seems to be that patients with painful conditions, especially chronic pain, will not improve unless effective treatment is given. However, there are many reasons why patients improve in the face of ineffective therapy, some of which are listed in Table 10.1. First, the natural history of many painful conditions is to improve spontaneously. This may be true even for patients with long-standing pain, who sometimes improve for unclear reasons. For acute conditions such as acute low back pain, rapid early improvement is the norm.15 Second are placebo effects, which are not well understood but are consistently underestimated and may be particularly important when assessing pain.7 Several factors may mediate placebo effects, including patient expectations,16 learning and conditioning from previous treatments, reduction of anxiety, and endorphin effects. Placebo effects for pain
treatments may be getting larger. In 1996, patients in US clinical trials reported that drugs relieved neuropathic pain 27% more than placebo, but by 2013, the difference had decreased to 9%, a trend that appeared due to a stronger placebo response in the setting of stable drug effects.

Another poorly appreciated factor is regression to the mean. This term was coined by statisticians who observed that in a group of patients who are assembled because of the extreme nature of some clinical condition, there is a tendency for the condition to return to some average level that is less severe over time. Figure 10.1 shows what we often assume to be the course of chronic pain problems, with a steady level of severity that falls after successful intervention. However, the second panel is more likely to represent the true natural history, with good days and bad days, and fluctuations being the norm. Patients seek health care when their symptoms are most extreme. We might easily be misled into believing that improved outcomes are due to the intervention, when in fact, random fluctuations are why their symptoms have returned toward a more average level. As Sartwell and Merrell pointed out, “the term chronic has a tendency to conjure up ideas of stability and unchangeability . . . it is changeability and variation, not stability, that is in fact the dominant characteristic of most long-lived conditions.”
A host of other nonspecific effects also can affect assessments of patient improvement. Increased concern, conviction, enthusiasm, and attention of a therapist, a researcher, and a clinical staff may all have positive but nonspecific effects on patient outcomes. Table 10.2 shows a potential consequence of all these factors, using data from a clinical trial of patients with chronic low back pain. The 31 patients in Table 10.2 have had back pain an average of 4 years. They received a clinical intervention that resulted in 20% to 44% improvements in pain frequency, severity, and function, all of which were highly statistically significant. However, this seemingly effective treatment for chronic pain was a sham transcutaneous electrical nerve stimulation (TENS) unit, along with hot packs twice a week. This was the control arm of a randomized trial and illustrates the substantial improvements that may occur among those with long-standing
Finally, an issue that has begun to receive more attention is that uncontrolled studies are highly susceptible to publication bias.\textsuperscript{21} There is little incentive for clinicians to publicize poor or even average results. Estimates of efficacy from uncontrolled studies that get published will therefore often overrepresent the most positive results.

There is considerable room for improvement in the design and conduct of uncontrolled studies of pain interventions.\textsuperscript{14,22} However, even when conducted well, the ability of uncontrolled studies to provide reliable information about treatment efficacy will always be limited. Exceptions can occur when the relationship between an intervention and outcomes is obvious, the effects are immediate, and the effects are so dramatic that they cannot be explained by other factors.\textsuperscript{23} Examples include surgery for appendicitis, eyeglasses for correction of refractive error, and cataract surgery. For nearly all pain conditions, however, there are many plausible alternative explanations for the observed changes in outcomes, and reliable conclusions about treatment efficacy require the use of more rigorous study designs. There is simply too much “noise” to sort out whether outcomes are due to the treatment or to other factors.\textsuperscript{24}

ineffective therapy, it is incumbent on investigators to have a comparison group of subjects with the same likelihood for improvement as a treatment group but who do not receive the active therapy. The goal should be to minimize the potential differences across groups in the effects of the various nonspecific causes for improvement that are listed in Table 10.1. With this goal in mind, the appropriate comparison group is unlikely to be one that receives no care at all. Patients in such a group would not experience placebo effects or the nonspecific effects of clinical concern and enthusiasm. The importance of having an adequate placebo is illustrated by a trial that found acupuncture more effective than no treatment for chronic low back pain but no more effective than sham acupuncture. Similarly, using a “waiting list” control group is often suboptimal because these patients experience none of the placebo or nonspecific effects of the intervention group. A preferable control group would be one that receives other credible, appropriate care that does not include the specific treatment under study. This might consist of “usual care” supplemented by a placebo of some sort. The placebo should be difficult to distinguish from the intervention under study so that it is perceived as being as likely to help as the active therapy. This is the reason for providing inactive pills in the control groups of drug trials, but even for nondrug treatments, credible placebos should be provided when possible. Examples include the use of sham TENS units in trials of TENS, the use of sham injections in trials of interventional therapies, the use of subtherapeutic weight in trials of traction, or “misplaced needling” as a control for acupuncture.

In some cases, it may be unethical or impossible to provide a true placebo. Examples include many surgical interventions, psychological therapies, and rehabilitation interventions. In such situations, a reasonable alternative is to provide a control treatment that creates some sense that patients are receiving an additional intervention and attention but is not likely to have a strong effect on outcomes. One example might be a brief educational brochure.

In addition to choosing an appropriate control intervention, it is also important to make the treatment and control groups as similar to each other as possible in other ways. Confounding is a critical concept that refers to
variables associated with both the intervention being evaluated and observed outcomes. A classic example of confounding is the association between alcohol consumption and lung cancer. This association is confounded by smoking, which is associated with alcohol consumption and is also an independent risk factor for lung cancer. Examples of common confounders in pain research include severity of baseline pain or functional deficits, psychological and medical comorbidities, age, and use of other therapies. The consequence of confounding is that the observed treatment effect is a poor estimate of the true effect. The modifying effect of the confounding variables result in either an overestimate or underestimate of treatment benefits and can sometimes even result in a positive effect when the true effect is negative (or vice versa).

Selection of controls to minimize the potential for confounding is often a challenge. Control groups that are convenient to assemble are also unfortunately frequently associated with important pitfalls. For example, it would be unwise to choose patients who did not have adequate insurance coverage for the treatment being provided as a control group because insurance coverage is related to important sociodemographic characteristics. Patients with the best insurance are typically those with the highest salaries and the most satisfying jobs, are happier with their insurance, and are more likely to practice healthy behaviors. Failure to adjust for socioeconomic status in observational studies could have resulted in the subsequently disproven belief in the positive cardiovascular benefits of hormone replacement therapy. Similarly, selecting patients nonadherent with intended therapy as a control group is a flawed strategy. In a large-scale study of cholesterol-lowering therapy, control patients were divided among those who took more than 80% of their placebo tablets and those who took less than 80%. Even after adjusting for 40 coronary risk factors, there were enormous differences in mortality between the adherent and nonadherent groups. Patients who were adherent with their placebos had a 5-year mortality of only 16%, whereas those who were not adherent had a 5-year mortality rate of 26% (P < .0001). These findings were probably related to important differences between the groups that were not reflected in their coronary risk factors. These may have included other health habits, behaviors, attitudes toward risk, and
occupations. Thus, nonadherent patients are often strikingly different from adherent patients, and we cannot assume that any differences in outcome are related only to treatment effects.

Sometimes, the issues of proper selection of control patients and treatments are intertwined. A study that assigned patients with presumed discogenic low back pain to intradiscal electrothermal therapy (IDET) or rehabilitation therapy based on their insurance coverage for IDET reported an average 4.5-point improvement in pain scores. Subsequent randomized trials found either no advantage of IDET or only a 1-point difference between IDET and sham treatment. In addition to potential socioeconomic differences related to differential insurance coverage, patients who were denied IDET probably had lower expectations about the likely benefits of rehabilitation therapy, particularly because some had previously received this treatment but had not responded.

Confounding by indication is particularly important in studies that assess treatment efficacy. It refers to the strong, natural (and appropriate) tendency for clinicians to selectively use therapies in patients most likely to benefit. A striking example of confounding by indication is a study of new users of nonsteroidal anti-inflammatory drugs that found use of ulcer-healing drugs associated with a 10-fold increase in risk of gastrointestinal bleeding or perforations. Obviously, ulcer-healing drugs do not cause ulcers. Rather, the increased risk of gastrointestinal complications in patients deemed appropriate for ulcer-healing drugs dwarfed any protective effect of the drugs.

There are ways to minimize or adjust for the effects of confounding. These include matching patient selection on the variables thought to be most important potential confounders, restricting enrollment to patients defined by a narrow set of inclusion criteria, and statistically adjusting and analyzing known confounders. Nonetheless, the effects of confounding can be dramatic even when one or more of these strategies are employed. For example, confounding by indication was strong in the study on ulcer-healing drugs, even though it attempted to restrict enrollment to lower risk patients without a previous ulcer or who had even been previously prescribed an ulcer-healing drug.

Matching also may not be enough to overcome effects of confounding.
Table 10.3 shows how one might assemble two groups of objects that are well matched on five different characteristics and yet literally be comparing apples and oranges.\textsuperscript{19} Table 10.4 shows real data from a comparison of outcomes of two groups of Medicare patients who underwent low back surgery. They were matched on diagnosis (all had spinal stenosis), gender, age, insurance (all Medicare), and surgical procedure (all had a laminectomy without fusion). Despite being well matched on these five characteristics, the likelihood of reoperations differed almost fourfold between the two groups. Differences of this magnitude might easily be attributed to some dramatic advantage of the treatment used in group A. However, these groups were intentionally assembled in such a way that group A was composed of African American patients who had not had prior surgery and group B was composed of white patients with prior surgery.\textsuperscript{19} These two characteristics, which might have easily been overlooked, accounted entirely for the difference in reoperation rates. Unfortunately, it usually is not as simple as matching on a few critical and easily measured variables. The cholesterol-lowering placebo study described earlier shows how even matching (or adjusting) for 40 different risk factors may not capture important differences between two groups of patients.\textsuperscript{28}

If waiting lists, patients with insufficient insurance coverage, nonadherent patients, or even carefully matched patients receiving appropriate placebo treatments make poor control groups, is there a better solution? Fortunately, the concept of random allocation provides an ideal method of establishing a comparison group that is likely to be similar in nearly all respects to an intervention group.

**Randomized Allocation of Treatment and Control Groups**

The term randomized trial has become familiar among clinicians and yet is often misunderstood. Some assume that a randomized trial is one in which patients are randomly selected from a population of interest. However, just the opposite may be true. Patients may be highly selected from a group of potential candidates based on specific characteristics that make the study treatment safe and likely to succeed. Randomization does not refer to the selection of patients to be studied but rather to the patients’ allocation to the treatment or the control group.

Why is randomization such a desirable way of creating a control group? It is attractive because the problem of confounding is largely eliminated.\(^\text{34}\) Because it is never possible to completely understand or measure all confounders, residual confounding is always a potential issue in studies that are not randomized.\(^\text{35}\) With random allocation, we may not even know the important prognostic factors, but they will be equally distributed (given a fair randomization and enough patients) between the treatment and control groups. Effective randomization requires the generation of a truly unpredictable (random) allocation sequence as well as its successful implementation via allocation concealment.\(^\text{36}\)

There is sometimes confusion about what constitutes randomization. Randomization requires using a list of random numbers that may be published or determined by a computer program. Each successive subject
has an equal likelihood of being assigned to each treatment arm, although the order in which they are assigned is unpredictable. Alternating assignment—that is, the first patient is assigned to treatment, the next to placebo, the next to treatment, and so on—is not random because it is predictable. Similarly, assigning patients without conscious bias, or haphazardly, is not the same as random allocation. Using hospital numbers, date of birth, or day of the week is also not randomization. If day of the week is used, a patient could simply come in (or be told to come in) on the day that the desired intervention will be offered. Allocation concealment means that the allocation sequence remains unknown until at least after patients have been assigned to therapy, thus preserving the actual randomization. A traditional method to help preserve allocation concealment is use of opaque sealed envelopes containing the treatment assignment. An increasingly common alternative is to have an offsite facility that keeps the random sequence, so research personnel cannot know the next assignment as a subject is enrolled.\(^{37}\)

A dramatic example of the effects of randomization in pain research is a systematic review of TENS therapy for postoperative pain that found 15 of 17 randomized trials of efficacy showed no benefit.\(^{38}\) By contrast, 17 of 19 nonrandomized studies showed a substantial positive treatment effect. Some investigators have also quantified the magnitude of bias that occurs when allocation concealment is inadequate. One such study, shown in Table 10.5, compared randomization with adequate allocation concealment with randomization with inadequate allocation concealment and with nonrandom allocation of controls.\(^{39}\) The investigators examined a series of treatments for acute myocardial infarction and, as the table shows, demonstrated that maldistribution of prognostic factors was least with randomization with adequate allocation concealment and greatest with nonrandom allocation. Similarly, the likelihood of finding a substantial improvement in case fatality rate rose dramatically, from just 9% of trials with randomization and adequate allocation concealment to up to almost 60% of trials with nonrandom allocation. Other studies suggest that on average, inadequate allocation concealment inflates results by about 40% compared to studies with adequate allocation concealment.\(^{37,40}\)

Why is allocation concealment so important? There are probably several reasons. Failure to conceal allocation makes it easy to subvert the randomization process. If this occurs, confounding by indication can be as much of a problem as in nonrandomized studies. Some overt methods that have been used to bypass randomization include adjusting treatment assignments based on posted allocation sequences or ignoring allocation to treatments perceived as less desirable. Inadequate allocation concealment can also have more subtle effects. If the investigator has a bias as to which treatment group is more effective—even a subconscious bias—he or she may approach the next subject differently based on knowledge of what the next treatment assignment will be. This may affect the way in which a clinical trial is presented to a patient, the enthusiasm with which consent is sought, or the rigor with which eligibility criteria are applied.

### Other Methods for Reducing Bias in Clinical Trials

Randomization is a powerful method for minimizing the possibility of confounding, but does not protect against other types of bias, or systematic errors in measurement. The quality of a trial refers to how rigorously it employs measures to protect against bias. Table 10.6 lists criteria that have been proposed for critical readers to evaluate the quality of studies on treatment efficacy. Lengthier and more detailed sets of criteria for evaluating clinical trials has been developed by the Cochrane Collaboration and by the Cochrane Collaboration Back and Neck Group. Additional guidance for clinical investigators includes recommendations on how to report the methods and results of randomized
trials. The list of criteria in Table 10.6 begins with random allocation, which was discussed in detail previously.

**TABLE 10.6 Evaluating Articles about Therapy**

These criteria can be used as a guide for evaluating the validity of study results and treatment efficacy.

- Were patient assignments randomized and were those groups analyzed?
- Were patients properly accounted for and attributed?
- Was follow-up complete?
- Were all study participants (including study staff and health workers) “blind” to treatment?
- Were groups similar throughout the trial?
- Were groups treated equally (other than the intervention being studied)?
- What was the extent of the treatment’s effect?
- Are the results applicable to my patient care?
- Do benefits of the treatment outweigh the risks and costs?

**BASELINE SIMILARITY OF STUDY GROUPS**

Randomization usually provides the best way to produce groups with equivalent prognoses. However, randomization may not always work, and investigators should present a comparison of baseline characteristics of patients in the treatment and control groups. In a properly randomized trial, any observed differences are chance occurrences but may still be sufficiently large to compromise the validity of the study. When this occurs, investigators sometimes adjust for baseline differences using statistical techniques. Such statistical adjustments should be based on how strongly the prognostic factor is thought to be associated with the outcomes and the clinical importance of baseline imbalances, not on the results of statistical tests for significant differences. Statistical tests can be misleading, as small differences may be clinically trivial but statistically significant in large trials, and large differences may be clinically important but statistically nonsignificant in small trials.

Even if adjustment is appropriate, it cannot control for differences in unmeasured confounders. It is also important to consider whether baseline imbalances could be due to intentional subversion of randomization. Minimization is a method for achieving balanced groups based on key predefined patient factors and the number of patients in each groups. Although it is not truly random, because patient factors influence treatment
assignments, minimization may provide better balance between treatment groups than standard randomization.

**BLINDING**

The importance of blinding is that it helps to create similar expectations on the part of patients and similar enthusiasm by the therapists. Furthermore, it ensures that the same level of attention and concern is provided to both a treatment and a control group. Blinding is particularly important in studies that assess subjective outcomes such as pain. In one study, lack of blinding inflated estimates of treatment effects by 30% in trials with subjective outcomes such as pain but had no effect on estimates in trials with objective outcomes.\(^{50}\)

It is common to talk about double-blind trials, but the term is often used ambiguously.\(^{51}\) Typically, it is meant to imply that the patient is unaware whether he or she is receiving active treatment or a placebo, and the person administering or prescribing the treatment is also unaware. In some cases, it may be impossible to “blind” patients or therapists, as in trials of surgical treatments or some rehabilitation and psychological interventions. There is also a third party that may be blinded—an independent assessor of outcomes. Maintaining such a blinded assessor should generally be feasible, even when it is impossible to blind patients and therapists. Trials should explicitly describe who was blinded rather than use nonspecific jargon such as “single-,” “double-,” or even “triple-blinded.”\(^{51}\)

As noted in the discussion of control groups, creativity can sometimes produce credible placebo or alternative treatments that at least help to maintain blinding. In many situations, it would be informative to test the success of blinding at the end of a study. This is not done frequently but is important for certain drugs and other interventions that have side effects or other characteristics that can give the treatment away.\(^{52}\) In a trial of TENS therapy for low back pain, for example, sham treatment does not produce the same sensation as active therapy, so patients could know they are receiving sham rather than active therapy. This would essentially result in an unblinded trial. In fact, one trial of TENS found that patients and physicians were able to guess better than random chance whether individual patients were in the treatment or control group, but the
magnitude of blinding failure was sufficiently modest that the results could be interpreted with some confidence.\(^53\)

In trials of drug therapy, crossover designs have commonly been used because they help to reduce the effects of interpatient variability in baseline and outcome measures. For many pain treatments, however, such designs may be undesirable because patients would experience both treatments and could determine with a high level of certainty whether they were receiving active treatment or placebo. For example, maintenance of blinding would be very difficult in a crossover study from sham TENS to true TENS, or from subtherapeutic weight to therapeutic weight with traction, or from mild exercise to strenuous exercise. Because of the potential for loss of blinding and other issues such as carryover effects and loss to follow-up from one intervention period to another,\(^54\) crossover trials may be undesirable for many types of pain therapy.

**WERE GROUPS TREATED EQUALLY EXCEPT FOR THE EXPERIMENTAL TREATMENT?**

Sometimes, patients in a treatment group are given multiple interventions, and yet, the authors or readers are tempted to ascribe the results to a single feature of the treatment. For example, a patient who receives a sclerosant injection into the spinal ligaments along with corticosteroids and spinal manipulation might be said to have improved because of the sclerosant therapy, and yet, much of the observed improvement might be due to the cotreatments.\(^55\) Thus, it is important that any cotreatments also be given to the control group and that the intensity of the treatments is equal.\(^56\)

Furthermore, use of multiple treatments for chronic painful conditions is common. Many patients obtain over-the-counter pain medications; visit multiple physicians; or seek alternative forms of therapy such as chiropractic care, acupuncture, or massage. In outpatient trials, it may be difficult to prevent patients from obtaining such cotreatments, and it may simply be necessary to inquire about these “cointerventions” and determine if they are roughly equivalent between two groups. Alternatively, investigators may make strenuous efforts to ensure that patients do not receive certain types of cointerventions, such as opioids or surgery. Even the nature of follow-up should be consistent between study...
groups. If one group has closer or more frequent follow-up, for example, more adverse events might be reported, or treatment might be given more intensively. Increased contact with a caring clinician can also have important nonspecific effects, as noted previously.

LOW LOSS TO FOLLOW-UP AND INTENTION-TO-TREAT ANALYSIS

The second item in the list in Table 10.6 concerns completeness of follow-up for patients who entered the trial. As discussed in the section on uncontrolled studies, investigators should attempt to follow up every patient who enters the study because those who drop out may be systematically different from patients who remain in the study, resulting in attrition bias. For example, disgruntled patients who have failed to improve may drop out of a trial, leaving an obvious bias in favor of the new treatment. On the other hand, patients with dramatic improvements may drop out because they are so much better they see no need for continued medical contact. Dropouts from clinical studies often differ systematically from those who remain in the study with regard to their baseline characteristics.

In highly mobile societies, such as the United States, obtaining complete follow-up can be difficult. Strategies for maximizing follow-up include gathering multiple telephone numbers at the time of enrollment for the patient, relatives, and friends; excluding patients who are planning to move in the near future; excluding patients who have no telephone; sending multiple mails of questionnaires; giving financial incentives to return data; maintaining contact with greeting cards or newsletters; using the briefest possible follow-up questionnaires; and using the Internet to track patients through public records.

A useful rule of thumb is that at least 80% to 85% of patients who enter a trial should be included at the end of the study to avoid attrition as a worrisome potential source of bias. Rates of attrition can be substantial in pain trials. For example, a systematic review of opioids for chronic low back pain found that attrition was >20% in all included trials, even though duration of follow-up was relatively brief. Attrition tends to increase as the duration of follow-up increases. One way to ensure that the results are
robust in the face of dropouts is to do a “worst-case analysis,” in which one assumes that all dropouts from the treatment group failed to improve, whereas all dropouts from the comparison group improved substantially. If this worst-case analysis does not change the conclusion, one can be confident in the findings.42 In one analysis, over half of trials that reported statistically significant results no longer reported statistically significant effects under a worst-case scenario.58 However, it is implausible that all persons lost to follow-up will experience the worse outcome. Under more plausible assumptions regarding outcomes of persons lost to follow-up, results of 0% to 33% of trials were no longer significant.

An alternative approach for handling missing data is “baseline observation carried forward.” This technique utilizes the baseline value for the outcome of interest for patients who are lost to follow-up.59 Although it has the advantage over “worst-case analysis” of being based on “real” data, it is based on the flawed assumption that the baseline values will not change during the course of follow-up or as a result of treatment. “Last observation carried forward” has an advantage over using baseline values in that it takes into account any recorded changes in outcomes. More sophisticated methods such as multiple imputation create several different plausible data sets for missing data based on the observed data and appropriately combine the results obtained from each of them.60

It is also important that patients be analyzed in the groups to which they were randomized (“intention-to-treat analysis”) regardless of whether they received the intended treatment, how well they adhered to the assigned therapy, and whether they completed the trial.61 We have seen the hazards of assuming that patients who are noncompliant are otherwise the same as compliant patients. Indeed, patients who do not receive the intended therapy may be systematically different from those who do. The only way to maintain the benefits of randomization and to avoid a biased comparison is to keep patients for analytic purposes in the group to which they were assigned. Intention-to-treat analyses take into account the fact that patients in clinical practice are autonomous and do not always follow the trial protocol to the letter—or at all. In some cases, intention-to-treat analyses can be difficult to interpret. In the Spine Patient Outcomes Research Trial of surgery, nearly 40% of patients crossed over from
surgery to nonsurgical therapy and vice versa. The intention-to-treat analysis still provides information about patient outcomes when they are advised to undergo surgery or nonsurgical therapy, even though many patients decided not to proceed with the recommended therapy. An as-treated analysis provides additional information based on which therapy the patients actually received. This can also be informative, so long as potential confounders are adjusted for and the high probability of some residual confounding is recognized.

Other Issues in Clinical Trials

MEASUREMENT OF OUTCOMES

What outcomes should be measured in a clinical trial? In traditional clinical trials, investigators often seek the most objective possible outcomes for evaluation, such as joint range of motion, spinal fluid endorphins, or dynamometer measures of muscle strength. Although the search for objective outcome measures is appropriate for many medical conditions, pain is inherently a subjective phenomenon and one that often correlates only modestly with these physiologic measures. Table 10.7 illustrates several examples of dissociations between physiologic measures and pain or functioning. Some researchers have argued that the essence of “hard” data is their reproducibility under the same circumstances. Happily, many subjective phenomena can be measured in reproducible fashion. A good example is the use of visual analog pain scales and other ordinal rating scales for quantifying pain.

</tbody>
</table>
In a clinical trial of rigid corset, improvements in symptoms with activity were observed but not in spine mobility or straight-leg raising.

For evaluation of therapies for chronic pain, trials should go beyond the self-report of pain to routinely examine patients’ behavior and function in their daily lives. Function should be considered a separate domain from pain and measured separately because improvements in pain and function often correlate only loosely with one another. For example, trials of opioids for chronic noncancer pain and exercise therapy for low back pain both found considerably smaller benefits according to measures of function compared to measures of pain. So how should function be assessed? Performance measures such as a series of timed tasks or an “obstacle course” may have the attraction of seeming objectivity, but performance can be highly influenced by motivation, mood, setting, financial incentives, and other nonphysical attributes of the patient and his or her environment. Such measures often do not correlate well with how a patient actually functions on a day-to-day basis. By contrast, a number of self-report measures of health status or functional status have been validated and are quite reproducible. Examples include the Sickness Impact Profile, the Brief Pain Inventory, and the Medical Outcomes Study Short-Form-36 as well as condition-specific scales such as the Roland-Morris Disability Questionnaire and Oswestry Disability Index for patients with back pain, the Arthritis Impact Measurement Scale, the Western Ontario and McMaster Universities Osteoarthritis Index physical function subscale, and many others. A simple three-item measure of pain and function adapted from the Brief Pain Inventory is the Pain, Enjoyment of Life, and General Activity (PEG) scale.

To provide a full picture of the effects of pain interventions, the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) recommends that clinical trials routinely measure outcomes in multiple “core” domains. In addition to pain, physical functioning, and emotional functioning, IMMPACT recommends assessment of participant ratings of global improvement and satisfaction.
with treatment, symptoms and adverse events, and participant disposition.\textsuperscript{66} A task force convened by the National Institutes of Health (NIH) Pain Consortium developed research standards for studies of chronic low back pain including reporting of outcomes addressing pain intensity, pain interference, physical function, depression, sleep disturbance, and catastrophizing.\textsuperscript{78}

Work status is often used as an outcome measure for chronic pain treatment because of its clear relevance to both patients and to society. However, it has a number of drawbacks as an outcome measure, most important of which is that it is influenced by many nonmedical factors. For example, studies have demonstrated that the likelihood of return to work in the face of a painful medical condition varies depending on job satisfaction, relationships with fellow employees and supervisors, regional unemployment rates, the presence of another breadwinner in the family, proximity to retirement age, and physical job demands. Similarly, the duration of pain-related disability is strongly associated with the patient’s educational status, income,\textsuperscript{79} and the generosity of disability benefits. For many members of our society, including students, homemakers, and retired persons, return to employment is simply not available as an indicator of outcome. Thus, although this measure of outcome is important in many settings and is recommended by the NIH Task Force on Research Standards for Chronic Low Back Pain as part of the minimum data set,\textsuperscript{78} it should be interpreted in light of these potentially confounding factors.

**REPORTING THE RESULTS**

Many clinical trials report mean outcome scores or mean differences in scores compared to baseline values. This can be difficult to interpret clinically, as a 10-point mean improvement on a 100-point scale could indicate that nearly all patients experienced only very mild improvement or that some proportion of patients experienced a clinically significant improvement, whereas others did not. The minimal important change, or the smallest change in outcome scores perceived by patients to be meaningful, is a key concept.\textsuperscript{80} It refers to the smallest amount of improvement perceived by patients as being important. For low back pain, a consensus group recently proposed a 30\% improvement from baseline in
pain or function as the minimum important change. A randomized trial found that the average difference between mindfulness-based stress reduction versus usual care was less than 1 point on a 0-to-10 pain bothersomeness scale at 1 year, indicating a relatively small average effect well below the threshold for clinical significance. However, the proportion of patients who experienced ≥30% improvement was greater in the mindfulness group (48% vs. 31%; relative risk [RR], 1.56; 95% confidence interval [CI], 1.1 to 2.1), indicating that persons who respond to mindfulness therapy often experience clinically meaningful improvements. Therefore, reporting the proportion of patients that meet a certain threshold for improvement can be very helpful for interpreting the clinical significance of results. This is sometimes referred to as a responder analysis and is recommended by the NIH Task Force on Research Standards for Chronic Low Back Pain in addition to reporting mean outcome scores.

In some studies, actual outcome measurements are not reported. Rather, only the P values for the significance of results are provided. A P value tells us the probability of obtaining a result that is at least as extreme as the one actually observed, assuming that the null hypothesis of no difference between treatments is true. However, this gives a reader no idea what the magnitude of treatment effects may have been. In a very large trial, a difference between groups may achieve statistical significance even though the difference is too trivial to be clinically relevant. On the other hand, in a very small trial, a large treatment effect might fail to achieve statistical significance. Thus, the magnitude of treatment effect is somewhat independent of statistical significance and should be reported. An ideal way to present the results is to give the actual estimate of success rates or mean scores along with 95% confidence limits, which allows the reader to see the range of results that would be consistent with the study findings. The 95% confidence limits are closely related to P values but give readers a better understanding of the potential range of effects compatible with the data.

**STATISTICAL POWER**

When a trial shows “no statistically significant difference,” it is often
interpreted as meaning that it has proven that there is no difference between the intervention and control groups. However, this interpretation is often incorrect. In fact, most trials are too small to prove that there is no difference between groups—rather, they only show an absence of evidence of a difference. This is a critical distinction. The likelihood that a true difference may not have been detected is referred to as type II (or β) error, in contrast to type I (or α) error (which is reflected in the P value). Statistical power (calculated as 1 − β) refers to the likelihood that a clinically relevant difference between groups will be identified. Larger sample sizes increase statistical power. On the other hand, statistical power decreases as the size of the clinical effect to be detected (typically the minimal important change) goes down. Nonstatistically significant results should always be interpreted in the context of the statistical power of the study.

**GENERALIZABILITY OF RESULTS AND EFFICACY VERSUS EFFECTIVENESS**

Even if a clinical trial is internally valid, its results may not be applicable (generalizable) to other patients and settings. Patients who enroll in low back pain clinical trials, for example, tend to be better educated, more frequently employed, and different in other prognostically important ways from patients in everyday practice. Clinical trials often exclude patients with medical or psychological comorbidities or use run-in periods to identify and exclude patients who experience adverse events before randomizing them. For example, older patients have often been excluded from trials of arthritis drugs, even though they are the most likely to receive such drugs in actual practice. Patients enrolled in clinical trials are usually recruited from tertiary care settings, and the resources available in clinical trials to help maximize patient compliance and follow-up are rarely available to most clinicians. A number of other threats to generalizability have been described. It is important for patients, treatments, and study conditions to be adequately reported so readers can determine whether they would be likely to apply to their own situations.

Related to generalizability is the concept of efficacy versus effectiveness. Most clinical trials are designed to evaluate efficacy: the
benefits of an intervention in optimal populations and under ideal conditions. Such studies generally focus on narrow, short-term outcomes. Effectiveness studies, on the other hand, are designed to evaluate whether an intervention will actually work under conditions encountered in usual practice. Of course, there is a continuum between efficacy and effectiveness, although most randomized trials fall squarely on the efficacy side of the spectrum. Factors that can enhance the ability of clinical trials to evaluate effectiveness are use of less stringent eligibility criteria, enrollment of patients from primary care populations, evaluation of multiple clinically relevant outcomes, and longer duration of follow-up. Observational studies can also be helpful for evaluating effectiveness once efficacy has been established in randomized trials.

**SUBGROUP ANALYSES**
Sometimes, analyses are performed to examine whether the effects of an intervention differ in clinically relevant groups of patients defined by some factor (such as baseline pain score, sex, or age). For example, a trial of glucosamine for osteoarthritis found no overall treatment benefit, but a subgroup analysis found that it was effective in patients with high baseline pain scores. There is a great risk that subgroup analyses may be overinterpreted, as results could simply represent chance effects, particularly when data are “mined” to look for significant results. Confidence in subgroup analyses is enhanced if the treatment effects are large, are unlikely to have occurred by chance (low P value), occur in an analysis based on a prespecified and plausible hypothesis, come from a small number of subgroup analyses, and are replicated in other studies.

**EFFECTS OF FUNDING SOURCE**
Commercially funded clinical trials are consistently more likely to report results that favor the funder than trials that are not commercially funded. This appears to be true for devices, such as surgical implants, as well as drugs. Why might this be? One reason is publication bias. This refers to the differential tendency for studies to be published depending on the strength and direction of results. Generally, studies that report statistically significant and more strongly positive results are more
likely to be published compared to those that report statistically insignificant or less striking results. The result is inflated estimates of treatment effects. Publication bias can occur no matter what the source of funding is, but commercially funded clinical trials appear to be particularly susceptible due to either overt or more subtle pressures.\textsuperscript{93,97,98} A related situation is the selective reporting of outcomes.\textsuperscript{99–101} This leads to bias because more favorable results tend to be reported and publicized, and there is often no indication to readers that other (less favorable) outcomes were even assessed. Results can also be “spun” to appear more favorable than they really are. One study found that of 36 industry-sponsored new drug approval trials of antidepressants viewed by the U.S. Food and Drug Administration (FDA) as having negative or questionable results, 22 had not been published, and another 11 were reported in a way that conveyed positive outcomes.\textsuperscript{102} Another questionable strategy that has begun to receive increased scrutiny is the practice of “seeding” trials following new drug approvals.\textsuperscript{103} Such trials are framed as scientific research but in reality are marketing tools designed to increase familiarity and use of the medication by experienced clinicians and often utilize scientifically suspect study designs driven by marketing staff, recruit underqualified investigators who prescribe competing products, overcompensate investigators, and utilize poor data collection methods.\textsuperscript{104}

This is not to say that commercially funded trials can not be conducted and reported rigorously. However, replication of results in non–commercially funded trials may be required to increase confidence in the findings of commercially funded trials, even when methodologic shortcomings are not readily apparent. Statistical and graphical methods are available to formally assess for the likelihood of publication bias, although all have some limitations.\textsuperscript{105} The FDA Web site can be a useful resource for identifying unpublished trials and unreported outcomes, but data are often incomplete or redacted. Ideally, publication and selective outcomes reporting bias would not only be detected but would also not occur in the first place. The development of clinical trials registries and mandatory requirements for researchers to submit trial protocols and full results in order to be considered for journal publication or for new drug approvals may help reduce the effects of these biases.\textsuperscript{106,107} The
usefulness of clinical trials registries will depend on how assiduously and quickly researchers comply with reporting requirements.

**ASSESSMENT OF HARMS**

In order to generate balanced conclusions about an intervention, it is important to understand both its benefits and harms. However, benefits have been accorded far greater prominence than harms when conducting and reporting clinical trials. In fact, most randomized trials lack prespecified hypotheses for harms. Rather, hypotheses are usually designed to evaluate beneficial effects, with assessment of harms a secondary consideration. As a result, the quality and quantity of harms reporting in clinical trials is often inadequate.

There are other problems with relying solely on clinical trials to assess harms. Few clinical trials have large enough sample sizes or are long enough in duration to adequately assess uncommon or long-term harms. For example, one systematic review found that trials of opioids for chronic noncancer pain averaged only 5 weeks in duration, even though patients frequently remain on these medications for years or indefinitely. In addition, patients who are more susceptible to adverse events are often excluded from clinical trials, although they may commonly receive the therapy in clinical practice. For example, all trials of opioids for chronic noncancer pain that reported information on history of drug addiction excluded such patients. Harms may also be downplayed or misrepresented if there is a vested interest in doing so. Aggressive promotion of unsubstantiated claims of lower abuse, diversion, and withdrawal risks of OxyContin (Purdue Pharma, Stamford, CT), a sustained-release formulation of oxycodone, eventually resulted in a criminal conviction and $634 million fine against the Purdue Frederick Company, along with three company executives.

Assessment and reporting of harms in clinical trials can certainly be improved. This is also an area where observational studies can be a very useful source of information. Unlike assessments of treatment benefits, confounding by indication is usually not an issue with unexpected or unpredictable adverse events because such outcomes are not related to the decision to use the therapy. An example is observational studies on
risk of myocardial infarction associated with cyclo-oxygenase-2 selective nonsteroidal anti-inflammatory drugs. Those conducted prior to knowledge regarding the cardiovascular risks of rofecoxib were unlikely to be affected by confounding by indication related to the baseline risk of heart disease. Observational studies can also provide important information on rare or long-term adverse events and in populations underrepresented in clinical trials (such as pregnant women, children, older adults, or those with important comorbidities). Even uncontrolled studies such as case reports have been invaluable for evaluating harms and may be the first or primary signal of a rare adverse event.

TRIAL-BASED COST-EFFECTIVENESS ANALYSIS

Even if the balance of benefits to harms of a treatment is acceptable, widespread implementation may not make sense if costs are very high. Clinical trials can also be designed to assess the question “Is it worth it?” by collecting cost data alongside clinical outcomes. Unlike decision analytic studies that model costs and clinical outcomes, such trial-based cost-effectiveness analyses directly measure the cost per some increment of clinical utility (often a quality-adjusted life-year). A challenge with cost-effectiveness analyses of clinical trials is that cost data are often associated with large variability, so estimates can be imprecise unless sample sizes are large. In addition, distributions of cost estimates are often quite skewed, which can pose a statistical challenge, and costs are frequently highly variable depending on locale and reimbursement factors and can rapidly change over time.

Alternative Study Designs

CLUSTER TRIALS

For certain interventions, it may be undesirable or unfeasible to randomly allocate individual patients to a treatment or a control group. For example, if one were testing a guideline that involved changes in clinic organization and changes in management by nurses or other ancillary staff, it might be extremely difficult to ensure that all involved gave one particular approach to some patients and not to others. Furthermore, individual physicians
would have difficulty treating certain patients according to a guideline and others not according to the guideline, which could increase treatment group contamination. In such a circumstance, one might wish to allocate clusters of patients, such as entire clinics, to intervention or control arms. Such studies are referred to as cluster randomized trials. When these designs are used, specific statistical methods are needed to account for the similarities among patients of a single physician or facility, which can inflate estimates of treatment effects. Analytic techniques such as the “cluster correlation correction” for such studies have been well described, and computer software is available to perform these analyses.

CROSSOVER TRIALS
In a standard parallel group randomized clinical trial, patients are randomized to a single treatment out of two or more possibilities. In a crossover trial, patients each receive two or more treatments in a random order, typically separated by a washout period. This allows a patient’s response to one treatment to be compared with the same patient’s response to another treatment. The crossover design confers a statistical efficiency advantage over parallel group trials because with the same number of subjects, the use of paired data enables more precise estimation of treatment effects. A key drawback of crossover trials is the potential for carryover effects, with effects of one treatment “carrying over” to the next. Thus, the washout period must take into account the likely duration of action for each treatment involved and may require testing for crossover effects. Attrition can also occur during the initial treatment period, making within-subject comparisons impossible for those persons lost to follow-up. Other factors that may impact the interpretability of crossover trials are period effects (due to changes in the underlying condition over time) or sequence effects (due to changes in effectiveness of treatments based on the order in which they are given). Crossover trials are most appropriate for chronic pain conditions in which the symptoms are relatively stable, generally inappropriate for acute pain, for which symptoms change rapidly, and should be reserved for treatments that do not have permanent effects on the underlying condition. Results of crossover trials tend to agree with those of parallel group trials, although some research indicates
a trend toward larger effect estimates in crossover trials.¹²⁰

**FACTORIAL DESIGN**

In a factorial design, patients are simultaneously randomized to receive or not receive two different treatments.¹²¹ In the United Kingdom Back Pain Exercise and Manipulation (BEAM) trial, for example, patients were allocated to receive exercise therapy versus no exercise therapy and to receive spinal manipulation or no spinal manipulation.¹²² Such factorial designs have important efficiencies if the dropout rate is low. If there is no statistical interaction between the two treatments (in this example, exercise therapy and spinal manipulation), then a factorial design provides an unbiased assessment of the effect of each treatment. Such designs might be useful in studying combinations of therapy such as an analgesic plus a muscle relaxant, drug therapy plus physical therapy, and other clinically relevant combinations. Indeed, factorial designs may be the best way to evaluate the multicomponent approach that is widely advocated for the treatment of chronic pain. If there is no synergy between treatments, the investigator essentially has two trials for the price of one. If there is synergy or additive effects between treatments, the factorial design can identify this effect. Factorial designs introduce analytical complexities that are avoided in simple parallel designs, but in some circumstances, the benefits may outweigh the disadvantages.¹²³

**New Directions in Clinical Trials**

**PRAGMATIC TRIALS**

With increased attention to effectiveness has come an increased demand for “pragmatic” trials that attempt to inform routine clinical practice better than traditional efficacy trials. Key features of pragmatic trials are that they are set in normal practice settings rather than highly specialized or controlled settings, apply few exclusion criteria, allow flexibility in use of treatment interventions, and assess key, patient-centered outcomes.¹²⁴ For example, a pragmatic trial of acupuncture for chronic low back pain was conducted in general practice and private acupuncture clinics in the United Kingdom, enrolled anyone aged 18 to 65 years with nonspecific low back
pain of 4 to 52 weeks duration (with few exclusion criteria), allowed acupuncturists to determine the content and number of treatments, and evaluated bodily pain as well as outcomes related to use of analgesics and patient satisfaction.\textsuperscript{125}

**ENRICHED ENROLLMENT RANDOMIZED WITHDRAWAL TRIALS**
A design that has become increasingly common, particularly for evaluation of pharmaceuticals, is the enriched enrollment randomized withdrawal design. In this design, potential study participants all receive the study drug for a specified period of time during an open-label prerandomization phase.\textsuperscript{126} Only persons who report benefits and can tolerate the drug proceed to the randomization phase, in which patients either continue to receive the medication or are randomized to a control (usually placebo). The enriched enrollment randomized withdrawal design has been proposed as a useful method for studying drugs for whom only a small proportion of patients benefit by focusing on those in whom the drug works and do not experience bothersome side effects.\textsuperscript{127} However, this design could exaggerate treatment benefits and underestimate harms because the population enrolled is purposefully skewed toward those who have already demonstrated good outcomes and few side effects on the treatment; blinding may be ineffective because all patients are familiar with the treatment due to exposure during the prerandomization phase; and for certain medications (e.g., opioids), development of tolerance from prerandomization exposure could lead to withdrawal symptoms in persons randomized to placebo, confounding interpretation of results. One analysis of clinical trials of opioids for chronic pain found that compared to standard trials, the enriched enrollment randomized withdrawal design did not appear to bias results for efficacy but underestimated adverse effects.\textsuperscript{126}

**EXPERTISE-BASED TRIALS**
For nonpharmacologic interventions such as surgery that are highly dependent on the skill and training of the clinician, “expertise-based” randomized controlled trials have been proposed.\textsuperscript{128} In the traditional
randomized controlled trial, participants are randomized to one of two interventions and individual clinicians provide intervention A to some patients and intervention B to others. In the expertise-based randomized trial, participants are randomized to individual clinicians with expertise in intervention A or to clinicians with expertise in intervention B. Proposed advantages of expertise-based randomized trials are that they can reduce the effects of differential expertise bias. In the case of surgery, this can be important, as many procedures require considerable experience to gain proficiency. In addition, the expertise-based design reduces potential effects of differential enthusiasm or skepticism for the different procedures, as each surgeon provides only the procedure that he or she believes is the best. As yet, however, there is relatively little evidence on the validity of expertise-based randomized trials.

**COMPARATIVE EFFECTIVENESS**

Another direction in clinical trials is toward increased evaluations of not just effectiveness of interventions versus placebo but comparative effectiveness of two or more interventions. Head-to-head trials that compare two interventions are the most direct method for evaluating comparative effectiveness. However, head-to-head trials are not always available. An alternative method for evaluating comparative effectiveness is through indirect comparisons. This refers to assessments of the relative benefits and harms of competing interventions based on how well each performs against a common comparator (usually placebo). Methods are available for conducting indirect comparisons that preserve some of the benefits of randomization as well as for more complex network analyses and mixed treatment comparisons that incorporate both indirect and direct evidence. In all cases, the validity of indirect comparisons is based on the critical assumption that treatment effects are consistent across all trials. This assumption can be violated due to a number of factors, including differences in study quality, patient populations, settings, outcomes, and other factors. In fact, large discrepancies between indirect and direct studies have been reported. For example, in patients with neuropathic pain, an indirect comparison found tricyclic antidepressants associated with a much higher likelihood of achieving pain relief compared to gabapentin,
but head-to-head trials found no significant difference.\textsuperscript{131} Indirect comparisons should only be used when the critical assumption of similarity of treatment effects is met and verified against results from head-to-head trials as they become available.

**EQUIVALENCE AND NONINFERIORITY TRIALS**

Traditional clinical trials are designed to determine whether an active treatment is superior to another treatment (often placebo). The null hypothesis is that there is no difference between the treatments being compared. In equivalence trials, on the other hand, the purpose is to determine whether one (typically new) intervention is therapeutically similar (equivalent) to another, usually established, treatment.\textsuperscript{132} This requires testing of a different null hypothesis—specifically, the null hypothesis that there is a difference being treatments. Noninferiority trials are similar to equivalence trials but are designed to focus on whether a new treatment is no worse than (rather than therapeutically similar to) an established treatment. For either type of trial, boundaries for what will be considered “equivalent” or “noninferior” must be defined in order to perform appropriate hypothesis testing. Unfortunately, many trials that report equivalence do not define these boundaries, or are based on misapplied or misinterpreted statistical analyses, often based on standard superiority hypotheses or inadequate sample sizes.\textsuperscript{133} Guidance is available to help improve the conduct, reporting, and interpretation of equivalence and noninferiority trials.\textsuperscript{132}

**STEPPED WEDGE DESIGN**

The standard cluster randomized trial utilizes a parallel design, in which patients receive different interventions according to their cluster at roughly the same time. The stepped wedge design is a variant on the cluster framework in which each cluster begins in the control condition and receives the intervention by the end of the study.\textsuperscript{134,135} The time to receive the intervention condition varies from cluster to cluster. The stepped wedge design may be more feasible to implement than a standard parallel group cluster design when the cost of implementing an intervention simultaneously in many clusters is high because the intervention is
implemented across the clusters in a stepped fashion, or when withholding an intervention is considered unethical or may pose a barrier to recruitment because all clusters will receive the intervention by the end of the study. As in crossover trials, the crossover from the control condition to the intervention within each cluster allows for within-cluster comparisons that may increase statistical efficiency; similarly, stepped wedge studies must guard against carryover effects.

**BAYESIAN STATISTICAL INFERENCE AND ADAPTIVE DESIGNS**

Another direction in clinical trials is the use of Bayesian frameworks of statistical inference instead of the standard classical (frequentist) framework. Although a full discussion of Bayesian statistical inference is beyond the scope of this chapter, in essence, the Bayesian framework incorporates new evidence or observations to update probabilities that a hypothesis might be true. Bayesian adaptive trials use Bayesian methods to incorporate data collected during the course of a trial in order to inform decisions regarding the need to update, modify, or stop the trial.

**Systematic Reviews**

The relatively rapid advances in other fields of medicine, such as oncology and cardiology, occur because a succession of large randomized trials, typically implemented in multiple centers, results in cumulative knowledge. Such large, multicenter trials are still the exception rather than the rule in pain treatment, perhaps in part because of lower research funding for nonfatal conditions. Nonetheless, more pain research trials are being conducted, resulting in an ever-growing body of literature. This growth has been exponential. Between 1950 and 1990, more than 8,000 randomized controlled trials of pain research were published, with over 85% appearing during the last 15 years of that period.

Given the amount of evidence, it is difficult for clinicians to keep up with the literature on even a circumscribed area of medicine. Review articles can be a useful way to summarize the evidence on a given topic. A systematic review is a particular type of review article that applies explicit
methods to reduce bias and error when summarizing evidence. This is in contrast with traditional or “narrative” reviews, which do not use explicit methods to identify, select, and assess evidence. Such review articles are relatively subjective and are apt to be based on incomplete, outdated, or flawed evidence. This increases the likelihood of incorrect or unsubstantiated conclusions.

A “systematic” review attempts to bring the same level of scientific rigor to the review article as should be used when conducting original research. Systematic reviews can be qualitative or quantitative. The latter are also referred to as meta-analyses, although strictly speaking, a meta-analysis is not necessarily based on systematic methods. Potential advantages of systematic review over traditional review articles are shown in Table 10.8. A high-quality systematic review minimizes bias and random error by using transparent, reproducible, and objective methods. In addition to summarizing existing data, systematic reviews can also increase statistical power for evaluating low-frequency events, provide more precise estimates of treatment effects, permit formal comparisons between studies, permit formal assessments of publication bias, and help delineate areas of uncertainty.

Before trusting the results of systematic reviews, it is important to critically evaluate whether rigorous methods were used. In fact, results of lower quality reviews can be misleading, as they are more likely than
higher quality reviews to produce positive conclusions about the effectiveness of interventions.\textsuperscript{138,140} Table 10.9 lists some factors that can influence whether a systematic review is likely to be reliable. A number of other methods for assessing the quality of systematic reviews are available, including the more detailed list of criteria in the Assessment of Multiple Systematic Reviews (AMSTAR)\textsuperscript{141} and AMSTAR 2 tools.\textsuperscript{142} All quality rating methods are based on the idea that systematic reviews that are comprehensive, up-to-date, and use appropriate methods to identify, select, assess, and synthesize the literature are more likely to provide a complete and unbiased picture than those that use suboptimal methods.

The Cochrane Collaboration is an international effort to systematically review the results of multiple randomized clinical trials and make the results widely available via the Internet. The number of Cochrane reviews on pain topics is rapidly expanding, and many have been published in conventional journals as well as in the Cochrane Library.

**Conclusion**

Despite the rapid growth of research literature on the treatment of pain, there remain wide variations in care and the successive use of fads that are later demonstrated to be ineffective when well-designed studies are performed. Both the prevalence of painful conditions and their associated disability are increasing, and there is only a limited professional consensus on optimal approaches to many painful conditions. The disappointing pace of progress may be partly the result of few comprehensive theories that would guide treatment innovations. However, an equally important factor
may be the methodologic inadequacy of the research used to justify the introduction of new or innovative therapies to clinical care. Flaws in research design jeopardize not only the internal validity of research results but also their generalizability to routine clinical practice. Greater attention to scientific principles in the design of clinical research should accelerate progress in this area, lead to more consistent clinical practices, and improve patient care.

PART TWO

Economic, Political, Legal, and Ethical Considerations

CHAPTER 11

Transdermal Pain: A Sociocultural Perspective

DAVID B. MORRIS

“Chronic pain is a transdermal phenomenon and the environment is always a player in the chronic pain patient’s predicament.”
—J. D. Loeser

“A threshold has been crossed,” writes sociologist Nikolas Rose. Rose is director of the BIOS Centre for the Study of Bioscience, Biomedicine, Biotechnology and Society at the London School of Economics and Political Science. He wants to avoid what he calls “breathless epochalization”—hyperbolic claims that human history is undergoing a single, abrupt, massive upheaval—and he understands the present instead as the unfolding of “multiple histories” that emerge from the intersection of numerous “contingent pathways.” Nonetheless, he also provides in The Politics of Life Itself (2007) an indispensable framework for considering how much has changed since the first edition of John Bonica’s groundbreaking text The Management of Pain (1953). Pain too has changed, especially chronic pain, as pain has moved from the status of symptom to diagnosis, from the category of what humans passively endure (a mark of our changeless humanity) to what patients and health professionals
together, as partnered agents of somatic change, now actively manage. These recent transformations in understanding pain hold important implications for pain management.

The dimension of change might be traced in the invention of the new discipline of pain medicine. “Prior to 1960,” writes distinguished pain specialist John D. Loeser, “there were no pain specialists.” He adds, “There were no journals devoted to pain, no dedicated research laboratories, and no funding programs aimed at pain research or training for clinicians. . . . Pain was always described as a byproduct of a disease state; the implication was that proper treatment of disease would relieve pain. The sensory nervous system was envisioned as a passive set of wires that conducted incoming impulses to the brain.” The Management of Pain in its first edition, reflecting this earlier and clearly imperfect state of knowledge, contained no discussion of relations between human pain and the sociocultural environment.

The rich biomedical literature currently exploring relations between human pain and the sociocultural environment is sometimes difficult to appreciate because we are in the midst of another momentous change. Nikolas Rose describes this change as what he calls “a molecular vision of life.” Contemporary medicine and the biotechnologies on which it relies increasingly understand life at a subcellular level—with consequences that extend far beyond such familiar categories as illness and health, pathology and normality, and treatment and enhancement. The new techno-medicine, Rose argues, does not just cure disease or correct organic damage but, in its promise to refigure human vital processes at the molecular level, even changes “what it is to be a biological organism.”

What it is to be a biological organism has always included vulnerability to pain, but it is not only our understanding of pain that has changed dramatically since 1953. Pain patients too have changed. A large subset of patients now regard themselves as well-informed, self-educated medical consumers, alert to the documented dilemma of medical error and actively embracing the apparent promise of what has been called our “genetic citizenship.” Women who carry the BRCA1 gene, for example, now understand that they face both an 87% risk of developing breast cancer and difficult medical options. Pain patients may expect that researchers simply
need to find the gene for pain and knock it out—without understanding that most researchers do not seek a single specific “gene for” but rather variations in multiple loci within multiple gene systems. Although older infectious diseases have almost disappeared, chronic pain seems almost ineradicable, even on the rise, less a predictable companion of old age or an image of the human condition than an unaccountable failure of the molecular gaze to identify a local culprit neuron. It leaves the modern patient locked out from the molecular promise of somatic optimization. The “incrementalism” required for slow, steady improvement (that likely falls far short of cure) is also frequently difficult for doctors to grasp. Thus, damage that chronic pain inflicts on body, mind, and spirit leaves many patients not at the threshold of a shining future but in a dark limbo or dystopia that negative psychosocial and sociocultural influences can turn into a prison or hell.

What follows, then, is an effort to place the new understandings of pain within a conflict-laced field where sociocultural and psychosocial forces may actively impede or assist treatment. In the new era of the molecular gaze, it is increasingly clear to health care professionals (if not to patients) that chronic pain in its numerous types, from migraine to cancer to garden-variety low back distress, is often more amenable to sociocultural analysis and to psychosocial therapies than to biomedical cure. Drugs and surgeries—perhaps the first choice of patients or insurance providers—may be exactly the wrong approach. Pain specialist Scott Fishman puts it this way: “When somebody comes in with 25 years of chronic pain, I might sit with them for 90 minutes to get the beginning of the story, to really understand what is happening. The insurers would rather pay me $1,000 to do a 20-minute injection than pay me a fraction of that to spend an hour or two talking with a patient.” The pain that patients experience in certain medical settings, as new research unmistakably demonstrates, also reflects racial, ethnic, and provider biases in health care professionals that directly or indirectly affect real-world assessment and treatment.

One quick caution. An attention to sociocultural and psychosocial influences on chronic pain does not imply rolling back decades of biomedical progress in which we now understand gout, for example, as a type of congenital arthritis and not—as in this 19th-century etching by
satirist George Cruikshank (Fig. 11.1)—a justified moral punishment for luxurious aristocratic lifestyles.

FIGURE 11.1 Introduction of the Gout by George Cruikshank, 1819 (this impression 1835). Colored etching. (Courtesy of Wellcome Library, London.)

Cruikshank, however, is not wholly wrong. The pain of gout correlates not only with molecular processes affecting serum uric acid levels but also with cultural and psychic forces underlying diet and socioeconomic position. Even today, gout has a sociocultural impact on patients’ lives that differs between African-American and Caucasian men and women. Bottom line: What most patients do not know about chronic pain—especially its concealed link with social institutions, cultural practices, and individual personal belief—is exactly what evidence-based pain treatment in the era of the molecular gaze cannot ignore.

What Is Transdermal Pain?

Pain, especially chronic pain, is a transdermal phenomenon in that it occurs not only within an individual nervous system, including the brain, but also within a social and cultural environment. “Our concepts of pain, impairment, and disability,” writes Wilbert E. Fordyce, “must consider environmental factors as well as the person.” Clinical practice frequently reduces environmental factors to three main stressors—employment, family, and alcohol or drugs—but this trio can serve as placeholder for a more extensive mix of sociocultural variables. The fundamental question is whether the sociocultural environment merely influences pain that already
exists as a purely biologic phenomenon, simply modulating it, or, alternatively, if the sociocultural environment (beyond mere influence and modulation) helps to construct and to constitute pain.

The difference between influence and construction is important, but its significance for assessment and treatment is unclear because chronic pain often reflects multivariate influences. Some pain—often called psychogenic—seems produced almost wholly by the brain or with little more than an innocuous trigger from the environment. In one study, researchers attached volunteers to an electrical stimulator and told them that its current might possibly produce a headache. Volunteers were not told that the stimulator was set to produce nothing beyond a low humming sound. The result? Half the volunteers reported pain. The environment need not cause or trigger pain in the way a hammer blow impacts a thumb. Positive or negative influences from the sociocultural environment may be as indirect as a whisper. Researchers, utilizing the molecular gaze, recently found that simply looking at the picture of a romantic partner reduced moderate pain by 40%. The sociocultural environment, in contact with human consciousness, may not create or construct pain, but it clearly possesses a resource for pain management too important to neglect or dismiss, and its importance increases in proportion to acceptance of the now widespread recognition that distinguishes between nociception and pain.

The transmission of nociceptive impulses may at times generate autonomic responses, the human equivalent of a rodent’s tail flick, but nociception alone does not constitute human pain. Pain, according to the prestigious International Association for the Study of Pain (IASP), is “always subjective” and “always a psychological state.” The subjective, psychological quality of pain, as human consciousness interacts with the sociocultural environment, is true in spades of chronic pain.

The crucial point here is that most pain specialists today attribute a significant role to the sociocultural environment—a truly historic change in thinking about pain and pain management.

Moreover, the new managers of pain, from a sociocultural perspective, are now doctors and health care professionals, working within complex interrelated systems in which health care costs in 2014 rose to 17.5% of
the U.S. Gross Domestic Product. Pain management now cannot be cordoned off from the surrounding medicalized culture and subcultures, where the molecular vision of life has (selectively but broadly) replaced a reliance on shaman, priest, or astrologer. This pervasive medicalization of pain, however, is not without consequences, especially when medical care seems to fail patients. Pain medicine thus is not a neutral or inevitable byproduct of scientific knowledge but rather a presence within the new sociocultural environment that influences pain. Many patients today, that is, experience pain only within a context that includes various specialists who deal with pain, from orthopedists, oncologists, and neurologists to acupuncturists, homeopaths, and practitioners of alternative and complementary medicine. Pain specialists cannot excuse themselves from discussion as if they were mere impartial technicians, objective researchers, or altruistic caregivers—who assess and treat pain but do not affect how patients understand or experience it. Louis Heshusius, a Canadian academic born in The Netherlands, suffered excruciating chronic pain in the aftermath of an automobile accident. Over an 11-year period, she lists some 240 appointments with doctors and specialists; nearly 500 appointments with alternative professionals; a dozen appointments for tests and assessments; and countless hours keeping track of prescriptions, bills, and insurance. Pain specialists are among the key players in the new sociocultural environment that not only indirectly influences pain but also helps constitute the chronic pain patient’s predicament.

The new active role for pain specialists is certainly driven by patient demand but not solely by patient demand, nor are its effects inconsequential. When clinicians employ evidence-based practices, chart pain as the fifth vital sign, or “game” insurance systems on behalf of their patients, such actions contribute to the maintenance of a significant sociocultural environment within which patients now experience pain. Although pain medicine did not invent insurance providers or disability systems, it operates today within a field of economic compensation that sets patients in a new relation to their pain. In a controversial recommendation, an IASP task force argues that chronic nonspecific low back pain in the workplace, in the absence of an organic lesion and under specified circumstances, should be reclassified not as a medical problem
but as “activity intolerance.” Activity intolerance is less a diagnosis than a tone-deaf counter-narrative meant to contest the implicit sociocultural narrative that regards chronic low back pain as redeemable for disability payments or for time off. The almost seamless but culturally mandated transition from person-in-pain to pain patient—whose inner life is now under the implicit surveillance of the molecular gaze—also involves an invisible agenda of forms to fill out, waiting rooms, secretaries, insurance companies, drugs, side effects, referrals, more waiting rooms, indignities, task forces, protocols, and still more waiting rooms. It situates pain and the pain patient within a web of sociocultural relations that reframe pain as transdermal.

**Ethnicity, Race, Sex, Gender, Age: Whose Pain?**

A molecular vision of life enfolds the modern pain patient within layers of unappreciated irony. That is, while patients increasingly adopt the expectations of a molecular gaze, pain medicine finds increasing evidence to support nonmolecular and sociocultural understandings of pain. Culture and biology both contribute to pain, of course, as the standard biopsychosocial model implies, but patients committed to the molecular gaze fail to grasp the extent to which human pain is not only always subjective but also always intersubjective. It intersects with shaping social systems from family, church, and nation to jobs and prisons, just as it meshes with variable cultural practices and beliefs from stoic dispassion to pharmaceutical trials. Such sociocultural environments are not necessarily material locales, like a doctor’s office, but bear more resemblance to internalized, individual subsets of what anthropologists would call a lifeworld—a lifeworld that we experience as a state of body, mind, and emotion. Consciousness is the hard-to-define locus of such complex states, and chronic pain (as a classic mind/body state) is thus inextricable from the individual, intersubjective lifeworlds that shape as well as frame it.

The clearest instance of how sociocultural environments shape as well as frame pain comes in long-standing medical undertreatment for pain. The hospital, that is, constitutes a distinctive microenvironment that demonstrates how sociocultural forces help alter the experience of pain.
The prestigious 1996 SUPPORT study found that 50% of hospitalized seriously ill or dying patients failed (according to family members) to receive adequate pain medication. Hospitals, like doctors, belong to the larger sociocultural environment where both drug abuse and fear of opioids have a strong presence, and the hospital as a distinctive microenvironment in some sense reproduces the mixed or self-contradictory beliefs and practices that surround it. Anesthesia belongs to the sociocultural environment of the hospital, where it is accepted as necessary, just as illegal street drugs belong to the environment of the street, where other necessities prevail. Pure pain—pain free from all direct or indirect sociocultural influences, including the artificial, scientific subculture of the laboratory—is a pain that exists nowhere except in theory. Pain as it inhabits the social world outside the laboratory proves always open to the modifying environmental influences of (among other often imprecise categories) race, ethnicity, sex, gender, and age.

Racial disparities in the assessment and treatment of pain are the focus of numerous medical studies. Differences in pain tolerance provide conflicting data, as in laboratory studies about racial tolerance for thermal pain. Some facts, however, are incontrovertible. In New York City, nonwhite patients who lived in disadvantaged neighborhoods (often black and Hispanic) had substantially less access to pharmacies than did white patients in more affluent neighborhoods. The pharmacies in disadvantaged areas moreover did not maintain adequate stocks of pain medication. A sociocultural environment that reduces access to analgesia has an indirect but powerful impact on pain. Although reduced access does not directly cause pain, sociocultural practices that unfairly burden racial and ethnic minority populations indirectly both maintain currently unrelieved pain and, in effect, permit the emergence of new pain that does not exist in primarily white, affluent, more pharmacofriendly communities. There is even neurologic evidence indicating brain and autonomic correlates with empathetic responses to pain in persons of other races. Fortunately, studies are now underway to improve clinician awareness concerning pain management disparities.

Race and ethnicity, then, are frequently discussed in recent studies on pain—but discussion is often impeded by failures to clarify underlying
concepts. Classic articles describe ethnocultural differences in the perception of pain and of chronic pain. Numerous researchers report ethnic differences in the prevalence and severity of pain, and they find interethnic differences in tolerance levels for clinical and experimentally induced pains. For example, attitudes toward pain show sharp differences along ethnic lines among surgical patients in Australia. Cancer pain among southwest Native Americans has its own specific ethnic signature. Race affects how we view others’ pain. It influences analgesia use in pediatric emergency departments. It affects analgesic access for acute abdominal pain in the emergency department. Among patients with arthritis and rheumatic conditions, race and ethnicity even impact treatment outcomes. Yet, exactly what are ethnicity and race?

Pain specialists need to engage with recent thinking about how to understand race and ethnicity. Bio-anthropologists contend that there is no genetic signature for race. In general, there is more genetic variation within (so-called) races than across races, which means that race and ethnicity are primarily sociocultural rather than genetic categories. Skin color alone links population groups as diverse as their languages: say, Italians and Swedes, Scots and Russians, and Belgians and Croats. Blackness, as a supposed racial marker, links West Africans with the historically very different East Africans, as well as with Haitians, African Americans, some Hispanics, and various hyphenated groups identified, roughly, by the mere color of their skin. Migration, intermarriage, and global travel have produced a wave of mixed-race offspring. The census term “Asian” has a different meaning in Europe than in America, and census data in Western democracies now define race and ethnicity not through genes, skin color, or geography but rather as a matter of self-identification. In a movement away from reductive ideas of racial science, the most helpful recent turn in health care discussion emphasizes population groups, where biology and genetics are relevant but far from determinative. “Key, here,” as Nikolas Rose explains, “is not so much race, but the belief that a particular community has specific health needs that may have a genomic basis, and that research on the genomic basis is essential if these needs are to be met.”

Pain assessment and pain management are caught up in the shifting
sociocultural and historical web of attitudes and practices that envelop race and ethnicity. Over half of Hispanics who presented at emergency rooms with long bone fractures, for example, were twice as likely as similar white patients to go without pain medicine.\textsuperscript{41,42} Hispanic ethnicity, according to a recent prospective 10-year evaluation, continues to impact pain management decisions in the emergency department.\textsuperscript{8} We need not posit conscious racism on the part of health care providers, although its presence in medicine (whether conscious or nonconscious) is well documented.\textsuperscript{43,44} It is enough to observe that medical degrees do not confer immunity from nonconscious acts of discrimination that reflect the racism of a surrounding culture. This fact should be cause for vigilance in health care settings. Although many blacks carry a gene that puts them at risk for sickle cell disease, their need for pain relief too often runs up against tacit medical stereotypes of drug-seeking behavior.\textsuperscript{45,46} Like the infamous Tuskegee syphilis experiments on black airmen, the history of sickle cell pain warns that sociocultural biases concerning race and ethnicity—not race or ethnicity themselves—pose a significant continuing danger to the achievement of color-blind, discrimination-free, equitable pain management. A means to identify and combat racial bias in pain treatment is now an urgent ethical issue in medicine.\textsuperscript{10}

Telltale absences of equitable pain management unfortunately continue to appear in multiple medical sites not limited to the pain clinic. African American cancer patients in nursing homes were 63\% more likely than whites to receive no pain treatment.\textsuperscript{47} Other minorities with cancer pain also experience inadequate pain relief.\textsuperscript{48} The unequal worldwide distribution and consumption of morphine means that medication for pain is far more available to first-world and mostly white patients than to nonwhites in the developing world.\textsuperscript{49,50} This difference is not mainly a function of income, although in the United States, there is a strong association between pain prevalence and socioeconomic position.\textsuperscript{51} The US campaign against illegal drug trafficking makes inadequate pain relief for Mexican patients also political in origin.\textsuperscript{52} Pain management teams, as they confront questions about clinical policy and research design, need to recognize that race and ethnicity are ill-defined, socially explosive classifications with little basis in genetic science. The laudable recent
interest in developing “cultural competence” among health care professionals who treat patients in pain cannot allow generic descriptions of group traits to replace a focus on the individual patient. Geronimo was not a typical Chiricahua Apache, and modern Apaches may share few cultural connections with modern southwestern pueblo peoples. Stereotypes based on race or ethnicity—often flawed or at least slippery concepts—are the enemy of good pain medicine.

Sex and gender raise additional complications in assessing sociocultural influences on pain. Sex differences appear real, if limited. Animal studies indicate differences between male and female rodents in pain processing, including a greater efficacy of µ-opioids in males. In humans, κ-opioids produce significantly greater analgesia in women than in men. Even among women only, red-haired women (in a study that did not test men) show increased sensitivity to thermal pain and reduced responsiveness to subcutaneous lidocaine because of specific mutations of the melanocortin-1 receptor. Biologically based sexual differences clearly play a role in women’s pain across a range of chronic pain conditions from migraine to irritable bowel syndrome, although the precise mechanisms are often unclear. Sex steroid hormones in men and women appear to modulate different nociceptive behaviors. Pregnancy, for example, whatever the television-dramatics associated with morning sickness and labor pain, creates an antinociception that involves δ-opioid and κ-opioid but not µ-opioid systems. Such biologic differences, however, are likely modest when compared with the exaggerated and shifting sociocultural representations of female and male pain—from Freudian hysteria to John Wayne machismo—that undoubtedly have a shaping influence on the experience of pain.

Pain researchers have been slow to investigate potential differences due less to sex than to gender. Sex, that is, depends on the biology of male/female difference, whereas gender splinters the standard male/female binary into a rainbow of orientations from gay and lesbian to bisexual and transgender. One prominent argument in the field of gender studies holds that gender is largely performative, meaning, gender—no matter how individual, eccentric, or dependent on hormone therapies—constitutes a quasi-public social role. The women whom Charcot in the 19th century
photographed in his famous hysteria wards clearly “performed” their illness for the camera, even if unknowingly, and today women tend to perform specific gender roles (e.g., as overextended caregivers) that are sociocultural and not entirely unrelated to pain. Caregivers, for example, are at increased risk for multiple maladies, from depression to heart disease. Men, too, perform certain gender roles directly or indirectly related to the capacity to endure pain, where the power to endure pain is a sociocultural rather than biologic trait. A pain treatment program that recognizes the complicating sociocultural role of gender—in addition to well-known differences in sex, race, and ethnicity—will be best equipped to grasp the multiple lines of influence, both biologic and psychosocial, that so often converge in chronic pain.

Age might stand as an icon for the multiple biologic and sociocultural convergences that influence chronic pain. Pediatrics and geriatrics both depend on biologic changes that accompany human growth, but childhood and old age are both also the site of numerous, tacit, culturally specific expectations. Pain research has devoted considerable resources to children, whose limitations in language and in perception require ingenious techniques for assessment. Techniques such as drawings that indicate the location and intensity of pain depend equally on the biologic facts of human linguistic development and on the sociocultural skills and learning associated with graphic design. Pain treatment geared to children also requires, in addition to carefully age-adjusted medications, an attention to childhood fears and feelings that belong to particular cultures. Much like ethnicity and race, age (especially cultural stereotypes of the elderly) has an impact on pain management decisions. Even in the emergency department, there appear to be disparities in pain treatment afforded to younger and older adults. Old age, however, whether defined by chronology alone or by organic and developmental changes, has received less attention than childhood in pain research, although the new field of palliative medicine is bringing rapid change. Indeed, one area in particular need of increased study is pain at the end of life. Dying is clearly a biologic process, but the funeral industry alone indicates how far death and dying are endowed with significance that is both economic and sociocultural. American and European medical attitudes clearly differ
about continuous deep sedation until death. Clear ethical guidelines on pain treatment at the end of life are greatly needed. Edmund Pellegrino, a giant of modern bioethics, defines the challenge to modern end-of-life pain medicine in what resembles a blunt, if indirect, ultimatum: “Not to relieve pain optimally is tantamount to moral and legal malpractice.”

Why is it important for medicine to recognize the sociocultural influences on human pain as reflected in race, ethnicity, sex, gender, and age? First, although drugs and surgery sometimes erase or control pain associated with clear organic sources, many conditions such as chronic nonspecific low back pain expose the limits of drugs and surgery, especially where sociocultural influences—such as family, job, and disability—are involved. Furthermore, organic lesions do not map exactly onto pain. Most adults who complain of back pain have lumbar disk disease, but so do many adults without pain complaints. In America, long-term functioning of patients treated for back pain is similar whether doctors prescribe medication and bed rest or self-care and education. Pain simply does not provide an accurate report of tissue damage. “The truth is that pain is a very poor reporting system,” writes Patrick Wall. He adds, “The doctrine that pain is a useful signal needs heavy qualification.” The erroneous belief that pain is a reliable alarm system not only justifies countless unnecessary surgeries but also cannot begin to explain why the two strongest signs predicting that an American worker will develop chronic back pain are job dissatisfaction and unsatisfactory social relations in the workplace. It is as if the American low back is wired directly into the sociocultural work environment. A study covering 18 countries found large international variation in the prevalence of disabling forearm and back pain among occupational groups carrying out similar tasks.

Second, the recognition of sociocultural influences on pain opens up possibilities for system-wide changes in pain management. In 1999, a memorandum directed to over 1,200 sites required the entire U.S. Veterans Health Administration to make policy and procedural changes implicit in the new principle that pain is the fifth vital sign. In one VA outpatient clinic, this change produced no measurable improvement in pain management quality. The possibilities for system-wide change are
impressive, however, especially when hospital accreditation now depends on requirements to chart pain levels. A similar requirement altered policies in pain management and in palliative medicine throughout all the hospitals in the vast southwest region of the U.S. Indian Health Service. Such changes acknowledge that pain management belongs to a surrounding sociocultural environment that includes the changing subculture of medicine. Systemic changes in pain management thus affect not only individual patients but also the wider sociocultural environments (from clinics and hospitals to digital media reports) within which both patients and nonpatients understand and experience pain.

The IASP in its glossary of terms describes pain as “always subjective” and “always a psychological state.” Pain, by implication, may change when a person’s subjective, psychological state changes sufficiently. Systemic changes in the sociocultural environment of medicine—including efforts to reduce provider bias based on age, gender, sex, ethnicity, and race—can materially alter individual experience and help relieve pain. Such changes also recognize that a patient’s race, ethnicity, sex, gender, and age have demonstrable effects on the experience of pain. Suppose that a woman from a minority group in a low-income neighborhood repeatedly fails to receive adequate pain medication from her local pharmacy. Frustration, humiliation, and rage, compounding the fear that she may already feel about her health, constitute a significant change in her subjective state not unrelated to pain. Fear, as researchers show, elevates pain intensity. Pain specialist Mark Sullivan argues that pain itself is best understood as an emotion. Patient education and improved access to care offer two additional and specific areas for systemic change, with consequences that promise a difference in both the psychology of individual pain patients and in the surrounding, interpenetrating sociocultural environments within which people of any sex and gender—patients, doctors, nurses, adults, children, workers—understand and experience pain.

Across Cultures: Beliefs, Attitudes, Perceptions, Behaviors
Pain varies across individuals, cultures, and times. This strong claim contradicts the universalist view that pain is a changeless sensory signal, identical in everyone, everywhere. Dental research has identified an effect of culture on pain sensitivity. Culture, of course, is a broad general concept and not a sufficient explanation for pain or for pain sensitivity. In women, sensitivity to a variety of experimental thermal, mechanical, and chemical pain-producing stimuli has a proven genetic contribution. Individual variations in reported pain intensity produced by exposure to an identical noxious stimulus correlate directly with altered brain patterns, which can hardly be explained solely as an effect of culture. Most researchers agree, however, that pain includes both sensory and affective components, and affective components of pain show wide variation across individuals and cultures. The 1950s era surgically lobotomized patients could still feel pain, reportedly, but said that the pain no longer bothered them. It may require a philosopher to decide if pain that fails to bother us still counts as pain. (It will not show up at pain clinics.) It did require philosophers to compile a volume of essays entitled Cultural Ontology of the Self in Pain (a rough translation: The Self in Pain as a Cultural Being). Pain that is both affect-free and culture-free constitutes almost a self-contradiction because researchers agree that personal emotions—far from being bio-hardwired at birth—are fundamentally cultural.

Real-world pain, then, is characterized by an affective quality of aversiveness open to wide modulation. This aversiveness depends on corticolimbic networks, much as anxiety correlates with activity in the septohippocampal system. Emotions associated with aversiveness, however, also in part socially constructed and socially modified, need not prove static or unresponsive to additional sociocultural input. Stoic philosophers in the age of Nero exalted the use of reason to overcome pain, and many Greek texts retell the story of the Spartan boy (trained in courage and in military discipline) who remains silent as a fox hidden in his cloak gnaws him to death. Athletes, dancers, yogis, and religious celebrants continue to demonstrate how minds and emotions, as shaped by differing sociocultural environments, help to modify pain and pain behavior. Such sociocultural environments are not neutral containers for bodies in pain—like stage sets—but rather, the setting and its sociocultural
forces shape the pain. Even pain clinics and research labs are, in a specialized sense, sociocultural spaces. They help to shape expectations and to reinvent pain as surely as ancient religions shaped and reinvented pain through authoritative teachings about demonic possession and original sin. Whatever the surrounding culture teaches us or shows us about pain (including false information, erroneous recommendations, and harmful tales) holds the power to modulate what we feel—for better or worse—with direct and indirect implications for the medical discipline of pain management.

Culture as a crucial force in shaping human pain across various eras, disciplines, and practices, from legal punishment to religion, is a subject of wide-ranging books and articles. An evidence-based pain medicine can draw particularly persuasive data from cross-cultural studies. For example, researchers compared chronic low back pain patients in Japan with a similar group in the United States and found the Japanese patients to be significantly less impaired in social, psychological, vocational, and avocational function. A cross-cultural comparison matching Portuguese chronic pain patients with English-speaking chronic pain patients showed strong similarities in associations between psychosocial factors and measures of pain experience: intensity, physical function, and psychological function. Just as various psychosocial factors may differ across cultures, psychosocial factors themselves (likely rooted in particular cultures) regularly affect the experience of pain. Of course, pain evoked in a lab or studied in reviews of medical literature may not replicate everyday pain experienced outside various controlled environments, and real-world sociocultural environments include not only visible institutions such as families, schools, and workplaces but also less visible currents of thought and feeling conveyed in advertisements, songs, sports, and personal interactions. Even parental models have an influence on how individuals understand specific pain events. Aboriginal people in Australia deal with pain in culturally specific ways. Hispanics and non-Hispanics show significant differences in their knowledge about hospice care, with a resulting impact on pain management at the end of life. Although similar illustrations might be greatly multiplied, they all tend to demonstrate how cultural attitudes and understandings permeate the experience of pain,
especially chronic pain. Nowhere is the interpenetration of culture and chronic pain so clear as in the growing medical literature on so-called pain beliefs.

Pain beliefs exist in an individual mind, but they also reside within cultures so that cultures are the effective origin of most individual pain beliefs. We cannot name or discuss pain except in a natural language—English, Spanish, Farsi—that inevitably colors our understanding and subtly shapes our experience. Pain thus comes always already interpreted, and pain beliefs silently infiltrate behavior through implicit cultural scripts or narratives, much as athletes often play out a prescribed role in which tolerance for pain affirms male courage, team loyalty, and physical strength. Such normative social practices and behaviors, like the beliefs that support them, often prove amenable to observation. In fact, observation of pain beliefs (mostly via questionnaire) is a robust subdiscipline within pain medicine. Research shows that specific beliefs affect the pain we experience, especially beliefs about cause, control, duration, outcome, and blame. These beliefs affect not only chronic pain but also acute pain and postoperative pain. Pain beliefs, moreover, are often linked with emotions: anger toward a negligent employer, fear of financial disaster, hope for monetary compensation, or the desire for caring attention from a spouse. Some pain beliefs strongly correlate with pain intensity. Patients function better, this research shows, who believe they have some control over their pain, who believe in the value of medical services, who believe that family members care for them, and who believe that they are not severely disabled. In one study, specific pain beliefs correlated directly with treatment outcomes. If you believe that your pain is disabling, this internal pain belief (played out as human consciousness alters feeling and behavior) already predicts that you will be disabled by pain.

The pain belief research that got underway in the 1990s shows no sign of slowing down. The vocabulary sometimes shifts from beliefs to perceptions to attitudes—and the patients under study now reflect an extended ethnic and global reach—but the findings consistently recognize the effect of culture on the understanding and experience of pain. It is important for pain management professionals in the United States to
understand African Americans’ distinctive perceptions of pain and pain management. New Zealand practitioners need to understand the attitudes and beliefs about back pain shared by New Zealanders. Studies of pain beliefs now extend to Somali women, inner city veterans, French Canadians, the general populace of India, as well as such distinctive groups as children and the obese. Research still tends to focus on what we might call the big three pain beliefs—catastrophizing, control, and disability—but researchers are beginning to study more diverse cognitive/emotional states associated with religious faith and spiritual practices. Especially important is pain-related research into attitudes about personal identity and self-efficacy. One review article posed the crucial question whether pain-related beliefs influence adherence to multidisciplinary rehabilitation. Conclusion: Treatment adherence is determined by a combination of pain-related beliefs either supporting or inhibiting chronic pain patients’ ability to adhere to treatment recommendations over time, and self-efficacy appears to be the most commonly researched predictor of treatment adherence, with its effects also influencing other pain-related beliefs.

Future studies might well expand their methods and focus to include a larger sense of meaning—its presence, absence, or indeterminacy—as intrinsic to human pain. Meanings of Pain (2017), a collection of multi-authored essays with a philosophical turn, offers a rich lode of thought. In adults, chronic pain often implies a continuous process of interpretation—conscious, nonconscious, personal, cultural—that both builds up and deconstructs meaning. Why me? Is it serious? Will I get better? Such questions about meaning as well as the responses that they elicit, even nonconscious responses, illustrate how meaning is not merely an add-on to pain. Meaning is intrinsic to pain even at the zero degree where patients (hooked on biomedical myths) assert the belief that pain is meaningless. Pain in its social functions often reverts to its etymologic (Latin) meaning of punishment. Childhood discipline, spouse abuse, and even self-punishing guilt belong to a punitive semantics of pain. Although drugs temporarily stop pain and bypass meaning, meaning does not therefore die out. The brief pharmaceutical erasure can simply perpetuate the belief that consumer purchases and drug therapies buy relief. Meaning
here passes imperceptibly into cultural myth, and myths matter for pain management when the meanings that they encode prove harmful. A growing medical literature now explores false, erroneous, or harmful pain beliefs.\textsuperscript{109,110} Such harmful pain beliefs are as damaging to patients as unsupervised multiple drug cocktails. Detoxification is often a necessary step in pain treatment programs, and it makes sense to consider various clinical techniques of semantic detox. Catastrophizing—a toxic compound of fears and of beliefs anticipating disastrous outcomes—proves the single most important predictor for lower quality of life in chronic pain patients.\textsuperscript{111}

Transdermal pain, then, is not a subclass of pain, but rather an encompassing tautology: All pain, especially chronic pain, is transdermal. It is shaped, invisibly, by sociocultural and intersubjective forces. This counterintuitive claim seems berserk to a weekend handyman who has just hammered his thumb, but pain (in addition to various neural networks and organic systems) depends on developmental learning and cultural editing. Ice packs on a throbbing thumb invoke an elementary cultural education, as does the commonsense but erroneous belief that pain correlates directly with tissue damage. Chronic pain requires a personal and cultural reeducation in which talk of genetic susceptibilities and neurotransmitters is compatible with research into modulating sociocultural variables.\textsuperscript{112} Even neuropathic pain in laboratory rats appears to show the impact of rodent-specific social variables.\textsuperscript{113} The medical literature on sociocultural variables in pain is too vast to review here, but future researchers might wish to explore what it might mean for pain management when sociocultural perspectives expand far enough to put assessment and treatment in contact with quasi-philosophical issues as large as narrative, ethics, and globalization.

**Pain and Narrative: Culture, Meaning, Ethics**

Philosopher Alasdair MacIntyre\textsuperscript{114} identifies the widest importance of narrative knowledge when he writes that “we all live out narratives in our lives” and “we understand our own lives in terms of the narratives that we live out.” Life, as the discipline of narrative psychology puts it, is
inherently “storiied.” In acknowledgment of this so-called narrative turn, Rita Charon writing in JAMA describes a new clinical approach she calls “narrative medicine.” Narrative (from Latin narrare = to tell) can be defined as simply as “someone telling something to someone about something.” Narrative medicine sets out to reframe the everyday act of talking with patients. Charon also reframes narrative as a specific form of knowledge—narrative knowledge—as distinct from what she calls the logicoscientific knowledge so valued in medicine. Narrative knowledge, as Charon describes it, is not in conflict with logicoscientific knowledge but rather, especially as an instrument for understanding pain, offers a valuable supplement or complement to the molecular gaze. The IASP multi-authored collection Narrative, Pain, and Suffering (2005) explores a series of relevant and illustrative cases.

Narrative can offer insights into human pain sometimes otherwise unavailable. As a vehicle for the communication of cultural beliefs and social practices, narrative clearly plays a role in transmitting attitudes and perceptions that pain patients may imagine to be strictly their own unique personal beliefs. A personal narrative may also convey fine nuances of meaning and troubling webs of self-contradiction that offer a significant tool for understanding treatment-related attitudes that elude the coarse grid of generic questionnaires. There is also a downside to narrative that affects pain management. Pain narratives, that is, sometimes encode mistaken beliefs, such as the dominant biomedical myth that regards pain as the invariable consequence and symptom of organic tissue damage. In truth, as the IASP explains, many people report pain “in the absence of tissue damage or any likely pathophysiological cause.” A narrative medicine for pain, as Rita Charon puts it, promises significant therapeutic benefits where other approaches fail or fall short.

A narrative medicine for pain might find one specific use in explicating the dilemma that occurs when chronic pain engages patients in the dynamics of what anthropologists call damaged or spoiled identity. Narrative, in this instance, offers insight into a patient’s experience of self and, in some cases, can provide a means for patients to construct a new or revised selfhood: an important step toward exiting the role of chronic pain sufferer. The findings in a study of fibromyalgia patients, for example,
suggest that narrative approaches helped participants both invent their own coping strategies and discover identities other than as pain patients.\textsuperscript{122} Participants in experiments asked to write about trauma demonstrate the astonishing power of narrative to moderate pain. Rheumatoid arthritis patients who wrote in narrative form about stressful experiences, for example, showed significant symptom reduction.\textsuperscript{123} Indeed, writing about trauma is associated with various measurable health benefits.\textsuperscript{124,125} The beneficial writing very often takes the specific form of narration. “Using our computer analyses as a guide,” explains psychologist James Pennebaker,\textsuperscript{126} “we realized that the people who benefited from writing were constructing stories.”

Narrative, like a scalpel or questionnaire, has limits to its uses as a therapeutic instrument.\textsuperscript{127} Pain can push both narrative and meaning to an extreme point of collapse, where nothing can be written or spoken: a black hole from which meaning cannot emerge. Victims of torture may undergo experience so horrific and chaotic that it blocks any possible narration.\textsuperscript{128} In less traumatic situations, however, stories offer helpful public and private uses through their explicit or inexplicit commerce with ethics. Narrative had no relevance to bioethics at its modern beginnings in the 1970s as a branch of analytic philosophy, wedded to a rationalist, universalist discourse of principles, often referred to as principlism. From a sociocultural perspective, ethics is not strictly a discourse about universal truths and timeless principles but, like medicine, an intersubjective project shot through with narrative meaning.\textsuperscript{129} Although pain medicine has developed ethical guidelines concerning research on animals and on humans, there is room and need for an ethics of pain that moves beyond professional guidelines and beyond principlism.\textsuperscript{130} Pain, like love, can call into question our relations with others, not only spouses or friends but also people who are radically other, nothing like us, enemies perhaps. Narrative ethics challenges us to understand pain as always embedded in the distinctive life-stories of individuals, where ethical choices may fail to map precisely onto a rationalist logic of universal principles. A narrative ethics can illuminate contingent choices and variable contexts in which universalized moral rules are less important for health than the clarification of contingent values.
Values, intricately layered with beliefs, have proven correlations with pain. Among adult patients in a pain management unit, success at living in accordance with one’s values correlated with measures of disability, depression, and pain-related anxiety. Religion and spirituality also engage value-based beliefs—relevant to pain—that narrative helps illuminate. Among predominantly white, Christian, mid-Western patients with chronic musculoskeletal pain, the religious and spiritual beliefs of patients differ from the beliefs of a healthy population, and long-time pain patients received less support than other patients from their church community, tending to lose hope and to grow bitter: angry at themselves, at society, and at God. The Journal of Pain and Symptom Management in 2010 published an article evaluating the FICA tool for spiritual assessment. In Europe, a spiritual-needs questionnaire has proved useful for treating patients with chronic pain and cancer pain. Such instruments are not attuned to narrative meaning, but spiritual needs regularly imply an underlying narrative structure of belief. Pain narratives turn especially complex, however, when personal, spiritual, and social values clash. Should pain management—in such instances, or perhaps generally—be understood as a basic human right? A response based on timeless principles or universal truths may prove less persuasive than extended discourse that identifies underlying narrative beliefs and ultimately hammers out a shared agreement on values. Pain management implicitly affirms a set of values perhaps less applicable to illness in general than specific to pain: values that attribute to pain the status of an imperative call. Pain in this sense—as in the familiar biblical narrative of the good Samaritan—calls out for (or requires) active assistance. Reason, like justice, is not timeless and universal but temporal and context-bound. Pain management in an era of increased global diversity may find more common ground in shared professional narratives—narratives of human rights or of service to others—than in principles at odds with the values of a surrounding culture.

Beyond the Gate: Consciousness and the Limits of a Molecular Gaze

610
The molecular vision of life—or its precursor in Foucault’s well-known clinical gaze—made its dramatic entry into pain studies in 1965 when anatomist Patrick Wall and psychologist Ronald Melzack published their influential gate-control theory. The gate-control theory focuses on the process of nociception and on neural impulses blocked or transmitted at specific organic locales, and it pays particular attention to the “gating mechanism” located in the dorsal horn of the spinal cord. This innovative gaze inside the anatomy of human pain certainly changed medical thinking in the latter half of the 20th century, when the gate-control theory achieved iconic explanatory status, and some 21st century pain specialists find the gate-control theory entirely adequate: It has stood the test of time. The legacy of the gate-control theory can be traced, for example, in research into molecular approaches to treat neuropathic pain. Others, however, remain quiet or uneasy. The uneasiness occurs in part because the gate-control theory applies far better to acute pain than to chronic pain. Ronald Melzack has radically revised or quietly abandoned talk of a dorsal-horn gate and now emphasizes what he calls a cortical “neuromatrix.” Distinguished pain specialist and neurosurgeon John D. Loeser—in a 1991 article entitled “What Is Chronic Pain?”—reflects a similar change in perspective when he asserts, “The brain is the organ responsible for all pain.” “All sensory phenomena,” he adds, “including nociception, can be altered by conscious and unconscious mental activity.”

Neuromatrix theory proposes numerous networked brain connections that, beyond nociception, call into play a range of conscious and nonconscious human mental–emotional activity often rooted in the sociocultural environment. A molecular gaze that focuses on a few anatomical “gates” may prove adequate for specific chronic conditions such as neuropathic pain, although treatment for neuropathic pain remains extremely difficult, but an explanatory theory that reduces all chronic pain to neural impulses blocked or passing through a spinal gate risks ignoring the complex mind/body interrelations characteristic of a transdermal perspective. The dilemma is clear: Insurers and peer reviewers want hard evidence, although chronic pain is often characterized by multiple influences not easily amenable to cellular repair or reducible to sound quantitative data. Research on chronic low back pain, for example, is
mostly restricted to high-income countries, where rates of low back pain run 2 to 4 times higher than in low-income countries. Within low-income countries, rates of low back pain are higher in urban populations than in rural populations. These socioeconomic variations suggest that low back pain—a signature instance of chronic pain—is not a likely candidate for molecular cure. Many multidisciplinary treatment programs now recognize the impact of psychosocial factors and emphasize cognitive-behavioral therapies, but “psychosocial factors”—reducible to the influence of families, jobs, and alcohol or drugs—often merely nestle uncertainly within a dominant, evidence-driven, biomedical model.

The challenge for pain management in the decades ahead is perfectly captured in the title of a recent research paper: “Cognitive Behavioral Therapy for Chronic Pain Is Effective, But for Whom?” The authors point out that the oldest and most educated patients showed strong treatment effects, whereas younger and less educated patients did not. It will require extensive additional research to confirm and to explain these findings. Unless the impact of age and of education are due entirely to anatomical or neural development, however, it appears that even the success of cognitive-behavioral therapies depends in part on changes ascribable to a sociocultural environment. Success, most patients would agree, is the goal of any pain management program, and a totally pain-free state is no doubt an unrealistic definition of a successful outcome. Pain management programs may at times unknowingly prove countertherapeutic if they provide an official confirmation of disability status or rigorously transform people in pain into long-term pain patients. Patienthood as an official or unofficial status brings its own sociocultural baggage. In pursuit of success, there is value in studying communities in which people who do not seek medical care for chronic pain—by choice or because modern medical care is unavailable—nonetheless lead, by their own accounts, happy, productive, successful lives. How do they do it?

Success for a person living with pain ultimately is a matter of consciousness. Of course, consciousness is a concept difficult enough to occupy teams of philosophers, neurologists, and students of artificial intelligence, but success for people in pain ultimately plays out in their conscious and nonconscious mental lives. Even chronic pain patients who
master coping skills have somehow changed their mental and emotional architecture. The new field of positive psychology argues persuasively for shifting focus away from dysfunction and instead seeking to understand what specific beliefs, attitude, and practices appear to promote effective function and personal happiness. Positive psychology suggests that there is value in identifying “success stories”: another narrative genre relevant to medicine. Such success stories might be drawn not only from people in pain who benefit from cognitive-behavioral therapies but also, perhaps especially, from people in pain who lead successful lives and do not enter pain treatment programs or research protocols. Hope and fear take on unusual, even primal power when pain strikes, as reflected in both the placebo effect and the nocebo effect. (“Voodoo death” is a documented fact.) Prayer and the belief structure reinforced in a church-centered community suggest resources that a biomedical or gate-control model of pain too often ignores in its quest to identify organic processes. An additional danger or limitation in an unrevised gate-control theory is that it may excuse specialists from an opportunity—ethical or medical—to address social and political pain-related conditions outside the nervous system.

Pain and Globalization: Power, Money, Systems

Sociologist Elliott A. Krause in Power & Illness (1977) shows how health and health care are “intimately involved with the political, economic, and social struggles of the present day.” Krause studied power as oppressive and coercive—a perspective that is relevant to current legal, military, and medical discussions of pain in torture, say, or in capital punishment. Michel Foucault, however, moves beyond his early focus on power as oppressive, top–down, and hegemonic, expressed in prohibitions and restraints. In his later work, Foucault views power as horizontal, distributed, even demotic, expressed as usable energies always circulating within a social system, like electricity coursing unseen and productively through the walls of medical facilities. This later perspective illuminates the recent, ongoing transformation of patients from passive (powerless) subjects of a colonizing biomedical gaze to active agents,
whose limited but real powers range from noncompliance and litigation to undisclosed alternative and holistic modes of self-care. Such changes, reflected in hospitals that openly post a patient’s bill of rights to adequate pain relief, suggest that pain management inescapably takes place now within the vast, disruptive, social, and economic power shift called globalization.

Globalization holds potent implications for the sociocultural dimensions of pain and of pain management. It brings patients from far-flung nations whose indigenous belief systems and whose inabilities to handle spoken English create new challenges across medicine. It also alters the commercial landscape within which medical care and pain management occur. For example, the publicly owned, family-run, mid-Western US pharmaceutical company Upjohn, which marketed ibuprofen and its over-the-counter (OTC) spin-off, Motrin, merged in 1995 with European conglomerate Pharmacia, headquartered in Sweden; the merged company Pharmacia & Upjohn in 2000 merged with Monsanto and took the name Pharmacia Corporation; and in 2002, Pharmacia Corporation was bought by the international colossus Pfizer in pursuit of full rights to the (now disgraced) blockbuster pain drug Celebrex. Marketplace dominance consolidated in a few transnational monoliths that underwrite activities, journals, and organizations in support of pain specialists justifies Foucault’s concept of biopower. Biopower refers to a modern, medical, state-sponsored, and corporate-inflected authority over health-related activities from sexuality to population control. Nikolas Rose proposes the related term biopolitics to describe a postmodern extension of biopower to far broader supra-state manipulations of human vitality, morbidity, and mortality. Pain management, not fully separable from the influence of a transnational pharmaceutical industry, cannot today be fairly represented as individual encounters between a patient and a caring doctor or health care provider. A full sociocultural analysis of modern pain management would need to situate the traditional doctor/patient dyad within a new supradyadic, globalized biopolitics as dominant (if unnoticed in most everyday affairs) as the force of gravity.

Money and pain? Pain patients are, of course, cared for largely within complex, high-tech, financially stable systems assuring—to put it crassly
—that health care professionals are paid. Local compensation issues are often influenced by national or international forces, such as the traffic in illegal drugs and its effect on domestic licensing and disciplinary boards charged with regulating opioids. Financial and political questions cannot be dismissed as merely crass in any full sociocultural perspective on pain. Who is eligible for treatment in a pain center or pain clinic? Political issues concerning citizenship and insurance coverage may be highly relevant. Is “likelihood of improvement” a formal criterion for enrolling patients? If insurance coverage is held to enhance the likelihood of improvement, then uninsured patients are de facto excluded. Some 10.4% of the US population still has no health insurance, despite recent changes, with percentages far higher among black and Latino minorities. These bland statistics reveal pain silently enfolded within larger, invisible systems of biopower and of biopolitics.

Biopower and biopolitics are not soft concepts but hard realities that influence the profound inequalities (in access to care and in treatment of pain) that face individual patients as the consequences of race, socioeconomic status, and the fast-changing configuration of national and international health care systems. In Haiti, for example, anthropologist-physician Paul Farmer struggles against global pharmaceutical companies and cost-driven policies of the World Health Organization to provide medication for HIV/AIDS patients with multiple drug-resistant tuberculosis (TB). Even national systems of universal health care cannot ignore cost in decisions about whom to treat and how. Among postoperative patients, patient-controlled analgesia (PCA) lessens pain, shortens hospital stays, and reduces pain medication, but it is also expensive, raising unresolved questions about cost-effectiveness, social justice, and access to care. Who gets it? In a balancing act that weighs cost against temporary discomfort, many patients and systems cannot afford adequate pain control. There is no mechanism for creating balance—indeed, no agreement about what constitutes balance. For HIV/AIDS patients in sub-Saharan Africa who may barely find enough to eat, pain medications and nondrug therapies alike are an unaffordable luxury. Here, too, the operations of biopower and biopolitics in a non-Western sociocultural environment help bring to light the less obvious
(more accepted) ways in which liberal democracies do or do not deal adequately in the management of pain.

The impact of changing worldwide health systems shows up in pain management as patient concern for alternative and complementary medicine. Patients today pick the latest secularized healing art from a menu of eclectic, health-related therapies marketed like vitamin pills to late-capitalist consumers in a new global “ethnomedicine.”\cite{157} In 1990, Americans made 425 million visits to providers of complementary and alternative medicine (CAM) or, as it was first called, “unconventional therapy.”\cite{158} This figure startled many analysts because it exceeded the population of the United States. It did not express an outright rejection of biomedicine, as 83% of these patients also sought treatment for the same condition from a medical doctor: Significantly, they also paid 75% of all costs out-of-pocket. A sense of the illicit nonetheless surrounded these excursions outside the biomedical model. The vast majority (72%) of patients who used unconventional therapies did not tell their physicians.

Official discourse and unofficial practice—including the practice and discourse of pain medicine—has begun to change in response to this new populist, eclectic self-care that draws its principles and therapies from around the globe. From 1990 to 1997, there was an almost 50% increase in visits to so-called “alternative medicine practitioners.”\cite{159} The number of visits soon exceeded the total visits to primary care physicians, and in 1998 the usually slow-footed US Congress established the National Center for Complementary and Alternative Medicine (NCCAM)—with a mandate to explore approaches to health and wellness “that the public is using, often without the benefit of rigorous scientific study.”\cite{160} CAM research increasingly supports the use of nontraditional treatments for symptom control among seriously ill and elderly patients.\cite{161} No mere lifestyle fad, this change extends even to cancer patients, who show a high prevalence of CAM use, especially among patients who are well-educated, well-off, young, and female.\cite{162} Three quarters of US medical schools now require coursework in CAM, and CAM therapies crossover to pain medicine with surprising ease. Among people reporting back or neck pain within the last 12 months, a national telephone survey in the United States found that 54% used complementary therapies (especially chiropractic, massage, and
relaxation techniques), compared with 37% who saw a conventional provider. Indeed, mind–body therapies have been shown both to cut the number of physician visits and to reduce arthritis pain. As attitudes change and as science catches up, American physicians and patients can now consult research-based data on topics from acupuncture to zinc enfolded within the Internet site of a new National Center for Complementary and Integrative Health.

Pain is now the focus of significant research into CAM therapies, and today the NCCAM has an annual budget over $100 million, representing not only a major institutional shift but also changes in the application of biopower. Review articles give mixed reports concerning the cost-effectiveness and clinical benefit of CAM therapies for various pain syndromes, especially chronic low back pain. Back pain is certainly the most common reason for visits to acupuncturists, chiropractors, and massage therapists. Although CAM mind–body therapies are not a popular treatment for pain as yet, most patients with chronic back pain expressed at least an interest in CAM therapies. The inconclusive and scattered data boil down to a strong initial preference among back pain patients for acupuncture, chiropractic, and massage: a view that pain management programs need to take into account not least because patient preferences encode pain beliefs and because beliefs as well as preferences change. Beyond an individual choice of therapies, however, a sociocultural perspective would emphasize how complementary and alternative therapies reflect changes in a globalized medical marketplace where drugs and surgeries for pain face increased competition from homeopaths, multicultural Internet remedies, mind–body meditation techniques, and assorted unconventional therapies. Consumer activism, global options, and perhaps even a discontent with traditional biomedicine are changing the culture of pain patients, and additional related changes are predictable for pain management.

The cultural system that has received most attention in its impact on chronic pain is disability insurance. Like most developed nations, for example, Scandinavian countries face rapidly mounting claims for pain associated with automobile accidents. Lithuania, however, which has no auto insurance, also shows no significant difference between accident
victims and a control group in reports of headache and neck pain. Chronic whiplash syndrome appears to be partly an artifact of social systems of accident and disability insurance. It is the systems, as much as persons in pain, that produce a call for pain treatment. This new post-1950s postmodern cash-driven disability narrative, however well intended, entails emotional costs for patients and financial costs for health care systems; it sometimes puts pain management programs in adversarial roles in relations to patients or to stage agencies; and it often makes successful treatment more difficult.

Pain today, in short, exists inside cultures where national health care systems and third-party insurers may inadvertently establish potential careers for patients as damaging as hysteria in the 19th century. Even the decision to become a patient is a cultural artifact: In a small Aboriginal community in Australia, back pain is not regarded as a health issue, people do not show public pain behaviors, and sorcery is a standard resource. Law as well as sorcery has an impact on pain. Some organizations require pain patients to sign contracts that transform prescription drug abuse into legal grounds for denial of treatment. Employers too play a role in reframing pain, as monotonous jobs and lack of workplace autonomy are predictors of chronic pain disability. The category of repetitive stress injury shows how sociocultural changes create new patterns of pain. Older employees with lower education and lower occupational status appear at increased risk for disabling chronic pain. Women of so-called “deprived” socioeconomic status run higher risk of pain and experience pain as more severe and disabling.

Families as a sociocultural system, like jobs, add significant complications to pain. Large-scale changes in family structure create new challenges for clinicians, as postmodern families emerge reconfigured as unstable, nuclear units fractured by divorce, blended across multiple marriages, mixed in race and gender, and marked by significant demographic shifts. The family dynamics of chronic pain has so far yielded inconclusive data. Researchers agree, however, that pain and families exist in an intricate loop of reciprocal relations, such that the patient’s pain affects the family and the family affects the patient’s pain. Among people with rheumatoid arthritis, spousal interaction
has a complex influence on pain-related catastrophizing. The precise family dynamics across specific disease conditions is less important here than identifiable links between family life and chronic pain patterns. As various emerging social roles and responses within the family structure grow clearer, pain specialists have particular reason to examine the related narratives and cultural forces that inescapably impinge on the individual experience of pain.

Conclusion: Summary and Synthesis

A sociocultural perspective is imperative for a full and adequate understanding of pain, especially chronic pain. The limitations of a molecular gaze for understanding chronic pain would seem clear in proposals that seek to reduce all pain to a single organic cause: for example, inflammation. Inflammation is a biologic process common in chronic pain, but chronic pain is always both biologic and cultural. Neither inflammation nor any other single molecular process can wholly explain the peculiar difficulties of treating chronic pain in children, for example, where cognitive development, linguistic abilities, and family relations are central. It cannot illuminate the challenges that face elderly chronic pain patients, people with HIV/AIDS, or dying patients. Pain, from a transdermal perspective, is never simply a matter of molecules, nerves, or neurotransmitters, just as the practice of pain management is never just or entirely a matter of unambiguous evidence or of applied science.

Overdetermination, in psychoanalytic theory, refers to the concept that multiple causes combine to produce a single behavior, emotion, symptom, or dream. Chronic pain, usually overdetermined in spades, is often described today not as a symptom but as a disease, although it is less a classic disease state than a complex, changing, multivariate event staged within human consciousness as always open to and modified by the surrounding sociocultural environment. Contemporary Barcelona sculptor Jaume Plensa, in his gigantic figure entitled Wonderland, offers a powerful image of how we might reimagine the human figure in pain—not so much contorted in agony but rather (no matter what the outward expression) as semitransparent: embedded within a surrounding, interpenetrating, and
changing sociocultural environment (Fig. 11.2).

The sociocultural environment today as it impinges on human pain includes skyscrapers, banking centers, multinational pharmaceutical corporations, civic plazas, monumental artworks, and pain management programs even as it includes less tangible beliefs, attitudes, behaviors, and perceptions—all flowing through whatever individual organic neuromatrix or brain state gives rise to the phenomenon (as yet invisible to the molecular gaze) that we call consciousness. Human consciousness is ultimately where the organic processes of nociception culminate in pain.

Consciousness—arguably, an emergent property of human brains, but no matter how we define or imagine it—modifies and interprets nociceptive sensory input in ways consistently responsive to the changing sociocultural forces within an individual’s immediate environment. It is an environment that for pain patients necessarily includes the clinician. Researchers recently confirmed, at least in electronic simulation, the hypothesis that patients who believe they share core beliefs and values with their clinician will report less pain than patients who do not.189 Such findings extend our general understanding that chronic pain is open to significant modification—for better or worse—from workplace, gender, ethnicity, belief, emotion, money, age, racial stereotypes, and narrative, to name a few. Children, in part because of a distinctive cultural, social, and linguistic background, may experience pain very differently than adults do.
First-generation immigrants may experience pain differently than their assimilated second-generation children do. Persons with HIV/AIDS may face a pain that is distinctive depending on how, in individual cases, a specific infectious disease engages the highly variable forces of geography, nation, social class, race, religion, stigma, and access to care. New media (such as Flickr and Tumblr) that combine visual images and multimodal elements are already extending and transforming traditional chronic pain narratives. Future media and new social forces, as their energies flow through the open mesh of human consciousness, will doubtless bring new changes to the experience of intractable pain. Chronic pain, in short, cannot be reduced to a static diagram of cellular processes. It is the always extracellular, nonmolecular, sociocultural dimensions of chronic pain that promise to offer difficult and continually changing challenges that pain management programs in the 21st century will need to confront and to address effectively.

ACKNOWLEDGMENT
For his assistance, I am grateful to John Loeser, who attributes the phrase “transdermal pain” to his colleague Wilbert Fordyce. Many thanks as well to Daniel B. Carr.

Gonzalez-Polledo E, Tarr J. The thing about pain: the remaking of illness narratives in chronic
The fourth edition of this book was the first to include chapters specifically addressing the ethical dimensions of pain management. This is curious because the duty of physicians to relieve pain and suffering has been acknowledged for centuries. Indeed, this duty has been deemed an essential component of the ethos of medicine, as fundamental as the diagnosis and treatment of maladies. The rise of ethical discourse on the relief of pain and suffering in the late 20th century was prompted by a growing recognition that all too often pain was not adequately treated, and far too many patients unnecessarily endured the pain and suffering engendered by their illness. The fact that failure to adequately treat pain was not viewed until relatively recently as an ethical problem may have been due in large measure to the prevailing perception in medicine that pain was a necessary concomitant of illness which the “good” patient must bear with equanimity. Indeed, that is a common dictionary definition of the adjectival form of the word patient.

In light of the preceding text, one can argue that the traditional view of the ethics of pain management, to the extent that it was articulated at all in the professional literature, provided a basis for undertreating pain, particularly if what was required to adequately relieve pain involved the administration of opioid analgesics. From the time of its development and inclusion in the medical pharmacopeia, morphine, and subsequent synthetic derivatives, has been recognized as a two-edged sword, carrying both the benefit of pain relief and the burden of potential addiction. The widespread phenomenon of undertreated pain seemed to be a product of a risk/benefit calculation by physicians that the risks of addition to opioids were unacceptably high, whereas the benefits of pain relief were relatively inconsequential. Particularly, in the second half of the 20th century, the clinical focus was on formulating a diagnosis and implementing disease-
directed therapies, not palliating symptoms.

During the last several decades, however, there has been a gradual but highly significant paradigm shift in the ethics of pain management. Until quite recently, as David Morris insightfully notes in his book, The Culture of Pain, “The everyday medical dealings with pain conceal unacknowledged ethical questions.” Even in the care of cancer patients, Morris continues, the clinical ethos has been tainted by “an unacknowledged moral code expressing half-baked notions about the evil of drugs and the duty to bear affliction.” He concludes with the grim observation that “the ethics of pain management, unfortunately, may not receive proper attention until the first doctor is successfully sued for failing to provide adequate relief.”¹ There was a remarkable precession to Morris’s suggestion, for in the very year in which his book was published, a jury awarded millions of dollars in both compensatory and punitive damages to the family of a patient whose terminal cancer pain was undertreated. That case is discussed in detail in Chapter 15 of this book. Similarly, the ethical issues pertaining to the care of the dying patient are discussed in depth in Chapter 13, and the laws and policies relating to opioid analgesia are surveyed in Chapter 14.

In the decade and a half since the publication of The Culture of Pain, the ethics of pain management has finally begun to receive the attention, discussion, and debate that had been so starkly absent before. This was the result not only of a heightened sensitivity to the phenomenology of pain and the suffering which it can engender or exacerbate but also of recognition of its multiplicity of sequelae. Also during this period, there was a remarkable shift in the prevailing view about the risk of addiction associated with medically directed opioid use. It is this last item that has undergone yet another significant transformation in the years since the fourth edition of this book was published. In the sections that follow, I consider the evolutionary process of the ethics of pain management and the current state of affairs.

**Pain, Suffering, and the Core Values of Health Care**

For centuries, the core values of medicine and the other health professions
never seemed to be in doubt. They were often, however, encapsulated in vague maxims of uncertain origin and authenticity such as primum non nocere (first do no harm) or “to cure when possible, to relieve often, and to comfort always.” The core ethical principles on which these maxims were grounded—beneficence and nonmaleficence—were unquestionably formulated by physicians during the long reign of paternalism as the overarching paradigm for the professional–patient relationship. What constituted benefit and harm, and when the zealous pursuit of cure should yield to the provision of comfort, or more radically still, occur simultaneously, was for the physician, not the patient, to determine. In the latter half of the 20th century, particularly but certainly not exclusively in the United States, the evolution of medical jurisprudence and the revolution in bioethics challenged the legitimacy of the paternalistic paradigm. This challenge was grounded on an emerging principle of bioethics—respect for individual patient autonomy. Indeed, by the end of that century, paternalism had been almost completely discredited, replaced by a new paradigm grounded on the legal duty to obtain informed consent (and to accept an informed refusal) supported by and in turn operating in affirmation of the most recent bioethical principle. The new paradigm for the professional–patient relationship became that of shared decision making.

Although beneficence and nonmaleficence were retained among the core principles of modern bioethics along with a fourth justice, the clinician was no longer considered the ultimate authority on what constituted benefit and harm in the care of any particular patient. It is, after all, the patient who must endure the rigors of medical interventions and/or the burdens of disease. Thus, in the case of intractable disputes between clinician and patient, the patient has come to be recognized as the final arbiter. The dissenting clinician’s option is to disengage from the relationship (but not precipitously to constitute abandonment) when and if respecting the patient’s wishes compromises professional ethics or personal conscience. The relief of pain and suffering, however, was not an integral part of this transformative process. Only quite recently have the legal, ethical, and public policy dimensions of pain management and palliative care begun to receive due consideration, thereby properly
placing them within the emerging bioethical, jurisprudential, and sociocultural framework. Providing the details of this process is the task of this chapter, and the others in this section of this book.

**THE DUTY TO RELIEVE PAIN AND SUFFERING**

When, over three decades ago, Eric Cassell began his seminal article on suffering and medicine in The New England Journal of Medicine, he did not think it necessary to build an extensive case for the proposition that physicians have a duty to relieve pain and suffering. Nevertheless, his initial inquiries into the attitudes of physicians and patients about pain and suffering revealed a curious phenomenon: Contemporary patients and laypersons attached appreciably more significance to that duty than did his physician colleagues. It is this disparity between laypersons and health care professionals in the prioritization of the need for and duty to provide not only treatment of disease but also relief of distress associated with it that caused, or at least significantly contributed to, the jury verdicts in legal cases alleging undertreatment of pain, which we consider in Chapter 15. If, in the ethos of ancient medicine, the relief of pain and suffering was the essence of beneficence (doing good) and nonmaleficence (avoiding harm), then something transformative took place in the transition to modern medicine. Otherwise, the opening passage of the preface to this book, which substantially expanded on Cassell’s original article, would be incomprehensible. That passage, a remarkably stinging indictment of his own profession, reads, “The test of a system of medicine should be its adequacy in the face of suffering . . . modern medicine fails that test.” In it, he analyzes in great depth important distinctions between pain and suffering, including notable instances in which a person can experience pain but not suffer as well as suffer in the absence of pain. However, most pertinent to this chapter and book is his observation that pain is the most common cause of suffering, and people in pain experience suffering when it is severe, uncontrolled, and seemingly without end.

**CURATIVE VERSUS PALLIATIVE PARADIGMS OF PATIENT CARE**

Continuing with Cassell’s analysis, the willful blindness that afflicts
modern medicine with regard to pain and suffering (with the exception of those who specialize in pain management and palliative care) relates to the complex nature of persons and the reductionistic tendencies of modern medical science. He cogently expresses the nub of the problem when he declares, “Bodies do not suffer; persons suffer.” The implications of this proposition are clear but nonetheless potentially controversial: If a clinician cannot relate to the patient as a person, rather than as a body that is merely the locus of some disease process, then he or she cannot even recognize suffering and certainly cannot begin to competently and compassionately respond to it. Unsurprisingly, many clinicians view this as a gross exaggeration, verging on caricature. However, other credible sources bolster Cassell’s point. Consider, for example, the following panegyric of the late Yale surgeon and writer Sherwin Nuland\(^7\) in his book How We Die the curative paradigm of medicine:

> . . . the challenge that motivates most persuasively; the challenge that makes each of us physicians continue ever trying to improve our skills; the challenge that results in the dogged pursuit of a diagnosis and a cure; the challenge that has resulted in the astounding progress of late-twentieth century clinical medicine—that foremost of challenges is not primarily the welfare of the individual human being, but rather, the solution of The Riddle of his disease.

Nuland\(^7\) is describing, with only a bit of grandiosity, one of the essential elements of the curative model cogently presented several years later by Ellen Fox.\(^8\) For ease of analysis, her delineation of the essential features of the curative and palliative models of patient care is illustrated in Table 12.1.

</table>
As illustrated in the table, point by point, the core elements of the reigning curative model are the diametric opposite of those in the palliative model, the latter being the one that presumably must be followed in order to respond appropriately to the pain and suffering associated with both acute and chronic illness. The clinical puzzle-solving element is precisely what Nuland\textsuperscript{7} waxes so euphorically about in his discussion of the zealous pursuit of “The Riddle,” which he maintains is the primary motivator and the ultimate goal of the best clinicians.

As previously indicated, ethical issues in end-of-life care will be the special focus of Chapter 13 of this book. Nevertheless, it is worth noting the stark contrast in the perspective on death and dying between the two models. The view of many clinicians in the full grip of the curative model that a patient’s death is the ultimate medical failure has led, as Nuland\textsuperscript{7} himself admits, to situations in which medical specialists have “convinced patients to undergo diagnostic or therapeutic measures at a point in illness so far beyond reason that ‘The Riddle’ might better have remained unsolved.” The type of clinical situations to which Nuland\textsuperscript{7} refers, particularly when patients are intentionally deceived or kept in the dark about the grimness of their prognosis or the dismal prospect that additional disease-directed interventions will produce any benefit, constitute a form of what might reasonably be characterized not only as “medical futility” but also as “therapeutic belligerence.”\textsuperscript{9}

**The Phenomenon of Undertreated Pain**

The zealous, single-minded pursuit of a diagnosis and the relentless delivery of disease-directed interventions means, as a practical matter, that precious little professional time, energy, or attention is available for assessing and managing pain or suffering, even for those patients in the intensive care unit (ICU) who may be unlikely to leave the hospital alive. That is the bleak conclusion reached by the investigators in the formidable Study to Understand Prognoses, Preferences for Outcomes, and Risks of Treatments (SUPPORT) project in the mid-1990s.\textsuperscript{10} The SUPPORT principal investigators sought to evaluate the quality of care in the ICUs of certain premier academic medical centers across the country. The ICU, of
course, is the locus of patient care in which the curative (disease-directed) paradigm of high-technology patient care reigns supreme. The findings of the SUPPORT investigators are quite concerning with regard to such considerations as the relief of pain and suffering, the extent to which a patient’s plan of care had been discussed with the patient or her proxy, or the likelihood that code status was consistent with what was known about the patient’s wishes or values. For purposes of this discussion, at least three fundamental principles of bioethics were frequently violated in ICU care: respect for patient autonomy, beneficence, and nonmaleficence. More particularly, SUPPORT revealed that there was at best a 50–50 chance that the care provided to patients was consistent with their wishes, values, or written directives, and half of the patients studied were believed to be experiencing significant pain or distress in the last days of their lives.

Similar disappointing findings about pain and symptom management have been reported in the care of pediatric ICU patients, nursing home patients, and in outpatient care of cancer patients. The pervasiveness of deficiencies in pain and symptom management encompasses virtually all patients regardless of age, type of disease, or locus of care and thus strongly suggests a problem that emanates from certain core issues in medicine and society to which we now must turn. Otherwise, we would be compelled to consider a highly implausible proposition; that is, that health care professionals are truly indifferent to the pain and suffering of their patients.

IDENTIFYING THE BARRIERS TO PAIN RELIEF

Beginning in the 1990s, an unprecedented amount of attention has been paid to the root causes of undertreated pain. A consistently cited set of barriers has been identified. At a basic level, these barriers exist with regard to all types of pain: acute, chronic noncancer, and pain associated with terminal illness. However, certain barriers are exacerbated in patients with chronic pain. The general categories into which these barriers are divided are professional, patient, and societal in nature and origin.

Professional Barriers

In one sense, as I will endeavor to make clear, the professional barriers to
pain relief are the most ethically significant, given the fiduciary nature of the clinician–patient relationship. The key elements utilized in assessing professional competence are knowledge, skills, and attitudes. Deficiencies in any one of these elements can result in inadequate and hence substandard patient care. Deficiencies in more than one for any type of patient care will markedly increase the likelihood that substandard care will result. Marked deficiencies in each of these dimensions have been documented in physicians (of all specialties), nurses, and pharmacists.\(^{14-16}\) What is most important from an ethical perspective is how deficiencies in one or more of these categories translate into behavior, that is, professional conduct. Given the pervasiveness of pain across the clinical spectrum, and the by now well-recognized sequelae of pain, only rarely may any clinician legitimately claim that such deficiencies pose no threat of harm to patients. As we shall further consider shortly, however, even clinicians who possess the requisite knowledge, skills, and attitudes may be reluctant to translate them consistently into effective pain management, particularly when what is clinically indicated may be opioid analgesia because of fears of regulatory scrutiny or other forms of potential legal liability. More recently, with the exponential increase in prescription drug abuse, addiction, and associated overdose deaths, deficiencies or other problems associated with a prescribing physician’s knowledge, skills, or attitudes may also imperil the lives or well-being of patients by inappropriately prescribing or failing to properly monitor a patient’s use of these medications.

None other than John Bonica himself pointed out many years ago that no medical school has been so bold and innovative as to establish and maintain a formal, required curriculum in assessing and treating the most common problem of patients who seek medical care—pain.\(^17\) This glaring deficiency that he described nearly 20 years ago persists. In data ascribed to the Association of American Medical Colleges in 2003, only 3% of medical schools have a separate required course in pain management, and only 4% require students to take a course in end-of-life care.\(^18\) The absence of any solid evidence of a formal curriculum in the assessment and management of pain in most medical schools warrants the conclusion that none actually exists. Some defenders of the status quo have
argued that the requisite knowledge, skills, and attitudes are imparted in other less formal but perfectly acceptable ways, such as in the care of actual patients in the clinical years of medical education. What undermines these assertions is the strong evidence that health care professionals continue to graduate and obtain licensure with major deficits in knowledge, skills, and attitudes concerning pain management and its relevance to quality in patient care.

The ethical significance of this phenomenon is the aforementioned “culpability of cultivated ignorance.” The absence of a pain curriculum in medical and other educational programs in the health professions may be an important reason why pain is often undertreated but is not an excuse for it. Medical schools have been, and continue to be, major culprits in the epidemic of pain. Evidence of the persistence of this epidemic continues to accumulate. The 2011 Institute of Medicine report Relieving Pain in America conservatively estimated that one-third of the adult population of the United States experience chronic pain.\(^{19}\) It is not merely an absence of required course work on up-to-date pain assessment and management techniques but also myths and misconceptions about the risks and purportedly unmanageable side effects of opioids that are deeply entrenched in the minds of clinical faculty and which are passed on from one generation of physicians to the next.\(^ {20}\) However, it is axiomatic that good ethics begins with good facts. In the past decade, further research and examination has suggested that with regard to the long-term use of opioids for the management of chronic pain, the purported benefits may have been exaggerated, whereas the real risks of abuse and addiction underestimated.\(^ {21}\)

Recognizing the curricular deficiencies in pain assessment and management that have plagued physician training for decades, when the American Medical Association developed the Education for Physicians on End-of-Life Care Project (EPEC), it adopted a train-the-trainer approach in the hope of maximizing the dissemination of current thinking on palliative care to experienced practitioners rather than medical students or residents.\(^ {22}\) Entering a profession entails a moral responsibility to ensure that one possesses and consistently applies the knowledge and skills essential to minimal competence. That one may in some instances enter the

\[639\]
profession with certain deficiencies does not provide a legitimate basis for cultivating ignorance that may be originally attributable to curricular deficiencies. The medical school curriculum should reflect the current standard of care and anticipate future improvements to it, but it does not set that standard in any definitive sense.

In California, the continuing absence of a pain curriculum in medical schools, combined with increasing public awareness of and outrage over a national, indeed international, epidemic of undertreated pain, moved one crusading member of the California Assembly to introduce and successfully pursue a statute mandating two things: (1) that pain management and end-of-life care be part of the medical school curriculum for applicants seeking a license as a California physician after June 1, 2000, and (2) that inpatient health facilities include pain as a fifth vital sign assessed along with other vital signs and noted in the patient’s medical record. In yet another example of lawmakers interceding to address professional deficiencies, the California Assembly in 2001 enacted a statute requiring that all licensed physicians in the state (with the exception of radiologists and pathologists) receive a minimum of 12 hours of continuing medical education prior to January 1, 2007. The statute, however, had a sunset provision. Because the California Assembly did not vote to extend it, this continuing medical education mandate is no longer in force.

These and the other legislative measures described hereinafter actually run counter to a well-established tradition in American government to leave the professions, particularly the health professions, virtually unfettered latitude and discretion to manage their affairs. Only when substantial evidence accumulates—and results in a high level of public concern—are lawmakers prompted to intercede. When morally troubling circumstances are allowed to persist by those who ostensibly have the power and authority to address them through nonlegal measures, the law has been invoked to address the problem. A graphic example was the Nuremberg Code that emerged from the Nuremberg tribunal’s prosecution of the Nazi doctors. The first principle of the Nuremberg Code was the right of human research subjects to informed consent. Twenty-five years later, when the public became aware that a number of clinical trials
conducted by prominent medical researchers in the United States were openly and notoriously violating the Code, which was an ethical–professional, not necessarily a legal mandate, the federal government stepped in with the first of what became many regulations of federally funded research involving human subjects.25

Similarly, in the early 1980s, a phenomenon known as “patient dumping” became the subject of significant public awareness and concern. When indigent or uninsured patients presented to emergency rooms, they were with increasing frequency shunted off to other (usually government-operated) hospitals for care, often with deleterious consequences from the delay in properly addressing an unstable medical condition. When neither the health professions nor national hospital organizations demonstrated any inclination to address the problem, the Congress of the United States passed the Emergency Medical Treatment and Active Labor Act (EMTALA), which imposed a mandate on all emergency departments to provide a medical screening examination to patients upon arrival, and to prohibit transfer of any patient found to be in an unstable medical condition prior to stabilization except under certain carefully described situations.26 Notably, EMTALA recognized pain as an indication of an unstable medical condition requiring prompt attention and effective remediation. These instances indicate that it is often the failure or refusal of health care institutions and/or professionals to put their own houses in order that prompts major governmental intervention in order to address an otherwise seemingly intractable problem.

One must ask whether there is a causal connection between the failure of health professional schools to recognize the need for a pain curriculum and the failure of the health professions and the institutions in which health care is delivered to make the prompt, effective, and consistent assessment and management of pain a priority in patient care. We noted early in this chapter how Eric Cassell was perplexed by the seeming indifference to the phenomenon of suffering on the part of physicians given the traditional core values of medicine. The same is true for pain because another professional barrier has been characterized as the failure of health care institutions and professionals to make pain relief a priority in patient care. One of the primary objectives of many of the policies discussed in Chapter
of this book, particularly the Federation of State Medical Boards (FSMB) Model Policy and The Joint Commission Accreditation Manual standards on pain management, was to disabuse their target audience of the perception that effective pain management was not an essential element of sound patient care.

The final professional barrier to effective pain management is fear of regulatory scrutiny and potential legal liability (civil or criminal). There is little question that the nidus of this concern relates to opioid analgesia. There is quite simply no discussion about such concerns arising out of nonpharmacologic pain management strategies. When one looks at the record of disciplinary actions by state medical boards, those relating in any manner to pain management practices were invariably characterized as excessive prescribing of opioids. Such cases are addressed in detail in Chapter 15 of this book. It is for this reason that the previously mentioned FSMB policy is of such potential significance, for it seeks to shift the focus of medical boards from “overprescribing” or “underprescribing” of opioids to inappropriate prescribing because both extremes pose risks to patients.

From an ethical perspective, it is a troubling state of affairs when clinicians fear that they are at risk of disciplinary action by their professional licensing board if they follow current national clinical practice guidelines on the use of opioid analgesics. Their concerns have not been without foundation, for an initial survey of the knowledge and attitudes of state medical licensing board members regarding opioids and pain management revealed significant knowledge deficits and attitudes that were at best unsupportive and at worst hostile toward the use of opioids, especially for patients with chronic noncancer pain. One analysis of the prevailing attitude among medical board members concerning opioid analgesia characterized it as an “ethic of underprescribing.” A follow-up study conducted after the promulgation of FSMB guidelines on prescribing opioids and a series of workshops across the country on pain management for medical board members not only revealed some improvement in areas that might be reassuring to those whom boards are charged with regulating but also noted the need for further education and wider acceptance of the FSMB model guidelines/policy.
When medical and other health professions’ boards issue new and presumably more enlightened policies on pain management, one cannot presume that most affected clinicians will become aware of them. There is still less of a basis to expect that these policies will, in the short term, have a direct and immediate impact on clinical practice even among clinicians who become aware of them. In the event that these new or updated policies were to become part of a mandatory continuing professional education program, there is nevertheless reason for concern that they would in fact be likely to significantly improve the usual custom and practice of minimizing the clinical significance of pain that has been mentored, modeled, and followed by generations of professionals. Concerted efforts must be made to reform practice patterns and the underlying clinical culture that sustains them by infusing more enlightened attitudes about the importance of pain relief to patient health and well-being.

The regulatory barriers also include the federal Controlled Substances Act, the policies and procedures of the U.S. Drug Enforcement Administration, and criminal prosecutions of physicians for drug diversion or trafficking when their prescribing practices are deemed far outside the ambit of mainstream medicine. These issues are dealt in depth in Chapters 14 and 15 of this book. The ethics of public policy formulation and law enforcement strategies and tactics are somewhat beyond the scope of this chapter. Nevertheless, such practices are fraught with moral implications because they affect the lives of many people. Much of the impetus for the new emphasis on balance intended to moderate between seemingly competing considerations of preventing drug abuse and diversion, on the one hand, and ensuring that patients in pain receive the analgesics they require for effective relief has been based on legitimate concerns that state and federal regulatory and law enforcement measures have been obsessively focused on the former and virtually indifferent to the latter. We consider the moral dimensions of pain policy and law further from the perspective of the health care professional in a subsequent section of this chapter as well, when we take up the demands of professionalism to make the patient’s needs and interests primary in a fiduciary relationship.

As the full scope of the national opioid overdose epidemic became apparent, the political and societal pressure to discourage physicians from
routinely and indiscriminately prescribing opioids has understandably increased. The statistics are striking. In 2014, roughly one in three accidental drug overdose deaths were related to prescription pain relievers. This data calls into question one of the lynchpins of the original challenge to the ethic of underprescribing of opioids for chronic pain, which was that the risks of addiction or abuse of such medications was relatively low.

Patient Barriers
Patient barriers to effective pain relief are in important ways related to physician barriers. Traditionally, clinicians were the primary source of patient information on medicine and health. If they did not themselves possess accurate and up-to-date information about the risks and benefits of pharmacologic and nonpharmacologic modalities of pain relief, they would not be able to fulfill their professional responsibility to educate their patients. Indeed, that is why pain management has historically been an area of clinical practice in which truly informed patient consent was virtually nonexistent. Now, however, in the Internet age, patients and family members may actually access up-to-date information on pain and its management as or more often than their physicians.

Without adequate information concerning the available range of pain management interventions and their relative risks and benefits, patients had no basis on which to formulate reasonable expectations with regard to pain relief. A major public survey on pain in the United States conducted in 1997 revealed that not only is pain pervasive, but the most common reason why people avoid seeking medication to relieve their pain is fear of addiction or physical dependence. Once again, recent data on prescription drug abuse and overdose deaths indicate that patient concerns about this risk are neither groundless nor frivolous. The clinical and ethical challenge for physicians is to accurately assess the risks and benefits of each pain relief option based on the patient’s particular circumstances.

Patients may also avoid seeking medical care when they experience pain because they fear it may be caused by some serious, perhaps even life-threatening, condition. Finally, patients experiencing pain that is associated with conditions for which they are currently receiving treatment
may not complain about their pain and seek more effective pain relief because of a mistaken assumption that pain is an unavoidable concomitant of therapy or that their physician would certainly be providing as much pain relief as possible. It is these latter perspectives that help explain how, until the legal cases discussed in Chapter 15 arose, no malpractice claims based on negligent pain management had been brought despite an epidemic of undertreated pain.\textsuperscript{33}

\textbf{Societal Barriers}

Pain and suffering are not just immensely complex and highly individualized human experiences. They occur within familial and other interpersonal contexts as well as social, organizational, and governmental configurations. Pain in particular may not only be a symptom of an underlying condition, but it may also, in the case of chronic noncancer pain, become a condition itself, hence the appropriateness of the term chronic pain syndrome. These are often, as Arthur Kleinman\textsuperscript{34} has observed, “Conditions in which the degree of pathology does not seem to explain the severity of perceived pain or the limitations in bodily functioning the pain produces.” This marked disparity between the patient’s pathophysiology and reports (often interpreted as complaints) of pain and disability produces a strong element of skepticism not only on the part of clinicians from whom the patient seeks care but also from family and friends. These doubts about the veracity of the patient’s experience of chronic pain can exacerbate the feelings of isolation and abandonment that characterize the chronic pain patient. At the end of this chapter, we further consider the special challenges for the clinician posed by the chronic pain patient.

American culture in particular has precious little patience with or sympathy for the chronically ill. Indeed, much of the recent momentum within the disability rights movement has been an understandably strong reaction to the widespread perception among the healthy and able-bodied that certain profoundly disabling conditions are categorically incompatible with any quality of life whatsoever. In response to such pervasive attitudes, perhaps the most high-profile disability rights organization took the name “Not Dead Yet.” Their message is clear to society in general and
health professionals in particular: We do not seek your assistance in ending what you consider our miserable existence but rather in enhancing what we consider to be our quality of life and our ability to be active and engaged members of our community.

Ethical Implications of the Barriers

There is a new emphasis in both undergraduate and graduate medical education on professionalism and communication. In some small measure, such curricular reforms may begin to address the larger and more fundamental problem identified by previously cited commentators such as Cassell, Fox, Kleinman, and Morris that is posed by medicine’s predilection for biologic reductionism and obsession with diagnostic and disease-directed interventions. The none-too-subtle point is that one does not enter into a professional relationship with or provide care to a disease process. Although a certain cadre of clinicians may romanticize the pursuit of “The Riddle” of disease, the professional relationship (fiduciary in nature) and communication are necessarily with the personhood, not the disease of the patient. The assessment of pain, for example, is all about effective communication between patient and physician concerning the subjective experience of pain. If effective pain assessment is absolutely essential to providing effective pain relief, then the clinician must be able to understand and appreciate the patient’s experience of illness in a manner and to an extent that may not be true for other aspects of patient care.

As previously noted, the concept of holding oneself out as a professional and the ethical demands of entering into a fiduciary relationship with another person entail the acquisition, utilization, and maintenance of the knowledge, skills, and attitudes necessary to ensure minimally sufficient competence. When a significant percentage of the practitioners of a profession such as medicine or nursing have been found to have major deficiencies in something as pervasive as pain and as integral to good patient care as are its assessment and management, invariably major ethical issues arise. It is in the recognition of these ethical issues that one demonstrates a grasp of the close relationship between ethics and professionalism. Yet, there was a period in the early years of the
movement to address the widespread phenomenon of undertreated pain when there was little acknowledgment of, and hence attention to, the ethical dimensions of these professional deficiencies.

Turning from barriers associated with knowledge deficits and problematic attitudes toward the significance of pain and its relief to those associated with legal and regulatory concerns, we encounter a challenging ethical quandary. As described in detail in Chapter 14, the regulation of opioid analgesics created a hostile environment toward their widespread use in pain management. Regulatory barriers, including a pattern of medical board disciplinary actions against physicians for so-called “overprescribing” of opioids, have, as previously noted, caused physicians to feel at risk even if they are scrupulously following state-of-the-art clinical practice guidelines.

A fundamental ethical question posed by this situation is as follows: To what extent is it reasonable to expect, indeed to demand, that physicians routinely engage in acts of moral courage in order to ensure that their patients with pain receive the medications and/or other therapies that they require for relief? The essence of the duty imposed on a professional when entering into a fiduciary relationship is that the other person’s interests become primary and any potential conflict of interest shall be resolved in favor of the person to whom the professional duty is owed. Therefore, prescribing inadequate doses of analgesics or opioids from a lower schedule of the Controlled Substances Act (e.g., Schedules III to V) when those from a higher schedule (e.g., Schedule II) are medically indicated in order to avoid regulatory scrutiny would constitute a breach of fiduciary duty. It is also the case, however, that a public policy posture and regulatory regime that routinely demands acts of moral courage on the part of professionals is a fundamentally flawed system that is vulnerable to strong moral critique. Such a critique is at least implied in the Report Card on state and federal pain policies that has been issued by the Pain & Policy Studies Group and which is discussed in some detail in Chapter 14.

**Embracing a New Ethic of Pain Relief**

Although it is important to understand the historical context in which
formerly prevailing attitudes toward pain and its relief with opioids
developed and ultimately became so pervasive and persistent, continuing
the momentum that has followed from more enlightened attitudes is
necessary to address emerging ethical concerns. The clinical specialty of
pain medicine has played a major role in the progress that has been
achieved in the last two decades. Ultimately, however, each of the health
professions has a responsibility to cultivate within its practitioners the
knowledge, skills, and attitudes that are essential to the provision of
effective pain management. The need for highly trained physicians and
nurses in pain and palliative care will continue to grow but so too will the
need for all physicians and nurses to possess certain minimal core
competencies in the assessment and management of pain.

The clinical and ethical challenge of providing appropriate pain and
symptom management has, if anything, increased in the last decade with
the mounting evidence of two previously noted phenomenon: (1) the
epidemic of prescription drug abuse and resulting deaths from overdose
and (2) studies indicating that long-term high-dose opioid therapy in many
instances is at best nonbeneficial and at worst harmful. Primary care
physicians, on whom most patients must rely for management of their
pain, find it increasingly difficult allocate the time and energy necessary to
deliver state-of-the-art pain assessment and management. This potential
conflict of commitment between fiduciary duties to individual patients and
contractual duties to employer or health care institutional policy and
procedural mandates or limitations is yet another source of ethical
dilemmas.

One of the new shibboleths in pain management is
“pharmacovigilance.” Of course, the judicious prescribing of
medications is an essential element of sound clinical practice in all
domains of medicine. However, with the prescription drug abuse epidemic
primarily associated with opioid analgesics, the insistence on
pharmacovigilance appears disproportionately in the pain management
literature. The implicit premise of this concept is that clinicians are not
truly confronted with a genuine moral dilemma of providing effective pain
relief for patients or preventing drug abuse and diversion. The basic
presupposition appears to be that the parameters delineated by
pharmacovigilance, as conceived by some of the thought leaders in pain medicine, enable a responsible prescribing professional to provide appropriate and effective pain relief to patients while at the same time significantly minimizing the known risk of addiction posed by opioids or their diversion to persons who have no legitimate need for them. In other words, pharmacovigilant pain management recognizes the need in clinical practice for a kind of balance that is similar to the balance sought in laws, regulations, and public policies affecting opioid analgesics as discussed in Chapter 14 of this book.

Even within the domain of pain management, the term has most often been invoked in the context of chronic pain management. Patients who have just undergone major surgical procedures, who have been the victims of traumatic injury, or those who are facing terminal conditions do not encounter the same credibility problems when they report high levels of pain and seek relief. The phenomenon of pseudoaddiction, in which patients with genuine pain that has been undertreated engage in behaviors that cause them to appear to be drug seeking (in some illegitimate sense), is most prevalent in the population of chronic noncancer pain patients. With regard to end-of-life care, it was once thought that undertreatment was the driving force behind the movement to legalize the prescribing of lethal doses of medication at the request of patients with terminal illnesses. However, the data accumulated as a result of the Oregon Death with Dignity Act reveal that undertreated pain is actually not even among the five most frequently cited reasons why dying patients seek a lethal prescription.

Some of the practices that have come to be advocated with increasing frequency under the rubric of “pharmacovigilance” or “responsible opioid prescribing” are opioid contracts and random urine drug screens. Both approaches raise critical questions of an ethical nature about the role of trust in the clinician–patient relationship as well as questions about why patients with chronic pain are special cases that require such measures when other patients whose conditions necessitate treatment with potentially dangerous medications and strict adherence to clinician recommendations do not. We focus here particularly on the contracts/agreements that are being so widely promoted, the form that they
take, the benefits that are claimed by their proponents, and the risks they pose to the establishment and maintenance of trust in the clinician–patient relationship.

There is an ethically more and less benign way in which to view and characterize the nature and role of these documents. The more benign approach is to simply consider the contract or agreement under the traditional rubric of a written informed consent document. Informed consent is a foundational concept in both medical ethics and medical jurisprudence and the primary mechanism by which respect for individual patient autonomy is demonstrated. The execution by patients of consent forms is a routine practice for any invasive medical procedure or other therapeutic measure. Thus, to the extent that an opioid contract were nothing more than a patient’s written informed consent to undergo opioid therapy, acknowledging thereby both the risks and benefits associated with it, there would be nothing remarkable about it and certainly nothing that would raise serious ethical concerns.

The authors of one important article on the subject state, “The contract is ideally intended to enhance the therapeutic relationship by initiating and supporting an alliance between the patient and the physician. It may enable a patient to have an active role in treatment. . . .” The keyword in this passage may be “ideal,” for there is growing concern among some that the primary reasons why opioid contracts are becoming routine among those physicians who are willing to consider opioid therapy for chronic noncancer pain patients relate to risk management and regulatory/law enforcement considerations rather than patient empowerment or well-being. For example, one review of opioid contracts that are currently in use revealed that over 90% had specific conditions warranting disciplinary termination of the agreement by the physician (e.g., if the patient were to violate a provision of the contract or miss appointments without adequate justification) and nearly 70% required submission to random drug screens, whereas only 5% stated the potential benefits of opioid therapy and just 3% provided general information regarding treatment. Because the latter two elements are most typically found on consent forms, their absence seriously undermines the argument that these contracts are merely more elaborate or formal consent documents.
Such contract provisions emphasize the physician’s power to impose conditions of treatment on patients rather than the autonomy of the patient to participate meaningfully in the consideration of therapeutic options according to the paradigm of shared decision making. The American Academy of Pain Medicine (AAPM) features a sample “Consent for Chronic Opioid Therapy” on its Web site. This agreement/consent form includes the more common provisions such as obtaining all opioid prescriptions from a single physician and filling them at a single pharmacy. The form states that the patient agrees to such random urine or blood tests as well as pill counts as may be “requested.”

The absence of such detailed therapeutic agreements in most other clinical settings in which the modalities of treatment and the need for patient adherence to the therapeutic regimen are of equal importance to patient well-being (e.g., cancer chemotherapy) suggests that chronic noncancer pain patients who require opioid analgesia for effective relief warrant a heightened level of suspicion. Furthermore, the widespread and routine use of opioid contracts by many physicians for all of their chronic noncancer pain patients receiving opioid therapy, but not for acute pain or pain associated with terminal illness, implies that there is something intrinsically untrustworthy or suspicious about this category of patient. Clearly, however, merely being a victim of chronic noncancer pain that happens to be refractory to nonopioid analgesics is not inherently suspicious. Such patients and syndromes exist, and a consensus of thought leaders in pain medicine has emerged in support of the position that opioid analgesia should generally be offered to these patients unless there are specific and significant contraindications.

Recent acknowledgment that earlier estimations of the risk of addiction associated with opioid analgesia were much too low does not undercut this consensus view. The best current evidence is that the incidence of addictive disorders (of all types) in the general population ranges from 3% to 26%, whereas the rate for hospitalized patients is 19% to 25%, and for major trauma patients as high as 40% to 60%. It is important to note that recently formulated model pain policies do not recommend the routine use of either opioid agreements or urine drug screens in all patients—even all chronic noncancer pain patients—but rather those patients who in the
exercise of sound clinical judgment are deemed to pose a “high risk for medication abuse or have a history of substance abuse.” Approaches to screening for addiction prior to the initiation of chronic opioid therapy as well as assessing for addiction during therapy (exclusive of urine toxicology screening) have been identified and utilized.

The imposition of random urine drug screening as one condition precedent to offering opioid therapy to a patient appears to have become a common practice among clinicians whose practice includes patients with persistent pain problems. As with opioid agreements themselves, random drug screens may be required of all patients who receive opioid analgesia for an extended period, not simply those whose histories raise questions or concerns about the likelihood that they will take the medications as directed. In this way, it might be argued that all patients for whom opioid analgesia is indicated are treated the same rather than certain patients being stigmatized by differential treatment that calls their capacity to adhere to the treatment protocol in question. Nonadherence to chronic opioid therapy may take a variety of forms, including consuming more (or less) than the amount of the prescribed drug directed by the prescribing clinician, using opioids obtained from other sources, and failing to take the drug prescribed, whether or not the drug is then sold or otherwise diverted from legitimate medical use.

Failure to comply with instructions concerning the taking of medication is not unique to chronic pain patients, and the risks of such behaviors by patients can have serious consequences in many different clinical settings, including diabetes, hypertension, epilepsy, and cancer therapy, to name only a few. Nevertheless, it has not yet become routine to insist on prescription medication agreements and laboratory screening for those patients, even when studies suggest that in some patient populations nonadherence to therapeutic regimens may exceed 50%. One important distinction between nonadherence to opioid therapy and nonadherence to other pharmacologic regimens that do not involved prescription medications that are subject to diversion and abuse is the risk posed to society. A patient who must take a prescription medication for a serious medical condition but who fails to do so as directed in most instances places only himself or herself at risk of adverse consequences.
However, when nonadherence to opioid therapy takes the form of selling or otherwise diverting these medications, there are significant adverse societal implications. There is no question that clinicians have responsibilities to their communities and the society at large and not only to their individual patients. Sometimes, as in the case of public health emergencies, there may be genuine conflicts between these two responsibilities. However, minimizing the risk of opioid addiction and diversion through the responsible use of treatment agreements and adherence monitoring enables the clinician to meet his or her obligations to both individual patient and society. As with the informed consent and information disclosure process itself, the manner in which such approaches are taken is as important as the details of the approach itself. Moreover, it may well be the case that the wider use of measures to warn patients about the risks of nonadherence to prescription medication regimens and to monitor such adherence may be a necessary and appropriate response by the health professions to the data documenting the extent to which patients fail to take their medications as prescribed. What is needed but presently does not exist are rigorous empirical studies evaluating the effects of patient agreements and drug screening on adherence to or the outcomes of treatment regimens. It is a problem with regard to many other aspects of pain medicine as well in that in the absence of sufficient evidence, clinical practice guidelines are often consensus-based.

It would not be surprising to find that some of the high-profile federal prosecutions of physicians with very liberal prescribing practices described in detail in Chapter 15 of this book have fueled the widespread adoption of rigorous opioid contract provisions. Those physicians were alleged to have, among other things, engaged in a form of willful blindness to a host of red flags that some of their patients either had no legitimate medical need for opioids or were flagrantly abusing or selling their medications. The recordkeeping and monitoring by the physicians was poor to nonexistent.

**Conclusion**

The ethics of pain management are in a profound state of flux. Neither the
term evolution nor revolution seems to be an apt characterization, for such
terms suggest a gradual and organic development process on the one hand
or a transformational paradigm shift on the other, neither of which can be
supported by the existing evidence. Rather, the current state of affairs
might well be characterized, without risk of serious exaggeration, as a
battle for the soul of medicine. For as we noted at the very beginning of
this chapter, seminal works on the place of pain and suffering in the
context of the patient’s experience of illness consistently remind us that
their relief is a core value of medicine with roots running back to the very
origins of the profession. In the modern era, when organized medicine
has confronted phenomena such as physician-assisted suicide (aid in
dying) or physician participation in lethal injection, prominent voices in
opposition to the legitimacy of the physician’s role in such practices have
consistently invoked statements of principle such as the following:
“Healing the sick and alleviating suffering is the primary role of
physicians in U.S. society.” Yet, those same voices have, for the most
part, been silent in the midst of an epidemic of undertreated pain that
afflicts chronic noncancer pain patients disproportionately. It has fallen to
organizations such as the World Health Organization (WHO) and the
International Association for the Study of Pain (IASP) to call for the
recognition of pain relief as a human right.

In no other aspect of patient care has the fundamental role of trust in the
clinician–patient relationship become more of a pivotal issue than in the
care of patients with chronic noncancer pain. With the proliferation of
detailed opioid contracts including provisions for routine urine drug
screens and rigidly specified grounds for terminating the relationship for
nonadherence, we may be at risk of distrust becoming the reigning
paradigm. A byword of the cold war era notably used by President
Reagan but originally traced to Vladimir Lenin was “trust but verify.” This
approach may well have a place in patient care and the standard of care
with which clinicians must comply. The challenge to the health
professions posed by the current ambivalence toward patients requiring
opioid analgesia for moderate to severe noncancer pain is formidable. On
one hand are prominent voices such as the WHO and the IASP calling for
recognition of a human right to pain relief for all patients. On the other
hand are dire warnings to clinicians about deceptive, drug-seeking patients who must be engaged with extreme caution, a robust skepticism, and rigorous scrutiny as well as all of the other essential elements of pharmacovigilance. The establishment of a solid consensus among clinical and regulatory stakeholders as to where we ought to situate a healthy and reasonable balance between extreme, unrealistic naivete and a rigid, pervasive cynicism about the role of trust in the care of patients with persistent pain should become a high priority for all conscientious and caring professionals.

CHAPTER 13
Ethical Issues in the Care of Dying Patients

DAVID BARNARD

Introduction

THE QUEST FOR MORAL ORDER AMID EXISTENTIAL DISORDER
To the dying person, his doctor, however much he is trusted and regarded as a source of treatment, is no longer one with the power to cure; to the doctor, the patient has become one whose death, despite every possible effort, he is impotent to prevent. This gives rise to problems in the special professional relationship which often develops between a patient and his doctor, and besides that, they have the difficulties that face any two people trying to adjust to the fact that one of them is shortly going to die.¹

This comment by John Hinton is a pointed reminder that the patient’s nearness to death places the patient and the doctor in a challenging and disturbing place, both in their relationship with each other and in their sense of personal identity. The direct encounter with death—in the guise of the death of the patient—has the power to disrupt the doctor’s relationship and communication with the dying person, throw rational decision making into confusion, and capsize carefully wrought treatment plans.

Robert Burt has commented on the “inherent unruliness of death and the persistence of individual and social ambivalence about death” as features that limit our ability to fashion social policies and practice guidelines that are free of moral ambiguity or the possibility for evil and abuse. At the conclusion of his study of the conflict-ridden policies governing abortion, the death penalty, and physician-assisted death in the United States during the last half-century, Burt writes,

Here is the paradox that we must learn to live with in regulating
death: that we must teach ourselves, through our rational intellectual capacities, that our rational intellect cannot adequately comprehend, much less adequately control, death. We are no more compassionate, honorable, or intelligent than our predecessors who embraced the pursuit of rational mastery over death and were led, without acknowledgment, into unreasoned evil. We would do better to admit, as W.H. Auden acknowledged, that “Death is not understood by Death; nor You, nor I.”

THE CONTRIBUTIONS AND LIMITATIONS OF ETHICAL ANALYSIS IN END-OF-LIFE CARE

Hinton and Burt suggest that the psychological and existential dimensions of the encounter with death destabilize the doctor–patient relationship and rational decision making. These dimensions also require that we acknowledge the limitations as well as the contributions of ethical analysis in end-of-life care. At the most general level, the discipline of ethics itself embodies the cacophony of voices, worldviews, cultural frameworks, and value systems characteristic of postmodernity. As philosophers such as McIntyre and Englehardt argue, no single, overarching standpoint or scale of values commands universal allegiance in a secular, pluralist society that is committed to the peaceable resolution of differences. Yet, without such a universally compelling standpoint, there is no means short of force to eliminate the contradictions between philosophical systems or the competing claims of multiple moral communities.

Two aspects of uncertainty more specifically related to clinical ethics near the end of life are worth particular note at the outset. Consider the commonly accepted public consensus on the ethics of end-of-life care. Its main points include the following:

2. Treatment refusals may include all forms of life-sustaining medical treatment, including artificially provided nutrition and hydration.
3. Complying with a competent adult’s informed wishes to refuse or discontinue life-sustaining treatment should be considered neither homicide nor assisted suicide.
4. From a moral and legal point of view, there is no difference between
withholding a treatment (not starting it) and withdrawing a treatment (stopping it after it has been started), if the treatment in question is inconsistent with a competent patient’s informed preferences.

5. For a patient who is terminally ill and who values comfort over prolongation of life, symptom control that has as a side effect the shortening of life is morally permissible and is not the moral equivalent of active euthanasia.

6. Incompetent or otherwise nonautonomous people have the same rights as competent people in these matters, with their wishes expressed either in the form of an advance directive or by a person authorized to make health care decisions for them.

To call these points the “public consensus” means that they capture a broad agreement in the bioethics literature, policy statements of professional organizations, judicial decisions, and the actions of state legislatures on the matters in question. It is probably safe to say that these points organize the notes of nearly every medical school and nursing school lecturer on the topic of “the ethics of end-of-life care” and that they are the guiding principles brought to bear on individual cases by the vast majority of clinical ethics consultants at large in the corridors of US hospitals. And yet, it must be admitted that the consensus, although undoubtedly broad-based intellectually and influential clinically, masks substantial differences and disagreements within the health professions and the larger society. These differences encompass matters such as the relative weight to be accorded to individual autonomy and the general welfare; the validity of the distinction between, say, “killing” and “allowing to die”; or the proper characterization of artificially provided nutrition and hydration as either “medical treatment” or “basic, humane care.”

A second aspect of uncertainty stems from the potential disconnect between an individual health professional’s espoused values and ethical commitments and his or her ability to act according to those commitments in specific clinical situations. To take one of many examples, since the 1960s, there has been an enormous shift in physicians’ stated attitudes toward disclosing bad news to their patients. Whereas physicians have historically been reluctant to discuss bad diagnoses such as cancer directly
with patients for fear of depressing them or eliminating hope, by the late 1970s, physicians who responded to surveys overwhelmingly favored full disclosure of a cancer diagnosis to the patient. Patients themselves, especially in Western societies, usually want to know the truth of their cancer diagnosis, and most also want a realistic estimate of how long they are likely to live. Yet, when Baile and his colleagues surveyed more than 500 oncologists attending a meeting of the American Society of Clinical Oncology (ASCO), nearly one-half rated their ability to break bad news as only fair or poor, and two-thirds rated themselves as not very comfortable or uncomfortable dealing with their patients’ resulting emotions. Only half had received any training in the subject. These findings are consistent with the fact that although many studies report general satisfaction on the part of patients and families with the information disclosure process, other studies report significant dissatisfaction with the level of information or emotional support that patients receive from their doctors.

With these considerations and qualifications in mind, this discussion of ethical issues in end-of-life care attempts to bring to bear the public consensus mentioned earlier on four major themes:

1. The transition from curative to palliative and end-of-life care
2. Surrogate decision making
3. Responding to demands for nonbeneficial treatment
4. Physician-assisted death

Although ethical analysis cannot pretend to eliminate moral doubt and disagreement—particularly on some of the most contested issues in these domains—some goals are quite realistic. These include (1) providing a blueprint or template for careful and systematic ethical scrutiny of a clinical situation; (2) organizing the dialogue among the various parties to an ethical dispute, thereby assuring that the concerns and perceptions of everyone with a stake in the outcome of a clinical decision are taken seriously; (3) providing a method for isolating particular sources of ethical disagreement, thereby making possible either the marshalling of additional facts or arguments to produce agreement or allowing people unable to agree to recognize their mutual good faith; (4) pointing to areas of agreement as the basis for creative problem solving that leads to decisions and actions consistent with people’s most important values; and (5)
encouraging educational efforts for health professionals—especially in the realm of patient–provider communication—to bring professionals’ behavior more fully in line with their avowed values and beliefs.

The Transition from Curative to Palliative and End-of-Life Care

Patients with serious disease and their physicians usually share three goals for the patient’s care: cure or long-lasting remission, prolongation of survival, and comfort and quality of life. As prospects for the first and second goals dim with the progression of disease and the exhaustion of curative therapies, physicians have the opportunity, and the challenge, of recommending that the third goal become the main focus of the patient’s continuing care. The World Health Organization defines palliative care as “the active total care of patients whose disease is not amenable to curative treatment. Control of pain, of other symptoms, and of psychological, social, and spiritual problems is paramount. The goal of palliative care is the achievement of the best possible quality of life for patients and their families.” J. Andrew Billings has suggested a more patient- and family-friendly definition:

Palliative care is a special service, a team approach to providing comfort and support for persons living with a life-threatening illness and for their families. We are nurses, social workers, chaplains, and physicians who work with your current health-care team to assure that you and your family receive excellent pain control and other comfort measures, get the information you want to participate in decisions about your care, receive emotional and spiritual support and practical assistance, obtain expert help in planning for care outside the hospital, continue getting good services in the community, and overall enjoy life as best you can, given your condition. We try to coordinate and tailor a package of services that best suits your values, beliefs, wishes, and needs in whatever setting you are receiving care.

For the doctor, arriving at the decision to focus primarily on palliative care rather than active, disease-modifying therapy can be complicated. It
usually combines scientific and technical skills related to prognosis and clinical judgment; communication skills, often involving bad news and the need to respond sensitively to the patient’s emotions; and negotiation of treatment preferences. Billings’ description of the doctor’s role at this juncture is:

The patient and the family need a doctor who respects their expertise and can help them clarify and choose what they want, yet who is authoritative, helping to bring clarity and control by saying, “Let’s keep trying” or “Let’s face the music, it’s time to stop.”

Billings’ formulation strikes a balance between the two poles that have characterized ethical debates about the doctor–patient relationship for the past several decades: the doctor as neutral respecter of patient autonomy and the doctor as authority figure under whose guidance patients suspend their own preferences in favor of the doctor’s superior insight into their best interests. Despite the strong emphasis on patient autonomy and self-determination in the bioethics literature, when patients are faced with very serious disease and complicated choices, few want to be left completely on their own to make treatment decisions. Billings’ formulation captures this reality by emphasizing both respect for the patient’s ultimate decision-making authority and the commitment not to abandon the patient by withholding the physician’s best professional judgment.

NEGOTIATING TREATMENT PREFERENCES: THE IDEAL DECISION-MAKING PROCESS

From the standpoint of ethics, treatment decisions near the end of life, as at any other juncture in health care, ought to be structured by the notion of informed consent. To be valid, the patient’s consent should be informed and free of duress or coercion and should reflect the patient’s genuine values and preferences. An ideal decision-making process for medical care would include the following elements:

- Joint participation of doctor and patient, with additional participation of significant others of the patient’s choice
- Clear and truthful communication by the physician
- Clear and thoughtful deliberation by the patient
• Consideration, by both doctor and patient, of medical and nonmedical factors, including
  • The patient’s medical condition and options for treatment (including no treatment)
  • The reasonable probabilities that particular goals can be achieved
  • The reasonably expected proportion of benefits of treatment to harmful or painful side effects
  • The patient’s values and life goals
  • The patient’s assessment of his or her quality of life and the essential elements for a positive quality of life
  • The patient’s tolerance for risks and uncertainty
• So that, the resulting decision
  • Reflects a reasonable accommodation to the medical facts
  • Is consistent with the patient’s values and the physician’s conscience

DEPARTURES FROM THE IDEAL
In the end-of-life context, several factors are likely to complicate the ideal. They can be divided into two large groups: factors related to the uncertainty of prognosis and clinical judgment and factors related to attitudes and values of both patients and physicians. After some discussion of each of these, this section concludes with some suggestions for approaching conversations with patients that attempt to accommodate both prognostic uncertainties and emotional reactions.

Prognosis and Clinical Judgment
There are now a number of resources available that provide prognostic information across a wide range of diseases and conditions, for example, in advanced cancer, heart failure, end-stage chronic obstructive pulmonary disease, dementia, cirrhosis, and coma following cardiopulmonary resuscitation. Although the general outcomes and trajectories of diseases that are the major causes of death in the United States are known, and a typical patient’s survival (assuming accurate diagnosis) can usually be estimated within a known range of probabilities, when any particular individual will die remains an inexact prediction.
Most people appreciate this, however, and the inability to give very precise predictions of a patient’s remaining life expectancy should not be a barrier to physicians’ participating in discussions with patients who want to have some realistic idea of their situation. As described further in the following text, the most important question for the physician is the level of information a patient desires to receive. The question “Doctor, how long am I going to live?” cannot be answered helpfully without some initial exploration of the meaning the question has to the patient, what has motivated the question, and the patient’s preferred level of detail.

A physician’s prognostic accuracy seems to vary inversely with the length of time the physician has known the patient. The longer the relationship, the more likely it is that the physician will overestimate the patient’s remaining time. Lamont and Christakis comment in relation to this data that a palliative medicine specialist, or some other physician with relevant expertise but with no prior relationship to the patient, is likely to be a helpful resource to the treating physician in formulating prognostic information for individual patients.

Another tendency of physicians that can diminish the usefulness of prognostic information is to provide it solely in terms of the quantity of remaining life (weeks, months, or years), without attempting to describe the quality of life the patient is likely to enjoy. Especially for people with chronic, degenerative conditions or conditions for which available disease-modifying therapies have significant side effects, their remaining quality of life is likely to be as important as a bare estimate of survival. Some issues that are likely to be of particular interest to the patient include the pace and timing of decreases in functional and/or cognitive status, pain and discomfort and the availability of the means to relieve them, loss of independence, and the expected burden on caregivers. It bears repeating that the physician’s offer to go into detail on any of these matters should be contingent on a signal from the patient that he or she does in fact want to discuss them. Some people would prefer not to have such a clear image of impending decline to look forward to, although they may wish someone in the family to have this information to be better prepared.

**Patients’ Attitudes and Values**
The physician’s first responsibility in preparing for a conversation about treatment preferences in the setting of end-of-life care is to assess the patient’s emotional and cognitive capacity to participate in the conversation. Among the emotional and attitudinal factors that may cause patients to depart from the ideal decision-making process are the patient’s denial of the seriousness of the disease, or the presence of depression or other psychiatric disorders, as well as other forms of cognitive impairment that may be related either to the disease or its treatment. Appropriate treatment of the underlying causes of the cognitive impairment should be the first order of business. If this is not possible, the physician should consider the availability of a surrogate decision maker, as discussed in the next section.

Other emotional factors short of psychiatric impairment can diminish the patient’s capacity to participate meaningfully in these discussions. For example, some patients may appear determined to continue pursuing active treatment for their disease because they believe other people want them to do this, not because it is their own preference. Some patients may worry about family members’ ability to cope with the patient’s worsening illness or about their future security and well-being once the patient has died. Some patients may find it hard to reject treatments because they do not want to disappoint the doctor.

On the other hand, patients may reject further treatments not because they genuinely believe this is in their best interest but because treatment refusal is a language for expressing other concerns, such as fear (of being a burden to others, of the treatment, of the process of dying), anger, exhaustion, helplessness, mistrust, or unrelieved physical symptoms. A similar phenomenon can underlie patients’ requests for physician-assisted death. Sensitive exploration of the background and motivations underlying the patient’s stated preferences is essential before the physician concludes that he or she has a clear understanding of the patient’s perspective.

**Physicians’ Attitudes and Values**

Several factors on the physician’s side can also cause a dialogue about treatment preferences to deviate from the ideal. The physician’s counterpart to the patient’s denial is the tendency for physicians to
overestimate expected survival, especially for patients with whom they have had long-term relationships. It is often easier to perceive the deterioration in the patients of one’s colleagues than in one’s own patients.

A number of conceptual and philosophical commitments may also lead physicians to minimize or avoid open discussion with the patient about the transition from curative to palliative care. For example, medical training is primarily focused on providing the tools and skills necessary for the active investigation, diagnosis, and treatment of pathology. This instills an ideology of intervention, according to which any pathologic state or process that is potentially reversible should be reversed. To stand back and look at the “big picture”—to accompany a patient into death without investigating or treating conditions for which (at least short term) remedies are available—requires a shift in perspective that many physicians find very difficult and contrary to their professional identity.

A closely related issue, especially in academic medical centers, is the imperative of research and therapeutic innovation. From this perspective, it is precisely the point in the patient’s illness when all known effective remedies have been exhausted that presents the greatest opportunity for scientific progress. The research imperative demands that these opportunities be seized for trials of new and unproven treatments to push back the boundaries of medical power. Many patients (especially if they are of a socioeconomic status that has entitled them to regular access to health care) are themselves caught up in the ideology of medical progress, having absorbed a lifetime of exhortations from doctors and hospitals to avail themselves of regular checkups and the very latest in medical technology to ensure a longer, happier life.

The power of medical technology to forestall the time of death, especially in the intensive care unit (ICU), gives rise, in Daniel Callahan’s phrase, to “technological brinkmanship.”24 This is the idea that we can and should employ our technology for its maximum life-extending benefit and then back off just at the point—but no later—when its marginal benefits begin to be outweighed by its burdens and costs. The reality is that the point of diminishing return is almost always only discernible in retrospect, after the patient has been subjected to a period of intensive and invasive treatments to no positive end and the family is left to wonder why the
patient could not have enjoyed a more peaceful death.

The availability of technology to forestall death creates an additional psychological pressure that derives from the apparently observable fact that the death of any individual patient (especially in the ICU) almost always results from a decision to withhold or withdraw medical treatment. In other words, although in principle, we ought to be able to take comfort from the fact that death is natural and universal—as in the ancient syllogism, “Socrates is a man; all men are mortal, therefore Socrates is mortal”—death for this patient now seems always to be optional. Its psychological reality for the doctor is that the death occurred only because he or she brought it about when he or she recommended, or acquiesced when the patient or family requested, termination of treatment.

Finally, a very common concern for physicians faced with recommending the transition from curative to palliative care (identified by nearly 60% of the respondents to Baile and colleagues’ ASCO survey as the most difficult part of breaking bad news) is “being honest without taking away hope.” This is particularly the case when “hope” is identified with cure or significantly extended life. In fact, there are many other objects of patients’ and families’ hope that physicians almost always can help them realize; for example, comfort and freedom from pain, companionship, completion of important tasks, and security for those who will be left behind. Indeed, as suggested by Billings’ previously quoted definition, these concerns are precisely the focus of palliative care. Nevertheless, the strong association of “giving up all hope” with the shift to palliation from active treatment can lead physicians to dread and put off serious discussion of a patient’s end-of-life treatment preferences.

COMMUNICATION WITH PATIENTS ABOUT TREATMENT PREFERENCES NEAR THE END OF LIFE

The physician has four primary goals in the dialogue with a patient in the context of end-of-life decision making:

1. To learn about the patient’s preferences for receiving information and to assess the patient’s coping style when confronting threatening situations
2. To provide the patient with sufficient information about his or her
current and projected medical situation and options for treatment and support to enable the patient to make choices that reflect his or her values and preferences

3. To establish rapport and trust in order to enhance the physician’s credibility as a source of reliable information and interpersonal support

4. To balance genuine appreciation of the clinical situation with realistic optimism to empower the patient—by mobilizing his or her adaptive capacities and social supports—to maximize his or her quality of life for as long as possible

The goal of effective information transfer, although obviously of cardinal importance, is only one of these several goals. If the others are not also satisfied, information transfer itself may not successfully occur. For this reason, most expert opinion on communication with patients about bad news recommends that the physician address the interpersonal and emotional dimensions of communication as well as the clear presentation of scientific facts.

In an extensive literature review, Penelope Schofield and her colleagues identified 10 major considerations for communication about the transition from curative cancer treatment to palliative care:

1. Preparation prior to the discussion
2. Eliciting the person’s understanding of the illness and preferences for information transfer
3. Providing information
4. Responding to emotional reactions
5. Negotiating new goals of care
6. Arranging for continuity of care
7. Addressing family concerns
8. Acknowledging cultural and linguistic diversity
9. Concluding the discussion
10. Documenting the discussion and appropriately informing other members of the treatment team

Baile and colleagues consolidate these dimensions in a six-step protocol with the mnemonic SPIKES. In their formulation, the physician’s communication with the patient proceeds as follows:
• Step 1: SETTING UP the interview
  Mental rehearsal, arranging for a private setting, involvement of significant others, sitting down, making eye contact, and taking steps to avoid interruption

• Step 2: Assessing the patient’s PERCEPTION
  Ask before telling: Ascertain what the patient knows, how they want to receive information; for example, “What have you been told about your medical condition so far?” or “What is your understanding of the reasons we did the MRI?”

• Step 3: Obtaining the patient’s INVITATION
  Ask before telling: Ascertain the patient’s preference for receiving information, recognizing that shunning information is a valid psychological response for some people. Asking this at the time of test ordering can help set the stage; for example, “How would you like me to give you the test results? Would you like all of the information, or just the big picture, with more time for us to talk about a treatment plan? Is there anyone else with whom you would prefer us to discuss this information?” Lamont and Christakis\textsuperscript{23} suggest, “Some people want to know everything possible about their illness and others prefer to know very little. How much about your illness do you want to know from me today?”

• Step 4: Giving KNOWLEDGE and information to the patient
  Give a “warning shot.” For example, “Unfortunately I’ve got some bad news to tell you. . . ” Start at the patient’s comprehension level, avoiding technical words (say “spread” rather than “metastasize”); give information in small chunks with pauses to check understanding; avoid phrases such as “there is nothing more we can do.”

• Step 5: Addressing the patient’s EMOTIONS with empathic responses
  Another mnemonic, NURSE, is helpful here.
  Name the emotion: You look (sound) as if this is a real shock to you.
  Understand: I cannot imagine what it is like to be so sick.
  Respect: I really appreciate how you have been coping with this.
  Support: I want you to know that regardless of what happens I will be there for you.
Explore: Tell me more.

• Step 6: STRATEGY and SUMMARY

Ask before telling: Determine whether the patient wants to discuss future treatment plans at the present time; check the patient’s overall understanding of what has been said; present treatment options if appropriate in the moment; offer time for the patient to reflect; offer to be available for questions that may arise after the interview; schedule a follow-up appointment.

In summary, the physician–patient dialogue about the transition from active treatment to palliative care can help the physician fulfill several aspects of the ideal decision-making process. By acknowledging emotional aspects of the situation that are likely to be present on both sides, by offering patients the opportunity to receive information—or not—at their own pace, by examining one’s professional biases and assumptions that may hinder an open discussion of the patient’s circumstances, and by attention to the interpersonal as well as factual aspects of information transfer, the physician is most likely to support treatment decisions by patients that reflect their genuine values and also to strengthen the foundations for the physician’s role as a supportive companion to the patient throughout the course of the illness.

Surrogate Decision Making

At the time end-of-life treatment decisions have to be made, patients may not be able to speak clearly for themselves. They may be too sick to speak, too confused to listen to medical information or to deliberate about preferences, or completely unconscious. Typical contexts when patients lack decisional capacity near the end of life include patients suffering from dementia or other long-term cognitive impairment; patients suffering from delirium as a consequence of their disease or side effects of its treatment (e.g., metabolic derangements, drug-induced delirium, “ICU psychosis”), severely depressed patients, patients with waxing and waning mental capacity, or who give inconsistent, contradictory answers to treatment-related questions within a short period of time; postoperative patients under the influence of anesthetics or medications to promote ventilator
compliance; patients suffering loss of consciousness due to stroke, cardiac arrest, or other traumatic event; and patients in coma or persistent vegetative state.

Surrogate decision making is the process by which these patients may be brought as close as possible to the ideal decision-making process described earlier. It involves the following basic elements: (1) assessment of the patient’s decisional capacity; (2) for patients deemed lacking in capacity, attempts to rule out or eliminate reversible causes; (3) identification of an appropriate surrogate; (4) clarifying the surrogate’s roles and responsibilities; and (5) anticipating, where possible, future needs for surrogate decision making through a process of advance care planning.

ASSESSING DECISIONAL CAPACITY
Decisional capacity is task-specific. Someone may be properly judged capable of making some decisions—Jell-O or custard for dessert, baseball or NASCAR on TV—and incapable of making other decisions—financial investments, whether or not to enter a nursing home, or, most relevant here, the choice of medical treatments in the setting of advanced disease. For the latter, the patient’s capacity should be assessed in terms of the following:

- **Understanding:** Does the patient understand the meaning of the diagnostic or prognostic information provided to him or her? Can the patient restate the information in his or her own words in a way that demonstrates this understanding?
- **Appreciation:** Does the patient appreciate the implications of the information for himself or herself? Does he or she appreciate that decisions have to be made from among alternative treatment plans and that his or her input is necessary for these decisions?
- **Deliberation:** Can the patient weigh the alternative treatments according to his or her personal goals and values?
- **Communication:** Can the patient communicate his or her treatment preferences in an understandable manner? Do the patient’s stated preferences appear logically related to the patient’s goals?

There is no rigid, quantifiable measure of the patient’s abilities in these
domains. In general, the more significant the decision that needs to be made—in terms of risks, benefits, and side effects—the more stringent our standards should be in satisfying ourselves that the patient has the requisite capacity.27

Contrary to common practice, especially in hospitals where psychiatric consultation is readily available, a formal psychiatric consultation is not required to assess a patient’s decisional capacity. Nonpsychiatrist physicians ordinarily are capable of forming a reasonable judgment of the patient’s abilities in these four domains. Moreover, even if a psychiatric consultant judges the patient to have capacity, it remains the attending physician’s responsibility to satisfy himself or herself that the patient is in fact capable of giving informed consent before proceeding with treatment. Where psychiatric opinion is most relevant is when the physician suspects mental illness or delirium as the (possibly reversible) cause of the patient’s lack of capacity or where appointment of a legal guardian is anticipated, in which case the court will be interested in authoritative medical opinion.

RULING OUT OR ELIMINATING REVERSIBLE CAUSES OF INCAPACITY
Reversible causes of incapacity can be biologic or situational. Biologic causes include transient delirium, treatable depression, or the side effects of anesthetic or analgesic medications. Situational causes include anxiety or fear as an immediate consequence of receiving bad news, confusion or anxiety due to the effects of hospitalization, the sensory overload of the ICU, and/or separation from familiar people. Before deciding that a patient’s lack of capacity warrants turning to a surrogate, realistically assess the importance of making particular decisions right away. If urgent decisions are not required, attempt to diagnose and eliminate the patient’s incapacity. This could entail adjustments of medication, psychosocial intervention, or simply the passage of time.

IDENTIFYING A SURROGATE
If the gold standard for ethical health care decision making is the thoughtful participation of an informed patient, the gold standard for surrogate decision making involves a surrogate who is:
• Authorized by the patient because the patient considers the surrogate to be trustworthy and in the best position to advocate for the patient’s best interests
• Willing to accept the patient’s trust and to fulfill the role of surrogate in good faith
• Informed, through prior acquaintance or explicit conversation with the patient, about the patient’s values and preferences regarding medical care near the end of life
• Capable of understanding the physician’s explanations of the patient’s condition and weighing treatment options in light of the patient’s preferences
• Available to represent the patient’s interests at the time decisions have to be made

Since Congress passed the Patient Self-Determination Act in 1990 in the wake of the Nancy Cruzan decision of the US Supreme Court, there have been many local and national efforts to encourage people to identify a surrogate in case of their own future incapacity. All 50 states have adopted legislation authorizing health care decision making by surrogates. Despite these efforts, most people for whom end-of-life medical decisions must be made have not designated a surrogate in advance.\(^28\)

A number of states have addressed this gap legislatively by prescribing, in lexical order, the persons who are empowered to act as the patient’s surrogate in the absence of the patient’s prior designation. A typical ordering begins with the patient’s spouse and then moves in descending order through adult children, parents, adult siblings, adult grandchildren, and (only then) other adults who may be in a position to know the patient’s beliefs about medical treatment. In states where this regime applies, physicians as well as patients may be faced with the situation where the prescribed surrogate does not fulfill the criteria noted earlier as well as someone lower on the list—or not on the list at all. Gay partners, for example, have legitimate reason to fear exclusion and disenfranchisement in decision making for each other under strict interpretations of these surrogacy laws.

From the point of view of ethics, the physician’s primary responsibility as the patient’s advocate is to identify the surrogate who meets those
criteria to the greatest extent. In cases where that person is available and willing to serve in the role, but another, less qualified, person with lexical priority is expressing conflicting preferences for care, it is advisable for the physician to seek consultation from an ethics committee or from a hospital’s legal counsel.

THE SURROGATE’S ROLES AND RESPONSIBILITIES

The surrogate’s primary responsibility is to interpret the physician’s recitation of the patient’s medical condition and recommended treatment in light of what the surrogate has reason to believe are the patient’s relevant values, preferences, and life goals. This is the “substituted judgment” standard for surrogate decision making. Unless the surrogate has been instructed differently by the patient, he or she ought to try to the best of his or her ability to express treatment preferences that reflect the patient’s goals and values, and not the surrogate’s, if there is a conflict between them. If the surrogate is not certain what the patient would prefer in a given situation, or if, despite a good faith effort on the part of all who are in a position to know, there is simply no evidence whatsoever of the patient’s likely preference, the surrogate ought to make the decision that appears to be, from an objective point of view, in the patient’s best interests. Ordinarily, this is determined by weighing, in the most informed manner possible, the likely benefits (to the patient) of various proposed treatments—or no treatment—against their likely burdens (again to the patient). This is (not surprisingly) the “best interests” standard for surrogate decision making.

Physicians and other members of the health care team have potential roles to play in helping surrogates do their job. Their most obvious role is to provide clear and helpful prognostic information and descriptions of proposed treatments according to the protocols outlined in the previous section. But they may also be able to enhance the surrogate’s ability to represent the patient’s interests and preferences by engaging in dialogue with the surrogate about the patient. The content of that dialogue is suggested by the discussion in the next section of the most useful elements of an advance directive for health care.
A REALISTIC PROCESS OF ADVANCE CARE PLANNING

Most commentators agree that policies to encourage people to use advance directives to prepare for future end-of-life decision making have been largely unsuccessful. As noted earlier, only a minority (between 20% and 30%) of American adults have filled out an advance directive. Evidence suggests that even for those who have them, advance directives do not influence decision making. Most particularly, if people expect that filling out an advance directive will ensure that the medical decisions made during their future incapacity will match the choices they themselves would have made had they been able to participate in those decisions themselves, they will almost certainly be disappointed.

Common difficulties are that the documents cannot be located when they are needed, they are too vague to give useful guidance in the patient’s actual circumstances, or the patient’s stated preferences are ignored in favor of a course of action that physicians and/or family members believe is more in accord with the patient’s present best interests. Hickman et al. have listed some of the main factors that may explain these difficulties. These include:

1. An overemphasis on the patient’s legal rights to refuse medical care, as opposed to the more general objective of enhancing people’s ability to influence their care according to their goals and values
2. Insufficient efforts by health professionals to educate patients as to realistic outcomes of various medical interventions
3. Overemphasis on patients’ preferences for specific medical interventions rather than the effort to ascertain the patient’s views about goals and values and about what constitutes an acceptable quality of life
4. The assumption that the planning process is complete as soon as an advance directive has been filled out rather than viewing the process as ongoing and subject to periodic reassessment and revision in light of changing medical circumstances
5. Failure to involve family members or other important people in the patient’s life in discussions about preferences for medical care
6. Absence of system-wide policies and procedures to ensure that
patients’ preferences for care are known and respected wherever the patient may be receiving care
7. Low community awareness of issues related to end-of-life planning
8. State advance directive laws that introduce barriers into the advance planning process

Three Basic Problems
As significant as Hickman and colleagues’ barriers are, there are three more basic problems with advance directives that frequently lead to frustration and disappointment even when patients have gone to the trouble of creating one. All three are related to the nature of medical care for the critically ill and the existential predicament of the person facing death. Stated briefly, and somewhat too simply, they are as follows.

Unpredictability
Because of the probabilistic and uncertain nature of prognosis, it is extremely unlikely that the scenarios a healthy person imagines when filling out his or her advance directive—either sitting at the kitchen table or in the doctor’s office—will match the actual circumstances the patient or surrogate will face in the future. The more general the terms of the advance directive, in order to capture a range of possibilities broad enough to fit an unknown and unknowable future, the less use they will be in providing specific guidance about treatment preferences. This is a structural problem that no preprinted advance directive form—no matter how elaborately or imaginatively it has been constructed—can solve.

Uncertainty
Related to the unpredictability of the time and manner of death in general is a more specific uncertainty as to the potential benefit of any particular medical intervention or treatment that might be used near the end of the incapacitated person’s life. Consider, for example, treatments such as antibiotics, oxygen therapy, blood transfusions, or even more invasive procedures such as kidney dialysis. All of these are typically among the items that, in advance directives, people indicate the desire to refuse in the case of terminal illness. Yet, each of these, although not capable of reversing the dying process, may be very useful for more particular goals
such as alleviating pain, clearing mental confusion, or simply keeping a person alive long enough for family or friends to gather at the bedside for a final farewell. The question “If you were mentally incapacitated and terminally ill, would you want blood products or antibiotics?” for example, is practically meaningless when asked far in advance.30

Ambivalence
The desire for a gentle death, free of tubes and machines, coexists in most of us with the powerful desire to stay alive. It is very difficult to predict how, in the moment of truth, a particular patient will respond to even a tiny chance of success for a life-prolonging treatment when the alternative to trying the treatment is likely to be imminent death. The difficulty of extrapolating a patient’s real-time choices from previous discussions is compounded by the “framing effect,” in which those choices will be strongly influenced by the way the alternatives are actually described.31

A Realistic Approach
Despite these difficulties, there are some very realistic and meaningful goals that advance care planning can help people achieve. One goal is to promote honest and open communication about important values and life goals within families and between patients, families, and health professionals in the face of serious illness. This type of communication is often of great intrinsic value whether or not it bears any relation to specific treatment choices. Another goal is to arrange for future medical decisions to be made, in case of future incapacity, by someone whose love and care the principal trusts—not on the assumption that this individual will infallibly make the “right” decision (if “right” means matching exactly the decision the principal would have made)—but, because any surrogate is apt to be “wrong,” it is often of great comfort to know that the decision maker is someone who loves and cares about you and is doing his or her best to serve your best interests. Finally, advance planning is an opportunity to reflect on those qualities of life that make life worth holding onto and, conversely, those qualities that might be worse than death and to communicate those values to a surrogate, who can then compare the likely outcomes of real-time medical alternatives to those benchmarks and make
choices in their light.\textsuperscript{32}

A reasonable and useful advance care planning document should probably contain information along the following lines:

1. Identification of a preferred surrogate decision maker and at least one backup

2. Statement of the extent of the surrogate’s authority and how much flexibility the surrogate has in responding to real-time circumstances in ways that might depart from any specific instructions

3. Evidence that the surrogate is aware of his or her appointment and understands the scope of his or her authority

4. A statement from the principal describing the qualities and aspects of life that the principal considers necessary for a minimally acceptable quality of life, accompanied by instructions to the surrogate to request the application or continuation of any and all medical treatments that have a reasonable likelihood—according to accepted medical judgment—of restoring to the principal that quality of life for a reasonable period of time. Similarly, the surrogate is instructed to decline or insist on the withdrawal of any and all medical treatments if those treatments do not have a reasonable chance—according to accepted medical judgment—of achieving or maintaining that quality of life for a reasonable period of time.

5. In general, the document should not specify particular treatments that the principal does or does not want. The statement in item 4 should provide sufficient guidance for the physician to make these specific treatment decisions in light of the principal’s overall criteria for an acceptable quality of life, combined with the principal’s preference for resolving medical uncertainties—see item 7. However, there may be some special circumstances in which particular treatments should be mentioned; for example, a Jehovah’s Witness may wish to decline blood or blood products, or a person who has previously been resuscitated and placed on a mechanical respirator may have become convinced by the experience that he or she would never want it to be repeated, or in states that require the administration of artificial nutrition and hydration unless they are explicitly included among treatments to be withheld. Otherwise, the broad statement of values
(item 4) and preference for resolution of uncertainties (item 7) should suffice for most people.

6. A statement of the principal’s willingness to undergo trial periods of medical treatments when physicians are uncertain of their likely benefit, as defined in item 4, accompanied by a clear statement of the surrogate’s authority to stop those treatments after the agreed-on trial period has ended.

7. A statement of the principal’s preference either that genuine medical uncertainties be resolved in favor of more aggressive treatment or less aggressive treatment, with a clear additional statement that the surrogate has the ultimate authority to resolve disagreements between conflicting medical opinions.

8. A statement by the principal that he or she wants all necessary measures to maintain comfort and to treat pain and that when medical treatments are deemed incapable of achieving the goals defined in item 4, pain and other symptoms should be treated aggressively even if adequate treatment carries the risk of hastening death. The statement should include the desire for treating physicians to consult with qualified specialists in pain management and palliative care whenever they or the surrogate deems it appropriate.

Beyond their value in suggesting what an advance directive should contain, these items are also intended to suggest some of the questions that physicians can ask—directly of patients in advance—or to help surrogates fulfill their roles in order to fashion a treatment plan more likely than not to respect patient values.

A further step beyond the preparation of an advance care planning document is the execution of a different sort of document, designed to turn a patient’s statement of treatment preferences into actionable medical orders to be followed by clinicians and emergency medical technicians wherever the patient happens to be. The Physician Orders for Life-Sustaining Treatment (POLST), originated in Oregon, was the first such document—whose successful implementation requires intensive efforts to educate clinicians as well as patients about the indications for and scope of the document—although at the present time, well over 30 states have adopted similar programs. 

33

680
It should be said in conclusion that many people experience end-of-life decision making that is smooth and uncomplicated, and for many survivors, the death of a loved one, although sad, is neither chaotic nor traumatic. When things do go awry, leaving people anguished and bewildered by events that seem to be tumbling out of control, it is usually not the fault of a missing or poorly worded living will or durable power of attorney for health care. Recall the perspectives of Hinton and Burt in the introduction. Death carries enormous power to frighten us and to discombobulate the best laid plans. Despite our rhetoric of management of symptoms, or of directing our health care providers to do (or not to do) this or that, we do not control death. In its presence, we bear witness and do the best we can.

Responding to Demands for Nonbeneficial Treatment

The ethical consensus respecting a competent adult’s right to refuse medical treatment—even life-sustaining treatment when the refusal is contrary to the physician’s professional judgment—does not extend to the patient’s or family’s right to demand medical treatments that, in the physician’s professional judgment, offer no prospect of patient benefit. This difference in the moral and legal status of refusals and demands occasionally gives rise to conflicts that are among the most vexing and emotionally draining that can occur in end-of-life care. Taken to their limit, these conflicts can be so destructive not only of the physician–patient–family relationship but also of the atmosphere and milieu of the patient’s dying that loved ones will take with them in memory, that preventing them is the physician’s foremost ethical responsibility. Preventive measures are not always successful, but their chances can be improved through systematic analysis of the nature of a conflict in its early manifestations (“differential diagnosis”) and a range of communication and conflict resolution strategies.

THE ETHICAL BASIS OF THE CONFLICT

Ethically, the difference in physicians’ obligations toward refusals of
treatment and demands for treatment stems from the way ethics and law customarily interpret the concepts of autonomy and self-determination. In bioethics, respect for personal autonomy and self-determination is rooted in the ideas of privacy and bodily integrity. The idea is that—with very few exceptions, such as a potential public health emergency—a person ought to be able to control what is done to, with, or for his or her own body. This is the foundation for the requirement of informed consent and for the patient’s right to say “No” to the physician’s recommendations for (even life-saving) treatment. Courts have tested the claim of patient self-determination, or the patient’s right to say “No,” against potentially competing claims such as the state’s interest in preserving life, the interests of third parties (e.g., spouses or minor children), the integrity of the medical profession, and the prevention of suicide. In every case, almost all courts have come down in favor of self-determination. The competing interests have been seen as too abstract, too remote, or too weak to override the individual’s interests in preventing the violation of his or her bodily integrity and limiting the power of others to enforce values or life goals that he or she does not share.  

The matter is quite different for the person who demands a particular treatment. (This distinction applies equally to requests for physician-assisted death, which are discussed in the next section.) Here, it is no longer a question of an individual protecting his or her bodily integrity by drawing a boundary and saying, “Do not cross.” Respecting this essentially negative right (the right to be let alone) requires physicians and everyone else simply to do nothing. The person who demands a treatment, however, would compel the physician, and potentially many other people, to act affirmatively to supply the treatment. Many more public and professional interests and resources are implicated in the positive satisfaction of a demand than in the negative respect for a refusal. And, especially when the demand is for a treatment that, according to accepted medical opinion, will not benefit the patient, ethical opinion is far more deferential to competing societal and professional interests than in the case of patients who are asserting their negative right to be let alone.

It is worth noting that only a very few courts have explicitly addressed the question of patients’ demands for lifesaving treatments that are
contrary to widely accepted medical opinion, and up to now, no clear judicial trend has emerged. Among the most likely reasons for the relative lack of such cases is hospitals’ reluctance—despite their desire to support their physicians’ professional judgment—to face the costs and potential damage to their public image of going to court to force the removal of life-sustaining treatment over a family’s vehement protests. However, as noted earlier, there are other, better reasons to avoid recourse to the very public, adversarial forum of a court of law to resolve these conflicts. Preserving a therapeutic relationship and protecting the special environment of the deathbed are very worthy motivations for the physician’s efforts to find a more constructive resolution.

THE CLINICAL CONTEXT OF THE CONFLICT
Many clinical scenarios have the potential to bring doctors into conflict with patients or their families over the continuation of medical treatments of little or no likely patient benefit; for example, continuous blood transfusion for the patient with inoperable bleeding, full resuscitation efforts for the elderly patient with sepsis and multiorgan failure, and additional courses of high-toxicity anticancer treatment for the patient for whom both standard and experimental therapies have failed to slow the spread of the disease. The paradigm case, however, continues to be the noncommunicative, ventilator-dependent patient, kept alive by mechanical means while suffering inexorable bodily deterioration and discomfort with little prospect of improvement. This is the patient who, in K. Danner Clouser’s words—as vividly applicable today as when he wrote them 40 years ago—“is on the borderline between treatment and torture, where therapeutic hope has vanished, and pain without point has taken over. The doctor’s time-honored admonition to preserve life and lessen pain is at a stupefying impasse.”

Faced with a family’s continuing insistence that “everything be done,” including, if necessary, chest compressions and electric shocks to the heart in order to keep the patient alive, the medical team chafes in resentment at another “family that does not get it.” Every evening, when the family arrives at the ICU, the same routine plays out: A physician from the team recites the grim medical facts, points to the patient’s deteriorating body,
and urges the family to allow them to withdraw the ventilator so the patient can die peacefully. The family listens to the explanations—the descriptions of failing organs, alarming laboratory values, hopelessly long odds—and insists that everything be done. The team wonders why a supposedly loving family is being so selfish and cruel and how it is possible for the obstinacy of one family to commandeer enormous medical resources that could and should be put to much better use. The family wonders why the doctors keep badgering them with their litany of doom and gloom when they should simply be about their business of keeping their loved one alive and how it is possible that the hospital can be so indifferent to the value of the life which the family has entrusted to it.

**DIFFERENTIAL DIAGNOSIS OF THE CONFLICT**

The frustrated medical team’s epithet, “The family does not get it,” is often shorthand for a common diagnosis of the cause of the impasse; namely, that for all of the medical team’s efforts to be clear about the patient’s serious medical condition and grim prognosis, the family has yet to fully comprehend. With every passing day, with its presentation of facts, laboratory values, and statistics, the team’s hypothesis appears to be confirmed by the family’s implacable opposition to changing the patient’s level of care. Perhaps, the team reflects, we are using too many big words. Perhaps, this is not a very well educated family. Maybe English is not their native language. The team redoubles its efforts to educate the family about the seriousness of the situation, only to remain stuck with the same result.

In fact, there are several possible explanations for the conflict between the doctor and the family, of which a lack of intellectual understanding is only one and not the most common in any event. But if lack of understanding is not the principal source of the conflict, repeated efforts to lecture the family about the medical facts are no more likely to resolve the impasse than a course of antibiotics is likely to succeed in treating a viral infection. From the outset, therefore, the ethics of prevention requires careful discrimination among the possibilities. Tables 13.1 and 13.2 suggest a differential diagnosis of physician–family conflicts surrounding medically nonbeneficial treatments.
TABLE 13.1 Conflicts Often Resolvable

- Lack of comprehension
- Emotional barriers to processing information
- Disagreement about the patient’s preferences
- Narrow understanding of “hope” and “caring”
- Mistrust of health care team
- Team conflict and mixed messages

TABLE 13.2 Conflicts Often Intractable

- Disagreement on legitimate goals of medical care
- Disagreement on acceptable probabilities of success or trade-offs between potential benefits and burdens
- Disagreement on an acceptable quality of life
- Waiting for a miracle

The principal difference between the two tables is that, in principle at least, all of the issues in Table 13.1 are amenable to resolution through sensitive, therapeutic dialogue, whereas the issues in Table 13.2 represent potentially intractable clashes of values or worldviews. Therefore, a good first step for the team is to try to elicit as specifically and clearly as possible all apparent sources of disagreement, sorting them if possible into the two categories and choosing strategies of mediation or conflict resolution accordingly.37

In Table 13.1, for example, even though problems of intellectual comprehension are infrequently the cause of profound disagreements about life-sustaining treatment, the team has the responsibility (always implicit in our ideal decision-making process) of communicating information about the patient’s illness in a language and in a setting that are conducive to patient/family comprehension. It is worthwhile cultivating the skill of inquiring, in a noncondescending way, whether a family can repeat back to the team the essence of the information the team has tried to convey. (A likely apocryphal story recounts the experience of a surgeon who hastily sketched the chambers of a baby’s heart for a new mother, drawing a schematic diagram similar to that shown in Figure 13.1, in an effort to explain the need for a valve repair, only to overhear the mother report to the father that their baby’s problem was that it had been born with a square heart.) Genuine misconceptions and misunderstanding usually can be
corrected with appropriate educational strategies.

![Figure 13.1](image)

**FIGURE 13.1** Physician’s sketch of infant heart in apocryphal story of miscommunication.

Other issues in Table 13.1 may deserve more consideration. For example:

- What may appear as a lack of intellectual comprehension may be a manifestation of emotional barriers to taking in information. The information may be too threatening, too unexpected, or too evocative of a deepest dread to be absorbed without the protective shields of numbing or denial. Most situations permit periods of supportive accompaniment of the shell-shocked, grief-stricken family before pressing forward with the team’s recommendations to change the focus of care. Communication strategies discussed earlier, particularly under the SPIKES and NURSE mnemonics, can be of great value in this setting.

- The team and family may have different understandings, or evidence, of the patient’s likely preferences. The patient may have expressed one view to the doctor and another to the family. Language in an advance directive may suggest one thing to the team but something quite different to family members who were present when the document was filled out. A tension-lowering approach in this setting is for someone (perhaps an ethics consultant) to open a physician–family conference with the statement, “Everyone in this room is trying to do exactly the same thing, which is to give [your husband, father, brother] the care that he would want if he could speak with us now.
Our challenge is to figure out what that is. Let’s go over what each of us knows about his likely preferences at this point, and how we learned this information.”

• Patients as well as physicians may equate “hope” exclusively with cure or prolongation of life and “care” with the provision of maximal medical treatment. Efforts to expand hope to include achievable goals more consistent with the patient’s condition and suggestions to the family of ways to express love and care through their presence, voice, and touch may offer the family emotional space to adjust their expectations of the medical team.

• Especially for families from marginalized, economically disadvantaged communities, the recommendation to limit intensive medical care can appear to repeat long-standing patterns of social injustice and deprivation. The medical team may represent one more agent of an oppressive power structure. In this setting, the family is unlikely to trust the team’s recommendations, even when they are made in good faith on the basis of solid scientific evidence. If the team suspects this dynamic may be at work, explicitly naming the lack of trust and offering to call in more trusted individuals from the family’s community may diffuse the conflict and promote eventual agreement on a treatment plan.

• Perhaps most common of all preventable or remediable sources of conflict, especially in the ICU, are mixed messages to the family about the patient’s condition. The attending physician may prepare the family for the patient’s inevitable death based on the overall combination of downward-trending prognostic indicators only to have a specialist consultant come by later to tell the family that “the [lungs, kidneys, blood counts] look a bit better today.” A team that repeatedly sends mixed signals to the family should not be surprised when the family holds fast to the most optimistic statements and insists on staying the course. The most urgent task is for the team to arrive at its own internal consensus.

A brief checklist (Table 13.3) can be part of a preventive ethics strategy to help the team first ascertain whether it is in fact dealing with a Table 13.1 type of conflict and, second, maximize its chances of resolving it.
Table 13.2 conflicts are more difficult to resolve solely within the context of therapeutic dialogue. This is because the terms of the disagreement reflect value differences or worldviews that are not necessarily amenable to rational persuasion or supply disputants with individually convincing yet mutually incompatible interpretations of agreed on facts. Institutional policies for mediation, which may include mandatory consultations with an ethics committee and—if these efforts fail to break the impasse—offers to transfer the care of the patient either to another physician or to another institution, are options of almost last resort. In the extreme case, where none of these options is feasible, the institution may be faced with the choice of going to court to obtain judicial authorization to stop the treatment—with no certainty of success but the virtual certainty of cementing the family’s enduring resentment. Alternatively, it may recognize that there are (fortunately rare) instances where, for reasons of compassion, “professional medical judgment” and “the rational use of medical resources” may yield to a family’s indomitable will. Although the team may view the patient’s dying as needlessly prolonged and even horrible, in the circumstances of a family’s passionate intransigence, it may be the least poor outcome. Support for the likely moral distress of the staff becomes another institutional responsibility in this situation.

**Physician-Assisted Death**

The vast attention paid to physician-assisted death in discussions of ethics at the end of life is far out of proportion to its actual significance in the experiences of most dying patients and their families. For most people, far more important issues are related to maintaining the energy and stamina to pursue valued activities and relationships amid the burdens of illness and

---

**TABLE 13.3 Checklist for the Team**

- Do team members agree on diagnosis and prognosis?
- Have team members and family compared sources of information about the patient’s preferences?
- Is the team speaking to the family with one voice?
- Has the team identified a spokesperson with the greatest rapport and credibility in the eyes of the family?
obtaining timely, skilled help with pain, anxiety, and other symptoms. Even in Oregon, whose first-in-the-nation Death with Dignity Act legalizing physicians’ prescriptions of lethal doses of medication for terminally ill patients spawned fears of a “suicide mecca” in the Pacific Northwest, the 133 deaths in 2016 that occurred under the law amounted to barely more than one-third of 1% of all deaths in the state that year.\textsuperscript{38,39} Nevertheless, the issue commands attention in part because of legitimate public concerns about the quality of care that our society makes available to the dying and because active campaigns to expand legalization of the practice beyond Oregon are ongoing in many states across the United States. As of 2017, four states (Washington, Montana, Vermont, and California) have chosen to do so.\textsuperscript{40}

**TERMINOLOGY**

As with many contested social practices, the language used to describe the various ways physicians can be involved in hastening the time of a patient’s death has evolved through many phases and fashions, with people’s preferred language often reflecting their prior moral evaluation of the practices in question. Thus, the literature abounds in discussions of the differences between “killing patients” and “allowing patients to die” or the differences between “passive euthanasia” and “active euthanasia,”\textsuperscript{41} and—more recently—the preference of organizations such as the American Public Health Association\textsuperscript{42} and the American Academy of Hospice and Palliative Medicine\textsuperscript{43} for the term physician-assisted dying rather than physician-assisted suicide. What seems to be at issue in the debates about terminology is the recognition that how we characterize an action (or an omission) often predetermines judgments of its moral status.

Because “killing” is nearly universally condemned in all but very carefully circumscribed situations, proponents of physician actions (or omissions) that hasten a patient’s death take pains to argue that those actions or omissions are not instances of “killing.” Similarly, because “suicide” carries wide social stigma and is often associated with mental illness, patients who make use of physician-provided lethal prescriptions and the physicians who provide them prefer to characterize what they are doing in terms other than committing or aiding in “suicide.” In fact, there
is usually room for reasonable people to disagree about the most accurate characterization of many actions. This is one reason why, as mentioned at the beginning of this chapter, the public consensus on many aspects of end-of-life care masks considerable uncertainty and debate within society. For convenience, the rest of this section will employ the term physician-assisted death to refer to a spectrum of actions and omissions by which physicians may influence the timing of an incurably ill patient’s death so that it occurs sooner than it probably would have without the physician’s involvement. There is a fairly strong public and professional consensus (with the qualifications previously mentioned) about the moral status of many points along the spectrum.

**ETHICAL CONSIDERATIONS ALONG THE CLINICAL SPECTRUM**

Requests for physician-assisted death confront physicians with troubling questions about the proper boundaries of medical practice and the nature of their duty to relieve suffering. There are at least six reasonably distinct actions or roles that a physician might take in the care of an incurably ill patient that could advance the timing of the patient’s death. Two lie at opposite ends of the ethical and legal spectrum. Respecting a competent patient’s wishes to forego or remove life-sustaining treatment is universally accepted ethically and legally in the United States. Administering a lethal injection with the intent of immediately ending the patient’s life (“active euthanasia”) is universally rejected legally in the United States and—although not universally condemned ethically—commands the least widespread support in the ethical literature. In between are four actions that remain somewhat controversial although in varying degrees, always allowing for the fact that characterizing an action as one of these four is itself often a morally significant choice.\(^{44,45}\)

The four intermediate actions are:

- Aggressive symptom management, usually with opiates and sedatives, despite the risk of hastening the patient’s death. The paradigm case is the use of large doses of morphine for pain relief that have the effect of causing fatal respiratory depression. In fact, this is an extremely unlikely side effect of skillful opioid administration to a patient who
has been receiving chronic opioid therapy for pain relief for a period of time. Nevertheless, the scenario is frequently brought up in discussion of the “rule of double effect.” This is the notion, originating in Catholic moral theology, that an action with foreseeable but unintended bad effects (here, the death of the patient) may under certain conditions be undertaken with the primary intent of bringing about its good effect (here, the relief of pain). The extensive debate over the philosophical coherence and clinical applicability of the rule of double effect is beyond the scope of this chapter.\textsuperscript{46–48} For present purposes, it is sufficient to note that the basic concept of treating patient suffering aggressively with appropriate medical therapies, even at the risk of the patient’s earlier death as a side effect of the therapy, is well accepted clinical practice and appears also to have received the sanction of at least some justices of the U.S. Supreme Court.

- Sedating the consenting, terminally ill patient to the point of unconsciousness to protect the patient from otherwise intractable physical or emotional suffering while also withholding artificially provided nutrition and hydration. This sits on the borderline between the previous action (in combination with the universally accepted practice of respecting patient refusals of medical treatment), on the one hand, and the far more controversial action of injecting patients with a lethal dose of medication. The argument against the practice is that although the sedatives themselves are not administered in an intentionally lethal dose as in the case of “active euthanasia,” when combined with the withholding of nutrition and hydration, the patient’s death is as inevitable as it would be at the lethal dose. That it takes place more slowly, in this view, does not avoid the appropriate characterization of the action as (“slow”) active euthanasia.\textsuperscript{49} The rejoinder to this is that, unlike active euthanasia, with its clear intent for immediate death, “palliative sedation”—as the practice has come to be known—is in principle always reversible (sedatives can be lightened to give the patient the opportunity to interact and change course if desired) and remains focused on alleviation of discomfort rather than bringing about the patient’s death.
• Counseling the patient about voluntarily stopping eating and drinking and, if the patient decides to do this, providing medication as needed to alleviate possible discomforts or anxiety over the ensuing period of the patient’s death from dehydration. This is another borderline action. On the one hand, it seems to avoid the moral conundrum posed by physician-provided prescriptions for lethal injection because the patient is solely responsible for his or her lack of nutrition and hydration. Moreover, the determination required on the patient’s part to persist in refusing to eat or drink until death is a safeguard against subtle manipulation or coercion of the patient. On the other hand, the physician clearly has played some significant role. Without the physician’s education of the patient about the option, his or her assurances of providing comfort measures, and actually providing them, many people would probably never consider this option at all, much less pursue it to its conclusion.

• Providing a prescription for a lethal dose of medication at the patient’s request and counseling the patient about how to take the medication to ensure a painless death, after ensuring the patient’s mental competence, providing information about palliative care as an alternative, and requiring both oral and written requests separated by a waiting period. This is the Oregon Death with Dignity Act. As with the previous action, the patient takes all of the decisive steps to bring about his or her death and may decide at many points to change his or her mind—indeed, since Oregon’s law was passed in 1997, a total of 1,749 people have had prescriptions written under the law, whereas only 1,127 have died from ingesting the medications. Nevertheless, by calculating the effective dose, writing the prescription, and counseling the patient on how to ingest the medication, the physician is complicit in the patient’s death in a way that he or she would not be were the patient to end his or her life in a completely private act.

**TWO LEVELS OF RESPONSE: SOCIAL POLICY AND CLINICAL CARE**

There are two important levels of response to the issue of physician-assisted death: the level of social policy (i.e., which actions along the
clinical spectrum should be legally permitted or prohibited) and the level of clinical care (i.e., how individual physicians should respond to their patients who request help in advancing the time of their death).

**Social Policy**

At the level of social policy, there are once again two positions at the ends of a spectrum, with ongoing active debates about positions in between. One end is occupied by advocates of a thoroughgoing libertarianism: The choice to end one’s life at the time and in the manner of one’s own choosing is so bound up with personal privacy and self-determination that no limits should be set on the actions of fully informed, mentally competent adults, or on those of a physician willing to help a terminally ill, suffering patient achieve a swift and painless death. The other end views physicians’ direct involvement in assisted death in the forms of providing prescriptions or injecting lethal medication as so contrary to the role and professional identity of the physician, and so destructive of important societal values, as to require universal and permanent legal prohibition. Physicians, on this view, should abstain from the practice even where it is legally permitted.  

The most active debate takes place between these extremes. The essential dispute is this: Given the improvement in the science and technique of palliative care and pain management over the last 20 years or so (much of which is documented elsewhere in this volume), is the number of people whose physical or existential anguish near the end of life is beyond the reach of effective palliation large enough to justify the societal risks that could accompany widespread legalization of physician-assisted death in its most direct and active forms? Those who say no—and at the state level that would include, as of now, all states in the United States except Oregon, Washington, Montana, Vermont, and California—worry that the possibilities for various types of abuse in a permissive legal system outweigh the benefits to the very small number of people who truly have no other acceptable options. These abuses might include acts of desperation by people without reliable access to medical care of any sort, much less state-of-the-art palliative care; subtle coercion of people to take advantage of legal means to end their lives, playing on their common
Those who say yes argue that these hypothetical, even if theoretically plausible, worries should not outweigh the actual suffering of identifiable people who are ravaged by disease and dying in uncontrolled misery or humiliation. Given what even most opponents concede that there are indeed some patients (small though their number might be) whose suffering is not remediable with standard measures of palliative care, proponents of legalization believe the more active forms of physician assistance should be available—and socially permissible—as a last resort. They contend that the Oregon experience itself should reassure skeptics that safeguards against abuse can work; and that, even if legally prohibited, physician-assisted death in its active forms is and will be carried out, whereas legalization will allow a more public, well-regulated practice to take the place of the “euthanasia underground.”

**Clinical Care**

Regardless of the resolution of these issues at the social and political level, individual physicians should be prepared to deal compassionately and therapeutically with patients who raise the possibility of physician-assisted death. Opponents and proponents of legalization of the more active forms of physician involvement usually agree that excellent palliative care—the active management and support for physical, psychosocial, and spiritual distress—is the standard of care for the seriously ill patient near the end of life. Quill and Arnold outline a set of responses within the physician–patient relationship and the therapeutic dialogue that can help assess and respond to patients, independent of the physician’s personal moral beliefs or the legal environment of his or her practice. They recommend that the physician who receives a request from a patient to help hasten death:

- **CLARIFY** what the patient is communicating: General thoughts about the desirability of ending his or her life? Wondering about the future if his or her condition deteriorates? Asking for help right now?
- **SUPPORT** the patient by giving reassurance that whatever the patient...
feels or desires, the physician is prepared to work together to find a mutually acceptable solution.

- **EVALUATE** the patient’s mental state and decision-making capacity; whether the request seems commensurate with the level of unrelieved suffering; whether there is evidence of treatable depression.

- **EXPLORE** the many possible sources of intolerable suffering, for example, poorly controlled physical symptoms, loneliness, sleep disturbances and exhaustion, psychological or spiritual anguish.

- **RESPOND** to the emotions associated with the patient’s request. Take them seriously while also trying to separate your own emotions from those of the patient.

- **INTENSIFY TREATMENT**, with the help of a multidisciplinary team, of any potentially reversible elements of the patient’s suffering. Only when all of these steps have been completed, Quill and Arnold recommend, should the physician respond directly to a patient’s persistent request for hastened death. Physicians who believe that affirmative assistance is justified beyond steps that fall within ethically or legally accepted practice have a genuine moral dilemma. Some may feel compelled to inform the patient that, despite their sympathy and solidarity, they cannot cross a particular legal or ethical boundary but may be willing to refer the patient to another physician. Others may be willing to, in Quill’s words—cited in a very valuable essay by John Arras—“take small risks for people [they] really know and care about.”

**Conclusion: Beyond the Patient–Physician Dyad**

Good care for a dying patient depends on more than the skillful efforts of the most conscientious physician. Dying is both an intensely private and an inherently social process. The ramifications of the patient’s illness spread throughout his or her social network, both in space—to family, intimate friends, workmates, and so on—and in time—lasting throughout the grief and bereavement of the survivors. Palliative care, which sets itself the task of ministering not only to the patient but also to the “family as the unit of care,” necessarily raises ethical and policy questions beyond the patient–physician dyad.
Some of these issues are closely connected to some of the familiar topics of clinical ethics, such as protecting the confidentiality of medical information or weighing the preferences or needs of family members against potentially incompatible wishes of the patient (e.g., the patient who insists on remaining at home to die even as family members are pushed beyond their physical or emotional limits by the demands of home-based care). Issues such as these push against an individualistic ethic that places the physician’s obligations to the best interests of his or her patient above all other moral considerations, and they often call for skills of negotiation and mediation that are not typically included in the interviewing and communication skills training in medical schools.

Other issues touch on broader questions of public policy and the allocation of society’s resources. Excellent palliative care requires systems of care that can match the particular needs of patients and their families across all the sites of care typical of the prolonged, chronic illnesses that precede most deaths in our society. These include, at a minimum:

- Systems to elicit and document meaningful information from patients about their values, preferences, and goals for medical care and to make sure the documentation accompanies the patient wherever they are in the health care system
- Systems to assure quality standards for the provision of palliative care in health care institutions, including hospitals, nursing homes, and personal care facilities
- Systems to train health professionals in the principles and practices of palliative care
- Systems for family and caregiver support that help families participate meaningfully in the lives and care of their dying loved ones without sacrificing their own physical, mental, and financial well-being
- Systems for financing care that reward professionals for the time-intensive nature of patient and family support and communication in palliative care

As has been mentioned more than once in this chapter, the disruptive power of death makes it impossible for even the best systems and most dedicated individuals to ensure that every person dies according to his or her ideals and hopes for meaning, dignity, and comfort. And the physician
is only one actor—albeit a very significant one—in the universal human process of coming to terms with life’s ending. Families, faith communities, neighborhoods, civic groups, employers, professional caregivers, and many others have the opportunity and responsibility to help a person die in ways that affirm the values and qualities that made his or her life itself worthwhile. The best social policies, laws, and regulations for the care of the dying will be those that make the efforts of all of these people easier rather than harder.

CHAPTER 14
Laws and Policies Affecting Pain Management in the United States

AARON M. GILSON and JAMES F. CLEARY

Introduction

PREVALENCE OF UNRELEIVED PAIN IS A PUBLIC HEALTH PROBLEM

In The Mystery of Pain, poet Emily Dickinson wrote,

Pain has an element of blank;

It cannot recollect
When it began, or if there were
A day when it was not.

It has no future but itself,
Its infinite realms contain
Its past, enlightened to perceive
New periods of pain.\textsuperscript{1}(p650)

Dickinson’s description personifies pain and reveals that the pain experience, conversely, depersonalizes the sufferer. As intense and prolonged pain becomes a defining trait of someone’s life, pain and that person’s existence become intertwined—defining not only the present and future but also the past. This loss of self, coupled with constant suffering, sheds light onto why some people feel hopelessness because of unremitting pain.\textsuperscript{2,3} Pain is, in fact, one of the most common physical complaints on a person’s admission into the health care system, and moderate to severe pain is frequently reported to be experienced throughout hospitalization, during treatment, and even after discharge. The Institute of Medicine (IOM) estimates that “at least 100 million Americans” live with chronic pain, including pain associated with the
disease of cancer, and recent research suggests that the prevalence of pain in people with cancer can vary considerably, depending on chronicity, severity, and site of the disease. In addition, the national prevalence of chronic pain (defined as pain every day for the past 3 months) is estimated at approximately 11%, whereas around 16% reported a lot of pain or the most severe level of pain. The costs of pain, both emotional and financial, can be enormous. Untreated or undertreated severe pain from any condition or any stage of disease can limit a person’s functioning, productivity, and ability to interact socially; sometimes, pain destroys the will to live. A recent study from the Johns Hopkins Center for Health Disparities Solutions and Department of Health Policy and Management indicated that cumulative US health care costs associated with pain exceeded $560 billion in 2010 and calculated an estimate ranging between $299 and $335 billion per year in lost productivity and wages. These estimates suggest that the financial cost of chronic pain has surpassed that of cancer, cardiovascular disease, or diabetes. Increasingly, unrelieved pain has been recognized as a significant public health problem in the United States.

Issues of public health demand a public health approach to develop informed and organized responses to these health problems. A public health approach is intended to protect the community and enhance the health and quality of life of this population by making available effective and economical interventions. Utilizing a social systems perspective, which incorporates input from various levels of the government (including administrative agencies), health care, education, and welfare systems, often is necessary to guide effective interventions. As inadequate pain management becomes accepted as an important public health issue, efforts to rectify this situation will necessarily involve the systematic utilization of methods to measure outcomes of improved treatment. Some of the most frequent outcome measures, including reduction in pain scores and indicators of quality of life enhancement, must be considered alongside more long-term objectives that denote optimal levels of health status. Before such approaches and outcomes can be conceptualized and achieved, however, the numerous factors that can combine to result in unrelieved pain for patients with chronic diseases or conditions must be
understood.

BARRIERS TO THE SAFE AND EFFECTIVE USE OF OPIOID ANALGESICS FOR PAIN MANAGEMENT

Unlike most countries in the world, the problem of unrelieved pain in the United States is not a function of needed medications being unavailable (see Chapter 16 for more detail about global medication unavailability). Patients who experience chronic severe pain still often do not have access to prescription opioid analgesics, which are considered essential medications for treating this level of pain. Of course, this does not mean that prescription opioid medications are to be considered the first-choice treatment option for every patient, a position that is apparent throughout this text, but rather one to be initiated and monitored when the clinical circumstances warrant. Access to effective pain management requiring prescription opioids is a direct function of the equity of health care services, and the reasons for inequity relate to a variety of issues.

Health care organizations and national experts suggest that a number of diverse factors can interfere with the legitimate medical use of opioid analgesics for the treatment of pain and can negatively affect patients’ access to safe and effective pain relief. Most studies have focused on issues in the patient or clinical domains, such as (1) patients’ and family perceptions about the use of opioids for pain relief; (2) patients’ characteristics such as race or ethnicity, substance use history, or the community in which they live; and (3) knowledge and attitudes of health care professionals about the legitimate use of opioids.

When considering whether to treat pain with opioid analgesics, health care practitioners must determine how to maximize benefit and minimize harm, which they have generally not been trained to do. Such inadequate preparation contributes to an unfamiliarity with pain management in general and with relevant treatment modalities in particular, as well as inconsistent use of risk mitigation strategies for patients and perceptions about regulatory or criminal sanctions resulting from prescribing the medications. As a result, there remains an urgent need to enhance clinicians’ skills and confidence and to explore the motivations and challenges to get both practitioners and patients involved.
in activities promoting pain management services. Many of the clinical and patient factors previously mentioned can contribute to the high prevalence of unrelieved pain in the United States, including characteristics of the health care system and health care professionals.\textsuperscript{50} Restrictive federal and state policies relating to drug control and health care practice (often referred to as regulatory barriers) also are recognized as potential impediments to pain management, especially considering the extent that practitioners know of and adhere to such policies. Since the early 1990s, national health care organizations have frequently voiced concern about the possible detrimental effects of regulatory barriers. In 1994, the Agency for Health Care Policy and Research (AHCPR) (now the Agency for Healthcare Research and Quality) published a clinical practice guideline on cancer pain relief, which recognized the existence of regulatory barriers, and recommended that laws and regulations aimed at preventing the abuse and diversion of opioids should not hamper their appropriate use in the treatment of cancer pain\textsuperscript{51}; these messages were retained a decade later when the American Pain Society updated the guideline.\textsuperscript{52} Around the time of the AHCPR guideline dissemination, the National Cancer Institute sponsored a workshop to define priorities in cancer pain–related research that included policy and regulatory issues.\textsuperscript{53} The American Cancer Society (ACS) later convened a Cancer Pain Management Policy Review Group to discuss regulatory challenges facing cancer pain management, with an emphasis on ensuring access to appropriate treatment given the national attention on the nonmedical use of pain medications. The Review Group developed several policy statements about various aspects of cancer pain management,\textsuperscript{54–56} including a description of regulatory barriers affecting quality pain treatment.\textsuperscript{55} Calls for studies to improve pain management and identify the legal and regulatory impediments to appropriately using opioids for pain relief have come from the ACS\textsuperscript{54} as well as the IOM\textsuperscript{57} and the National Institutes of Health (NIH).\textsuperscript{58} For the United States, this involves an understanding and examination of both federal and state laws.

**POLICIES GOVERNING THE USE OF OPIOID ANALGESICS FOR PAIN MANAGEMENT**
Governments, at both the federal and state levels, can create and change public policies that influence the health of the population. Laws reflect governmental decisions that are largely influenced by social values but provide the legal basis for actions that affect public health, including pain management. For example, given the increasing recognition of pain relief as a basic human right, health care facility licensing regulatory standards (e.g., for hospitals, nursing homes, residential care units, and hospices) have even emphasized the pain care of their patients. The World Health Organization (WHO) embraces the incorporation of human rights principles, acknowledging the need to “balance effective responses to disease risks” with respect for fundamental individual freedoms. However, a patient receiving effective pain relief currently is viewed more as a right in the moral sense but generally not in the sense of law or regulatory content.

Legislative bodies typically create laws (i.e., statutes) that are broad and general and depend on the relevant regulatory agency to interpret and implement the laws through regulations. In fact, legislatures that avoid making considerably detailed law would likely require less frequent amendments to such laws because the accompanying regulations contain the professional or technical details that would need to be revised periodically to keep pace with changing practice standards. For medicine, for example, the legislature grants authority to the state medical board to define and implement its laws through regulation (or administrative rules); regulations must be consistent with legislative provisions. Even given this structured process, pain-related law has not kept pace with advances in medical and scientific understanding. Although professional boards may revise their pain management policies in reaction to updated professional standards, legislation has been slow to change. This has particular implication for pain management, including opioid prescribing, where such legislation tends to have extensive detail and may not reflect current medical standards (see “State Pain Policy Development: An Emerging Trend” section for examples).

In late 2016, Pain Medicine published Daniel Carr’s President’s Message to the American Academy of Pain Medicine readership, entitled “Patients with Pain Need Less Stigma, Not More.” According to Dr.
Carr, who is the founding director of the Tufts Program on Pain Research, Education and Policy, the ubiquitous clinical scenario surrounding the treatment of patients with chronic pain (especially noncancer pain) is characterized by, among other things:

- “Stigma—shaming and shunning—continues to befall patients with chronic pain, as do inequities in access to care.” 63 (p1391)
- “[The] most damaging barrier now facing patients with chronic pain [is] the unprecedented rise in illegal diversion and abuse of opioids, often involving prescription painkillers, with pervasive societal consequences from addiction, crime, overdose, and death . . . [despite the] general agreement that most patients prescribed opioids for chronic noncancer pain are not these problematic outliers.” 63 (p1392)
- “Practice guidelines put forth or proposed by different governmental agencies are not uniform, leaving prescribers uneasy that by prescribing opioids at any dose, to any patient, they place themselves in harm’s way . . . unleashing a torrent of blame and stigma directed towards all opioid prescriptions, prescribers, and patients.” 63 (p1392)
- “Increasing numbers of legitimate patients are voicing personal narratives of long-term benefit from a chronic modest dose of an opioid, now finding such care terminated by policies based upon administrators’ interpretations of group statistics never meant to guide individual care.” 63 (pp1392–1393)

Within these statements, Dr. Carr recognizes that health care professionals must practice in an environment of legal and regulatory influences, one that can seem particularly ambiguous when it comes to chronic pain, opioid therapy, and risk of addiction or other serious harms. In such an environment, understanding current practice policy requirements is critical.

Although practitioners generally do not receive training in legal and regulatory issues related to prescribing of opioid analgesics and can be unfamiliar with the federal and state laws that govern their practice, there has been an increasing call for clinicians to acquire knowledge about the policies under which they practice. 13,16,64,65 This chapter attempts to create a resource to address this need by describing the three layers of laws in the United States that create the policy framework for both the diversion and
legitimate medical use of opioid analgesics: (1) international treaties governing drug control; (2) federal laws and regulations governing drug control, which includes the legal parameters for prescribing controlled substances; and (3) state laws and regulations governing drug control and health care practice, including prescribing controlled substances. The chapter also discusses other policy considerations related to prescribing practices, highlights the need for communication and implementation as a means to improve practitioners’ understanding of policy requirements, and suggests the influence that diversion of medications can have on opioid-related harms.

International Treaties: Establishing Balance between Drug Control and Medical Use

Treaties form the basic legal framework to control international and domestic production and distribution of drugs—including medications—that have a recognized abuse liability. The drugs subject to these more rigorous controls are therefore referred to as controlled substances and include, but are not limited to, opioid analgesics. The principal treaty establishing controls for prescription opioids used to treat pain is the Single Convention on Narcotic Drugs of 1961 (Single Convention).\(^66,67\) It should be understood that the term narcotic, which includes opioid analgesics, is now primarily used in legal contexts, such as in reference to the international drug control treaty or relevant laws; narcotic, which generally is defined as an agent that produces stupor or insensibility, is not considered “useful in a pharmacological context” when describing opioid medications.\(^68\) The Single Convention establishes a number of basic requirements for a country’s laws and regulations to create effective measures against drug abuse and diversion. Many of these measures relate directly to the health care setting, including:

- A country’s government must duly authorize everyone involved in the medical distribution of narcotic drugs (Article 30).
- Opioid medicines are to be possessed with only legal authority—that is, a valid prescription issued to a patient by a properly licensed practitioner for a legitimate medical purpose in the usual course of
professional practice (Articles 30 and 33).

- All licensees are qualified and adhere to their obligation to prescribe and dispense controlled medicines in full and faithful execution of the law, as well as maintain records for medication manufacture, acquisition, and disposal (Article 34).67

Although established as international law aimed at preventing drug abuse, this treaty also recognizes that many controlled substances are indispensable to public health and that there is a need to ensure their availability for legitimate medical and scientific purposes (United Nations,67 Preamble). Becoming a party to this treaty obligates a government to take steps to make controlled substances available in adequate amounts to effectively treat medical conditions. Most, but not all, of the world governments are parties to the Single Convention, including the United States, which means that they formally accept the obligation to develop a legislative and administrative framework to implement the treaty’s objectives.69

The long-standing dual obligation of country governments to (1) establish a system of controls to prevent abuse, trafficking, and diversion of controlled substances and (2) simultaneously assure their medical availability, is referred to as Balance.70 Balance maintains that opioid analgesics, although designated as controlled drugs, also are essential medicines, are absolutely necessary for adequate pain relief, and must be accessible to patients who need them for medical purposes. Within this framework, the status of these medications as “controlled substances” is not meant to diminish their medical usefulness or create the perception that practitioners should avoid their use when there is a clear clinical indication. Moreover, the principle of Balance does not sanction medication use outside an established system of control, recognizing that only properly licensed health care practitioners can use opioid analgesics for legitimate medical purposes in the course of professional practice.67 Governments that achieve and implement balanced policy continue to maintain an opioids supply sufficient to meet medical demand and empower practitioners to rationally prescribe, dispense, and administer opioids in the course of professional practice and in response to individual patient needs. With these efforts, it is clear that medication availability is
supposed to be limited exclusively to medical and scientific purposes. The International Narcotics Control Board (INCB), a United Nations–affiliated agency responsible for monitoring governments’ implementation of the Single Convention, has historically observed, and continues to note that the global medical need for opioid analgesics is not being fully met. Opioids remain insufficiently available to meet medical needs throughout the world for many reasons, including severely restrictive drug control policies; the real and overriding concern about drug abuse and addiction also has motivated the creation of laws that when put into practice hamper the appropriate medical use of opioids, including for the treatment of cancer pain.

. . . the reaction of some legislators and administrators to the fear of drug abuse developing or spreading has led to the enactment of laws and regulations that may, in some cases, unduly impede the availability of opiates. The problem may also arise as a result of the manner in which drug control laws and regulations are interpreted or implemented. More recently, such international organizations as the Council of Europe, the World Medical Association, the WHO, WHO HIV/AIDS, the INCB, the United Nations Commission on Narcotic Drugs, and the United Nations Economic and Social Council have called for governments to identify and address regulatory barriers in their narcotics control policies.

For example, a common requirement found in international drug control policies has been and continues to be the use of multiple-copy prescription forms (also commonly called “serialized forms”), which the Single Convention encourages when a country’s government considers such a control measure necessary or desirable (United Nations, Article 30(2)(b)(ii)). This requirement typically involves the need for physicians to issue prescriptions using a special form so that a designated regulatory or enforcement agency can monitor the prescribing and dispensing of certain drugs. These forms are designed and enacted primarily to prevent forgery of narcotic prescriptions and can vary in type, from the use of prescription pads with counterfoil or carbon pages to an extreme where the physician
must complete the same required prescription information repeatedly on a number of separate forms. Serialized prescription forms are government-issued, but they may be difficult to obtain and can increase the health care and social stigma associated with prescribing opioid medications. As early as 1990, the WHO Expert Committee on Cancer Pain Relief and Active Supportive Care addressed how special government-issued prescription forms can influence prescribing:

Record-keeping and authorization requirements should not be such that, for all practical purposes, they eliminate the availability of opioids for medical purposes. Multiple-copy prescription programmes are cited as means of reducing careless prescribing and “multiple doctoring” (patients registering with several medical practitioners in order to obtain several prescriptions for the same, or similar drugs). There is some justification for [this], but the extent to which these programmes restrict or inhibit the prescribing of opioids to patients who need them should also be questioned. Some governments have concluded that multiple-copy prescription forms create burdens to physicians’ practice that can unduly limit access to covered medications, and have changed the requirements of these forms to respond to these problems—this has occurred in such countries as Austria, Italy, and Mexico and in numerous states in the United States. These positive programmatic changes are not meant to undermine the drug control capacities inherent in the serialized forms but rather to make it less likely that they hinder patient care. Other ways that countries have established overly restrictive drug monitoring and control systems include establishing extremely short medication supply limits (e.g., 3 days) and only allowing physicians with certain specialties to prescribe. Again, countries’ governments are addressing these potential barriers in law, which is described in detail in Chapter 16.

It is apparent that the international narcotics treaty is intended for drug control and to maintain drug availability for medical purposes, which the World Health Assembly has historically reaffirmed. However, some countries have implemented the treaty too strictly, resulting in
abuse/diversion mitigation while making the use of opioid medications for
pain management difficult if not impossible.\textsuperscript{110} Given this reality, it may
help to understand the current status of national laws and regulations. The
next section describes the extent that the United States is meeting its
obligation to prevent medication diversion and abuse while continuing its
responsibility to ensure the appropriate medical use of opioid analgesics.

**US Federal Law: Preserving Balance between Drug
Control and Medical Use**

**THE FEDERAL FOOD, DRUG, AND COSMETIC ACT**

Under the authority of the Federal Food, Drug, and Cosmetic Act of 1962
(FFDCA), the U.S. Food and Drug Administration (FDA), which is part of
the U.S. Department of Health and Human Services, is responsible for
promoting public health by ensuring that all medications, including opioids
and other controlled substances, are safe and effective for human use.\textsuperscript{111}
The FDA’s approval decisions for marketing a particular drug always
involve an assessment of the benefits and risks,\textsuperscript{112} including its abuse
liability. The drug manufacturer must provide to the FDA all relevant data
related to safety by the time a new drug application is submitted.\textsuperscript{113} When
the benefits of a drug are considered to outweigh its risks, and when the
labeling instructions allow for safe and effective use, only then does the
FDA consider the drug safe for approval and marketing.\textsuperscript{114} To further
reduce opportunities for adverse events, patients also are expected to use
the medications according to the prescriber’s instructions.\textsuperscript{115} Of course,
use of any medication outside of the prescriber’s instructions, for
nonmedical purposes, or absent medical supervision, undermines the
safety profile of that medication and increases the likelihood of harms.

When reviewing a new drug application, or after the FDA approves a
medication, a determination can be made that the manufacturer also must
submit plans for a risk evaluation and mitigation strategy (REMS) to
ensure that the benefits of the medication outweigh its risks.\textsuperscript{116} In the
context of pain management, the FDA approved a shared class-wide
REMS for long-acting (LA) and extended-release (ER) opioid analgesics
in mid-2012, which has been updated with new products every year
since\textsuperscript{117}; as of this writing, this REMS program encompasses 65 separate
generic or branded LA/ER products.\textsuperscript{117} In addition, a REMS for
transmucosal immediate-release fentanyl (TIRF) products was begun in
2011 and subsequently has been applied to additional products, at this time
covering a total of ten TIRF medications.\textsuperscript{118} Within the primary objective
of REMS programs to enhance medication safety, there remains an explicit
commitment to “enable patients to have continued access to such
medicines by managing their safe use” (webinar statement).\textsuperscript{116}

A REMS program contains steps to address morbidity and mortality
and, according to law, requires a timetable to assess the strategy at 18
months, 3 years, and 7 years after the strategy is approved,\textsuperscript{119} whereas the
LA/ER REMS specifically mandates that assessments be submitted to the
FDA at 6 months and 12 months and then every year thereafter.\textsuperscript{120} Again,
the goal of the REMS relates to reducing serious adverse outcomes from
the misuse and abuse of, as well as to ensure appropriate access to, the
covered medications.\textsuperscript{120} Two components comprise the adopted REMS:
(1) a medication guide and (2) elements to assure safe use. A one-page
medication guide is designed for each covered opioid product, either
generic or branded,\textsuperscript{121} and are to be provided through the pharmacy when
an LA/ER opioid is dispensed outside of a hospital setting. Elements to
assure safe use are satisfied through voluntary REMS-compliant training
for prescribers, with the training content conforming to learning objectives
outlined in the FDA Blueprint.\textsuperscript{122} The learning objectives relate broadly to
the consideration of medication-related risks and benefits throughout
treatment, including during initial patient assessment; initiating,
maintaining, or discontinuing opioid therapy; and counseling patients and
their caregivers.\textsuperscript{122} In addition, the training is designed to improve
practitioners’ general and specific understanding of LA/ER opioid
medications.\textsuperscript{122}

Various methods are being used to enhance prescribers’ awareness of
available REMS training opportunities, as a means to achieve explicitly
defined performance goals.\textsuperscript{120} Such methods include developing and
maintaining a REMS-related Web site, sending letters to all practitioners
registered to prescribe relevant medications, and requesting that
informational letters be disseminated through state health care licensing
and disciplinary boards (i.e., boards of medicine, nursing, and dentistry) as well as their national associations (i.e., the Federation of State Medical Boards of the United States [the Federation], the National Council of State Boards of Nursing, and the American Association of Dental Boards) and professional societies and associations. Another important resource included in these methods is the availability of a one-page counseling document, which health care practitioners are expected to give to patients when treatment involves LA/ER opioids. It is clear that these LA/ER REMS characteristics conform to general programmatic elements defined in law to include a communications plan to health care practitioners about the medications, such as (1) sending letters, (2) disseminating information about the REMS to explain certain safety protocols or to encourage implementation by health care practitioners of applicable components of the REMS, and (3) using professional societies to disseminate information about serious drug risks and protocols to enhance safety.

Available research suggests, cumulatively, that implementation of REMS-compliant prescriber training contributes to increases in practitioner knowledge; better patient awareness of medication risks; and lower occurrence of abuse, overdose, and death while not creating a barrier to appropriate medication access. When searched on March 22, 2017, almost 80 REMS-compliant continuing education (CE) training courses were available either at no cost or for a nominal fee, some extending into 2018 (https://search.er-la-opioidrems.com/Guest/GuestPageExternal.aspx), whereas Cepeda et al. indicated that more than 500 such courses were offered in 2013 and 2014. Despite these opportunities, proportionally few prescribers have completed REMS-compliant training. Many reasons account for this low completion rate, including the voluntary nature of the training, participation in non–REMS-compliant CE training (which does not cover all of the content outlined in the FDA Blueprint), and incomplete documentation such as failure to submit a posttest evaluation and the prescribing of an LA/ER opioid in the last year.

The FDA is responsible for reviewing and sanctioning product labeling, with the purpose of providing information for the patients’ safe and effective use of the medication. The FDA also has an
obligation to ensure that postmarketing promotional materials are consistent with the approved labeling information. Historically, the FDA’s statutory authority applied primarily to the evaluation of premarketing testing and, after drug approval, the agency’s role was limited. However, in September 2007, the FFDCA was expanded to comprise active postmarket risk identification for approved drugs. Activities under this mandate include ongoing analysis of drug safety data from disparate data sources as well as adverse event surveillance using electronic data from the federal government (e.g., the FDA Adverse Event Reporting System) and the private sector (e.g., the Researched Abuse, Diversion and Addiction-Related Surveillance [RADARS] system). Information from these sources can lead to safety-related label changes to address new safety data. For example, in 2013, LA/ER opioid medications underwent an indication revision. As a result, LA/ER opioids are no longer indicated for the treatment of moderate to severe pain but rather “for the management of pain severe enough to require daily, around-the-clock, long-term opioid treatment and for which alternative treatment options are inadequate.” This change has the benefit of characterizing a more explicit clinical circumstance warranting opioid therapy and implicitly reinforces the standard that these medications are to be initiated only after other modalities have been at least considered and ruled out as unsatisfactory. Overall, the collaborative process engendered through the 2007 legislative change is designed to improve the quality and efficiency of postmarketing drug safety risk–benefit analysis and to allow for the public disclosure of safety and effectiveness data in a timely, systematic, and transparent manner.

A potentially important contribution to the FDA regulatory process comes from a 2017 report from the National Academies of Sciences, Engineering, and Medicine on opioid medications and pain management. The report contains a series of recommendations that, among other things, advises the FDA to conduct a full review of currently marketed and approved opioid products to further ensure the benefit and safety of those modifications both on patients and to public health. Accomplishing this objective is further enhanced when the review is conducted within a framework of what is called a “comprehensive systems
approach,” in which the following factors are urged to be considered:

- “Benefits and risks to individual patients, including pain relief, functional improvement, the impact of off-label use, incident opioid use disorder (OUD), respiratory depression, and death;
- Benefits and risks to members of a patient’s household, as well as community health and welfare, such as effects on family well-being, crime, and unemployment;
- Effects on the overall market for legal opioids and, to the extent possible, impacts on illicit opioid markets;
- Risks associated with existing and potential levels of diversion of all prescription opioids;
- Risks associated with the transition to illicit opioids (e.g., heroin), including unsafe routes of administration, injection-related harms (e.g., HIV and hepatitis C virus), and OUD; and
- Specific subpopulations or geographic areas that may present distinct benefit-risk profiles.”

To the extent that this recommended approach is informed by available evidence that considers the benefit/risk profiles with those for whom the medications are indicated and prescribed, as well as those for whom the medications are not prescribed (e.g., use for nonmedical purposes), this would be a highly valuable and illustrative decision-making process. Another important consideration for an FDA review will be to ascertain whether the prescribing conforms to current practice standards, including patient risk stratification and ongoing treatment monitoring as well as whether patients were compliant with practitioner instructions or product labeling directions. Along with additional attention to illegal drug markets and diversion activity (see the “Taking Diversion into Account” section), there can be a more complete understanding of the degree to which demonstrated harms result from legitimate medical, compared to nonmedical, use.

Of course, prescribing decisions are part of medical practice. The FFDCA is intended neither to regulate medical practice nor to interfere with the authority of a licensed health care practitioner to use controlled substances for a legitimate medical purpose. It is the responsibility of the states, and not the US federal government to regulate professional
health care practice. However, both the state and the federal government share drug control responsibilities.

**US FEDERAL CONTROLLED SUBSTANCES LAW**

Controlled substances laws provide an additional layer of control over the distribution of prescription drugs that have an abuse liability (i.e., using criteria related to the potential to produce psychological or physical dependence), establishing a closed distribution system to minimize their abuse, trafficking, and diversion. The federal Controlled Substances Act (CSA)\(^{133}\) is part of the Comprehensive Drug Abuse Prevention and Control Act of 1970,\(^{134}\) and is the principal drug control law in the United States and conforms to the international treaties—it establishes criminal penalties for the illicit possession, manufacture, and trafficking of controlled substances and prohibits their nonmedical use while, at the same time, recognizing that they are necessary for public health and that their medical availability must be ensured. The CSA creates a comprehensive regulatory framework designed to ensure that controlled substances are only produced and distributed through proper channels and for proper medical purposes. In fact, the CSA is a culmination of more than 50 pieces of federal legislation adopted since 1914 relating to drug control and diversion.\(^{134}\)

The CSA specifies five classification schedules for controlled substances, each carrying different penalties for unlawful uses. A drug’s medical usefulness and abuse liability form the basis for the decision to assign it to a particular schedule.\(^{135}\) Schedule I drugs have no currently accepted medical use, no accepted safety for use under medical supervision, and a high potential for abuse (e.g., ecstasy; heroin, LSD, marijuana, methaqualone, and peyote) and are available only for scientific research. Drugs that have an FDA-approved medical use are placed in Schedules II through V according to potential for abuse in the following manner:

- Schedule II medications have the highest potential for abuse and include such opioids as codeine, fentanyl, hydrocodone (including combination products since 2014),\(^{136}\) hydromorphone, meperidine, methadone, morphine, and oxycodone (including combination
products) as well as nonopioids such as short-acting barbiturates (e.g., pentobarbital), amphetamine, methamphetamine, methylphenidate, and cocaine.

- **Schedule III medications** have a lower abuse potential than Schedule II drugs and include opioids such as dihydrocodeine and codeine combinations with aspirin or acetaminophen as well as nonopioids such as buprenorphine, intermediate-acting barbiturates (e.g., butalbital), and the synthetic cannabinoid dronabinol.

- **Schedule IV medications** have a lower abuse potential relative to drugs in Schedule III and include opioids such as dextropropoxyphene, pentazocine, and tramadol as well as nonopioids such as benzodiazepines (e.g., alprazolam and diazepam), LA barbiturates (e.g., phenobarbital), and certain nonamphetamine stimulants (e.g., pemoline).

- **Schedule V medications** have a lower abuse potential compared to drugs in Schedule IV and include compounds or preparations containing limited quantities of opioids such as codeine or opium, which may be used for over-the-counter preparations to treat cough or diarrhea, respectively, as well as antidiarrheals containing diphenoxylate and difenoxin, and pregabalin.

Under federal law, the Drug Enforcement Administration (DEA) is the primary federal agency responsible for enforcing the CSA and, thus, has regulatory authority over controlled substances. The DEA is an agency of the federal Department of Justice, headed by the attorney general of the United States.

To conduct research with, or manufacture, distribute, handle, dispense, administer, or prescribe, controlled substances, a person or business must be registered with the DEA (and, in some cases, also with the relevant state agencies). Licensed and registered practitioners can prescribe, dispense, or administer controlled substances only for legitimate medical purposes and in the usual course of professional practice; the DEA and federal courts have interpreted this to mean that prescriptions must be issued “in accordance with a standard of medical practice generally recognized and accepted in the United States.” Registrants’ distribution of Schedule I and II controlled substances are made using a
special order form (DEA Form 222) to monitor all transfers of these controlled substances within the “closed” system.\textsuperscript{142,143}

A number of federal standards are relevant to pain treatment involving controlled medications. For example, prescriptions for Schedule II medications must be written and may not be refilled,\textsuperscript{144,145} whereas five refills are permitted for drugs in Schedules III and IV.\textsuperscript{146,147}

The requirement for a written prescription is additionally fulfilled through federal law’s allowance of prescribers to issue electronic prescriptions for Schedule II controlled substances\textsuperscript{148}; electronic prescriptions remain an option that is not designed to completely supplant written paper prescriptions. For this reason, pharmacists and health care facilities are required to have the technologic infrastructure to process e-prescriptions as a means to create a transparent environment that is auditable and DEA-compliant.\textsuperscript{149} Regulatory requirements governing this process are quite elaborate. Every aspect of the technology requires certification by the DEA, such as supervised pre-enrollment, maintaining records, the cryptographic signing module, the authentication software and hardware, and the routing of the prescription to the pharmacies (with those pharmacies needing a certified technology platform).\textsuperscript{148} Generally, many practitioner obligations involve maintaining information and transmission security, including the need to promptly report security breaches.\textsuperscript{150} The same legal responsibilities exist when issuing electronic prescriptions as with hard-copy prescription forms for controlled substances, especially the need to issue for a legitimate medical purpose and in the course of professional practice. Clearly, electronic prescriptions must be issued in conformity to applicable laws, as with any other prescription. All states have modified their laws to accommodate this federal authorization,\textsuperscript{151} and as of January 1, 2015, about 70% of pharmacies and 4% of practitioners have the ability to issue electronic prescriptions for controlled substances (Rick Camp, marketing director of Surescripts, as a comment to HealthIT Buzz’s “The Electronic Prescribing of Controlled Substances Is on the Rise,” \url{https://www.healthit.gov/buzz-blog/health-information-exchange-2/electronic-prescribing-controlled-substances-rise/}).

Federal law also allows oral or faxed (but not electronic) transmission of prescriptions for Schedule II controlled substances in medical emergencies.
under specific circumstances, as well as for the partial dispensing and faxing (but not oral or electronic data transmission) of prescriptions under certain specific clinical circumstances. There are penalties, both criminal and civil, for violating federal requirements.

Although prescriptions for certain controlled substances must be in writing, and refills are limited, the fact that a drug has been approved for medical use does not change when it becomes a controlled substance. This principle is conveyed by the CSA statement that

many of the drugs included within this title have a useful and legitimate medical purpose and are necessary to maintain the health and general welfare of the American people.

Overall, the legislative history, as well as language contained in the CSA itself (and its related regulations), makes it clear that efforts to prevent drug abuse and diversion are not to interfere with legitimate medical practice and appropriate patient care.

The Controlled Substances Act Ensures Availability of Controlled Substances for Medical Purposes

The CSA authorizes the DEA to establish production quotas for a number of opioids and other controlled substances as a means to stem diversion resulting from excessive unused supplies. Such quotas also must maintain sufficient supplies to accommodate all medical and scientific needs as well as to establish and maintain reserve stock. Despite this apparent standard, however, insufficiently low quotas have occurred for various controlled substances. For example, 30 years ago, the DEA set a very low quota for methylphenidate to restrict its production in an effort to control diversion. As a result, the methylphenidate supply was inadequate to treat patients with attention-deficit/hyperactivity disorder and narcolepsy, which are legitimate medical uses. An official statement was promulgated in response to this action, establishing the principle of an “undisputed proposition” of drug availability:

The CSA requirement for a determination of legitimate medical need is based on the undisputed proposition that patients and pharmacies should be able to obtain sufficient quantities of methylphenidate, or
of any Schedule II drug, to fill prescriptions. A therapeutic drug should be available to patients when they need it. To accomplish this, a smooth flow of distribution is required . . . the harshest impact of actual or threatened shortages falls on the patients who must take methylphenidate, not on the manufacturers to whom the quotas directly apply. Actual drug shortages, or even threatened ones, can seriously interfere with patients’ lives and those of their families.\textsuperscript{157}(pp50593–50594)

Following this statement, the DEA recalculated the methylphenidate quotas to accommodate its demand for medical purposes. The same situation later occurred for amphetamines as a treatment for attention-deficit/hyperactivity disorder.\textsuperscript{158}

The DEA has, over time, expressed a willingness to grant additional quotas for controlled substances necessary to treat medical conditions, including prescription opioids for pain.\textsuperscript{159–161} In fact, in response to concerns about natural disasters or other unanticipated situations resulting in prolonged interruption of medication availability:

DEA included in all schedule II aggregate production quotas, and certain schedule I aggregate production quotas, an additional 25% of the estimated medical, scientific, and research needs as part of the amount necessary to ensure the establishment and maintenance of reserve stocks. The established aggregate production quotas reflect these included amounts.\textsuperscript{1}(p59980)

However, the most recent proposed quotas have removed the 25% buffer that were in effect over the last few years, an action that some have interpreted to exemplify a potentially problematic supply reduction (see Anson\textsuperscript{162} for example). It is possible, though, that activities such as increased sales to meet prescription demand or product development will prompt the DEA to revise the quotas. Such quota revisions are indeed permissible under federal law.\textsuperscript{163}

\textbf{The Controlled Substances Act Does Not Regulate Medical Practice}

The CSA’s legislative history demonstrates health care professionals’
overriding concern that the drug control law ultimately would give law enforcement inappropriate authority over medical and scientific decisions.\textsuperscript{155} Abundant professional testimony resulted in Congress establishing a procedure in which the federal health agency (now the U.S. Department of Health and Human Services) makes medical determinations under the CSA. This history makes it apparent that the federal government is obligated to create criteria for drug control, including the legal parameters for prescribing controlled substances and to investigate intentional criminal conduct (e.g., issuing prescriptions not for a legitimate medical purpose and in the usual course of professional practice). That is, cases involving questionable prescribing are to be evaluated to determine whether the relevant practice is intentional criminal conduct or substandard professional practice.\textsuperscript{64,164–166} Such a distinction historically has helped assure proper jurisdiction: Good faith professional practice, even if poor, can insulate a practitioner from criminal prosecution\textsuperscript{167}; both state and federal case law supports this differentiation.\textsuperscript{168} If a practitioner’s conduct is intentionally outside legitimate professional practice, law enforcement interventions from federal, state, or local agencies seem warranted.\textsuperscript{165} That is, a prescription issued or dispensed other than in good faith (i.e., the practitioner knew, or intended, that the prescription would not be used for a legitimate medical purpose) could form the basis for criminal sanctions.\textsuperscript{165,169} By extension, unwarranted criminal charges against practitioners may become less frequent, at least in part, to the extent that investigations clearly and consistently consider criminal behavior as distinct from unprofessional conduct. Chapter 16 of this text provides much more descriptive detail about this legal foundation through a discussion of legal cases involving pain management within four primary domains of law: administrative proceedings, civil litigation, criminal litigation, and constitutional cases.

Given this context, the federal government clearly does not have the statutory authority to regulate medical practice. This authority belongs to the states and is based on the police power in state constitutions and underlies the medical practice acts that are designed to protect the public health and safety.\textsuperscript{170} The CSA is not intended to supersede the authority of the FFDCA and provides no authority for the DEA to define or regulate
medical practice, including the treatment of pain or the indications for which a drug may be prescribed.

The DEA’s enforcement authority is intended to relate to clinicians involved in unlawful distribution of controlled substances that is outside legitimate health care practice (i.e., behaviors that are clearly criminal in nature). To this end, a prescription for a controlled substance is only lawful when issued for a legitimate medical purpose and in the usual course of professional practice. David Brushwood, a pharmacist and attorney and now professor emeritus from the College of Pharmacy at the University of Florida, Gainesville, has interpreted a useful distinction between the phrases “legitimate medical purpose” and “course of professional practice,” which define the boundaries of practitioner investigations and prosecutions for the DEA:

“Legitimate medical purpose” has no meaning unless “illegitimate medical purpose” has meaning. Yet medicine is inherently legitimate; there is no such thing as “illegitimate medicine.” A practice that is not medical is neither legitimate nor legal under the DEA regulation. A practice that is medical is legitimate and is legal under the DEA regulation. DEA does not regulate within medical practice but simply discerns whether a practice is medical or nonmedical. . . . The DEA regulation has nothing to do with the credentials or qualifications of a health care provider. It has everything to do with the activities of the health care provider. If those activities are not professional health care activities, then they are illegal under the DEA regulations; if they are professional health care activities, they are legal. DEA has no authority to pass judgment on the merits of a professional practice. Its role is limited to determining whether a practice is a professional practice.

This critical distinction remains relevant today.

Further evidence that the CSA was not intended to interfere with legitimate medical practice is found when Congress enacted a law in 1978 to implement another international treaty (i.e., the Convention on Psychotropic Substances of 1971). Consequently, the control of psychotropic substances such as benzodiazepines became a responsibility
within the CSA to:

insure that the availability of psychotropic substances to manufacturers, distributors, dispensers, and researchers for useful and legitimate medical and scientific purposes will not be unduly restricted . . . and nothing in the Convention [on psychotropic substances] will interfere with ethical medical practice in this country as determined by the secretary of Health and Human Services on the basis of a consensus of the American medical and scientific community.173

The Controlled Substances Act Distinguishes Treatment of Addiction from Treatment of Pain, but Legal Definitions Create Confusion

Under the CSA, a separate registration by the federal government as an opioid treatment program (OTP) is required for the purpose of maintenance or detoxification of opioid addiction with certain opioid medications.174 The use of medications approved for the purpose of addiction treatment, such as methadone and buprenorphine, must comply with federal and state regulations. Methadone and some buprenorphine products, however, are indicated for analgesic purposes according to the same laws for prescribing any other Schedule II or Schedule III opioids.

The accurate application of terminology is central to shaping a balanced policy on drug control and professional practice, especially in the United States where extended opioid therapy to maintain addiction (without a separate registration) is illegal. Addiction often is perceived as being based solely on the development of physical dependence or tolerance, both of which are expected physiologic consequences of using opioids for a prolonged period, which runs counter to current diagnostic nomenclature.175 Practitioners who consider these related, but separate, phenomena as synonymous can inappropriately label a patient with pain who is receiving opioid therapy as an “addict,” which can influence care decisions and inflate determinations about iatrogenic addiction. Given this situation, one must carefully differentiate between treating a patient’s pain and maintaining or detoxifying a person with an addictive disease and to understand and use terms correctly.
The CSA defines addict as

an individual who habitually uses any narcotic drug so as to endanger the public morals, health, safety, or who is so far addicted to the use of narcotic drugs as to have lost power of self-control with reference to his addiction.\textsuperscript{176}

This definition is characterized by the use of circular, imprecise, and outdated language and is not comparable to the WHO’s current International Classification of Diseases [ICD10] concept of dependence syndrome,\textsuperscript{177} the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM) classification of substance use disorder,\textsuperscript{175} or the American Society of Addiction Medicine’s definition of addiction.\textsuperscript{178} Given its inconsistency with more recent nomenclature, the CSA could indeed be updated to conform more completely to current terminology and standards.

Although not contained in the CSA, in 1970, a definition of drug-dependent person was added to the federal Public Health Service Act (now the Public Health and Welfare Act).\textsuperscript{179} The Interstate and Foreign Commerce Committee of the House of Representatives\textsuperscript{180} considered the adopted definition as similar to the WHO’s terminology of the time. Drug-dependent person was defined as

a person who is using a controlled substance . . . and who is in a state of psychic or physical dependence, or both, arising from the use of that substance on a continuous basis. Drug dependence is characterized by behavioral and other responses which include a strong compulsion to take the substance on a continuous basis in order to experience its psychic effects or to avoid the discomfort caused by its absence [italics added].\textsuperscript{179}

Although indeed similar, there is a critical interpretive distinction between the resulting US legal term and the WHO term from which it was adopted. Unlike the US definition, the WHO conceptualization did not provide the opportunity for physical dependence alone to characterize drug dependence. In 1998, the WHO reaffirmed this conceptualization when it replaced the term drug dependence with dependence syndrome and further
emphasized the biopsychosocial nature of compulsive drug seeking.\textsuperscript{181} Even given the medical and scientific evolution of addiction-related terminology that has occurred in the last 50 years, the 1970 Public Health and Welfare definition continues to have the potential to legally codify as “drug dependent” a patient with pain who has been taking opioids for a prolonged period.

Despite the inconsistent and incorrect use of addiction-related terminology in federal law, it remains lawful under federal law to use opioids to treat pain in patients, even when they have a history of substance use or current addictive disease. For example, in 1993, the DEA initiated action to revoke an Ohio physician’s prescribing authority because prescriptions were issued to patients who were “known” drug abusers and drug traffickers. A DEA administrative law judge ruled, however, that the physician’s controlled substances prescriptions were lawful because they were issued for legitimate medical purposes (e.g., pain relief, muscle spasm, and anxiety).\textsuperscript{182} This ruling represented the critical distinction between a practitioner’s ability to prescribe controlled substances to treat pain, even though the patient has an addictive disease, and clearly criminal behavior in which controlled substances are distributed without regard to their purposes or ultimate use. Such a judgment upholds the fundamental principle that, when considering the legality of a particular prescribing practice, the determination must be based, at least in part, on the purpose of the prescribing and not the type of patient being treated.

**The Controlled Substances Act and Regulations Do Not Limit Prescription Amount or Duration**

As stated previously, federal law establishes requirements for what constitutes a lawful controlled substances prescription.\textsuperscript{139} At this time, neither the CSA nor the Code of Federal Regulations (CFR) sets limits on the amount or duration of medication for which a practitioner can prescribe, administer, or dispense at one time. This still holds true after the DEA amended the CFR in late 2007 to allow practitioners to issue multiple prescriptions of a Schedule II controlled substance, each issued on the same date and filled sequentially (called a “prescription series”).\textsuperscript{183}
A prescription series is a method for a practitioner to provide a patient with a large enough amount of a Schedule II medication, for example, for a 3-month supply, without using a single prescription. Rather, the practitioner can now issue several prescriptions, each for one-third of the total amount needed. These prescriptions, each issued on the same day and containing written instructions for the date on which they are to be dispensed, would be delivered to the pharmacist and then dispensed sequentially on the dates indicated on the prescriptions. This procedure allows patients access to the medications they need and results in fewer doses dispensed at a time, thereby reducing the potential for diversion. A practitioner’s ability to specifically issue a prescription series for Schedule II controlled substances was not previously authorized within the CSA; the CSA, when adopted in 1970, did not address this practice because continual pain treatment was uncommon at that time.184

The DEA said it wanted to reassure health care professionals and patients that it is legal for practitioners to provide a prescription series to individual patients during a single office visit,184,185 and authorized multiple prescriptions for “a total of up to a 90-day supply of a Schedule II controlled substance.”183 The DEA clarified that allowing a 90-day prescription series did not alter the fact that the CSA and the CFR do not limit the quantity or number of days for which a single prescription for a Schedule II controlled substance can be written:

The [Final] rule in no way changes longstanding federal law governing the issuance of prescription for controlled substances . . . the CSA and DEA regulations contain no specific limit on the number of days worth of a schedule II controlled substance that a physician may authorize per prescription.183(pp64923–64924)

In addition, the DEA verified that the new prescription series rule did not preclude additional practice standards to which health care professionals must conform, especially in relation to a practitioner’s responsibility to minimize the potential for medication abuse and diversion186:

Under this Final Rule, practitioners who prescribe controlled substances are subject to the same standard in preventing diversion as
they always have been under the CSA and DEA regulations. Section 1306.12(b)(iii) of this Final Rule is intended to make clear that a practitioner may not simply comply with the other requirements of this Final Rule while turning a blind eye to circumstances that might be indicative of diversion. Thus, section 1306.12(b)(iii) merely underscores that the longstanding requirement of providing effective controls against diversion remains in effect when issuing multiple schedule II prescriptions in accordance with this Final Rule.183(p64926)

The intent of the CFR amendment is commendable, with the DEA wanting to reaffirm a practitioner’s legal authority to issue a prescription series for Schedule II medications.183, 184, 187 Multiple prescriptions for sequential dispensing permit health care professionals to better manage chronic pain in stable patients while exercising improved control over potential medication abuse and diversion, which is consistent with the principle of Balance.188 The DEA also recognizes the need to maintain balanced policy:

. . . DEA, through its enforcement of the CSA and its implementing regulations, must prevent the diversion and abuse of controlled substances while ensuring that there is an adequate supply for legitimate medical purposes. DEA supports the intent of this Final Rule to address patients’ needs for schedule II controlled substances while preventing the diversion of those substances.183(p64929)

Indeed, the federal prescription series regulation was an important step to improve the regulatory environment for both diversion control and providing pain management and palliative care.

**Regulations Implementing the Controlled Substances Act Now Authorize a Greater Variety of Secure Disposal Opportunities for Controlled Substances**

An even more recent change to the CFR, effective on October 9, 2014, relates specifically to reducing the public health threats inherent in large volumes of unused medications.189 Under federal law, certain entities who have a DEA registration to handle controlled substances now can volunteer to become a collector of controlled medications for the purpose of
destruction using a variety of prescribed methods. The DEA registrants permitted to become collectors are manufacturers, distributors, reverse distributors, OTPs, hospitals or clinics with an on-site pharmacy, and retail pharmacies. These registrants can accept back the controlled substances using either mail-back programs or collection receptacles (also called “drop boxes”), or both. In addition, authorized hospitals and clinics and retail pharmacies now have broader authority for maintaining drop boxes at long-term care facilities, when so authorized. Finally, a reverse distributor can also acquire these drugs from law enforcement and from other collectors. Of course, the new rule requires additional registration, security, methods of controlled substances destruction, and record-keeping procedures.

Given the introduction into federal law of these disposal standards, now more than ever before there is an acknowledged need for ultimate users (i.e., patients or their caregivers) to have additional ways in which their controlled medications can be collected and destroyed. Although this new law does not give prescribers (e.g., physicians, osteopathic physicians, nurses, and physician assistances) the option to become a collector, there could be a way that these practitioners could help achieve the purpose for which these regulations were developed. If up-to-date resources were easily available that identified local collection opportunities, practitioners could at least advise their patients about the variety of disposal options within the vicinity. Such information could motivate patients to take advantage of the more widespread secure disposal system that may be present in their community. However, the authors are unaware of whether such data are available or even if data exist about the overall proportion of relevant registrants who have chosen to become authorized as collectors.

**US State Laws: Striving for Balance between Drug Control and Medical Use**

Both federal and state laws regulate the prescribing, dispensing, and administering of controlled medications as well as establish controls to mitigate the unlawful distribution and use of all controlled substances. Federal and state laws prohibit the nonmedical use of controlled
substances; set potential penalties and sanctions for violations; and are enforced by local, state, or federal law enforcement. In addition, states are solely responsible for regulating health care practice, including medical, pharmacy, and nursing practice. State licensing boards establish minimum expectations (or standards) for health care practice and the use of controlled substances to treat pain and can discipline practitioners for unprofessional conduct. Given this reality, it is important for practitioners to understand the legal and regulatory framework for the treatment of pain, including when it involves the use of opioid analgesics or other controlled substances. State policies, historically, have not consistently supported the availability of needed medications to the extent of international treaties and federal law. For example, most state laws do not specifically recognize the appropriate medical use of controlled medications as important to public health, which is a concept inherent in federal law. Some state policies also establish more requirements on the prescribing and dispensing of opioids, compared to federal law, which can ultimately interfere with medical decision making, decision making that should be based both on the expertise of the practitioner and the individual patient needs. Policy impediments at the state level have been known to contribute to inadequate pain management. In response to this knowledge, both international organizations and national organizations have called for studies to improve pain management by identifying and addressing the legal and regulatory impediments to using opioids for pain relief. A number of governmental and national authorities, such as Congress, the National Conference of Commissioners on Uniform State Laws, and the Federation, have recommended controlled substances or medical practice policy that permits medication access to patients when needed while restricting nonmedical use by either patients or people to whom the medications are not prescribed.

STATE PAIN POLICY DEVELOPMENT: AN EMERGING TREND
Since the late 1980s, there have been an increasing number of state pain-specific policies, including legislatively issued statutes and health care
regulatory board regulations and guidelines or policy statements. Such policy adoption typically promoted the safe and appropriate use of controlled substances when clinically warranted and recommended ways to reduce abuse or diversion of those medications. In some cases, however, these policies led to additional restrictions and requirements with the potential to create barriers to the effective treatment of pain.

As an early example of this occurrence, intractable pain treatment acts (IPTAs) were statutes that created immunity from regulatory sanctions for physicians who prescribe opioids to patients with intractable pain, and thus were intended to improve access to pain management; however, many IPTAs imposed additional requirements and restrictions on prescribing opioids to such patients.\textsuperscript{196,212–215} IPTAs often implied that opioid use for “intractable pain” was outside of ordinary medical practice, which produced greater rather than less government regulation when treating pain with controlled substances. For physicians who prescribe to patients whose pain did not satisfy the definition of “intractable pain,” there was question about whether an IPTA provides immunity and created ambiguity for the clinician. Many IPTAs did not contain clear statements supporting enhanced pain management or instructing practitioners about how to provide safe and appropriate access and maintenance to such care.

Some advocates have recently recognized the potential negative impact of these characteristics on patient care and have worked with the legislature to remove ambiguities and restrictions from their state’s IPTA. Iowa and Michigan became the first states, in 2002, to delete the term intractable pain from law. More recently, Arizona, California, North Dakota, Oregon, Rhode Island, Tennessee, and Texas repealed a number of restrictive provisions from their IPTAs, including removing the term and definition of intractable pain; the resulting laws now govern treatment for all types of pain. Indeed, IPTAs were the first instance of legislation created specifically for the treatment of chronic pain (i.e., “intractable pain”), which differed from the approach commonly taken by regulatory boards at the time to address the issues related to pain management in general.

As an alternative approach to creating legislation, which often is difficult to modify to keep pace with evolutions in medical and scientific
understanding, many states chose to develop health care regulatory board guidelines or regulations to encourage better pain management and to address physicians’ expressed anxiety surrounding investigation and sanction. Early reports suggested that concerns about regulatory scrutiny were prevalent and could hinder the availability of opioids for patients who may clinically benefit from these medications. Apprehension about disciplinary action for opioid prescribing has been documented for a variety of health care practitioners, including primary care physicians, oncologists, pain specialists, medical residents, pharmacists, and nurses. To address these concerns directly, for more than 30 years, health care regulatory boards have promulgated regulations, guidelines, and policy statements perpetuating the message that pain management, including the appropriate use of controlled substances, is an accepted part of professional practice; a typical goal of such policies was to reassure clinicians that they had nothing to fear from their licensing agency if reasonable professional practices are followed when using controlled substances for appropriate patient care.

State medical boards’ issuance of recommendations for pain management was aided considerably when, in 1998, the Federation adopted a policy template to promote consistency in state medical board policy, entitled Model Guidelines for the Use of Controlled Substances for the Treatment of Pain (Model Guideline). In May 2004, the Federation revised the Model Guideline as the Model Policy for the Use of Controlled Substances for the Treatment of Pain (Model Policy). The 2004 Model Policy is substantially the same as the 1998 guideline but encouraged state boards to consider the failure to treat pain as worthy of disciplinary sanction; undertreated pain previously had been identified as an important clinical topic to address in state policy. These models were later supplanted by the Model Policy on the Use of Opioid Analgesics for the Treatment of Chronic Pain in 2013 and then, most recently, the 2017 Guidelines for the Chronic Use of Opioid Analgesics. Interestingly, these newer templates relate specifically to the treatment of chronic pain related to noncancer conditions (i.e., excluding “acute pain, acute pain management in the perioperative setting, emergency care, cancer-related
pain, palliative care, or end-of-life care\[13[p2]\]) rather than offering
guidance for pain management in general as was done in the previous
versions. They do, however, offer a benefit by providing more descriptive
recommendations than older templates about altering or discontinuing
opioid treatment when clinical evidence supports such an approach.
According to the Federation, most state medical and osteopathic boards
have adopted policies based, at least in part, on these model templates (see
https://www.fsmb.org/Media/Default/PDF/FSMB/Advocacy/GRPOL_Pain

EVALUATING THE QUALITY OF STATE PAIN POLICY
Since the early 2000s, a criteria-based policy research methodology has
existed to evaluate federal and state drug control and health care regulatory
policies related to pain management, palliative care, and end-of-life care
(issued in a report called an Evaluation Guide).\[98,188,238–242\] The basis for
this policy evaluation was the aforementioned principle called Balance,
which is a fundamental and long-standing national and international
principle of drug regulation and medical ethics. Balanced state policies
maintain drug controls and avoid undue restrictions to appropriate health
care practice and patient care and support pain treatment, including the use
of controlled substances when warranted, as a component of quality
medical practice.\[98\] Although additional efforts are necessary to assess the
presence and effectiveness of current state-level drug control frameworks
to minimize abuse and diversion, the purpose of this evaluation has been to
characterize pain-related issues covered in state policies.

The principle of Balance was used to derive 16 evaluation criteria. Each
criterion relates to one of two categories: (1) positive provisions—policy
language that can enhance pain relief and (2) negative provisions—
language that can impede pain relief. A complete description of the
criteria, the evaluation methodology, and the policy language from all
states (including the District of Columbia) that satisfies each criterion, can
be found at http://www.painpolicy.wisc.edu.

Policy Evaluation Findings
Policy language was identified that promotes appropriate pain
management; such language is common in the policies from state
regulatory agencies rather than from legislative statutes. The frequency with which states’ policies contained such language in 2015\textsuperscript{60} is as follows:

- A statement that recognizes medical use of opioid as legitimate professional practice (in all states)
- A statement that recognizes pain management as part of general medical practice (in 45 states)
- A statement that encourages pain management (in 40 states)
- A statement that addresses practitioners’ concerns about regulatory scrutiny (in 39 states)
- A definition or statement in which addiction is different from physical dependence or analgesic tolerance (in 38 states)
- A statement that recognizes medication amount or duration as insufficient to determine legitimacy of a prescription (in 32 states)

Policy language that appears less frequently than the earlier concepts, but that also promotes effective pain control and patient care, was identified and relates to three broad domains: (1) health care professional issues (e.g., encourages patient evaluation and discussion relating to potential benefits and risks of opioid treatment, recognizes that the goals of pain treatment should include improvements in patient functioning and quality of life, and recognizes the need for a multidisciplinary approach to pain management [integrative pain care]), (2) patient characteristics (e.g., assures that no person will be considered an “addict” based solely on taking a medication pursuant to a lawful prescription issued by a physician in the course of professional treatment for legitimate medical purposes and exempts certain patient populations from undue prescription requirements), and (3) regulatory or policy issues (e.g., encourages health care professionals to understand and follow federal and state laws governing their practice and specifically acknowledges that drug control policies should not interfere with legitimate medical use of controlled substances). A state’s drug control laws, appropriately, focus on the abuse potential of controlled medications but often to the exclusion of recognizing their public health and medical benefit when used as directed for legitimate purposes unlike more positive provisions contained in federal law (see, for example, CSA\textsuperscript{154}; Federal Food Drug and Cosmetic
It has been, and continues to be, possible to adopt state policies designed to prevent drug abuse and the transfer of medications to an illicit distribution system without creating ambiguity for health care decision making that conform to and do not conflict with current standards of professional practice, and that eschew imposing excessive burdens on patients. In 2015, however, the frequency with which states’ policies contained such language is as follows:

- A definition or statement in which addiction is synonymous with physical dependence or analgesic tolerance (in 13 states)
- A statement that seems to require a specialist consultation for every patient who is prescribed Schedule II controlled substances (in 7 states)
- A statement that seems to completely prohibit prescribing of controlled substances to certain patients (in 5 states)
- A requirement that limits the amount of time that a Schedule II prescription is valid to less than 2 weeks (in 2 states) (see Table 14.1 for specific restrictions for each state)
- A requirement that limits the number of dosage units of pain medications that can be prescribed and dispensed at one time (in 1 state) (see Table 14.2 for the specific restriction)

These evaluations also consider, at least to a limited extent, laws that create and implement prescription monitoring program (PMP), which are primary diversion control mechanisms in the United States, specifically at the state level. PMPs historically were characterized as multiple-copy prescription programs (MCPPs), which use multiple-copy government-issued serialized prescription forms (usually required in triplicate or duplicate). The prescription forms were required for Schedule II medications only (i.e., the only medications indicated for severe pain) and the programs were administered by state law enforcement, such as the state Department of Justice. The purpose of early PMPs was to provide law enforcement and prescribers and dispensers with information on “doctor shoppers,” “scammers,” and dishonest physicians. Unfortunately, prescription information collected through MCPPs was not real-time and often took a considerable time to compile, which severely undermined their ability to actively monitor diversion or abuse activity. MCPs also focused exclusively on Schedule II medications and used unique forms that practitioners had to order from the government to prescribe only those medications. Research suggested that linking the government-issued prescription form only to those medications in Schedule II often motivated practitioners to prescribe lower scheduled medications to avoid being monitored\textsuperscript{244–248}; this phenomenon has come to be known as the substitution effect.\textsuperscript{248} Of course, practices influenced by concerns about governmental oversight, rather than solely by patient needs and clinical circumstances, usually characterized the substitution effect as the potential for inappropriately treated pain. It is also true that decreased prescribing of Schedule II medications often has been interpreted, by itself, as evidence that the program was effective in reducing diversion,\textsuperscript{249,250} rather than considering outcomes more descriptive of diversion.

MCPPs have been replaced by electronic data transfer (EDT) programs that collect prescription information about more than Schedule II controlled substances (usually Schedules II, III, and IV).\textsuperscript{251–253} Monitoring multiple schedules minimizes a potential substitution effect because there are few other medications with which they could be replaced. EDT programs tend to be administered by state health agencies, such as the pharmacy board, and the policies that implement the programs generally
emphasize that this effort to reduce abuse and diversion is not meant to interfere with appropriate patient care. The information from these programs is collected in a more timely fashion, although it is usually not real-time. However, there is still limited evidence to demonstrate the programs’ effects either on practitioner prescribing or on incidents of medication abuse and diversion.

As of this writing, all but one state and the District of Columbia have a functional PMP that is an EDT system for a variety of medication schedules. Over half of these programs were created since the early 2000s, primarily as a result of the Harold Rogers Prescription Drug Monitoring Program grant program through the U.S. Department of Justice. Requirements for states to apply for such grants has been described as “relatively simple.” At around the same time, an additional funding mechanism was introduced through the National All Schedules Prescription Electronic Reporting Act of 2005 (NASPER) and administered through the U.S. Department of Health and Human Services. NASPER also provides grants to states to develop PMPs only if the programs are EDTs that apply to medications in at least Schedules II to IV; states can create programs with different characteristics, but they are not fundable under NASPER. Federal law mandates that the Secretary of Health and Human Services evaluates the safety and efficacy of the programs established through NASPER. In this context, “safety” refers to the extent that the programs avoid creating barriers to prescribing to patients for legitimate medical purposes, such as for pain management. “Efficacy” means the ability of the program to validly identify instances of abuse and diversion. Although there seems to be less chance for EDTs to restrict patient care, especially when compared to MCPPs, empirical documentation remains mixed about either the safety or efficacy of these programs.

In addition to the discrete occurrences of policy language that can either enhance or impede the appropriate treatment of pain, including with opioid analgesics, some state policies contain requirements or concepts that are contradictory and can create ambiguous practice expectations. For example, as identified previously, policies in 38 states define addiction as a psychological/behavioral disorder that is not synonymous with either
physical dependence or tolerance. Laws in 13 states also have a definition that could legally classify patients being treated chronically with opioids as “addicts” only because they are physically dependent. As a result, 8 states have at least one policy that defines addiction according to current official standards and another that defines the concept differently (see Table 14.3 for a listing of the discrepant definitions). There is no clear guidance for practitioners in these states about how patients with pain who are being treated with opioids are to be viewed, given the inconsistencies among the legal, regulatory, and health care classification. Achieving positive uniform policy often depends on potentially discrepant practice standards being identified and corrected.

harm. Physical dependence and tolerance are normal physiologic consequences of extended opioid therapy for pain and are not the same as addiction. (Medical Board: Pain Management Guidelines)

**Louisiana**

“Substance abuse” or “addiction” means a compulsive disorder in which an individual becomes preoccupied with obtaining and using a substance, despite adverse social, psychological, or physical consequences, the continued use of which results in a decreased quality of life. The development of controlled dangerous substance tolerance or physical dependence does not equate with substance abuse or addiction.

(La. R.S. 40:961(38))

“Drug-dependent person” means a person who is using a controlled dangerous substance and who is in a state of psychic or physical dependence, or both, arising from administration of that controlled dangerous substance on a continuous basis. Drug dependence is characterized by behavioral and other responses which include a strong compulsion to take the substance on a continuous basis in order to experience its psychic effects or to avoid the discomfort of its absence.

(La. R.S. 40:961(18))

**Maryland**

It is important to realize that habituation and tolerance to drugs are not the same as addiction. These are expected consequences of long-term analgesic therapy and do not have the characteristics of sociopathy and psychological dependence associated with addiction.

(Medical Board: Prescribing Controlled Substances)

Drug-dependent person—“Drug-dependent person” means a person who (1) is using a controlled dangerous substance and (2) is in a state of psychological or physical dependence, or both, that (i) arises from administration of that controlled dangerous substance on a continuous basis and (ii) is characterized by behavioral and other responses that include a strong compulsion to take the substance on a continuous basis in order to experience its psychological effects or to avoid the discomfort of its absence.

A PROGRESS REPORT CARD TO MEASURE CHANGES IN THE QUALITY OF STATE PAIN POLICIES

The criteria-based evaluation of state pain policy also serves as the basis for a methodology to quantify a state’s policy based on its quality, creating a single metric that can then be used to compare all states and track policy changes over time.\textsuperscript{60,188,258–262} This metric, along with the content of the Evaluation Guide, has helped states identify policy provisions that could be considered for modification.\textsuperscript{263}

In the latest report using cumulative policy data from the state profiles, grades were calculated for the state policies in effect in 2015.\textsuperscript{60} The grades, and the methodology used to calculate the grades, are contained in the most recent report, entitled “Achieving Balance in State Pain Policy: A Progress Report Card” (Progress Report Card), and is available at https://www.acscan.org/sites/default/files/National\%20Documents/Achieving\%20Balance\%20in\%20State\%20Pain\%20Policy.pdf

Grades can range from A to F, using midpoint grades (e.g., B+, C+, D+) to characterize more precisely each state’s overall combination of positive and negative provisions. A higher grade means a state’s policies have many positives and few negatives and are, therefore, more balanced in relation to appropriate pain management. An A is achieved only if a state has a high number of positive provisions and no instances of unduly restrictive or ambiguous language. A lower grade is associated with the presence of provisions that contradict current medical knowledge; are inconsistent with policy guidance recommendations from authoritative sources; or fail to communicate the appropriate messages about pain management to professionals, patients, and the public. An F results when a state has abundant negative provisions and no positive language.

Progress Report Card Findings

Results show that the quality of pain policies continues to vary across states as of December 31, 2015, which were reported in the most recent Progress Report Card\textsuperscript{60} (see Table 14.4 for a list of each state’s grade). In the aggregate, 13 states achieved an A. An A means that there is prevalent language in laws or regulatory policies, or both, that promote safe and effective pain management as well as there being no language that can create inflexible barriers or ambiguities for clinical decision making.
Eighteen states had a B+, 13 states had a B, 6 states had a C+, and only 1 state had a grade of C. In terms of population coverage, the 13 states achieving an A comprise 19% of the total US population, and states with a B or B+ make up almost 65% of the US population. Another 16% of the US population live in the 7 states that have grade of C or C+.

A variety of policy changes contributed to these current grades. Within the past few years, a total of 11 states had adopted legislation or regulations mandating CE about prescribing controlled substances or opioid medications, pain management, or palliative care for licensees or for those who prescribe as staff of pain clinics. Eight states either adopted, adopted by reference or adopted based on, or updated to the Federation’s 2013 Model Policy on the Use of Opioid Analgesics in the Treatment of Chronic Pain16 (the most recent version of the Federation’s models that was current at the time of the evaluation), whereas another 10 states added or updated other statutes or regulatory policies governing pain management, and an additional 2 states now require the development of rules governing prescribing for pain. Four states adopted legislative or regulatory language initiating or expanding their pain management,
hospice, or palliative care standards in various health care facilities. Importantly, two states also added a law containing a statement that directly supports the principle of Balance. Further improvements were made through the following policy adoptions:

- A regulation for offering addiction treatment services in the office that provides a definition of “addiction” that not only distinguishes it from physical dependence or tolerance but also explicitly acknowledges that physical dependence occurring with a “patient on long-term opioid analgesics for pain” is distinct from ICD10 or DSM diagnostic classification systems.
- A statute governing a state PMP will now offer educational information to the program Web site and will regularly send updates of such information to registered program users, whereas another state’s PMP regulations now offer training to practitioners and pharmacists and their delegates, as well as to other users, about how to use program information.
- A statute that appears to allow pharmacists to dispense up to a 10-day supply of a Schedule II or Schedule III opioid medication from a prescription issued by an out-of-state practitioner (while needing to notify the practitioner of the partial dispensing), rather than prohibiting any such prescriptions.
- A statute that initiated an interdisciplinary advisory council within the Department of Health as a mechanism to create, maintain, and evaluate state palliative care initiatives.

In addition to adopting policy language that promotes safe and effective pain management, a number of states further improved policy quality by repealing restrictive or ambiguous provisions from statutes or regulatory policy. Such recent abrogations involved a 1-week prescription validity period; the requirement that the standard for “unprofessional conduct” be met by a failure to strictly adhere to a clinical practice guideline, which does not allow for treatment flexibility based on reasonable cause; a prescription filling standard with broad interpretive latitude for pharmacists; an entire IPTA, along with the various requirements and ambiguities typically contained in such policies (see “State Pain Policy Development: An Emerging Trend” section); an immutable requirement
for patients to undergo other treatment modalities before being prescribed opioids and other controlled substances, regardless of the clinical circumstances; and definitions of drug-dependent person, chemical dependency, and dependence that could be established by the presence of physical dependence only and, thus, could legally apply to a person who is being treated with opioid pain medications.

As with previous evaluations, only a very few states adopted any type of policy containing restrictive or ambiguous policy language. As such, states have generally avoided adopting new policies that could impede pain management and the medical use of controlled substances. Considering current policy content, states wanting to achieve an A can be classified into four domains. First, three states currently have no restrictive or ambiguous language in their state’s pain policies and can change to an A simply by adopting additional positive language. Second, 32 states (84%) of the remaining 38 states that do not have an A can improve their grade only by repealing restrictive or ambiguous policy language. Of these states, six continue to not only have a considerable number of beneficial provisions but also have many potentially problematic provisions, which represent a noteworthy challenge. These particular states must undertake a continued focus on reducing the number of restrictive or ambiguous provisions for any grade improvement to occur. Third, as of December 31, 2015, four states have neither medical nor pharmacy board policies addressing the treatment of pain (including the use of controlled substances), palliative care, or end-of-life care. In these states, clinicians are not provided guidance from their licensing agency about what is considered acceptable approaches related to patient pain care. Finally, when striving for an A, two states now face the challenge not only of adopting positive policies but also of removing restrictive or ambiguous language from legislation or regulations. Even for those 13 states that currently have an A, a potential remains for additional policy activity (however well-intentioned) to introduce policy provisions that ultimately can lower the state’s grade. Continued state policy efforts to improve patient pain care, including through activities to address clinical and societal harms related to prescription opioids, can seek to maintain grade improvements.
THE IMPORTANCE OF IMPROVING STATE PAIN POLICY

In the aggregate, the last decade witnessed notable improvement in the quality of many states’ drug control and professional practice laws and regulatory policies. This policy advancement was in response to continuing national and state acknowledgment that adopting positive policies governing health care practice and patient care is part of improving safe and effective pain treatments for patients with cancer, HIV/AIDS, and other chronic diseases or conditions. States typically have avoided adopting new policies that could inadvertently impede pain management, including treatment involving the medical use of controlled substances when clinically justified. Members of government and regulatory agencies, as well as health care professionals, are in a position to continue seeking policy approaches that eschew requirements that could confound medical decision making or lead to unintentional consequences on pain treatment. Such improvements, as evidenced by higher state policy grades, are a necessary part of an overall multifaceted plan to enhance pain and symptom management while stemming prescription medication abuse and diversion.60,98

Much of the positive content inherent in state pain policies has resulted historically from individual health care regulatory boards taking advantage of the Federation’s policy templates to promote consistency in state medical board policy.16,210,211 Throughout the templates, the importance of documenting various aspects of treatment is mentioned. These templates also have, at various points in time, encouraged safe and effective pain relief, perpetuated the message that pain management and the appropriate use of controlled substances was an accepted part of professional practice, and reassured clinicians that they should not be concerned about disciplinary action from their licensing agency if reasonable professional practices are followed when using controlled substances for patient care. In addition, the policies promote assessment of both potential benefits and risks when considering opioid treatment, especially for patients with more chronic conditions. Patient risk assessment, as well as the periodic monitoring for adverse events and the manifestation of abuse-, addiction-, and diversion-related behaviors, have been an explicit component of the
Federation’s templates since their first inception\textsuperscript{264,265}; in fact, the clinical need for risk stratification strategies was emphasized even more in the most recent policies issued in 2013\textsuperscript{16} and 2017.\textsuperscript{13} Importantly, health care regulatory boards (e.g., medical, osteopathic, pharmacy, and nursing) in many states have worked together to adopt joint guidelines for pain management, palliative care, or end-of-life care.\textsuperscript{60} Such policies tend to emphasize the value of an integrative multidisciplinary approach to treating pain; recognize that the goal of pain treatment should include improvements in patient functioning and quality of life; and assure that a broader variety of health care practitioners can engage in practice that generally conforms to adopted treatment standards without being apprehensive about regulatory sanctions from their licensing board.

Given this notable regulatory progress, most states now can focus on maintaining policy improvement and consider efforts to remove long-outdated restrictive or ambiguous language from law, some of which has been present for over 30 years. This is especially the case with drug control laws that contain outdated definitions of “drug-dependent person” (or “addict”) that are based on the concept of physical dependence and developing a withdrawal syndrome. Such definitions can, when interpreted strictly, legally classify as an addict any patient who is taking an opioid for analgesia (see Table 14.3 for examples of these types of definitions).\textsuperscript{98} Repeal from law of decades-old restrictive language has received less attention compared to the work of professional licensing boards to adopt positive policy.\textsuperscript{60} Avoiding such language ensures that patient care decisions requiring medical judgment are not overly limited by governmental laws.

The Need to Implement and Communicate Policy
Inadequately treated pain is a multifactorial phenomenon. As such, focusing solely on changing state policy is likely insufficient to guarantee better patient access to appropriate pain relief and symptom control.\textsuperscript{266} Addressing this single factor, however, often remains a necessary activity to attain a supportive professional practice and regulatory environment for the appropriate treatment of pain. Adoption of such policies also requires broad dissemination and communication to relevant practitioners to help
enhance compliance to the policy recommendations or requirements, because an evaluation of practice should always involve a determination regarding adherence to applicable policy.

Improving state policies covering pain-related issues requires a strategic approach, often beginning simply by determining the types of policies in need of improvement. For example, the revision of statutory law requires legislative activity, whereas a change in regulatory policy involves engaging with the relevant health care administrative agency such as the medical, pharmacy, or nursing board. Health care practitioners increasingly have assumed a leadership role in collaborating with legislators or members of administrative agencies to help construct state policy that avoids interfering with appropriate decision making or creating ambiguities, recognizes the professional obligation to treat pain, and promotes effective patient pain care. This activity has been accomplished when practitioners have acted alone, in conjunction with a state pain initiative or other organization, or as a member of a legislatively created advisory committee.

**Considering Additional US Policies**

The aforementioned policy evaluation reports synthesize the content of numerous state-level statutes and regulatory policies governing drug control and medical, pharmacy, and nursing practice. Because this evaluation was policy-specific, it did not consider reports or projects from federal or state agencies that related directly to pain, such as the IOM’s Relieving Pain in America, the U.S. Department of Health and Human Service’s National Pain Strategy, and the NIH’s Federal Pain Research Strategy (https://iprcc.nih.gov/FPRS/FPRS.htm). The finalized methodology also was never meant to imply that the reviewed policies are the only policies relevant to pain management. In fact, various other policy types may affect patient pain care but ultimately fall outside the scope of the evaluation process. Examples of unevaluated policies include, but are not necessarily limited to, physician assistant’s practice, controlled substances scheduling, advance directives or living wills, workers’ compensation, institutional (including chain pharmacies) policies, and
program grants to state agencies. Another unconsidered, but especially important, influence on treatment considerations is the multitude of federal and state laws establishing standards for reimbursement of therapeutic interventions, covering such areas as prior authorization, drug formularies, medication synchronization, and abuse-deterrent formulations for opioid medications. Efforts to understand the beneficial or potentially problematic ramifications of these policies, as well as the impact of such policy requirements on professional practice and patient care, are warranted.

It also is important to keep informed about the content of proposed statutes being introduced in the state legislature but which have not yet been signed into law (i.e., bills). Some recent bills, including some that have been drafted with the objective of improving public health and safety by reducing prescription medication abuse and diversion, may inadvertently create barriers to the availability of medications to people who use them therapeutically for pain relief and to maintain quality of life (see http://sppan.aapainmanage.org/legislation). Coordinated reactions to both draft and introduced legislative bills, and also to proposed regulatory policies whenever possible, can create opportunities to make policymakers aware of potential unintended consequences and recommendations for language modifications. Engagement with legislators and regulators during policy development can effectively reduce the prospect of future policy impediments and can even strengthen the policy’s ability to achieve its stated objectives.

One of the most prevalently considered policies, which has been recently promoted to improve patients’ pain care and reduce opioid-related overdoses and other harmful consequences, is dosing thresholds based on cumulative morphine equivalent daily dose (MEDD) milligram amounts. At this time, these thresholds typically are limited only to the treatment of patients with chronic noncancer pain and exempts patients with the disease of cancer and those undergoing palliative care or end-of-life care. These MEDD thresholds have been described as “a precautionary signal to get the prescriber to press pause before moving forward with dose escalation.” Meeting or exceeding the dosage threshold is often coupled with a recommendation for the prescriber to obtain an expert consultation (see Paice and Von Roenn for example). Washington was
the first state (in 2007) to establish a recommended MEDD threshold, at 120 mg, in a clinical practice guideline. Since that time, some states (including Washington) eventually established such amounts in law (see, for example, Washington Administrative Code). Measures even were put into place to evaluate outcomes from codifying the Washington MEDD, with the goal of:

[making] sure any interventions to prevent problematic use don’t adversely affect the vast majority who are appropriately using their medications.

An inherent by-product of codifying these dosage amounts into law is that this now establishes a legal liability for practitioners who fail to comply with the requirements. This concern was especially important for a state like Maine, which in 2016 adopted a 100-mg MEDD amount for treating chronic pain that generally could not be exceeded but has since been modified to allow for therapeutic exceptions through a documentation of medical necessity.

In addition to the MEDD threshold itself, the American Academy of Pain Management (now the Academy of Integrative Pain Management) issued a statement reviewing requirements contained in the Washington law, and consequently also contained in similar policies adopted subsequently by other states, which could create uncertainty for practitioners attempting to comply to this distinctive regulation. Such provisions included (1) use of a written prescriber–patient agreement for those judged to be at a high risk of substance abuse, have a history of substance abuse, or have psychiatric comorbidities; (2) requiring certain prescribers to obtain a consultation with a “pain management specialist” under certain circumstances, including exceeding the dosing threshold; and (3) establishing qualifications for prescribers who can serve as adequately prepared specialist consultants. Within this statement, though, the possibility was raised that any practitioner reluctance surrounding this law may relate more to perceptions based on an inaccurate understanding of the legal requirements, rather than being founded on a direct reaction to the mandatory conditions themselves. That is, it is acknowledged that policy barriers to practice can occur as much from misinterpretations about
policy requirements than from perceptions about legal liability based on actual policy content.

A more recent commentary by Ziegler has identified additional substantive concerns related to policies establishing MEDD dosage thresholds. These potentially problematic issues include the implied emphasis on potential harms only at higher dosage levels (although risks are heightened at any dosage level, especially without proper treatment monitoring); neglect of other, separate, factors that could contribute to clinical harms; nonstandard and erroneous conversion formulas for morphine equivalence; and an insufficient number of pain management specialists available for required consultations. These considerations, as well as those mentioned earlier, support the need to thoroughly assess the various reasons for practitioners’ reactions to such laws to help formulate ideas about addressing health care professionals’ perceptions. This is especially feasible now because some of these policies have been in effect for a few years, so practitioner awareness should be higher than it would have been closer to the policy adoption. Ultimately, it can be determined whether any identified practitioner concerns are more likely remedied through modifying (to any degree) the requirements or recommendations contained in the laws or other regulatory policies, increasing resources to aid more broad and consistent implementation, or improving practitioners’ understanding about the policy standards and promoting their clinical utility, or through a combination of approaches.

**Taking Diversion into Account**

In addition to efforts to promulgate pain policies that enhance benefits and minimize harms from treatments for patients with pain, drug control measures must be established, through both the same and separate policies, to reduce the potential for transferring prescription medications into illicit channels. Even given the numerous and varied legislative and regulatory requirements that have been implemented over time in the United States to govern the closed distribution of controlled medications, opioid analgesics can still be diverted from all levels of the distribution system. Diverted opioid medications often become illegally available for illicit distribution.
and nonmedical use, which can contribute to harmful outcomes such as overdose and death. It should come as no surprise that using controlled medications obtained through means other than a valid prescription issued by a properly licensed practitioner for a legitimate medical purpose, or in ways that do not conform to practitioner instructions, compounds the risk of harmful consequences.

Given the risks inherent in all controlled substances, health care professionals who provide treatment with opioid medications have a responsibility to protect patient and public safety by taking actions to avoid contributing to abuse and diversion. Prescribing or dispensing more dosage units than medically necessary is potentially problematic because these medications may go unused, accumulate in volume, and become susceptible to theft or perhaps accidental use by others.\textsuperscript{279,280} When a practitioner’s issuance of prescriptions reaches a level or pattern considered “excessive,” in some states, it can fulfill the criteria for “unprofessional conduct” in which the practitioner is subject to license revocation or other civil penalties under law (see New Mexico Medical Board\textsuperscript{281} as an example).

Patients receiving prescription-only controlled medications for pain treatment also share responsibilities under law, which has only recently begun receiving attention in earnest. Warnings on prescription labeling denote that it is a violation of law for patients to transfer the medications prescribed for them to any other person.\textsuperscript{282} More generally, any person who possess controlled substances, including opioid analgesics, without a valid prescription, as well as someone who acquires these medications by theft, fraud, or misrepresentation, is in violation of federal and state laws. Opioids may even be prescribed legitimately but, when they are not stored securely in the patient’s home, they are vulnerable to diversion through loss or theft. These scenarios reinforce the reality that learning whether a person acquired an opioid from peers or family, or even through a dispensed prescription, is often not enough information to inform a sufficient response—it is necessary to additionally consider the circumstances leading up to how the opioid was obtained initially.

There is a potential for opioid medications to be diverted from throughout the entire medication distribution system, including before they
are prescribed. Consequently, there are many potential sources that feed the use of prescription opioids for illicit purposes. Examples of such activities, from each level of the distribution chain, include the following:

- **From the wholesale level:** Criminal diversions of large quantities are reported by manufacturers and distributors.
- **From the retail level:** Criminal activities by organizations and individuals, including some patients, to obtain opioid analgesics unlawfully
  - Armed robberies and night break-ins from pharmacies
  - Thefts, including employee pilferage, occurring from pharmacy supplies in nursing homes and hospitals
  - Fraud and misrepresentation, such as “doctor shopping” or prescription form theft, forgery, or alteration
  - “Script doctors” and “pill mills,” which are illegal activities by rogue physicians who still have the necessary authority to prescribe, or to purchase and dispense, controlled substances
  - Misuse of Medicare and Medicaid drug coverage
- **From the ultimate user level:** Intentional or unintentional behaviors
  - Patient sharing with friends or family members
  - Patient selling to strangers
  - Caregiver stealing directly from patient
  - Stealing from unsecured amounts

Such a variety of diversion opportunities makes it clear that efforts to reduce nonmedical drug use should include, but must be more comprehensive than, focusing on prescribing and dispensing practices and patient access.

Although potential diversion sources can be identified through knowledge of the medication distribution system, little empirical evidence exists about the degree to which these numerous conceivable diversion activities are involved in prescription medication–related abuse, addiction, overdose, and death. However, understanding the multiple ways that diversion can occur substantiates use of a broad multifaceted approach for effectively addressing nonmedical use of prescription opioids. Such an approach is exemplified at a federal level by the Office of National Drug Control Policy’s (ONDCP’s) Prescription Drug Abuse Prevention Plan.283
which was unveiled in April 2011 and then updated each year as part of the US national drug control strategy (see ONDCP\textsuperscript{284} for example). Under the ONDCP’s Plan, multiple federal, state, and local regulatory and enforcement agencies are collaborating to address four distinct domains: (1) Education—to enhance practitioner and public awareness about the risks and benefits of prescription medications, to investigate the production of analgesics with less or no abuse liability, and to promote research to demonstrate changes in abuse trends; (2) Tracking and monitoring—to support the funding, breadth, and use of PMPs, to promote electronic prescribing of controlled substances and other treatment technologies, and to evaluate the utility of federal database for epidemiologic purposes; (3) Proper medication disposal—to reduce the volume of unused medications through enhanced disposal opportunities; (4) Enforcement—to train law enforcement members and others to address pill mills and other drug-trafficking activities and to focus on doctor shopping or pharmacy hopping.\textsuperscript{283} This collaborative and systematic strategy has the benefit of seeking to more comprehensively address the multiple means by which prescription medications can become available for illicit use, including through the practitioner–patient relationship. Such an approach, as well as detailed multiagency policy initiatives now underway in some states, symbolizes an apt appreciation for the intricate nature of the national public health problem of nonmedical drug use.\textsuperscript{285–287}

Conclusions

In the United States, destructive consequences related to the use, misuse, and abuse of, as well as addiction to, prescription opioid analgesics have been increasing for more than a decade. These occurrences can create a potential to put at odds, and even conflate, the needs of those who are being harmed through the often-illicit use of prescription medications with patients who may benefit from their therapeutic use.\textsuperscript{288} It is beneficial to contemplate, however, how current US legislative and regulatory policies can provide a critical reference point for considering the needs of these two separate, but sometimes overlapping, populations.

As has been described throughout this chapter, both US federal and state
governmental and regulatory policies can contain language that establishes an effective drug control system that reduces the likelihood that these medications become available for inappropriate or unlawful use while also promoting medication access to patients when clinically warranted (i.e., Balance). These dual objectives are promoted by many national and international entities and sanctioned by international treaty and federal law. Even given the substantial progress in reducing legal and regulatory barriers, there is a need to maintain ongoing vigilance to new or changing policy content. For this, the principle of Balance remains an unassailable conceptual framework to guide the continuing development of state policies governing health care practice and controlled substances prescribing.

Importantly, improved policy does not guarantee that the ideal outcomes of safe and effective pain management and reducing deaths and harm associated with the nonmedical use of controlled medications will be achieved. For example, it certainly is feasible that nonconformity to the recommendations inherent in a state-issued regulatory guideline could adversely affect the benefit/risk determinations necessary to best reach treatment decisions, as well as undermine the strategies offered in the policy to identify and address potential abuse or diversion behaviors. This scenario does not even account for the numerous factors within the health care system that can work against policies with balanced content, including a lack of understanding or misperceptions about a policy or poor or nonexistent implementation of a policy. Because of such influences, any policy improvement that is accomplished may not produce results that reflect its inherent Balance. Realizing true Balance requires an understanding of not only the actual policy content but also the extent of practice adherence to that policy content and then effectuating interventions based on this knowledge.

Although Balance is a principle conceived in, and intended for, policy development in an effort to maintain patient care with controlled medications during implementation of a broader abuse/diversion mitigation regulatory infrastructure, it has even been applied to activities outside of policy. This principle is useful for delineating the appropriate roles and responsibilities of health care professionals, members of
regulatory agencies, and law enforcement officials regarding the issues of pain treatment and stemming the nonmedical use and prescription opioid–related harms. A practitioner’s responsibility, of course, is patient health care—when providing pain treatment using opioid therapy, that practitioner is also expected to monitor for the abuse and diversion of the prescribed medications and to identify possible comorbidities and other patient factors that may have treatment implications; such an outcome represents Balance. Conversely, drug control is chiefly a responsibility of certain regulatory agencies and law enforcement—when planning efforts to curb abuse and diversion, these efforts can avoid interfering in legitimate medication availability, health care practice, or patient care; this, too, represents Balance. From this national and international medicolegal concept, it is clear that the actions of members of health care, regulation, and law enforcement often overlap in the obligations related to medication availability and efforts to minimize abuse and diversion.

In addition, recent national efforts to curb harms involving prescription medications, such as practitioner educational initiatives, clinical practice guidelines, and a Surgeon General’s report have acknowledged the value of maintaining appropriate pain treatment. Clearly, these examples demonstrate a widespread belief in, as well as a commitment to, the ability to contemporaneously address the dual public health problems of undertreated pain and prescription medication abuse/diversion without sacrificing either. Attaining either objective at the expense of the other represents a failure of the drug control or health care regulatory systems, or both, that demands immediate corrective action. The laudable goals expressed through these activities will, hopefully, be demonstrated through the routine collection, assessment, and consideration of relevant outcomes to document whether implementation of any adopted approach effectively reduces harms and eschews deleterious unintended consequences for health care practitioners who provide pain management services using opioids.

Given these considerations, it is time to move beyond the call to evaluate policies. The increased research focus on degree of opioid prescribing concordance with clinical practice guidelines establishes the precedent that attention must now turn toward determining the effect of
pain policy content on clinical practice, including the assessment of factors influencing compliance with policy requirements or recommendations. Translating policy content into clinical practice and patient care outcomes representing both facets of Balance is necessary to optimize public safety as well as treatment safety and benefit for all patients requiring opioid therapy. This goal remains necessary until effective and readily available nondrug alternatives and nonopioid analgesics, as well as opioid analgesic products without an abuse potential, make such an approach obsolete. Certainly, achieving such an ideal treatment scenario is something that we can all support.

In recent decades, issues arising in the context of pain management have increasingly been raised in the context of law and public policy. Indeed, one of the major professional journals, Pain Medicine, now has an entire section devoted to this area of activity (i.e., forensic pain medicine). Although technically, forensic pain medicine encompasses all instances in which pain medicine and the law converge, this chapter focuses on the area of convergence that is most often associated with the term forensic—litigation. Other aspects of law and public policy affecting pain management are covered in the pain policy chapter of this book (Chapter 14).

American jurisprudence is divided into two broad categories of jurisdiction—state and federal—and four distinct domains within both categories: administrative, civil, criminal, and constitutional. Cases involving pain management have arisen in all four domains, and in this chapter, we will consider representative cases in each and identify the important lessons for practitioners. We will begin with administrative proceedings, all of which involve disciplinary actions by state medical licensing boards against physicians. In reviewing these cases, it will become clear how the pendulum has been swinging over the last 20 to 25 years. Beginning in the early 1990s, the long-standing concern about “overprescribing” of opioid analgesics was disrupted by several cases in which health care institutions and professionals were charged with substandard practice for their failure to provide seriously ill or dying patients with adequate management of pain and/or symptom distress. These proceedings reflect an emerging policy trend among licensing boards to emphasize the important role of pain management in patient
care. With the ever-increasing evidence in the last 10 years that opioid overdose deaths have reached epidemic levels in some parts of the country, state boards and federal regulators have begun to revise policies and guidelines to reflect the current level of risk posed by the indiscriminate prescribing of opioids. These policy permutations are more fully discussed in the pain policy chapter (Chapter 14).

The aspect of civil litigation that most often involves health care professionals is medical malpractice. Such claims are a species of tort claim in which an injured party, the plaintiff, asserts that they have sustained compensable injury as a result of the negligence of the other party, the defendant. In order to be successful, medical malpractice claimants must establish four essential elements. The first element is the existence of a duty owed by the defendant to the plaintiff. The generic characterization of such a duty is “due care.” In professional liability cases, this translates to compliance with the prevailing standard of care. However, a health care professional–patient relationship must exist before such a duty may be deemed to have arisen.

The second element is breach of the duty owed, hence in medical malpractice litigation, a material departure from the standard of care. A dispute as to what constitutes the relevant standard of care by which the defendant professional’s conduct is to be evaluated is usually the critical issue in a medical malpractice case, and the outcome often depends on whose expert witness or witnesses are deemed by the jury to be most convincing. Consequently, medical malpractice cases have come to be characterized as little more than a “battle of the experts.” Traditionally, the usual custom and practice of physicians in the same or similar situations to the defendant has set the standard of care. Evidence of compliance by the defendant physician with the custom tended to create an irrefutable presumption that the applicable standard of care had been met. Over the last several decades, there has been a gradual trend by the courts toward a recognition of instances in which the custom and practice of clinicians has lagged noticeably far behind advances in medical science and technology, or physicians have failed to adopt safer or more effective clinical practices such as those advocated by national clinical guidelines. In such situations, the courts have acknowledged that rigid and unreflective adherence to the
customary practice might demonstrate a failure to exercise appropriate clinical judgment. We will consider that issue further in the section of the chapter pertaining to civil litigation.

The third element of a tort claim is damage or injury. The breach of a duty of due care that fails to produce an injury or other harm is, from a strictly legal perspective, of no consequence. It is characterized in the law as damnum absque injuria (a wrong without injury). Such circumstances may be of interest to risk managers and quality improvement personnel, but they do not give rise to tort liability. The intriguing aspect of harm in the context of pain management is whether subjecting patients to unnecessary pain through substandard care would be deemed by juries as on the same level as medical errors that produce demonstrable physical injury or even death. The cases we will examine confirm that this is indeed the case, at least for patients who were at the end of life.

Finally, the plaintiff must establish that the breach of the duty of care by the defendant was the proximate (direct and immediate) cause of the damage or injury he or she sustained. In the cases we will be considering, the plaintiff must persuade the jury that pain management consistent with the standard of care would have, to a reasonable degree of medical probability, ensured that the patient did not suffer to the same extent as she did.

In the fourth section of the chapter, we will review criminal prosecutions by both the state and federal governments that concern the prescribing of opioid analgesics for terminal or chronic noncancer pain patients. Finally, in “Constitutional Cases” section, we will consider three US Supreme Court cases in which constitutional issues are raised in the context of cases related to pain management and/or end-of-life care.

**Administrative Proceedings**

Until recently, disciplinary actions by state medical licensing boards involving the prescribing of opioid analgesics targeted the phenomenon of “overprescribing,” and it was the leading cause of both investigations and disciplinary actions. Some of these actions were well-founded efforts to punish physicians who prescribed controlled substances inappropriately or
without a legitimate medical purpose, thereby endangering their patients and/or society. Others, however, sought to punish physicians who were engaged in a good faith effort to manage chronic noncancer pain and demonstrated either a dismissal by the boards of the plight of chronic pain patients or an ignorance of the risks, side effects, and benefits of opioid analgesia. We will consider two cases from the second group in which the practices of the accused physicians were ultimately vindicated by state appellate court decisions.

IN THE MATTER OF DILEO

Dr. Lucas DiLeo, a general practitioner, prescribed opioid analgesics for some of his patients with significant chronic nonmalignant pain. One of these patients, for example, was an ironworker who had fallen over 40 ft onto concrete and sustained 153 fractures, 93 in the face, as well as shattering his knees, ankles, and left femur. He underwent 10 operations, and continued thereafter to suffer with chronic pain. In 1992, the Louisiana Board of Medical Examiners filed an administrative complaint against Dr. DiLeo alleging that his prescribing of opioids to seven patients (an eighth patient was treated for obesity with a combination of benzphetamine [Didrex] and alprazolam [Xanax]) was not for a legitimate medical purpose, demonstrated incompetence, and fell outside acceptable standards of medical practice.

The board’s expert witness, Dr. Linda Stuart, a board-certified family practitioner and addiction specialist, did not question that the seven patients receiving opioids had serious pain problems nor did she challenge the doses prescribed as excessive. However, she did testify that in her opinion, opioid analgesia was provided for too long a period of time, thereby posing an unacceptable risk of addiction and withdrawal symptoms. She acknowledged, however, that there were different schools of thought on this issue in the medical profession. As for the obesity patient, Dr. Stuart questioned the prescribing of Didrex and Xanax at the same time because she considered the former to be a stimulant, whereas the latter was a depressant.

Five of Dr. DiLeo’s patients testified on his behalf, as did a physician whose specialty was internal medicine/endocrinology. The medical board
ruled against Dr. DiLeo, and that ruling was affirmed by a trial court. The Louisiana Court of Appeals reversed and dismissed all charges against him after finding that no evidence had been presented by the board to support Dr. Stuart’s assertion that the duration of Dr. DiLeo’s prescriptions was excessive. Indeed, the Court of Appeals held that the board had failed to present any evidence as to what the relevant standard of medical practice was for prescribing opioids for chronic pain. In the absence of such evidence, the unsupported assertions of Dr. Stuart were insufficient to justify the disciplinary measures imposed on Dr. DiLeo, and the charges against him were deemed by the court to be arbitrary, capricious, and an abuse of the board’s discretion.  

**HOOVER V AGENCY FOR HEALTH CARE ADMINISTRATION**

Katherine Hoover, MD, was a board-certified internist who had a number of chronic pain patients in her practice. For some of them, she elected to prescribe opioid analgesics for an extended period of time. The state medical board took a dim view of this and initiated disciplinary proceedings for “inappropriately and excessively” prescribing Schedule II drugs to seven patients. The board’s case against Dr. Hoover consisted of two physicians who had reviewed pharmacy computer printouts documenting the prescriptions written for these patients by Dr. Hoover, and their opinions that the dosages she had prescribed were “excessive, perhaps lethal.” None of these patients had, in fact, suffered any adverse effects from the prescriptions written by Dr. Hoover. Rather, they rallied to her support because she had diligently and successfully worked to manage their pain and restore their ability to function, whereas other physicians had either discounted their reports of pain or refused to prescribe opioids.

The board’s experts did not review the medical records for any of these patients. Also, on cross-examination, these “experts” acknowledged that they did not treat chronic pain patients in their practice. Indeed, under the more stringent standards for expert testimony that have developed in the last 10 years, one could reasonably argue that the medical board’s experts were not really experts in pain management. The hearing officer in the case may have taken the same view because she ultimately ruled that the
evidence presented at the hearing supported a conclusion that Dr. Hoover’s care of these patients was entirely appropriate. Nevertheless, the Board of Medicine took the remarkable step of disregarding the hearing officer’s findings and conclusions and imposed sanctions that included an administrative fine of $4,000, continuing medical education (CME) on the prescribing of “abusable drugs,” and 2 years of probation.

Dr. Hoover appealed, and in a scathing opinion by a three-judge panel of the Florida Court of Appeals, the ruling of the medical board was reversed. Noting a disturbing pattern and practice by the medical board, the opinion declared, “The board has once again engaged in the uniformly rejected practice of overzealously supplanting a hearing officer’s valid findings of fact regarding a doctor’s prescription practices with its own opinion in a case founded on a woefully inadequate quantum of evidence.” Elsewhere in the opinion, the court referred to the board’s “draconian policy of policing pain prescription practice.” Similar to the decision by the Louisiana Court of Appeals in DiLeo, the Florida Court of Appeals noted that the medical board had failed to introduce competent, credible evidence of the standard of care by which Dr. Hoover’s prescribing practices could be evaluated.

One very important implication of the DiLeo and Hoover cases is that the courts will not simply sit back and allow medical boards to declare what the standard of care is in any particular clinical situation. Rather, the board must present persuasive evidence in support of the prevailing standard of care. Moreover, such cases as these appear to represent an “ethic of underprescribing” on the part of state medical boards that persisted for decades. It was the deeply engrained and pervasive nature of this ethic that prompted some state legislatures to adopt the intractable pain treatment acts (IPTAs) that are discussed in Chapter 14. The thrust of such legislation was to send a message that the public policy of the state should not be to discourage physicians from providing effective pain management to patients with chronic nonmalignant pain, even if in some cases, that would involve the extended use of opioid analgesics. The Hoover case suggests how difficult it was to surmount the prevailing ethic in some boards because that case was brought shortly after the State of Florida had enacted an IPTA. The medical board rationalized its attempt to
discipline Dr. Hoover by arguing that she had treated the patients in question prior to the effective date of the Florida law. The Florida Court of Appeals critiqued the cramped and legalistic way in which the board attempted to flaunt the statute, noting that what the board failed or refused to recognize was that the public policy of the state did not support its approach to punishing physicians who dared to prescribe opioids to patients with chronic noncancer pain.

As noted earlier, beginning in the mid-1990s, a few state medical boards adopted policies on pain management that were intended to reassure physicians that the board was not, in fact, hostile to good pain management practice and sought to outline how physicians could care for such patients in a manner that was consistent with good medical practice. Then, in 1998, the Federation of State Medical Boards (FSMB) promulgated model guidelines for the use of controlled substances for the treatment of pain.

The gradual dissemination of medical board policies promoting effective pain relief as an essential component of quality patient care signaled the beginning of a paradigm shift. Heretofore, the idea that if there could be such a thing as overprescribing of opioids, then as a matter of logic and consistency, there must be an opposite side to the coin (i.e., underprescribing of opioids) seemed to be unintelligible to many medical boards. The inconsistency between perception and reality was truly remarkable. Whereas the medical literature in the 1980s and 1990s was replete with data indicating that pain was significantly undertreated in almost all patient care settings, no medical board had ever encountered a case in which underprescribing was deemed to constitute incompetent or unprofessional conduct.

OREGON BOARD OF MEDICAL EXAMINERS V BILDER
Paul A. Bilder is a pulmonary specialist who in the late 1990s was practicing in a small Oregon community. In 1999, the Oregon Board of Medical Examiners (OBME) initiated disciplinary action against Bilder following an investigation of complaints concerning his alleged failure to properly manage the pain and other distressing symptoms of six patients over a period of 5 years. The disciplinary action ultimately led to a
stipulated order in which Bilder agreed to certain remedial measures. Two of the six were elderly patients with metastatic cancer who were enrolled in hospice. In each instance, the hospice nurse requested an increase in the dosage of pain medication in what turned out to be the last hours of the patient’s life which Dr. Bilder refused to provide because he considered the amount requested excessive. In the other three cases, he refused to provide morphine or similar pain medication to a patient with congestive heart failure (CHF) who was do not resuscitate (DNR) and gasping for breath. The other three cases involved patients who were ventilator-dependent because of chronic obstructive pulmonary disease (COPD) or pneumonia. Dr. Bilder ordered paralytic agents but refused to order antianxiolytics or pain medication.

By the terms of the stipulated order, Dr. Bilder agreed to a 10-year probation, a formal reprimand, successful completion of the board’s Physician’s Evaluation Education Renewal Program, and an approved course in physician–patient communication as well as continuing psychiatric treatment with regular reports from the treating psychiatrist to the board. The Oregon Board once again found it necessary to take disciplinary action against Dr. Bilder 2 years later for similar instances of failure or refusal to appropriately respond to clear indications of patient suffering.

**ACCUSATION OF EUGENE WHITNEY, MD**

In 2003, California became the second state to take disciplinary action against a physician for failure to provide appropriate pain relief. The patient in question was an 85-year-old man with advanced mesothelioma. The care of Lester Tomlinson in the last weeks of his life was the subject of both civil litigation and medical board disciplinary action. The civil litigation will be discussed in the next section of this chapter.

Mr. Tomlinson spent 5 days in a local hospital receiving treatment for pneumonia and pleural effusion. He was then transferred to a skilled nursing facility (SNF) and came under the care of Eugene B. Whitney, MD, for the duration of his stay, which ended with his death approximately 3 weeks later. The care of Mr. Tomlinson at the SNF generated a great deal of contention between the members of his family.
(wife and daughter) and the caregivers. Each administration of pain medication, which began on the fourth day following his transfer from the hospital, was precipitated by a complaint from the family that he was in pain. Medication orders progressed from remazepam (Restoril) to hydrocodone/paracetamol (Vicodin) to various strengths of fentanyl transdermal (Duragesic) patch. Only after the family specifically requested morphine for Mr. Tomlinson’s increasing pain did Dr. Whitney discontinue the hydrocodone/paracetamol (Vicodin) and ordered morphine (Roxanol) 20 mg, 10 mg orally every 6 hours.

Dr. Whitney saw Mr. Tomlinson only once during that period of time, 2 days after the first administration of Roxanol. He found the patient to be in pain and ordered morphine sulfate controlled-release (MS Contin) oral solution 10 mg every 4 hours as needed. As noted in the medical board charges against Dr. Whitney, MS Contin comes in tablet form only and should be provided on a regular schedule and not on an “as needed” basis. Dr. Whitney discontinued the prior order 2 days later and instead ordered MS Contin 5 mg every 2 hours for breakthrough pain. As further noted in the medical board accusation, halving the dose of an opioid analgesic and doubling the frequency of administration will not increase the analgesic potency. Nursing notes at the SNF in the subsequent 2 days until Mr. Tomlinson’s death indicate uncontrolled pain and anxiety.

The Medical Board of California charged Dr. Whitney with unprofessional conduct and incompetence for his failure “to understand the unique properties of Roxanol solution and MS Contin tablets and to prescribe the medications properly.” The board and Dr. Whitney entered into a stipulation for public reprimand, the terms and conditions of which require that he obtain CME in pain management, the prescribing of opioid analgesics, and communication with patients and families.

At this point, it is still too early to conclude that the medical board actions against Drs. Bilder and Whitney represent any sort of lasting paradigm shift in philosophy and practice of medical boards generally in regard to opioid prescribing by their licensees. Two cases do not constitute a trend. The FSMB Model Policy concerning controlled substances for pain relief has undergone a number of periodic updates, expansions, and revisions over the last two decades. In the most recent iteration (2013), it
states that “evidence for the risk associated with opioids has surged, while the evidence for benefits has remained controversial and insufficient.”

The current document admonishes prescribing professionals to recognize that appropriate pain management includes an ongoing risk–benefit assessment of opioid analgesia versus nonpharmacologic measures.

A majority of state medical boards had adopted the model policies or promulgated policies that emphasize the need to incorporate sound pain management practices into patient care. To some extent, the shift in attitudes about the role of pain management in patient care, and the influence of those new attitudes in the formulation of medical practice guidelines and policies, can be traced to a few dramatic legal cases. We turn now to these cases and their role in informing public attitudes and policies about pain and its management.

Civil Litigation

Despite growing evidence in the clinical literature that pain is often undertreated, and a medical malpractice crisis purportedly arising out of a plethora of malpractice claims yielding significant monetary damage awards, prior to 1990, there had never been a malpractice suit seeking damages for failure to provide appropriate pain relief.

Although somewhat speculative, there are several possible explanations of this curious state of affairs. First, the phenomenon of widespread undertreated pain was not well known outside of the health professions. It had yet to become a featured topic in the print or electronic media. Moreover, laypersons held the erroneous belief that pain was the inevitable result of traumatic injury, serious illness, or a major surgical procedure. Finally, the generally high repute in which health care professionals were held presupposed that they would most certainly not allow a patient to experience unnecessary pain or suffering. The pervasiveness of pain in the clinical setting must, on this view, result from the sheer intractability of the pain associated with major illness and most certainly with the process of dying. From this perspective, the case we now consider is all that more remarkable in its outcome.
ESTATE OF HENRY JAMES V HILLHAVEN CORPORATION

Henry James was a 75-year-old man who carried the diagnosis of stage III adenocarcinoma of the prostate with metastasis to the lumbar sacral spine and left femur. In December of 1986 and January of 1987, he spent nearly 2 months in a local hospital receiving treatment for a pathologic hip fracture. During that hospitalization, in addition to bone debridement and radiation therapy, Mr. James was evaluated by hospice and received Roxanol 150 mg every 3 to 4 hours around the clock for his pain. Progress notes indicate that his pain was well controlled on this regimen.

After a very short stay at home, he was admitted to an SNF owned and operated by the Hillhaven Corporation. The continuing orders for pain medication included 150 mg per day of Roxanol, along with two tablets of acetaminophen (Tylenol) every 4 hours as needed and propoxyphene napsylate and acetaminophen (Darvocet-N) 100 mg. His family had ensured that he received the medication when he was at home and made certain that the nursing home staff was aware of it on his admission.

In preparation of the SNF admission documents, a nurse offered the opinion that Mr. James was addicted to morphine and on that basis declared her intent to significantly reduce the amount of opioid analgesia and replace it with a tranquilizing agent. Remarkably, she was able to effectuate this change in the pain management regimen without the review and approval of the patient’s physician. His family learned about the change only after he had been discharged from the facility and was interviewed by investigators for the North Carolina Department of Human Resources, the licensing agency for the facility. Their investigation revealed that at no time during his 23-day stay did he receive pain medication as ordered.

Thereafter, the family consulted an attorney and suit was filed against the nurse and the facility for failure to properly treat Mr. James’s pain. In order to prevail in such a case, the plaintiff (Mr. James’s estate) had to establish by a preponderance of the evidence that (1) a recognized standard of care for the management of his pain existed, (2) the standard was violated by the defendants, and (3) the departure from the standard of care caused him to experience pain to an extent that he would not had the
standard been met. If the jury answered each of those questions in the affirmative, then it must proceed to determine what several weeks of unnecessary pain should be worth in monetary damages. During the course of the trial, expert witnesses called by the plaintiff challenged the position taken by the nurse at the Hillhaven facility that the dose of morphine prescribed for Mr. James was excessive and not necessary to control his pain.\textsuperscript{17}

The jury answered each of the questions in the affirmative and awarded the plaintiff compensatory damages of $7.5 million. However, the jury did not stop with that award. In a civil action, when a defendant’s conduct is sufficiently egregious to meet certain criteria, punitive damages may be awarded. The purpose of such damages, as the term suggests, is not to compensate the plaintiff, but rather to make a negative example of and punish the defendant. The jury in this case assessed another $7.5 million in punitive damages. Apparently, the jurors were convinced that there is or ought to be something like a right to effective pain relief, at least for patients in the circumstances of Mr. James, and that the defendant corporation and/or its agent consciously disregarded that right and in the process subjected an elderly, dying patient to unnecessary pain and suffering. In a subsequent section of this chapter, we will consider two cases in which the US Supreme Court appears to adopt a similar position as a matter of constitutional law.

Several years after the verdict and subsequent out-of-court (and confidential) settlement of the Estate of Henry James v Hillhaven Corporation case, North Carolina joined a number of other states in enacting tort reform legislation. Consequently, the same result could not be achieved today even in the same or a very similar case. Punitive damages are now capped at 3 times the amount of compensatory damages or $250,000, whichever is greater. Furthermore, punitive damages cannot even be sought unless the plaintiff can prove by clear and convincing evidence (a higher burden of proof than a preponderance of the evidence) one of the following aggravating factors: (1) the defendant acted out of malice, (2) fraudulently, or (3) in willful and wanton disregard of the rights or safety of the defendant. Punitive damages could not be recovered from a corporation (such as Hillhaven) unless the officers, managers, or directors
participated in or condoned the conduct that constituted the aggravating factors.\textsuperscript{18}

**BERGMAN V CHIN, MD, AND EDEN MEDICAL CENTER**

William Bergman was an 85-year-old man in severe pain when he arrived at the emergency department (ED) of Eden Medical Center. He had been taking the Vicodin prescribed by his physician but without receiving adequate relief. He was given morphine by the ED physician and experienced significant relief. In order to do a more extensive workup, he was admitted to the hospital and came under the care of a hospitalist, Wing Chin, MD. Out of concerns about the side effects of morphine, in particular respiratory depression, Dr. Chin discontinued it and wrote a standing order for meperidine (Demerol), 25 to 50 mg every 4 hours “as needed.” This order remained in place throughout the 5-day hospital stay, during which the nurses charted pain levels in the range of 7 to 10 on the standard 10-point scale. On the date of Mr. Bergman’s discharge, his numerical pain score was noted to be a 10; nevertheless, Dr. Chin planned to send him home with a prescription for Vicodin. When Mr. Bergman’s daughter protested, Dr. Chin ordered another administration of Demerol and a fentanyl patch.

During the hospitalization, the medical workup was strongly suggestive of lung cancer, although Mr. Bergman refused to consent to a lung biopsy that Dr. Chin believed was indicated in order to make a definitive diagnosis. Despite a diagnosis Dr. Chin deemed less than definitive, shortly following his discharge, Mr. Bergman came under the care of a hospice nurse, who prevailed on another physician in the community to write a prescription for morphine after she found the fentanyl patch to be inadequate to manage Mr. Bergman’s pain. He died 3 days following discharge. No autopsy was performed. The cause of death was considered to be complications from lung cancer.\textsuperscript{19}

The children of William Bergman became convinced that the last days of their father’s life were severely compromised by a clinical failure to provide effective pain relief. Their conviction resulted in part from a review of his medical record by an expert secured through the assistance of
the organization Compassion in Dying (now Compassion and Choices). The family initially filed a complaint against Dr. Chin with the Medical Board of California. In an interesting approach to the case, the board’s own investigation and independent expert review confirmed that the pain relief Dr. Chin provided to Mr. Bergman was inadequate. Nevertheless, the board notified the family that it would not take any adverse disciplinary action against Dr. Chin based on only one episode of inadequate patient care. Displeased by this response, and with continuing support from Compassion in Dying, the Bergman family secured legal counsel and filed a civil action against Dr. Chin and Eden Medical Center. The medical center settled with the plaintiffs prior to trial.

The complaint against Dr. Chin that was tried to a jury was unusual in that it was not a straightforward medical malpractice claim. Such a claim could not have any chance of success in California because, as a result of tort reform legislation, damages for pain and suffering resulting from medical malpractice can only be recovered by the patient; they are not deemed to “survive” such that they can be recovered following the patient’s death by the personal representative. The only challenge to the medical care provided by Dr. Chin related to his alleged failure to properly manage Mr. Bergman’s pain; hence, the only damages that could be awarded would be for unnecessary pain and suffering. However, if the pain and suffering can be proven to have resulted from acts or omissions that constitute “elder abuse,” under California law, the personal representative of the “victim” of the abuse can recover damages. Consequently, the Bergman family’s suit against Dr. Chin and the hospital alleged elder abuse.

Another complicating factor about an elder abuse claim in California is that it carries an elevated burden of proof. Rather than a mere preponderance of the evidence, the plaintiff must establish by “clear and convincing evidence” that the defendant was guilty of recklessness, fraud, or malice in perpetrating physical, financial, or fiduciary abuse or neglect. Prior to this case, no physician had ever been accused of elder abuse, and the claim that failure of a health care professional to provide effective pain management might constitute a violation of the statute was an even further stretch. From all appearances, the trial of the case
proceeded as would a typical medical malpractice claim. The plaintiffs offered the testimony of two physician expert witnesses, both of whom testified that there were serious problems with the type, dose, and schedule of administration of analgesia to Mr. Bergman while a patient at Eden Medical Center. In rebuttal, Dr. Chin called two physician expert witnesses who testified that in their opinion, the measures he employed in an effort to manage Mr. Bergman’s pain did not constitute a material departure from the custom and practice of similar physicians caring for patients like Mr. Bergman.  

During the course of the trial, despite Dr. Chin’s contention that there was no conclusive evidence that Mr. Bergman had lung cancer, the judge allowed the plaintiffs to introduce into evidence the Agency for Health Care Policy and Research Clinical Practice Guideline Managing Cancer Pain. That evidence tended to bolster the testimony of the plaintiff’s experts that Dr. Chin’s pain management strategy was deficient in significant ways. The guideline provides, for example:

- Treatment of persistent or moderate to severe pain should be based on increasing the opioid potency or dose.
- Medications for persistent cancer-related pain should be administered on an around-the-clock basis with additional “as needed” doses, because regularly scheduled dosing maintains a constant level of drug in the body and helps prevent recurrence of the pain.
- Meperidine (Demerol) should not be used if continued opioid use is anticipated.

Dr. Chin testified that he had no familiarity with these or with the Medical Board of California’s 1994 guidelines and policy on pain management. He also stated that he did not take the nurses’ notes on Mr. Bergman’s pain levels into account because he did not have any confidence in that form of pain assessment.

The nurses involved in the care of Mr. Bergman testified on behalf of Dr. Chin that whenever Mr. Bergman reported pain in the moderate to severe range, they administered another 25-mg dose of Demerol consistent with the standing order. Interestingly, however, they testified that the reason the medical record did not reflect what they insisted to have been consistent achievement of pain relief in response to these administrations
was that at Eden Medical Center, pain was charted “by exception.” In other words, pain was only noted when it was outside of normal limits. Such an approach begs the question of what constitutes an authoritative source for the “normal limits” of pain for any particular patient. This charting anomaly worked against the defendant because the medical record was replete with pain levels in the moderate to severe range each day but not in the mild to nonexistent range that would have supported their claim that the opioids administered to Mr. Bergman during his hospitalization were sufficient to meet his needs.

Ultimately, the jury reached a verdict in favor of the plaintiffs and awarded $1.5 million in damages. They came within one vote of awarding an additional amount in punitive damages. The trial judge reduced the award to $250,000 on the theory that the statutory cap on monetary damage awards for medical malpractice claims applied even though this claim was filed pursuant to the elder abuse statute. The judge awarded nearly $1 million in attorney fees and litigation costs to the plaintiffs as well. Outstanding posttrial issues were resolved by confidential agreement between the parties; hence, no appeal was taken by either side.

News of the verdict in the Bergman v Chin case shook the medical community. The stark contrast between the reaction of the Medical Board of California to the allegations in the case and that of the lay jury seemed to support an observation by the physician Eric Cassell nearly 20 years earlier: “The relief of suffering, it would appear, is considered one of the primary ends of medicine by patients and lay persons, but not by the medical profession.”23 Because the verdict came in the context of an elder abuse claim against Dr. Chin, it seemed particularly punitive in nature and raised the issue of how to most appropriately and effectively “rehabilitate” physicians whose knowledge, skills, and/or attitudes were not conducive to the effective assessment and management of pain. We will revisit this issue after the discussion of the Tomlinson case that follows.

**TOMLINSON V BAYBERRY CARE CENTER, ET AL.**
We have previously discussed the Tomlinson case in the context of the elder abuse claims filed against both the acute and long-term care facilities in which the patient received care in the last month of his life as well as the
physicians who were responsible for that care in both clinical settings. The claims in that case bore a striking resemblance to the claims in the Bergman v Chin case. Perhaps, because of the jury verdict in the prior case, as noted, all of the defendants in Tomlinson settled prior to trial. Interestingly, as alluded to previously, the Medical Board of California took a much different position in dealing with the complaint by the Tomlinson family against Dr. Eugene Whitney, who was the responsible physician when Mr. Tomlinson was in the SNF (Bayberry Care Center) than it did with regard to the complaint filed by the Bergman family against Dr. Chin. The Medical Board of California sanctioned Dr. Whitney for his failure “to understand the unique properties of Roxanol solution and MS Contin tablets and to prescribe the medications properly” pursuant to a stipulated disciplinary order he entered into with the board. He was required to undergo an extensive evaluation of his professional knowledge and skills and work with the board in developing a detailed remediation plan. Also, the California Department of Health Services issued a notice of deficiency against Bayberry Care Center based on the many problems with the care Mr. Tomlinson received at that facility.

Just as one can speculate that the defendants in the elder abuse claims by the Tomlinson family were motivated to settle prior to trial because of the earlier jury verdict against Dr. Chin, it is also tempting to suggest that the decision of the Medical Board of California to take disciplinary action against Dr. Whitney in response to the complaint filed against him by the Tomlinson family was influenced by the highly negative public response to the board’s refusal to take similar action against Dr. Chin, particularly when a lay jury deemed the same conduct not just malpractice but elder abuse and the California legislature was motivated to pass a law mandating CME in pain management for California physicians. It is certainly possible that one influenced the other, but there is no way to authoritatively establish that proposition.

More contemporaneously, some patients who have developed addiction to prescription opioids have initiated legal actions against their physicians. In a recent West Virginia Supreme Court ruling, a number of patients sued several physicians and a clinic alleging negligence in the prescribing of opioid analgesics. What is remarkable about the cases consolidated for
review of questions submitted by the trial court was that the plaintiffs admitted not only that they had abused controlled substances before they sought treatment from the defendant physicians but also that they had engaged in criminal conduct involving opioids such as obtaining them through fraud. The West Virginia Supreme Court ruled that the plaintiffs' criminal misconduct would not, under its interpretation of state law, act as a complete bar to their claims of negligence against the defendants.27 Dissenting opinions in the case noted that in many other jurisdictions such wrongful conduct by a plaintiff would preclude the action from going forward.

One of the physician defendants in this case was Kathrine Hoover, whose ultimate legal victory over the Florida medical board was discussed earlier. She was alleged to be the number one prescriber of opioids in the state. The clinic where she practiced was raided by law enforcement, but she was never criminally charged.

**Criminal Litigation**

Criminal prosecutions of health care professionals for acts or omissions resulting in death or grave harm to patients are exceedingly rare.28 By far, the most common means of imposing sanctions on health professionals for negligent or even reckless patient care are those we have already considered—disciplinary action by state licensing boards or professional liability (malpractice) claims. The exceptional case that prompts a criminal prosecution is almost invariably one involving the death of the patient and conduct by the professional that is considered egregious in nature or in the extent to which it departs from a consensus view of what constitutes the parameters of responsible professional conduct.

Because our focus is necessarily on pain management and palliative care, we will consider several instances in which physicians have been prosecuted in either state or federal court. Some of the more high-profile state prosecutions have involved the care of dying patients, whereas those in federal court have been pursuant to the Controlled Substances Act (CSA) and involved prescribing opioids for chronic noncancer pain patients. We begin with a highly instructive state prosecution.
STATE V NARAMORE

In 1994, the attorney general of Kansas filed a two-count criminal complaint against L. Stanley Naramore, D.O. Both counts related to his care of patients almost 2 years before who were facing terminal conditions. Early in 1996, a jury returned guilty verdicts related to each count and the court sentenced Dr. Naramore to concurrent terms of 5 to 20 years. We will focus on the case that gave rise to the first count and on the subsequent reversal of both convictions by the Kansas Court of Appeals.

The patient, Ruth Leach, was a 78-year-old woman suffering from advanced breast cancer that had metastasized to her bones, lungs, and brain. She had been hospitalized and her condition deteriorating. The fentanyl patches no longer controlled her pain, and she was restless and agitated. A nurse suggested to the family that Dr. Naramore be called and asked to prescribe stronger pain medication. Upon arriving at the hospital, he examined Ruth Leach and spoke with her two adult children. Together, they reached a decision to increase her pain medication. Dr. Naramore explained that there was a risk of depressed respiration. He then administered 4 mg of midazolam (Versed) and 100 micromilligrams of fentanyl. Thereafter, the nursing notes indicate that the patient’s respiration slowed and grew irregular.

From this point on, the accounts of what transpired take on a curious, disjointed quality. To the extent they are accurate, it is not difficult to understand why there was a failure to maintain a consensus among the family and caregivers concerning the goals of care and how each subsequent action would be consistent with the reasonable pursuit of those goals.

The patient’s son, who had training as an emergency medical technician, is reported to have asked Dr. Naramore if his mother was dying, and Naramore was said to have observed that she was but that the effects of the fentanyl could be reversed by the administration of Narcan. This statement suggested to the patient’s son and the nurse on duty that an overdose of pain medication must have been given. Thereafter, when Dr. Naramore began to prepare for continuing IV infusion of analgesics, the son insisted that he not administer any more and was quoted as saying, “I’d rather have my mother lay there and suffer for 10 more days than you do anything to
speed up her death.” In an effort to dissuade the son, Dr. Naramore told him that “it just gets terrible from here on out . . . the next few days are going to be absolutely terrible.” When the son remained intransigent and assured Dr. Naramore that he would hold the doctor accountable for anything that happened, Dr. Naramore withdrew from the case. The next day, Ruth Leach was transported to another hospital, where she was given morphine for her pain and died 3 days later of her underlying terminal illness.

The patient’s family became convinced, and they in turn persuaded the Kansas Attorney General that Dr. Naramore had intended to hasten her death through administration of excessive doses of analgesics. Dr. Naramore was charged with attempted first-degree murder. He was also charged with second-degree murder of another patient from about the same time period, Chris Willt.

In order to convict a defendant of attempted first-degree murder, the jury must find that the prosecution has proven beyond a reasonable doubt that the defendant (1) performed an overt act toward the commission of the crime, (2) did so with the intent to commit the crime of first-degree murder, and (3) failed to complete the commission of that crime. The elements of murder in the first degree include intent to kill a person, the intentional performance of an overt act toward that end that is both deliberate and premeditated.

The prosecution presented several medical experts. The director of Emergency Medicine at the University of Kansas Medical Center testified that in his opinion, Ruth Leach was near death after the administration of Versed and fentanyl and that she would have died if the morphine Dr. Naramore had ordered had in fact been administered. This view was similarly expressed by a specialist in anesthesiology and critical care medicine at the University of Vermont College of Medicine who had previously practiced in Kansas. He testified that a dose of Versed combined with that of the fentanyl were excessive and in short order would have caused the patient to stop breathing. An additional respiratory depressant such as morphine would simply have added to the certainty of her death.

In his defense, Dr. Naramore called several expert witnesses. One, a
physician who had cared for Ruth Leach for 5 years prior to her death, noted that she had received a variety of medications for her pain, none of which had brought it under control. He found it to be “phenomenal” that anyone would accuse Dr. Naramore of trying to kill her under these circumstances. A family physician from another small Kansas community said that if Dr. Naramore had actually intended to kill Ruth Leach, he would have used 10 times the dosage administered. He characterized the care provided as “concerned and compassionate.”

Another witness for Dr. Naramore, the president of the Kansas Association of Osteopathic Medicine and a family medicine practitioner, characterized Dr. Naramore’s efforts to control Ruth Leach’s pain and distress as exemplary. Finally, another family physician who served on the peer-review committee for Blue Cross/Blue Shield of Kansas testified that given her significant history of opioid analgesia and the extent of her distress at the time, the dosages of Versed and fentanyl were reasonable and in no sense an overdose.

The convictions of Dr. Naramore for the attempted murder of Ruth Leach and for the second-degree murder of the other patient were reviewed and reversed by the Kansas Court of Appeals. In its opinion, the Court of Appeals made numerous references not only to the expert witness testimony on his behalf at trial but also to amicus curiae (friend of the court) briefs filed on behalf of Dr. Naramore by the Kansas Association of Osteopathic Medicine, the American Osteopathic Association, and the Kansas Medical Society. The court also noted that it had done its own substantial research on the subject of palliative care. Moreover, its review of the case law revealed “no criminal conviction of a physician for the attempted murder or murder of a patient which has ever been sustained on appeal based upon evidence of the kind presented here.”

In articulating the rationale for its decision that the criminal convictions must be reversed, the Court of Appeals declared,

We have made a thorough review of the record [of the trial court proceedings], which contains a wealth of undisputed evidence and expert medical testimony. We find that no rational jury could find criminal intent and guilt beyond a reasonable doubt based on the record here. When the issue is whether there is reasonable doubt, a
jury is not free to disbelieve undisputed facts. What occurred here is generally known. The jury was not free to disbelieve that there was substantial competent medical opinion in support of the proposition that Dr. Naramore’s actions were not only noncriminal, but were medically appropriate.

. . . When there is such strong evidence supporting a reasonable, noncriminal explanation for the doctor’s actions, it cannot be said that there is no reasonable doubt of criminal guilt . . . All three amicus briefs . . . note that if criminal responsibility can be assessed based solely on opinions of a portion of the medical community which are strongly challenged by an opposing and authoritative medical consensus, we have criminalized malpractice, and even the possibility of malpractice. The instant case is a very good example of this.29

The quoted language of the court mentioned and subsequent statements in the court’s decision regarding the absence of any jury instructions “relating to the medical and moral responsibilities of care givers for the critically or terminally ill patient” are of considerable consequence because of their implications for a wide range of criminal prosecutions of physicians for care provided in an effort to manage the pain and adverse symptoms associated with terminal or serious chronic conditions. Although physician fears persist concerning the risk of potential criminal prosecution for actions taken to relieve the distress of dying patients, such prosecutions are quite rare.30

Despite his ultimate vindication in these proceedings, Dr. Naramore’s legal travails did not end. After relocating to Ohio, in late 2009, he plead guilty to conspiracy to distribute methadone to over 100 patients whom he acknowledged were likely distributing the pills, thereby promoting drug trafficking. He was sentenced to 48 months in prison.31

Several more recent cases reflect the mixed results of state criminal prosecutions of physicians for based on their prescribing of controlled substances. In October of 2015, southern California physician Hsiu-Ying “Lisa” Tseng was convicted of second-degree murder after three of her patients died as a result of drug overdoses. According to the prosecutor, this is the first time a physician has been convicted of murder for
prescribing practices leading to overdose death. Dr. Tseng’s defense was 
that at worst her conduct amounted to negligence, not criminal homicide. 
The prosecutor and the jury disagreed. In February of 2016, Dr. Tseng 
was sentenced to 30 years to life in prison. In issuing the sentence, the trial 
judge criticized Dr. Tseng for blaming the patients, pharmacists, and even 
other physicians rather than accepting any responsibility. The prosecution 
had argued to the jury that despite having been notified by medical 
examiners or law enforcement of the death of a patient, Dr. Tseng did not 
change her prescribing practices.

At about the same time, Florida physician Gerald Klein was acquitted of 
first-degree murder and other serious drug charges by a Palm Beach 
County jury. Although one of his patients died of a drug overdose, the jury 
did not find sufficient evidence to hold the prescribing physician 
responsible for it. Only one charge, “sale of alprazolam,” resulted in a 
conviction. Interestingly, the patient in that transaction was at the time a 
chef for billionaire Donald Trump.

Before concluding this discussion of civil and criminal cases against 
physicians at the local and state level, we should also note the multiplicity 
of ongoing litigation against major pharmaceutical companies concerning 
their marketing of prescription pain medications. The most frequent target 
of these cases is Purdue Pharma LP and its aggressive marketing of 
oxycodone HCl (OxyContin). In late December of 2015, the company 
settled a case filed by the State of Kentucky in 2007 charging it with 
misleading marketing of the drug to induce physicians and patients to 
discount its potential to lead to addiction. According to the terms of the 
settlement, Purdue Pharma will pay $24 million over a period of 8 years.

In July of 2016, Pfizer entered into an agreement with the City of 
Chicago to adhere to a written code of conduct for marketing opioids. The 
code calls for disclosure that opioid analgesics may pose a serious risk of 
adoption in some patients even when used properly as well as an 
assurance that it will not promote opioids for “off-label” uses. The City of 
Chicago filed a lawsuit against Pfizer, Purdue Pharma, and several other 
pharmaceutical companies alleging misleading marketing of this type of 
medication.
Federal Criminal Prosecutions

Recent federal criminal prosecutions of physicians pursuant to the federal CSA for prescribing practices in the care of chronic noncancer pain patients are not entirely aberrational. They follow in the history and tradition of earlier cases, and the appellate courts reviewing these cases cite the earlier decisions profusely as correctly interpreting and applying the intent of the Congress when enacting the CSA. It therefore behooves us to review key elements of one such precedent-setting case before taking up the contemporary examples.

UNITED STATES V ROSEN (1978)

Although Dr. Isadore Rosen was prosecuted under the CSA for prescribing controlled substances to patients for weight loss as part of an “obesity practice,” and not for pain management, the language of the appellate court decision and its analysis of the CSA are often cited in later cases involving the prescribing of controlled substances for pain. Also, the prosecution of Dr. Rosen was based in large measure on the testimony of undercover law enforcement agents who came to him posing as patients seeking to lose weight. The use of such tactics generally gives rise to a claim of “entrapment” by the defendant; that is, that the government agents induced him to engage in one or more unlawful acts that he was not otherwise contemplating and in which he never would have engaged but for their inducement. As often happens, the court in United States v Rosen easily disposed of this defense by noting, “When a person is shown to be ready and willing to violate the law, the providing of an opportunity therefore by undercover agents or police officers is not entrapment.”

In order to convict Dr. Rosen of the 25 counts of distributing controlled substances in violation of the CSA with which he was charged, the government had to prove the following three elements of the offense beyond a reasonable doubt:

1. That he distributed or dispensed a controlled substance
2. That he acted knowingly and intentionally
3. That he did so other than for a legitimate medical purpose and in the usual course of his professional practice

Dr. Rosen conceded the first two elements but asserted as to the third
that each of the agents who came to him posing as patients presented symptoms for which the drugs he prescribed or dispensed were medically appropriate. It is important to note that although the prescribing of certain types of medications for the purpose of weight reduction is subject to some controversy, for purposes of this decision, the court noted that all of the drugs prescribed by Dr. Rosen have legitimate therapeutic uses.

The crux of Dr. Rosen’s argument on appeal of his criminal conviction was that the trial court relied on what it considered to be evidence of substandard medical practice as a basis for finding criminal intent. This point is critical as it will arise in the discussion of more recent prosecutions under the CSA. If the third element listed earlier is deemed to have been established beyond a reasonable doubt by the evidence, then the courts treat the physician not simply as a negligent, or even in some instances a reckless physician, but simply as a drug dealer. The court in United States v Rosen reviewed a number of earlier convictions under the CSA and identified the following list of “red flags” suggesting that a physician may be acting illegitimately or outside the course of professional practice.

1. An inordinately large quantity of controlled substances was prescribed.
2. Large numbers of prescriptions were issued.
3. No physical exam was given.
4. The physician warned the patient to fill the prescriptions at different pharmacies.
5. The physician issued prescriptions to a patient known to be delivering the drugs to others.
7. The physician used street slang rather than medical terminology for the drugs prescribed.
8. There was no logical relationship between the drugs prescribed and treatment of the condition allegedly existing.
9. The physician wrote more than one prescription on occasions in order to spread them out.\textsuperscript{37}

The routine followed by Dr. Rosen’s weight loss “clinic” included many
of these red flag elements according to the testimony of the government agents who posed as patients seeking to lose weight. In particular, Dr. Rosen did not take a medical history or perform a physical exam other than to have the patients weighed and their blood pressure taken on the first visit by a staff member who was not a nurse. He provided no instructions on how to take the medications or warnings of risks or side effects to be concerned about, nor did he schedule follow-up appointments. Based on this and other evidence at trial, the court of appeals ruled that the government had met its burden of proof that Dr. Rosen’s prescribing or dispensing of controlled substances to the undercover agents was not in good faith for legitimate medical purposes in the course of his professional practice.

UNITED STATES V HURWITZ
Dr. William Hurwitz was a medical doctor who operated a pain medicine practice in McLean, Virginia. So widespread was his reputation as a liberal prescriber of opioids that many of his patients came from great distances—39 states—seeking medications from him that other physicians would not prescribe. In 1992, he was reprimanded by the District of Columbia medical board because of his “liberal” prescribing practices, and in 1996, the Virginia board revoked his license and subsequently reinstated it with ongoing monitoring of his prescribing practices. Ostensibly, that monitoring was still taking place when, in 2004, a federal grand jury indicted him on 62 counts, including drug trafficking resulting in death and serious bodily injuries, health care fraud, and criminal forfeiture. He was subsequently convicted on 50 of those counts and sentenced to 25 years in prison. Throughout the criminal process, Dr. Hurwitz was portrayed by the federal prosecutor and officials of the U.S. Drug Enforcement Administration (DEA) as “no different from a cocaine or heroin dealer peddling poison on the street corner.” At the trial, however, several nationally prominent experts in pain medicine testified on behalf of Dr. Hurwitz. During the trial, immediately following the testimony of the government’s chief expert witness, six former presidents of the American Pain Society (APS) took the unprecedented step of sending a letter to the trial judge expressing their deep concerns about “serious
misrepresentations” that had been made by the government’s expert, who was also a past president of the APS.

When Dr. Hurwitz appealed his convictions to the Fourth Circuit Federal Court of Appeals, the American Academy of Pain Medicine, the American Pain Foundation, and a group of nationally prominent experts in pain management, among others, filed amicus curiae (friend of the court) briefs in support of his appeal. These briefs asserted, among other points, that “seriously erroneous rules of law and scientific theories [were] relied upon to convict [Dr. Hurwitz].”

It is important to understand the significance one can reasonably attach to the willingness of these prominent organizations and individual members of the pain medicine community to go on record in this case. The government’s position was that Dr. Hurwitz’s prescribing of controlled substances had absolutely nothing to do with pain management. It was drug trafficking, pure and simple. The persons to whom he dispensed or prescribed these drugs were not patients but rather drug seekers who sought either to feed their addiction or further disseminate them in the illicit market for prescription drugs. The thrust of the argument on the other side was not that Dr. Hurwitz was practicing exemplary medicine, or in some instances, even prescribing within the minimal standard of acceptable care for chronic pain patients but rather that however far out of the mainstream his prescribing practices were, he was nevertheless a physician and not a drug dealer. The appropriate societal sanctions for physicians who practice negligently are medical malpractice liability claims or disciplinary action by licensing boards. In egregious circumstances, appropriate sanctions might include the permanent revocation of licensure. Nevertheless, physicians who practice substandard medicine are nonetheless physicians, and their patients remain patients in need of medical care, even if in some instances, the care they require is for addiction.

The Fourth Circuit Court of Appeals reversed the Hurwitz conviction and remanded the case to the District Court for a new trial. In doing so, it sought to make clear where the trial judge had erred and how the retrial should be conducted to provide Dr. Hurwitz with a fair trial. At the end of the new trial, he was convicted of 16 counts of drug trafficking and
sentenced to 57 months in prison.

**UNITED STATES V MCIVER**

Dr. Ronald McIver had approximately 1,000 patients in his South Carolina practice, most of whom saw him because of problems with chronic noncancer pain. In response to reports from the Columbia, South Carolina, police department about Dr. McIver’s prescribing practices, the DEA initiated an investigation of his practice in 2002. Based on investigatory findings that among McIver’s patients, there were those who regularly received prescriptions for what were characterized as “massive quantities” of oxycodone, hydromorphone hydrochloride (Dilaudid), OxyContin, methadone, and morphine; he was indicted on 15 counts of drug trafficking related to his treatment of 10 patients, 9 of whom testified for the government at his trial. The remaining patient was deceased, the cause of death having been characterized as an “oxycodone overdose.”

The major thrust of the prosecution’s case at trial was based on the expert testimony of a Dr. Steven Storick, an anesthesiologist who the court deemed to be duly qualified as an expert in pain management. After reviewing the medical records of the patients in question, he concluded that Dr. McIver’s treatment of several of them fell outside the parameters of legitimate medical practice. For example, in the case of a patient with a history of substance abuse, Dr. Storick asserted that prescribing opioids to such a patient was “like pouring gasoline on a fire.” A Medicaid patient who sought treatment from Dr. McIver for fibromyalgia traveled almost 3 hours to see him, paid for his services in cash, and filled prescriptions for methadone, OxyContin, oxycodone, and morphine costing thousands of dollars. The patient testified that she sold the methadone and morphine and was addicted to oxycodone. With regard to her treatment, Dr. Storick testified that Dr. McIver’s conduct was “way outside the course of legitimate medical treatment.”

The jury convicted Dr. McIver of multiple counts of unlawful distribution of a controlled substance and one that resulted in death. He was sentenced to 30 years in prison. On appeal to the Fourth Circuit Court of Appeals, the same court that granted Dr. Hurwitz a new trial, Dr. McIver’s counsel attacked Dr. Storick’s testimony as reflective of a hostile
and suspicious approach to the care of chronic noncancer pain patients in that he insisted on objective signs of tissue damage before prescribing opioids, and he refused to acknowledge that physicians could be deceived by some patients’ reports of pain and yet still be legitimately prescribing opioids for them based on a reasonable belief that they had significant pain.

The appeal also challenged the jury instructions, which Dr. McIver claimed suggested to the jury that he could be convicted if he “deviated drastically from accepted medical practice.” The Court of Appeals, in affirming the conviction, disagreed, noting that the jury was instructed that the prosecution must prove not only that the defendant acted “outside the course of professional practice” but also that he acted “for other than a legitimate medical purpose.”

Federal criminal prosecutions of physicians concerning pain management do not always result in convictions. As part of the initiative to aggressively pursue “pill mill” operations in the state of Florida, a federal prosecutor indicted Debra Roggow, MD, who was board-certified in physical medicine and rehabilitation, on 10 counts of drug trafficking based on allegations that she was inappropriately prescribing opioids to some of her patients. However, based on significant part on her meticulous patient records carefully documenting the justification for the prescribing of opioids in the case of each patient, the jury acquitted her of all charges.

Before concluding the discussion of these federal prosecutions of physicians who were at the far liberal end of the prescribing continuum, it may be helpful to delineate the parameters of that entire continuum, and perhaps even to suggest where, as a matter of law and public policy, the line should be drawn between “the bounds of medicine” and the realm of drug dealing and trafficking by health care professionals. The thrust of the argument goes something like this: Just as we do not criminally prosecute clinicians whose failure or refusal to provide pain relief subjects some of their patients to physical and mental anguish, neither ought we to criminally prosecute clinicians whose excessive prescribing creates or exacerbates some of their patients’ addiction disorders or propensity to engage in drug dealing under the guise of being a pain patient. In the most
egregious instances at both ends of the continuum, the appropriate public policy stance is to suspend or permanently revoke their professional licensure.

Currently, however, at least clinicians at the far liberal end of the prescribing continuum, such as Hurwitz and McIver, prosecutors, and judges (through approved jury instructions) invite juries to act as though no real physician–patient relationship existed. As suggested by the Kansas Court of Appeals in the Naramore case, whenever the criminally charged clinician is able to present expert testimony that what he or she did was within the “bounds of medicine,” the mere fact that the prosecution can offer expert testimony maintaining that it was not should never be sufficient for a conviction. Such a conflict of testimony should necessarily create the reasonable doubt that precludes a jury verdict against a criminal defendant.

Constitutional Cases

Several decisions by the Supreme Court of the United States in the last two decades have addressed issues related to the treatment of pain. Each case also involved highly controversial ethical and political issues: physician-assisted suicide and medical marijuana. As is typical of the Supreme Court, the rulings in each case were not an effort to decide which side was correct on the ethics or the politics but rather to determine what was consistent with the Constitution and a reasonable interpretation and application of federal statutes.

The first of these, the companion cases of Washington v Glucksberg and Vacco v Quill decided in 1997 directly involved the question of whether there was a constitutional right on the part of dying patients to be able to acquire lethal doses of medication from willing physicians for purposes of hastening their death. In the process of unanimously ruling that there was no such constitutional right, five of the nine justices joined in two concurring opinions that have been interpreted as a recognition by a majority of the court of a constitutional right on the part of terminal patients to receive palliative care. The language from these companion cases most consistently cited for this proposition include the following
passage from the concurring opinion by Justice O’Connor:

The parties and amici agree that in these states [Washington and New York] a patient who is suffering from a terminal illness and who is experiencing great pain has no legal barriers to obtaining medication from qualified physicians, to alleviate that suffering, even to the point of causing unconsciousness and hastening death.

Combined with language from a separate opinion by Justice Breyer:

Were the legal circumstances different [than in Washington and New York]—for example were state law to prevent the provision of palliative care, including the provision of drugs as needed to avoid pain at the end of life—then the law’s impact upon serious and otherwise unavoidable physical pain (accompanying death) would be more directly at issue. And as Justice O’Connor suggests, the Court might have to revisit its conclusions in these cases.46

The focus on pain and suffering at the end of life by the concurring justices may simply be a consequence of the fact that a right to lethal medication was asserted by the plaintiffs in these cases only as to patients with terminal illness. However, a right to appropriately aggressive palliative care as opposed to a lethal prescription, especially if defined quite broadly as the relief of pain and suffering, might be of even greater significance for a patient with severe chronic noncancer pain than for a terminally ill patient because it could persist for years or decades rather than merely weeks or months. Only future cases will illuminate whether there might be constitutional protection from unreasonable governmental barriers to pain relief for such patients.

The constitutionality of the Oregon Death with Dignity Act (ODWDA), pursuant to which the state of Oregon legalized and regulated physician-assisted suicide (referred to by its proponents as physician aid in dying) was not directly at issue in either Washington v Glucksberg or Vacco v Quill. However, those decisions by implication upheld the ODWDA because they determined that there is neither a constitutional right to nor a constitutional prohibition of such a practice. Consequently, it is a matter for each individual state to determine as part of its authority to regulate the practice of health care professionals.47
In 2001, Attorney General John Ashcroft issued an interpretive rule (IR) of the federal CSA, maintaining that prescribing a controlled substance for the purpose of assisting a patient in ending his or her life, even pursuant to a state statutory scheme such as the ODWDA, contravened the CSA and rendered the prescriber vulnerable to federal prosecution. Because all lethal prescriptions written pursuant to the ODWDA were federally controlled substances, the Ashcroft IR would essentially nullify the Oregon law. The State of Oregon immediately challenged the IR in federal court and obtained first a temporary restraining order and subsequently an injunction prohibiting enforcement of the IR pending resolution by the courts. When Ashcroft resigned as attorney general, his successor Alberto Gonzales decided to continue the legislation. By then, review of adverse rulings by the federal district and Ninth Circuit Court of Appeals had been sought and the case was pending before the US Supreme Court.

The central issue decided by the Supreme Court in Gonzales v Oregon was “who decides whether a particular activity is ‘in the course of medical practice’ or done for a ‘legitimate medical purpose.’”\footnote{48} The attorney general claimed authority under the CSA to define standards of medical practice at least insofar as the prescribing of scheduled drugs. Taking into consideration the legislative history of the CSA, the Supreme Court majority ruled that the intent of Congress was to combat a national problem of recreational drug abuse by ensuring that scheduled narcotics were secured within the health care setting through the prescribing by licensed practitioners for legitimate medical purposes. Nothing in the language or the legislative history of the CSA suggests that Congress intended to confer on the attorney general, in his capacity of law enforcement, to usurp the usual authority of the individual states in regulating the practice of medicine, which includes the writing of prescriptions. For this and other reasons discussed at length by the Court, the IR was held to exceed the authority of the attorney general under the CSA.

The legalization of physician aid in dying has gained a great deal of momentum in the past decade. Following the lead of Oregon, the state of Washington passed a similar law through the referendum process. The Vermont and California legislatures have more recently enacted aid-in-
dying legislation. In Montana, the state Supreme Court ruled that current law did not preclude physicians from providing such assistance to terminally ill patients with decisional capacity who requested it. The issue is also currently before the New Mexico Supreme Court.

In 2015, the Canadian Supreme Court ruled that sections of the criminal code violated the national Charter of Rights to the extent that they prohibited physician-assisted death for a competent adult who (1) clearly consents to the termination of life and (2) has a grievous and irremediable medical condition (including an illness, disease, or disability) that causes enduring suffering that is intolerable to the individual in the circumstances of his or her condition. The decision was stayed in order to provide the government with time to enact legislation consistent with the ruling. In June of 2016, the Canadian House of Commons and Senate passed an aid in dying law. However, because it limited the access to patients whose natural deaths were reasonably foreseeable, it is currently being challenged in court.

The issue of the legitimate medical use of marijuana reached the Supreme Court in the case of Gonzales v Raich. The plaintiffs in this case, Angel Raich and Diane Monson, were California residents suffering from a variety of serious medical conditions. Raich carries at least 10 diagnoses, including an inoperable brain tumor, seizure disorder, and several chronic pain syndromes. Monson suffered from severe chronic back pain and muscle spasms related to a degenerative disease of the spine.

California was one of a growing number of states that enacted legislation insulating seriously ill patients or their physicians from prosecution under state law for cultivating or possessing cannabis for use by the patient pursuant to the physician’s written recommendation or approval. The plaintiffs in this case argued that they were being treated by board-certified family practitioners who had determined after prescribing a wide variety of standard medications that marijuana is the only drug available that provides effective relief of their symptoms. As a Schedule I drug, the CSA recognizes no legitimate basis for patients such as Raich and Monson to possess or use marijuana, even though their physicians authorized it pursuant to the California statute. The plaintiffs filed suit against Attorney General Ashcroft and the administrator of the DEA in
federal district court seeking declaratory and injunctive relief preventing the federal government from prosecuting them under the CSA. The crux of their argument was that enforcement of the CSA against them required that interstate commerce be implicated in their acquisition and use of medical marijuana. The district court ruled against the plaintiffs, finding that the Commerce Clause of the Constitution applied to them despite the fact that the marijuana they used was grown in California.

The Ninth Circuit Court of Appeals reversed the district court, holding that the plaintiffs’ intrastate, noncommercial cultivation, possession, and use of marijuana for personal medical purposes on the advice of a physician does not constitute drug trafficking. Much of the court’s discussion involved arcane legal principles and Supreme Court precedents. Ultimately, it was these very principles and precedents that provided the basis for the Supreme Court’s reversal of the Ninth Circuit. Simply stated, the Court held that “Congress’ power to regulate interstate markets for medicinal substances encompasses the portions of those markets that are supplied with drugs produced and consumed locally. . . . The CSA is a valid exercise of federal power, even as applied to the troubling facts of this case.” Thus, the Court’s ruling in Gonzales v Raich cannot be understood as a pronouncement on the clinical question of whether the known risks and purported benefits of medical marijuana use ever justify a physician recommending it to patients when standard therapies are found to be inadequate.

Since this decision, not only have additional states permitted the use of “medical marijuana” but also some have legalized recreational marijuana and other states have this change on the ballot in November of 2016. Nevertheless, the DEA in August of 2016 reaffirmed its position that marijuana has no legitimate medical purpose and will remain a Schedule I drug that is illegal for any purpose.

Lessons from the Litigation

Generalizations that meet minimal criteria of accuracy and practicality concerning the lessons one should learn from the varieties of litigation surveyed in this chapter are both difficult and dangerous. They are difficult
because of the wide variation in cases; for example, state and federal courts, some patients who were dying, others facing chronic noncancer pain, still others who were addicted to prescription drugs or simply “planted” as a part of ongoing investigations by law enforcement. They are dangerous when they constitute gross oversimplifications of complex phenomena that have only superficial similarities. Nevertheless, some attempt at synthesis is both necessary and appropriate.

- Lesson 1: A new medical ethos has clearly emerged, grounded on the recognition that timely and effective assessment and management of all types of pain is essential to sound patient care. Nationally recognized clinical practice guidelines and organizational policies (such as The Joint Commission) affirm this basic proposition.

- Lesson 2. Evidence- or consensus-based guidelines and policies reinforce the proposition that there are recognized standards of care for the management of acute, chronic noncancer, and pain associated with terminal illness. These standards apply to all clinicians who care for patients with pain and not merely pain medicine or palliative care specialists.

- Lesson 3. Material departures from these standards render clinicians vulnerable to a variety of adverse legal consequences. Egregiously conservative approaches to opioid analgesia may result in civil liability for undertreatment of pain or professional licensing board sanctions. Excessively liberal approaches to the prescribing of opioids, particularly when a reasonable clinician would have recognized red flags or other warning signs, may result in criminal prosecution at the state or federal level.

- Lesson 4. Prudent practitioners should ensure that their knowledge, skills, and attitudes (at least insofar as they affect professional practice) are informed by the current authoritative clinical practice guidelines and policy statements. When that is the case, their approach to pain management will reflect a reasonable balance between effective pain management for their patients and due diligence to ensure that their prescribing practices are neither harming their patients nor contributing to the phenomena of prescription drug abuse and diversion.
• Lesson 5. As with any other aspect of patient care, timely, accurate, and thorough documentation in the medical record that reflects not only what was done but also what informed the decision on what to do and what alternatives were considered is absolutely essential. In every legal setting, incomplete, inaccurate, or untimely documentation of professional conduct is problematic, sometimes devastatingly so.

• Lesson 6. Clinicians who heed Lessons 1 to 5 earlier are not at any serious risk of adverse legal action arising out of their responsible efforts to relieve the pain of their patients.

Over three decades ago, the World Health Organization (WHO) concluded that most pain due to cancer could be relieved if health professionals followed a simple medical treatment method called the three-step analgesic ladder, which recommends using various types of analgesics (including opioid analgesics), in combination with adjuvant drugs when needed, depending on the severity of the patient’s pain. This approach also has been recognized by the WHO as appropriate with HIV/AIDS patients experiencing pain throughout the disease.

United Nations (UN) health and regulatory agencies have repeatedly appealed to governments and health professionals to cooperate in order to implement the WHO analgesic method and remove barriers that block patient access to opioid pain medications. Although drug regulations and opioid availability have improved in some countries, the vast majority of cancer and HIV/AIDS patients in low- and middle-income countries (LMICs), and many in high-income countries (HICs), still lack access to these essential medications. The inadequate access to opioids is further illustrated by the disparity in reported medical consumption of opioid medicines between HICs comprising a small proportion of the global population and the large and growing population of LMICs. With the shifting burden of cancer to LMICs, the public health problem of inadequate availability of pain medications and unrelieved pain is projected to become far worse.

The purpose of this chapter is to outline the body of knowledge and experience that is relevant to understanding and improving national opioid availability and patient access to controlled pain medicines. It is critically
important for health care professionals and government drug regulators, as well as advocates involved in the area of palliative care and pain relief, to understand the policies that govern the use of opioid medicines and how they can impact medication availability and patient access to opioid medicines. This chapter begins with background about the importance of pain relief in cancer and HIV/AIDS control. Focusing on opioids indicated for the relief of moderate to severe pain (e.g., hydromorphone, fentanyl, morphine, oxycodone), this chapter discusses the designation of these opioid medicines as both essential and controlled by international authorities. The disparities in opioid consumption globally and regionally are detailed, followed by an overview of common barriers preventing the adequate availability and accessibility of opioid medicines. Lastly, the UN’s recommendations to address the barriers to opioid availability are described followed by a summary of recent initiatives to improve the availability and access to opioid medications.

**Pain Relief Is Part of Cancer and HIV/AIDS Control**

The global incidence and prevalence of cancer and HIV/AIDS is a public health problem of great concern. The WHO estimates that in 2012, approximately 14.1 million individuals were newly diagnosed with cancer and more than 8 million died from this noncommunicable disease.\(^{17}\) Experts predict that the cancer burden will increase by 70% in the next two decades, with major impacts on LMICs, where it is estimated that the majority of new cases and deaths from cancer, including children, will occur.\(^{17}\) The global occurrence of HIV/AIDS is also a public health problem of great concern. The Joint United Nations Programme on HIV/AIDS (UNAIDS) indicated that in 2015, 36.7 million people were living with HIV, and 1.1 million people died from HIV/AIDS.\(^{18}\)

People with HIV/AIDS\(^ {19,20}\) and/or cancer\(^ {21–25}\) experience pain and a variety of other symptoms during the course of their disease that have a negative impact on their quality of life. Patients who are approaching the end of life are likely to experience even more severe symptoms,\(^ {7,8,26,27}\) which include pain, anxiety, constipation, cough, depression, dyspnea, and nausea.\(^ {1,7,8}\) Although it is necessary to address all symptoms, this chapter
focuses on the need for adequate pain relief and access to opioid pain medications. In LMICs, most cancers are diagnosed in late stages of the disease, when people often experience severe pain.  

**PAIN AND PALLIATIVE CARE**

Palliative care, including the critically important component of pain management, is a model of care aimed at relieving symptoms of disease and its treatment and improving the patient and family’s quality of life throughout the course of the disease. The WHO has long recognized that relieving pain and other symptoms in cancer and HIV/AIDS is a necessary part of palliative care, including for children. In 2014, the Worldwide Hospice and Palliative Care Alliance and the WHO collaborated to produce the Global Atlas of Palliative Care at the End of Life, which examines the state of palliative care and hospice programs globally, quantifying the need for and availability of palliative care worldwide. They found that over 20 million people require palliative care at the end of life every year, with the highest proportion of adults in need of palliative care (78%) living in LMICs. Despite this great need, palliative care is underdeveloped in most of the world, and access to quality palliative care is very rare in LMICs.26

Palliative care and pain relief medicines should be available and accessible to all individuals who have pain and other symptoms. There is a strong international imperative that palliative care, including pain management, should be included in national cancer and HIV/AIDS control efforts. The WHO has repeatedly reaffirmed the necessity of including palliative care as a critical component of cancer or HIV/AIDS control efforts in a country. At the country level, national policies should provide a policy framework for developing and expanding health care services to reach patients who need disease treatment as well as relief of pain and other symptoms. Notably, in 2014, the World Health Assembly (WHA), for the first time in its history, adopted a palliative care resolution that urges member states to integrate palliative care into their health care systems, to improve training for health care workers, and to ensure that relevant medicines, including strong pain medicines, are available to patients.
Opioids Are Essential Medicines and Controlled Substances

Guidance from the WHO dating back to 1986 acknowledges the need for a varied approach to managing pain, including nonpharmacologic therapies, and that not all types of pain will respond equally, if at all, to opioids. Indeed, there are many useful pharmacologic and nonpharmacologic therapies for treating cancer pain. And yet, opioid medicines, and in particular orally administered morphine, are regarded by international health experts as the first choice for relieving moderate to severe pain due to cancer. Since 1977, the WHO Expert Committee on the Selection and Use of Essential Medicines has designated morphine as an essential medicine for the treatment of cancer pain. According to WHO, essential medicines are those medicines that “... satisfy the priority health care needs of the population ... are selected with due regard to public health relevance, evidence on efficacy and safety, and comparative cost-effectiveness.” By giving them this designation, the WHO is asserting that these medicines “... are intended to be available within the context of functioning health systems at all times in adequate amounts, in the appropriate dosage forms, with assured quality and adequate information, and at a price the individual and the community can afford.”

In 2012, at the request of the WHO, the International Association for Hospice and Palliative Care (IAHPC) led an expert group to develop a summary of the evidence available for essential medicines for palliative care. As a result of these recommendations, the WHO’s 18th Model List of Essential Medicines published in April 2013 contained a new section specific to palliative care, which included both immediate- and sustained-release morphine for the treatment of pain and listed hydromorphone and oxycodone as alternatives to morphine. The WHO’s 20th Model List of Essential Medicines published in March 2017 expanded the opioid medicines indicated to treat cancer pain to include transdermal fentanyl and methadone.

In addition to being medicines that are essential for relieving pain, opioids have a potential for being misused or abused, which can result in harms. Therefore, they are designated as controlled substances by an
international treaty, the Single Convention on Narcotic Drugs, 1961, as amended by the 1972 Protocol Amending the Single Convention on Narcotic Drugs, 1961 (Single Convention) (Fig. 16.1). The term narcotic drugs refers to a subset of controlled substances and is a legal term that will be used where the context requires. Nearly every government in the world has formally acceded to the Single Convention, thereby agreeing to adopt laws, regulations, and administrative procedures to carry out the dual aims of the Single Convention, which are to prevent the abuse and diversion of opioid medicines while making them available for medical purposes.

![The United Nations Single Convention on Narcotic Drugs, 1961, as amended by the 1972 Protocol Amending the Single Convention on Narcotic Drugs, 1961.](image)

The Single Convention establishes an international framework of prohibitions and requirements for governments concerning the legitimate production, manufacture, and distribution of narcotic drugs that is intended to prevent illicit trafficking, nonmedical use of narcotic drugs, and
diversion (the illegal movement of controlled medications from the licit distribution system into the illicit market). The principal international requirement is that the legitimate trade in narcotic drugs is regulated, including the cultivation of opium and manufacture of medicinal opioids such as codeine and morphine. To prevent diversion, an import–export system is established to limit trade to the amounts necessary for medical use; trade is regulated by the International Narcotics Control Board (INCB), an independent and quasi-judicial monitoring body to implement UN international drug control conventions.43

The Single Convention establishes several national obligations, among them that governments must regulate all entities that handle controlled substances. The goal is to create a closed distribution system, including security and record keeping. Only clinical professionals authorized under national law, using “medical prescriptions,” may prescribe and dispense controlled substances to individuals and only for medical purposes. Distribution outside of the regulated system is prohibited in order to prevent diversion of controlled drugs from medical to nonmedical uses. Efforts to prevent diversion should be balanced so as not to interfere in medical practice and patient care.4,10

Examples of efforts to lessen the risks of abuse and diversion include clinical training of health care professionals and students regarding appropriate pain management as a means to reduce inappropriate use.6,44–46 Some countries have provided informational sessions for health officials and drug regulators when policies were updated to facilitate their knowledge of the new legal requirements.45,46 Some areas of India47 and countries such as Sierra Leone48 and Uganda49 have successfully increased the availability of morphine without experiencing diversion and abuse of these medicines; such activities require sound security, record keeping, and prescriptive practices.

GOVERNMENTS MUST ENSURE ADEQUATE OPIOID AVAILABILITY

In addition to controlling drugs to prevent their diversion and nonmedical use, the Single Convention stipulates a second obligation to ensure adequate availability of narcotic drugs for medical and scientific purposes.
The Single Convention clearly recognizes the importance of narcotic drugs as analgesic medications and asserts that medical access to opioids for relief of pain is to be assured by governments because they are obligated to conform their laws to the Single Convention, “...the medical use of narcotic drugs continues to be indispensable for the relief of pain and suffering and that adequate provision must be made to ensure the availability of narcotic drugs for such purposes.”

The availability obligation is no less important than the obligation to prevent diversion, but it is poorly understood and implemented by health professionals and governments. There is no indication that the medical value of controlled substances is lessened as a result of scheduling under the Single Convention. Scholars of international narcotic drug policy have concluded that the Single Convention, as amended, recognizes that the basic purpose of international drug control is to reduce the availability of drugs for nonmedical purposes but “that this should not affect or limit their therapeutic use.”

The Single Convention establishes a critically important policy framework, the principle of balance, which asserts that governments’ obligation to control controlled medicines is not only to prevent drug abuse but also to ensure their availability for medical purposes. Controls aimed at preventing drug abuse and diversion must not prevent the adequate availability of opioid medicines for patients’ pain relief. Drug abuse controls that hinder opioid availability and patient access to effective pain treatment would be considered unbalanced and should be identified and corrected (Table 16.1).

<th>TABLE 16.1 The Central Principle of “Balance”</th>
</tr>
</thead>
<tbody>
<tr>
<td>The central principle of “balance” represents a dual obligation of governments to establish a system of control that ensures the adequate availability of controlled substances for medical and scientific purposes, while simultaneously preventing abuse, diversion and trafficking. Many controlled medicines are essential medicines and are absolutely necessary for the relief of pain, treatment of illness and the prevention of premature death.</td>
</tr>
<tr>
<td>To ensure the rational use of these medicines, governments should both enable and empower healthcare professionals to prescribe, dispense and administer them according to the individual medical needs of patients, ensuring that a sufficient supply is available to meet those needs. While misuse of controlled substances poses a risk to society, the system of control is not intended to be a barrier to their availability for medical and scientific purposes, nor interfere in their legitimate medical use for patient care.</td>
</tr>
</tbody>
</table>

812
To accomplish these dual objectives, the Single Convention requires that governments adopt laws, regulations, and administrative procedures to implement two specific mechanisms that are intended to ensure adequate availability of opioid medicines in countries while preventing nonmedical use. First, governments must annually establish an estimate of the amounts of opioids that will be required for all medical and scientific needs for the coming year.\textsuperscript{51} Licit trade in narcotic drugs can be lawfully conducted only within this amount. If imports exceed a country’s estimated requirements, exporters are obligated to refrain from further trade with the country, unless the INCB approves a supplementary estimate from the importing country that increases the estimated amount of the narcotic. Governments are encouraged to develop valid estimation methods, to establish estimates that take increasing demand into consideration, to cooperate with health professionals to obtain information about unmet needs, and to increase the estimate whenever necessary to always satisfy medical needs.\textsuperscript{51} Second, governments must report the amounts of each narcotic drug consumed (i.e., distributed to the retail level) to allow identification of consumption that either exceeds or falls short of the estimate.\textsuperscript{52}

Each Party to the Single Convention is expected to establish a drug control program not only to prevent illicit trafficking and diversion but also to ensure the adequate availability of narcotic drugs for medical and scientific purposes\textsuperscript{4} and to designate an agency called the Competent National Authority (CNA) to implement the functions required by the Single Convention.\textsuperscript{43} This office is usually located in the pharmaceutical department of the Ministry of Health, the national drug control, or public security agency, or the functions may be divided between agencies. The CNA is the principal national administrative authority for carrying out the estimation and statistical reporting procedures that are necessary for ensuring that opioid medicines are adequately available for medical and scientific purposes. Guidelines for estimating the amounts of opioids required for medical and scientific use and for reporting consumption
statistics are useful for those who want to understand the administrative procedures to be followed by CNAs. The INCB provides guidelines for CNAs to comply with the Single Convention, including the administration of effective mechanisms to ensure opioid availability.

Disparities in Opioid Consumption

The Single Convention requirement that national governments report annual consumption statistics provides a unique source of data to describe global and national opioid consumption trends and to study disparities. Consumption means the amounts of opioid medicines distributed for medical purposes to the “retail” level in a country (i.e., to those institutions and programs that are licensed to dispense to patients, such as hospitals, nursing homes, pharmacies, hospices, and palliative care programs). The INCB uses consumption statistics to (1) monitor compliance of governments with the provisions of the Single Convention, (2) identify trade discrepancies between importing and exporting countries, (3) detect imbalances between quantities of medications available and disposed within a country, (4) identify trends in the worldwide availability of opioids and other drugs for medical needs, and (5) monitor and maintain a global balance of supply and demand of opioids for medical and scientific needs.

Opioid consumption statistics have several useful applications for those who study and improve opioid availability to (1) identify whether a country has available opioids that can relieve moderate to severe pain, (2) learn whether the amounts indicate any substantial current consumption or progress over time, and (3) evaluate the outcome of efforts to improve opioid availability.

Consumption statistics provided in INCB reports have several limitations that should be considered when using them as an indicator of opioid availability:

1. In any given year, the data may be incomplete or invalid as a result of some governments reporting late, not reporting for a particular year or period, or submitting inaccurate data. These deficiencies may be corrected in subsequent years. Each year, the INCB publishes
updated statistics for the previous 4 years of data which reflect corrections to previous reports and data submitted after the deadline.

2. The INCB’s published reports do not include the exact amounts of consumption for quantities less than 1 kg. Instead, the symbol “<<” is used to signify that a country reported between 0 and 0.499 kg, and consumption amounts between 0.5 and 0.999 kg are rounded up to 1 kg.\(^{55}\) Knowing the exact amounts of small quantities of controlled medicines consumed is particularly important for countries with small populations or those which have recently initiated efforts to increase their consumption of controlled medicines for pain or other health care needs.

3. Consumption statistics are reported as one aggregate amount of controlled substance consumed. Therefore, they do not provide information about
   a. The proportion of the amount used for different clinical indications. For example, methadone is used to treat pain and dependence syndrome, and fentanyl is used for analgesia or anesthesia.
   b. The location where the controlled substances are being used, such as hospitals and hospices, or
   c. Which products or dosage forms of an opioid are available within a country (i.e., whether an opioid is in oral, parenteral, or transdermal form).

4. Consumption statistics are not a valid clinical indicator of the quality of pain control in a country.

   Each year for nearly two decades, the Pain & Policy Studies Group/WHO Collaborating Center for Policy and Communications in Cancer Care (PPSG/WHOCC) has received from the INCB consumption data for six principal opioids used to treat moderate to severe pain (fentanyl, hydromorphone, methadone, morphine, oxycodone, and pethidine). The PPSG/WHOCC has developed an in-house global database of opioid consumption statistics and provides these data on its Web site (Table 16.2).

**TABLE 16.2 Pain & Policy Studies Group/World Health**

**MORPHINE EQUIVALENCE METRIC**

For decades, the WHO has considered a country’s annual consumption of morphine to be an indicator of the extent that opioids are used to treat severe cancer pain and an index to evaluate improvements in the capacity for treating pain. However, additional opioid analgesic medications and formulations such as fentanyl, hydromorphone, and oxycodone have been introduced in global and national markets over the past 30 years, which should also be taken into consideration when studying opioid consumption in a country, region, and globally.

In an effort to compare morphine consumption with the consumption of other opioids, the PPSG/WHOCC developed a morphine equivalence (ME) metric for five principal opioids used to treat moderate to severe pain: fentanyl, hydromorphone, morphine, oxycodone, and pethidine. A total ME statistic combines consumption of those opioid medicines into one metric. The conversion values were based on standard units of measurement for presenting drug utilization statistics from the WHO Collaborating Centre for Drug Statistics Methodology in Oslo, Norway.
All ME statistics are adjusted for population, expressed in milligram per capita, allowing for cross-country or regional comparisons. These data are obtained directly from the INCB, thereby eliminating the small quantity limitation; however, the other limitations of opioid consumption statistics apply to the data expressed in the ME metric.

In a 2013 study, PPSG/WHOCC statistically examined the extent that morphine consumption reflected the aggregate consumption of all other opioids consumed on the global, regional and national levels, finding that over time, morphine has become less and less of a valid indicator of overall opioid consumption. Most recently, in 2014, PPSG/WHOCC conducted a descriptive analysis of opioid consumption trends, which is presented in the following section including the most recently available data from the INCB.

**GLOBAL OPIOID CONSUMPTION TRENDS**

The 35-year global opioid consumption trend ending in 2015 in Figure 16.2 shows that prior to 1986, morphine consumption was very low and stable throughout the world and was paralleled by total ME opioid consumption. After WHO announced its cancer pain relief three-step analgesic ladder in 1986 and encouraged use of oral morphine, morphine consumption began to increase with total ME consumption increasing more rapidly and diverging from morphine use. With the emergence of additional opioid products and dosage forms in the mid-1990s, total ME opioid consumption increased even more so that morphine use became less and less of a valid indicator of global opioid consumption. In 1986, global morphine consumption was 33% of total ME opioid consumption, compared to 12% in 2015. And yet, morphine has continued, until recently, to be designated by WHO as the primary essential medicine for the treatment of severe cancer pain. IAHPC included both immediate-release and sustained-release oral morphine in their recommended list of essential medicines for palliative care. Furthermore, several notable clinical guidelines continue to recommend morphine as one option for first-line treatment of severe cancer pain.
Since the late 1990s, fentanyl and oxycodone accounted for the greatest portion of opioid consumption, at least for the global aggregate data. The global total ME opioid consumption trend mirrors the trend lines for oxycodone and fentanyl, which have been increasingly consumed throughout the world. The increasing clinical use of opioids other than morphine is reflected in WHO’s recent expansion of their Model List of Essential Medicines to include oxycodone and hydromorphone as alternative opioid medicines for treating cancer pain\textsuperscript{40} and methadone and transdermal fentanyl for the treatment of cancer pain.\textsuperscript{41} Fentanyl is commonly used intravenously in the perioperative period which may account for some of its increase.

Another noteworthy trend is the long-term decline in consumption of pethidine (meperidine), likely due to increasing recognition of the potential risks associated with accumulation of the toxic metabolite norpethidine. Pethidine has been used in many countries mainly by injection for postoperative pain because of a perception that its very short duration of action reduces the risk of dependence. Pethidine is no longer recommended by the WHO for the treatment of pain,\textsuperscript{63,64} although it continues to be used. Programs that move away from pethidine should ensure that other suitable opioids are accessible; if pethidine is available, there should be no regulatory barrier to this transition, as pethidine and other opioids such as morphine are controlled in the same schedule and are typically subject to the same international and national controls.
DISPARITIES IN CONSUMPTION BY INCOME LEVEL

At the national and regional level, there are great disparities in the amount of morphine consumed between HICs and LMICs. The INCB has consistently reported that a small number of HICs consume most of the morphine in the world, whereas the remaining countries, which are composed of over 80% of the world’s population, consume a small fraction. A recent statistical analysis of opioid consumption over an 11-year period by the INCB found substantial increases over time and confirmed that HICs in North America, Oceania, and Europe accounted for the large increase in consumption, whereas LMICs experienced very little change in consumption levels.

Regional Opioid Consumption Trends

ME opioid consumption trends for each of the six WHO geographic regions (Table 16.3) illustrate great variability in consumption in different parts of the world (Fig. 16.3), notably that opioid consumption tends to be significantly lower in regions predominantly composed of LMICs and higher in regions with many HICs. Throughout the 35-year period, the WHO region of the Americas (AMRO) had the highest consumption of all regions and was substantially higher than the global ME consumption. In 2015, AMRO ME consumption was more than 4 times higher than the global mean consumption (43.5 mg per capita). The WHO region for Europe (EURO) had the next highest consumption, which also consistently exceeded the global ME consumption over the years, followed by the Western Pacific region (WPRO), whose ME opioid consumption was lower than EURO but considerably higher than the other three WHO regions (EMRO, AFRO, and SEARO), likely due to the influence of the HICs in the region. The remaining three WHO regions (EMRO, AFRO, and SEARO) had substantially lower ME opioid consumption than the global mean throughout the period, and in 2015, their ME consumption represented 5%, 3%, and 1% of the global mean ME consumption, respectively.

FIGURE 16.3 Global and World Health Organization regional annual total opioid consumption in morphine equivalence (ME) (milligram per capita). AFRO, Africa Regional Office; AMRO, America Regional Office; EMRO, Eastern Mediterranean Regional Office; EURO, Europe Regional Office; SEARO, Southeast Asia Regional Office; WPRO, Western Pacific Regional Office.

Examining ME opioid consumption trends within each WHO region provides information about which opioids were available for the treatment
of pain throughout the 35-year period.

WORLD HEALTH ORGANIZATION REGION FOR AFRICA (AFRO)

From the early 1980s to the late 2000s, the total ME consumption trend in the AFRO was largely composed of morphine and pethidine consumption with some minimal contributions of fentanyl and oxycodone (Fig. 16.4). Beginning in 2008, fentanyl ME consumption began to increase surpassing pethidine consumption. Following a spike in 2010, fentanyl ME consumption decreased but still remained higher than ME pethidine consumption.

![Opioid consumption in the World Health Organization Regional Office for Africa (AFRO), in morphine equivalence (ME) (milligram per capita).](image)

WORLD HEALTH ORGANIZATION REGION FOR THE AMERICAS (AMRO)

Prior to the mid-1990s, the total ME opioid consumption in the AMRO was composed of a somewhat equivalent contribution of all the individual opioid consumption trends (Fig. 16.5). Beginning in the late 1990s, there was a notable and consistent increase in oxycodone and fentanyl consumption, while at the same time, morphine consumption increased steadily, and hydromorphone consumption rose notably beginning in the early 2000s. It is likely that opioid consumption in HICs in North America
(e.g., Canada and the United States) primarily drives the regional consumption trend. Furthermore, as discussed earlier, the total ME consumption trend for the AMRO is the most similar to the global total ME opioid consumption trend. However, when considering the opioid medicines that individually contribute to the overall trend line, for AMRO, oxycodone consumption is the highest followed by fentanyl, and for the global trend, it is the opposite as fentanyl consumption is higher than oxycodone.

![Opioid consumption in the World Health Organization Regional Office for the Americas (AMRO), in morphine equivalence (ME) (milligram per capita).](image)

**WORLD HEALTH ORGANIZATION REGION FOR THE EASTERN MEDITERRANEAN (EMRO)**

For EMRO, the total ME opioid consumption has increased fairly consistently since the mid-1990s (Fig. 16.6). Of all the opioids included, fentanyl consumption has risen the most steadily, particularly since 2000 when it exceeded morphine consumption, whereas morphine consumption has seemingly leveled off for more than 20 years, with the exception of a temporary increase in 2014. Oxycodone consumption was low and stable but has slowly increased since 2000, with an upswing in use from 2008 to 2013. Prior to the 1990s, pethidine consumption represented the total ME trend line, but by 2003, fentanyl consumption surpassed it and generally continued to do so. Pethidine consumption, however, remained the second
largest contributor to this region’s overall ME opioid consumption until about 2010. Hydromorphone consumption was variable, but steady and relatively low, from 1980 to 1991, and then in recent years, it has begun to increase.

FIGURE 16.6 Opioid consumption in the World Health Organization Regional Office for the Eastern Mediterranean (EMRO), in morphine equivalence (ME) (milligram per capita).

WORLD HEALTH ORGANIZATION REGION FOR EUROPE (EURO)

In the EURO, composed of mostly HICs, total ME opioid consumption increased by the largest percentage between 1980 and 2015 as compared with other regions (see Fig. 16.3). Fentanyl consumption has contributed the most to the region’s total ME consumption since 2000 (Fig. 16.7). This substantial and steady increase in fentanyl consumption in EURO represented the highest consumption of that medicine for any region, accounting for 73% (90 mg per capita) of the total ME for EURO in 2015 with the next closest region of fentanyl use being AMRO at 26% (49 mg per capita) of that region’s total ME for 2015. This strong role of fentanyl in EURO further substantiates the prominent contribution of these countries to the global aggregate consumption. Morphine consumption has been steady since the mid-1990s and has been a distant second in overall contribution to EURO’s total ME consumption, until 2012 when oxycodone consumption surpassed it. Hydromorphone consumption has
steadily increased during the 35-year period but seems to be leveling off in recent years, whereas pethidine consumption has been consistent and quite low in this region.

**FIGURE 16.7** Opioid consumption in the World Health Organization Regional Office for Europe (EURO), in morphine equivalence (ME) (milligram per capita).

**WORLD HEALTH ORGANIZATION REGION FOR SOUTHEAST ASIA (SEARO)**

Unlike other regions for which the total ME consumption trend increased steadily throughout the 35-year period, the SEARO total ME trend (Fig. 16.8) has been quite irregular with many sharp temporary increases in consumption from the early 1980s until 1990, followed by a sharp decline in morphine and pethidine consumption (which had been the two largest contributors to total ME consumption). In 1990, morphine use dropped below pethidine and remained as such from 1990 to 2006, except for a few years when morphine and pethidine had relatively uniform usages. However, in 2007, morphine use increased substantially but returned to lower levels in 2008 and spiked again in 2014, sharply decreasing in 2015. Fentanyl use had been markedly stable since early 2000s when a very slow by steady increase was evidenced since 2009. As a result, fentanyl and morphine consumption equally contributed more to SEARO’s consumption pattern than the other opioids, with fentanyl consumption substantially higher than morphine in 2015 and pethidine consumption slightly declining over the years. Oxycodone and hydromorphone
consumption was very low and stable throughout the time period.

**WORLD HEALTH ORGANIZATION REGIONS FOR THE WESTERN PACIFIC (WPRO)**

As demonstrated in Figure 16.9, the total ME opioid consumption trend for WPRO has been generally increasing over time with a sharp increase beginning in the early 2000s, which appears to be leveling off in recent years. Since about 1999, the top contributor to the WPRO total ME has been fentanyl consumption. Morphine consumption was steadily increasing until the late 1990s but has been relatively constant since 2000. Both fentanyl and oxycodone consumption have exceeded morphine consumption around 2005 and 2009, respectively. Since 2000, fentanyl consumption has accounted for about half of the total ME, whereas in recent years, oxycodone has contributed to a quarter of the overall trend. Pethidine and hydromorphone consumption have been low and stable throughout the 35-year period.
Barriers to Opioid Availability and Accessibility

A number of factors, or barriers, contribute to the inadequate availability and accessibility of opioid medicines which is reflected in low consumption statistics in most of the world. The presence and severity of these barriers varies from country to country. Over the years, a number of barriers to opioid availability and accessibility have been identified through surveys of both government representatives and health care professionals. Because national laws govern the import, manufacture, and use of controlled substances, including controlled opioid medicines, it is critical to know how government drug regulators perceive the issues relating to opioid availability. In 1995, in consultation with the WHO, the INCB conducted their first survey of national governments about impediments to opioid availability in their countries. In 2014, the INCB again surveyed governments about impediments to opioid availability and found that there were some changes since 1995 in the frequency that particular impediments to opioid availability were identified. The barriers in Table 16.4 are listed in the order of how many governments identified them, with those listed first being the most frequently identified.

| Table 16.4 Barriers to Availability of Opioid Medicines as Identified by the 1995 and 2014 International Narcotics Control | 827 |
Surveys of health care professionals and, in particular, those with expertise in palliative care have identified very similar barriers as reported by governments to the INCB. A 2006 survey of health care professionals and hospice/palliative care staff from Asia, Africa, and Latin America identified the following barriers to accessing oral morphine: (1) excessively strict national laws and regulations; (2) fear of addiction, tolerance, or side effects; (3) poorly developed health care systems and supply of morphine; and (4) lack of knowledge about pain control and use of morphine on the part of health care professionals, the public, and policy makers.65

Another survey of palliative care professionals in 40 countries throughout the world found that there were very limited educational opportunities for health care professionals, 33 of the countries had restrictive regulations on morphine prescribing and nearly half of respondents said that health care professionals have fears of patients
developing dependence syndrome or respiratory depression when taking opioids.\textsuperscript{66}

The Global Opioid Policy Initiative (GOPI) conducted a survey of practicing palliative care or cancer clinicians in 2011 with responses from 104 countries and states,\textsuperscript{67} identifying across-the-board insufficiencies in formulary availability of opioids and regulatory restrictions likely limiting appropriate medical opioid consumption in Africa,\textsuperscript{68} Asia,\textsuperscript{69} India,\textsuperscript{70} Latin America and the Caribbean,\textsuperscript{71} and the Middle East.\textsuperscript{72}

In recent years, some analyses of the barriers have focused on legal and regulatory policies that have the potential to impede adequate access to opioid medicines. One initiative, the Access to Opioid Medication in Europe (ATOME) project,\textsuperscript{73} reviewed relevant national legislation in 11 Eastern and Central European countries to identify legal and regulatory barriers to opioid access. Results of the review indicated that each of the study countries had several potential barriers in the evaluated policies, such as restrictions on controlled medicine prescribing, dispensing, usage, trade and distribution, manufacturing, affordability, and penalties.\textsuperscript{74} Another project, led by the PPSG/WHOCC involved a systematic criteria-based evaluation of a selection of countries’ policies in Latin America\textsuperscript{75} identifying policy language that has the potential to impede opioid availability.

This chapter focuses on the opioid-related barriers involving health professionals, government drug regulatory policies, and medication distribution systems. The barriers are categorized into the following groups:

1. Knowledge and attitudes about pain, opioids, and dependence syndrome
2. Excessively strict laws or regulatory policies
3. Medication distribution system
4. Economic factors (including affordability)

Distinguishing one type of barrier from another is necessary to appropriately target efforts to address them. For example, it would be ineffective and a waste of resources to improve professional education as a solution to what in reality is a regulatory restriction or to work to change national law when its administration or the opioid medication distribution
system are the root cause of the problem.

**KNOWLEDGE AND ATTITUDES ABOUT PAIN, OPIOIDS, AND DEPENDENCE SYNDROME**

Incorrect or insufficient knowledge about pain, opioids, and addiction (i.e., now referred to as dependence syndrome in the 10th WHO International Classification of Diseases)\(^76\) often underlies beliefs or attitudes that are reflected in policy and the opioid distribution system, potentially acting as barriers to adequate availability or accessibility.

**Inadequate Education of Health Care Professionals**

The inadequate education of health care professionals was identified by governments who responded to the INCB surveys\(^4,6\) as well as two global surveys of palliative care professionals identified health care professionals’ lack of knowledge about pain control and use of morphine and limited training opportunities as significant barriers to adequate opioid access.\(^65,66\)

Many health care professionals do not have the necessary knowledge to appropriately assess and manage pain.\(^66,77–80\) Professional education programs often do not include training in current pain management practices, and therefore, clinicians may either be unwilling to care for patients with pain or lack the self-confidence to prescribe medications like morphine. If health care professionals do not understand the importance of pain management, they may be reluctant to treat pain or lack the confidence to prescribe strictly controlled medications like morphine. In a 2016 report focused on the accessibility of controlled substances for medical purposes, the INCB added that physicians with insufficient education and training on pain management will likely underestimate the extent that pain can be relieved with appropriate treatment.\(^6\) Indeed, given the major advances in knowledge regarding the treatment of pain, opioids, and dependence syndrome in the last few decades, it is likely that what health professionals and the public learned 30 years ago is now considered outdated and inaccurate.

**Concerns about Dependence Syndrome (Addiction)**

In 1995, the barrier identified most frequently by government authorities
in the INCB survey was concern about opioid-related dependence syndrome (referred to as addiction in the report), and in 2014, it was the second most identified impediment to opioid availability. Likewise, surveys of health care professionals have identified similar fears of addiction.

In the past, it was thought that mere exposure to morphine or other opioids would result in becoming addicted to it, and evidence of a withdrawal syndrome (a physiologic phenomenon expected from extended opioid use) was thought to be the primary characteristic of addiction. However, more recent research about the biopsychosocial mechanisms of dependence syndrome has led to official recognition that its diagnosis depends on the primary characteristics of compulsive behavior and continued use despite harm and not only on the presence of a withdrawal syndrome or analgesic tolerance. Evidence suggests that dependence syndrome, when defined correctly and diagnosed accurately, can occur but is not an expected result when opioids are used appropriately to relieve pain, especially when the patient has no history of substance abuse or is not experiencing psychosocial stressors. Despite this reality, misperceptions about dependence syndrome contribute to some health care professionals refusing to prescribe opioids and other controlled medicines, which impedes adequate treatment for individuals experiencing severe pain. Continuous efforts are needed to not only increase health care professionals’ awareness of the current definition of dependence syndrome but also appropriately apply the diagnostic criteria and, if necessary, treat or refer the patient.

Misinformation among health care professionals about the use of opioid medicines, morphine in particular, appears to stem in part from continued use of outdated knowledge and concepts about opioids and dependence syndrome, coupled with a vivid history of legitimate international concerns about developing a dependence syndrome to illicit opioids (such as opium and heroin), which led to the control of opioids as narcotic drugs.

In some cases, opioids are also legally referred to as dangerous drugs and toxic substances, designations that do not communicate their important medical aspects. The WHO recommends that such stigmatizing terminology should be avoided. Despite the WHO designating morphine
and other opioids as essential medicines for the relief of pain, misunderstandings persist about the risks as well as the benefits of opioid medicines.

**Concerns about Potential Side Effects**

There are many concerns about the use of opioid medicines and potential side effects because of the long-standing, widespread stigma associated with these medicines. For example, patients and families sometimes fear that managing pain with opioid medicines will result in side effects (e.g., constipation, sedation). Some people assume that the use of opioid medicines for pain means that death is imminent, and for those patients who are near the end of life, frequently, they believe that opioids will hasten death. However, evidence suggests that opioid analgesics do not hasten death, when administered appropriately, and that adequate pain relief can actually improve quality of life and survival.87–91

And yet, health care professionals should be aware that there is a real possibility of side effects related to treatment with opioid medicines which should be continuously monitored and addressed when needed. Side effects include constipation, sedation, and nausea as well as the potential for transient cognitive impairment, hyperalgesia, sexual dysfunction, changes in hormone levels, and immune system changes.35,36,85,92 Health care professionals should be knowledgeable about the potential for these side effects, discuss the benefits and risks of opioid analgesic treatment with the patient, and periodically assess for their possibility throughout treatment.93

**Health Care Professionals’ Fear of Prosecution or Sanction**

The WHO has recognized that health care professionals may be reluctant to prescribe or stock opioid medications when they fear loss of their professional license, or even criminal prosecution, if governmental bodies misunderstand or do not recognize the legitimate medical use of opioids to relieve pain.7 Such fears of prosecution or sanction were identified by the INCB surveys governments4,6 and surveys of health care professionals and attributed to ambiguous legislation, a lack of legal knowledge, and harsh penalties, which sometimes were for unintentional violations.66,74
Some national drug regulations limit the patients who are eligible to receive prescription opioid medicines based on their diagnosis; restrict the dose or the amount that can be prescribed at one time to very low, subtherapeutic quantities; and establish heavy fines and prison sentences for violations. It should be noted that health professionals also may not have accurate information about regulatory requirements, which can contribute to exaggerated concerns and doubts about prescribing opioids. When policy changes are made to improve the regulatory environment for medical use of controlled medicines, it is important that health professionals, law enforcement, and regulatory personnel be educated about clinical aspects of modern pain management as well as the policy changes.

EXCESSIVELY STRICT LAWS OR REGULATORY POLICIES

Clearly, governments’ main responsibility is to protect public health and safety, so it is reasonable and necessary for governments to take steps to prevent harms related to diversion and abuse of opioid medicines for nonmedical purposes. The WHO,7,9,10,94 the INCB,3–6 and UN member states through the Economic and Social Council (ECOSOC),12,95 Commission on Narcotic Drugs (CND),96,97 and the UN General Assembly98 have repeatedly recognized, however, that that some legislators and administrators have attempted to minimize drug abuse by enacting laws, regulations, and administrative policies that ultimately impede the legitimate availability of opioid medicines. Inadequate knowledge and negative attitudes about opioids often underlie overly restrictive drug control policies.

It is clear that some countries have gone beyond the minimum control measures required by the Single Convention and have established very stringent controls, especially in relation to drug prescription and distribution.1 These include complex prescription forms and prescription books that must be obtained from the government with considerable difficulty, restrictions that limit the diagnoses of eligible patients, limitations on prescription amount to a few days, limitations on daily dose, and elaborate licensing requirements for palliative care programs. In
countries with states, as in India and the United States, some states have enacted restrictive laws and regulations that interfere with opioid distribution and patient access to opioid pain medications. 99–101

The Single Convention clearly recognizes that governments have the right to regulate narcotic drugs more strictly than required by the Single Convention. 42 While recognizing that this is permissible, the 34th WHO Expert Committee on Drug Dependence (ECDD) said that governments should bear in mind that the aims of the Single Convention are to ensure availability for medical use as well as to prevent abuse. The ECDD called on national authorities to carefully consider whether “. . . any such measure currently in force could be modified to permit access for patients in need.” 94

Examples of regulatory barriers include the following:
• Complex prescription forms and prescription books that must be obtained from the government with considerable difficulty
• Restrictions that limit treatment based on the diagnoses of eligible patients
• Limitations on prescription amount to hours or a few days
• Severe limitations on the number of days that a prescription is valid until dispensed
• Elaborate licensing requirements for health care practitioners or palliative care programs

Table 16.5 provides specific country examples of regulatory requirements with the potential to impede pain management, many of which have since been amended.

**India**
Prior to 1998 regulatory changes, the national government required all palliative care programs to have a drug license to possess morphine, which would require employment of a pharmacist. Several states have amended their regulations to eliminate the previous requirement of import, export, and transport licenses to move medical morphine from one state to another. In 2014, India passed an amendment to the Narcotic Drugs and Psychotropic Substances Act, a central government policy, which streamlined the process of importing and exporting controlled medicines across state lines within India.

**Mexico**
Prior to 2015 law changes, Mexico’s general health law required that prescriptions for controlled medications carry barcoded stickers, which could only be issued by the health and sanitation authorities at one location in each state’s capitals.

**Uganda**
Prior to 2004, only physicians were allowed to prescribe morphine and other opioids. In 2004, the Ugandan government passed an amendment to the National Drug Policy and Authority Statute allowing specially trained palliative care nurses and clinical officers to prescribe morphine. This greatly expanded the number of health care professionals able to prescribe morphine and allowed Ugandans living in rural areas to have pain relief in their homes.

**Vietnam**
Prior to a new opioid prescribing regulation in 2008, opioids, such as morphine, could only be prescribed only by doctors working at government hospitals. Opioid prescriptions were not allowed on an outpatient basis, requiring patients to obtain medications in person.

**MEDICATION DISTRIBUTION SYSTEM BARRIERS**
In any country, opioid medications must first be approved and then procured by importation or domestic manufacture from narcotic raw materials or drugs seized by law enforcement. A system of government-regulated distributors then distributes to the retail level of pharmacies, hospitals, clinics, nursing homes, hospices, and palliative care programs, where registered health care professionals prescribe and dispense them to patients. The entire system of medication acquisition and disbursement is referred to as the medication distribution system. Figure 16.10 illustrates the key components of a medication distribution system. Common medication distribution system barriers that can interfere with patient access to opioid medicines include the following:

- Government has not made arrangements for the importation or domestic manufacture of procured opioids.
- There are delays in government decision making about procurement.
• Government’s official estimate of type and quantity of opioids required is insufficient.
• Government’s method for estimating opioid requirements does not take into consideration the actual needs.
• Manufacturers and distributors do not distribute opioids in a timely way.
• Number and geographical distribution of health professionals, pharmacies, and patient care facilities authorized to procure and dispense opioids to patients who need them are insufficient.
• Governments do not have the systems in place to guarantee a safe and effective transfer of medications from wholesalers to retailers.

![Medication Distribution System Model](image)

**FIGURE 16.10** Controlled medication distribution system model. PC, palliative care.

In some countries, opioid medicines are only available in certain locations, such as a cancer hospital or pharmacies in urban areas. Failure to distribute medications throughout the country can occur for a number of reasons: (1) low demand because of an insufficient number of prescribers and dispensers; (2) lack of reliable modes of transport; (3) lack of information about the need for opioid medicines, including in remote or rural areas; (4) lack of experience in making opioids available; and (5) high cost of medications, making them unaffordable.
In 1996, the WHO called on governments to ensure that opioids are available in locations that are accessible to as many cancer patients as possible. In 2011, the WHO emphasized that having a well-functioning system of procurement and distribution is part of a government’s obligation to ensure adequate availability and accessibility of controlled medicines.

Restrictions on where opioid medicines can be dispensed can pose a significant barrier to the adequate distribution of opioid medicines throughout a country. The 2011 GOPI survey of palliative care experts in several regions found that restrictions on where opioids can be dispensed were common among reporting countries in Africa, Asia, the Middle East, and India. In most cases, opioids could only be dispensed at hospital pharmacies in urban areas, and often times, these pharmacies were very difficult to access for patients and families who live far away.

**ECONOMIC FACTORS INCLUDING AFFORDABILITY**

Economic factors can also be barriers to the availability and accessibility of opioid medicines. The price of opioid analgesic products can be prohibitive when procuring these medicines, as well as when distributing them to the retail level, where they are dispensed to patients. In particular, the dispensed price of opioid analgesic medicines has been identified by international organizations and researchers as a barrier to opioid access. Comparative studies of HICs and LMICs have found that opioid costs relative to income was significantly higher in LMICs than in HICs.

The GOPI study found that certain formulations of opioid medicines were only available at a high cost for patients. Furthermore, the IAHPC Opioid Price Watch project identified that there is a disparity in the dispensed price between HICs and LMICs, finding that the dispensed price of immediate-release oral morphine (10 mg) was nearly 6 times higher and less affordable for patients in LMICs than in HICs. Similarly, 32% of the governments who responded to the 2014 INCB survey identified limited financial resources as a barrier to opioid availability, which can be very problematic when the prices of opioids are high.

In some cases, overly restrictive measures limit the availability and
accessibility of opioids for pain relief by affecting their affordability. Government-imposed controls and safety measures to minimize the potential for diversion can sometimes affect the dispensed price of opioids, making them more costly for patients.¹⁰⁷ For example, the WHO mentions licenses and registrations for opioids can be prohibitively costly and required safety measures for stocking opioids can be very expensive, preventing pharmacies from procuring them and stocking them.¹⁰

The cost of procuring opioid formulations can affect government procurement decisions. Immediate-release oral morphine is considered to be a better choice than sustained-release oral morphine as a first-line treatment for acute or cancer pain and is important for initial titration, especially for patients who have never had opioids.¹⁰⁹ At the same time, sustained-release formulations are more costly than immediate-release formulations. Despite this, immediate-release oral morphine is often not available in LMICs, whereas sustained-release oral morphine is typically more widely available. In fact, in some countries, sustained-release oral morphine is being made available prior to, or instead of, immediate-release oral morphine, which may act as a barrier to adequate pain relief.⁶⁷,¹⁰⁸,¹¹⁰

In 2012, the global pain and palliative care community released the Morphine Manifesto calling for governments to ensure the affordable availability of immediate-release oral morphine in advance of sustained-release morphine and other more costly opioids.¹¹¹ It is important to consider what other opioid analgesic medicines and formulations are available, rather than considering efficacy or cost alone, to facilitate the best practice for pain management and palliative care.

Therefore, the WHO recommends that countries examine the extent that their control and safety measures are affecting the price of opioid medicines and consider whether the control measures are proportional to the actual risk of diversion. If necessary, countries should work to address any identified barriers.¹⁰

United Nations’ Recommendations

A brief historical review of the recommendations of UN bodies shows they have made a number of useful observations and recommendations to
governments and health professionals, including that they should cooperate with each other to ensure adequate availability of opioids for medical purposes including pain relief throughout the world. Indeed, representatives of national governments, acting through their membership in UN bodies, such as the ECOSOC and its CND, and the WHA, have for a number of years called attention to the inadequate availability of opioids and have requested governments to evaluate their national drug control policies for impediments and to improve the availability of opioid medicines for medical purposes.

Beginning in 1989, a consultation between the INCB and the WHO Cancer Unit produced an authoritative recognition of the opioid availability problem and a strong recommendation that governments should act to evaluate their national laws. The INCB requested governments throughout the world to “examine the extent to which their health-care systems and laws and regulations permit the use of opiates for medical purposes, identify possible impediments to such use and develop plans of action to facilitate the supply and availability of opiates for all appropriate indications.”

In 1990, the WHO Expert Committee on Cancer Pain Relief and Active Supportive Care made a recommendation similar to that of the INCB, requesting that national governments should conduct a “regular review [of legislation], with the aim of permitting importation, manufacture, prescribing, stocking, dispensing and administration of opioids for medical reasons, . . . [and] review of the controls governing opioid use, with a view to simplification, so that drugs are available in the necessary quantities for legitimate use.”

In 1995, the INCB returned to the subject of opioid availability for pain relief and conducted a survey to determine whether governments had responded to its 1989 recommendations. The responses of the 65 responding governments were analyzed and published along with several pointed conclusions and recommendations including that “governments that have not done so should determine whether there are undue restrictions in national narcotics laws, regulations or administrative policies that impede prescribing, dispensing or needed treatment of patients with narcotic drugs, or their availability and distribution for such
purposes, and should make the necessary adjustments.” The INCB called specific attention to the role of health professionals, recommending that their organizations, including the International Association for the Study of Pain (IASP), teach students and practitioners about the medical use of opioids, their adequate control, and the correct use of terms related to dependence. The INCB further recommended that IASP and other nongovernmental organizations establish ongoing communication about national requirements, unmet medical needs, and impediments to availability with the CNAs in their countries. Such recommendations are consistent with the ethical responsibilities of physicians not only to comply with all laws and regulations but also to work toward changing them if they interfere in the practice of medicine and patient care.

One INCB recommendation in particular was to the WHO to develop “methods that can be used by government and nongovernment organizations to identify impediments to the appropriate medical availability of narcotic drugs.” Subsequently, the WHO revised its seminal publication Cancer Pain Relief to include a Guide to Opioid Availability and designated the PPSG as a WHO Collaborating Center (WHOCC), with terms of reference to develop methods to improve opioid availability.

In 2000, the WHO published a method for evaluating national policy, Achieving Balance in National Opioids Control Policy: Guidelines for Assessment. In coordination with the WHO, PPSG/WHOCC led the development and review of these guidelines which were also endorsed by the INCB. They constituted a consensus at the highest level of international health policy and drug regulation. In 2011, the WHO updated the guidelines, publishing a second and revised version, Ensuring Balance in National Policies on Controlled Substances: Guidance for Availability and Accessibility of Controlled Medicines. The updated guidelines are broader in scope than the first edition as they cover all controlled medicines, rather than solely focusing on opioid medicines. However, the focus of this chapter is on access to opioid medicines. The WHO guidelines are a central resource as they provide specific criteria to evaluate national policies, their administration, as well as the medication distribution system.
In 2005, the UN ECOSOC adopted a much more specific resolution about the treatment of pain using opioid medicines.\textsuperscript{12} It recognized that medical use of narcotic drugs is indispensable for the relief of pain and suffering, that low national consumption of opioids is a matter of great concern, and that opioids such as morphine should be available at all times in adequate amounts and appropriate dosage forms to relieve severe pain. A resolution by the WHA,\textsuperscript{115} Cancer Prevention and Control, in the same year called for the development of a funding mechanism to facilitate the actions necessary to improve the availability of opioids for the treatment of pain.

In 2010, the CND passed Resolution 53/4 entitled Promoting Adequate Availability of Internationally Controlled Licit Drugs for Medical and Scientific Purposes While Preventing Their Diversion and Abuse, calling on member states to take measures to establish a balanced drug control system through various measures including complying with INCB reporting requirements, removing overly restrictive barriers to medication availability, and educating and training health care professionals and patients on proper medication usage.\textsuperscript{96}

The following year, the CND adopted Resolution 54/6, which reiterated the same desired outcomes and also requested the United Nations Office on Drugs and Crime (UNODC) to assist in updating the Model Law on controlled substances as well as create a technical guide for members in the regional offices to help member states implement the Single Convention requirements in the least restrictive manner.\textsuperscript{97}

Also in 2011, the INCB again returned to the subject of opioid availability for pain relief making this the focus of a special report, entitled, Report of the International Narcotics Control Board on the Availability of Internationally Controlled Drugs: Ensuring Adequate Access for Medical and Scientific Purposes.\textsuperscript{5} INCB again recommended that governments identify undue restrictions in national laws and regulations and address them as necessary. Notably, INCB also called on governments to determine whether the laws and regulations included important language supporting the availability of and accessibility of opioids such as statements recognizing that they are indispensable for the relief of pain and suffering and that it is the government’s responsibility to
ensure that they are adequately available. In 2014, the WHA again demonstrated a commitment to pain management by adopting a palliative care resolution entitled, Strengthening of Palliative Care as a Component of Comprehensive Care Throughout the Life Course. Three of the Resolution’s seven recommendations for member states were to integrate palliative care into health care systems, to improve training for health care workers, and to ensure that relevant medicines, including strong pain medicines, are available to patients.

In 2016, the UN General Assembly held a Special Session on the World Drug Problem. At the conclusion of the General Assembly, UN member states adopted an outcome document that for the first time ever made a prominent and strong call for countries to ensure that controlled substances are adequately available for medical use. Controlled medicines are discussed under their own heading in the Outcome Document, expressing concern about the lack of their availability and calling on countries to take a variety of steps to address the issue, including reviewing policies.

Prior to the 2016 UN General Assembly Special Session on the World Drug Problem, the INCB again published a supplementary annual report focusing access to controlled substances for medical and scientific purposes. This report contained several recommendations from the INCB, reiterating the importance of evaluating policies and removing overly restrictive language when necessary.

Taken together, these findings and resolutions form an unmistakable and uncontroversial imperative from the highest level of international and national government health and regulatory authorities in the world that governments and health professionals should work together to identify and remove impediments to the adequate availability of opioids for medical purposes. Additionally, they represent significant momentum to raise the issue of medication availability at the global level and pave the way for concrete actions on the part of UN bodies and member states and other governments.

Efforts to Address Barriers and Improve Opioid
Availability and Accessibility

Throughout this chapter, we have explored the relationship between government policy and pain relief, learning how policy and governmental administration is supposed to function to achieve balanced drug control so that opioid medicines are adequately available for medical needs and patient care.

Following the many high-level resolutions, reports and statements made in the last several years by the INCB, the UN ECOSOC, and the UNODC, these bodies have taken action and developed initiatives directed at improving the availability of opioids for pain relief. For example, in the mid-2000s, the WHO developed the Access to Controlled Medications Programme (ACMP) in consultation with the INCB to improve legitimate access to all medications controlled under the international drug conventions. The ACMP’s goal was to address all barriers to obtaining controlled medicines for medical treatment including legislative and administrative procedures, as well as knowledge among policy makers, health care workers, patients, and their families. The ACMP facilitated the ATOME project, a collaborative project for improving access to opioid medicines in 12 Eastern and Central European countries. This project also included the revision and update of the WHO Guidelines on Balance in 2011.

Another example of joint INCB and WHO cooperation is the joint 2012 publication, Guide on Estimating Requirements for Substances Under International Control (the Estimate’s Guide), to assist governments in improving the methods and process used to calculate their national estimated requirements for controlled medicines. In particular, the Estimate’s Guide was designed to address the needs of countries with low consumption of controlled substances for medical purposes in an effort to improve their estimates to better reflect actual requirements. This publication, and the multiagency expert working group that drafted it, represent collaboration among international drug regulatory and health authorities. The INCB continues to offer support for governments in their use of the Estimate’s Guide and has held a number of regional workshops to assist CNAs in improving their method to calculate their estimated...
requirements. Another collaborative effort between international drug and public health authorities, which also included civil society is the partnership between the UNODC, the WHO, and the Union for International Cancer Control (an international nongovernmental organization) to provide an organizing mechanism for a global response to improving access to controlled medicines while preventing the potential for abuse and diversion. Ultimately, the goal of the joint global program is to increase the number of patients globally who are able to get the appropriate treatment for medical conditions, such as cancer pain. Supported by contributions from member states (e.g., Australia, Belgium, United States), this effort to date has included assistance to improve country-level activities such as data collection, regulatory revision and reform, training about estimates and statistics, procurement and distribution, and community-based health care.

Global and regional nongovernmental organizations focused on improving pain and palliative care have also led efforts to improve opioid availability. Over the years, several regional workshops to improve opioid availability have been held drawing together government and nongovernment stakeholders to guide the identification of barriers and develop an action plan. Some of these workshops were organized cooperatively by the PPSG/WHOCC, the WHO, and national and/or regional nongovernmental organizations that had an interest in relieving pain due to cancer and HIV/AIDS, whereas other workshops were organized and sponsored by other organizations, such as IAHPC or the African Palliative Care Association. These workshops typically have included carefully selected teams of health care and regulatory professionals from five or six countries, often including the CNA. Drawing together country teams from the same region has allowed for participants with cultural similarities and languages to learn together about the methods to improve opioid availability and the challenges and opportunities that often were similar in the region. These workshops culminated in the development of an action plan, which often has led to subsequent implementation of national projects to address barriers to opioid availability.
Similar to regional workshops, national or state workshops involving regulators, expert health care practitioners, and patient care programs have been held to initiate or continue the dialogue between government and health professionals to improve opioid availability for medical needs. Such workshops have been valuable opportunities to exchange information about pain management, palliative care, laws and regulations, and the need for opioids, which has led to increased awareness about the importance of opioid availability. Some national workshops have resulted in action plans that have led to significant changes.

Another important initiative to improve opioid availability at the national level is the International Pain Policy Fellowship (IPPF) program, developed by PPSG/WHOCC in the mid-2000s to expand leadership for improving opioid availability in more countries and increase the rate of positive changes. The goal of the IPPF is to empower motivated health professionals and policy makers from LMICs with the knowledge and skills necessary to identify and overcome barriers to the use of opioids for pain control and palliative care in their country, without sacrificing the security of the existing drug control system. To date, there have been four cohorts of Fellows, comprising 30 individuals from 25 countries, which represents about one-third of the world’s population (Table 16.6). The IPPF program has four components including a training program which involves developing an action plan, an in-country project to implement the plan, continuous mentorship from global experts, and an update and review meeting to share progress and challenges with other Fellows.

There are numerous examples of positive outcomes that have resulted from the Fellows’ efforts, working with government representatives, experts, PPSG/WHOCC staff, and colleagues both within and outside their countries. Several articles have been published describing Fellow’s in-country efforts to improve opioid availability and accessibility. These positive country-level outcomes, facilitated by the IPPF program, have likely contributed to increases in the very small amounts of opioids consumed prior to the IPPF. For example, in Serbia, total consumption of strong opioids increased more than twofold between 2006 and 2012, and from 2009 and 2014, the amount of immediate-release oral morphine sold to hospitals more than tripled. Furthermore, a recent study found that Serbia’s adequacy of opioid consumption increased by nearly 83% between 2006 and 2010.

After completing the IPPF, several Fellows have served as mentors to subsequent Fellows. Many have developed as leaders and experts on access to opioid medicines, published articles about their work, attended international meetings on forming policy,
and successfully advocated for positive changes in the laws and regulations in their countries.

**Conclusion**

Deepening disparities between HICs and LMICs in the extent of availability of opioid pain medicines means that pain and suffering in the world is an increasing public health problem. This is cause for alarm and should precipitate concerted action by health professionals, their organizations, and their governments. Actions should be guided by an understanding not only of the need for pain medicines but also of the barriers, the drug control policy framework, and how to work with government drug regulators.

However, health care professionals from any country are not likely to know about these topics because they have not generally been included in basic professional education or continuing education about pain and palliative care. The purpose of this chapter is to outline the body of knowledge, methods, and experience that is relevant to understanding and improving national opioid availability and patient access to pain medicines.

Although the body of knowledge about the control and availability of opioid medicines may not be well known, the process of working with individual countries to improve opioid availability borrows from a method with which health professionals are very familiar. The elements of the medical model can be applied to solving problems in opioid availability: evaluation, diagnosis, and a treatment plan. Indeed, health care professionals and governments within countries have worked together to diagnose opioid availability barriers and implement action plans to remove the barriers. More recent efforts to diagnose and treat barriers have been led by International Pain Policy Fellows in LMICs.

There are hopeful signs of progress in some countries, but it is not likely that this progress—which is still in an early developmental phase—is sufficient to gain on the deepening global disparities in access to pain relief medications. Greater leadership and sustained efforts are needed to continue to make policy and regulatory improvements to ultimately relieve
patient suffering. The increasing prevalence of NCDs in LMICs and reduced funding opportunities will likely continue to be challenges for years to come. Now more than ever, there is a critical need for support and action on the part of UN agencies, governments, and palliative care nongovernmental organization to work collaboratively to relieve this suffering.

Introduction

Pain, as every textbook will report, is a warning system designed to protect our bodies from injury. To do this well, we must be able to determine the site of pain, its intensity, its meaning, and how much it should bother us.

All pain has four dimensions:

- The sensory experience (what it feels like)
- The cognitive experience (what it means)
- The affective experience (how much it bothers you)
- Autonomic activation (rapid heart rate, elevated blood pressure)

When we ask people to rate their pain, most patients will understand this as a rating for the first dimension alone. This is of course what most clinicians are after and document. But, how can patients separate these dimensions to rate only one part?

The role of a pain assessment is to sort out the different contributors to each dimension and their relative importance in affecting the functional impact of pain in each individual. This assessment should then direct treatment recommendations for each individual.

Consider this scenario. On a particularly bad Friday, a physician discovers that he has been suspended from practice following a college
review. (He does not recall this review but opened the letter late on Friday, too late to call the college for details!) Distracted while driving home, he is involved in an accident and discovers his car insurance has lapsed. Distraught, he arrives home, in a taxi, and hears a family argument in the kitchen. Walking up the steps, he stubs his toe, and it bleeds. At that moment, his partner opens the door, notices the hopping behavior and the blood and asks, “Where would you rate your pain between 0 and 10?” The clinician, still hopping, shouts, “15 out of 10!!!!”

Later, in a calmer environment, he finds out his partner had renewed his auto insurance but had left the papers at home. On Monday, he finds out the college letter was meant to go another provider of the same name, and on Tuesday, he wins the local lottery, more than enough to retire on. That Friday, while walking up the steps of the theater to pick up the ceremonial lottery check, he again stubs his toe and it bleeds. His partner notices this and again asks, “Where would you rate your pain between 0 and 10?” The clinician, beaming, strides unbroken murmurs, “What pain?” and proceeds to center stage.

In both of these scenarios, the injury is both acute and identical, but the pain ratings are not. What then is the clinician rating?

He is rating primarily how much the pain bothered him, not what it meant or the stimulus intensity.

In a different scenario, a young women with a history of a slow growing tumor waits in the reception area for the results of her magnetic resonance imaging (MRI) to find out if her recent back pain is due to tumor recurrence. When completing the assessment forms that morning, she rated her back pain, then present for a month, at 8/10. One hour later, at the end of a consult which showed no recurrence of her tumor, she now rates her back pain at 4/10.

What was she rating? The sensory experience? Or perhaps the rating and the reduction more accurately reflected the cognitive component of the pain, what it meant to her.

Identifying each of these dimensions and the role they play in any individual’s total pain forms the basic “layers” of an initial chronic pain assessment. Each layer will have important contributors, and this chapter attempts to provide an outline to assist the clinician or team perform an
accurate and detailed assessment.

In addition to identifying each dimension of the pain experience, the clinician is expected to also identify the layers of each dimension. For example, with regard to the pain stimulus, research suggests that it is important not just to make a diagnosis but to identify individual pain mechanisms.

Is the pain of chronic knee arthritis nociceptive, neuropathic, centrally driven, or a combination?
Is the pain local, segmental, or regional or widespread?
Is the location of the pain due to abnormalities in the tissues, nerve terminals, nerve transmission, the dorsal root ganglion, dorsal horn, midbrain, cortex or forebrain, or several of these areas?

As a result of the location of the pain and the mechanisms involved, what does the patient report and what can we find on examination? Provoked or unprovoked pain? Muscle spasm, weakness, tremors, or reduced range of motion? Sensory changes of small fibers (changes to thermal stimuli or pinprick) or changes of central pain processing (widespread pain, light touch allostomy, cold hyperalgesia, or pressure alldynia.)?

Assessing for layers of the affective component of the pain means asking about adverse childhood events and current stressors and screening for anxiety, depression, posttraumatic stress disorder (PTSD), addiction, and others. Are patients having problems with motivation, insomnia, difficulties with memory, and focus?

Assessing for layers of the cognitive component means looking for pain beliefs. The two commonest beliefs to be assessed are the tendency to catastrophize and to experience fear of movement. Perceived injustice is another construct that seeks to look at the effect on an individual when he or she experiences chronic pain as a result of, or the perception of, another’s error or negligence. If these “cognitive distortions” are present, how have they affected the patient? Do they have limited coping skills, deconditioning, or other problems?

Creating an individual “layer cake” for each patient fosters a very different approach that removes the focus from the pain and provides an image of potential treatment opportunities (Figs. 17.1 and 17.2).
FIGURE 17.1 The multidimensional layers of chronic pain. Although this may identify the individual factors contributing to the overall pain experience, treatment will depend on the amount that each “layer” contributes to the loss of function. In certain patients, additional layers including the contribution of genetics or the role of additional diseases such as Parkinson will be relevant. (Image courtesy of Dr. Atul Khullar, 2013.)

FIGURE 17.2 Five examples of patients with chronic knee pain and pain scores of 8/10. Determining the degree of contribution of each factor contributing to pain would dictate very different treatment recommendations for each of these patients. (Image courtesy of Dr. Atul Khullar, 2013.)

In a traditional biologic model of pain, the pain is proportional to the tissue injury. In persistent pain, this linear relationship is often lost, and the patient may be labeled with pain out of proportion to physical findings. Under certain circumstances, this may be associated with malingering (a
legal not a medical diagnosis) or secondary gain, but for most patients, this simply represents a clinician’s inability to identify all of the layers contributing to the total pain.

The overall effect of persistent pain is a result of a complex interplay between the pain itself, other comorbidities, physical, psychiatric, and psychological as well as psychosocial factors such as support from significant others, financial factors, and job stability. Failure to identify and address these factors may lead to mutual frustration between the patient and the health care provider and poor therapeutic results.

For example, patients with kinesophobia fears moving because they believe the pain with movement is causing additional tissue damage. This leads to progressive physical deactivation and pain exacerbation with further loss of function. This can lead to feelings of unworthiness and poor self-esteem. If this affects their ability to work and leads to financial stress, this can exacerbate anxiety and depression. Compounding these issues, the medications themselves may be a cause of fatigue and debility.

In today’s health care environment, time to evaluate complex pain patients is limited. Where appropriate, this chapter suggests time-saving, self-assessment, nonproprietary questionnaires that can help a clinician to know where to perform a more detailed evaluation now or later.

Response to therapy should be gauged more by functional improvement than by a decrease in the pain score. The patient’s trust in the health care provider is important. Patients should feel that they have been listened to, their fears have been acknowledged, and the provider is “there for them.” People will forget what you said and forget what you did but never forget how you make them feel. This latter statement does not imply the practitioner has to feel the suffering of the patient. The practitioner should remain empathetic and compassionate to the patient’s issues while trying to remain emotionally resilient.

The examination of the patient presenting with the various specific persistent pain syndromes is not addressed in this chapter. These are described in the chapters allotted to those problems. This chapter addresses some of the practical problems of assessing the patient with persistent pain so that treatment can be individualized. Some tools are provided that may assist the clinician and are included as appendices.
The appendices include the following:
1. Example of an initial history questionnaire to be completed by the patient
2. Colored pain diagram
3. Goal setting information for the patient
4. Example of a follow-up progress questionnaire to be completed by the patient

GENERAL GUIDELINES FOR ASSESSMENT OF PERSISTENT PAIN

Guidelines summary
- Consider using the term persistent pain.
- Persistent pain is complex and needs devoted time for the initial assessment and plan.
- Initial and follow-up pain questionnaires are important.
- Having a significant other accompanying the patient can be invaluable.
- Identifying goals of therapy is a difficult but important part of the assessment.

The assessment and treatment of a patient with ongoing chronic pain begins with the recognition that a complete pain cure is unlikely. Consider changing the name of the problem to persistent pain, which may have less of a pejorative meaning to the patient. The best long-term results are achieved by utilizing approaches that involve both the available community resources as well as the patient becoming more engaged in his or her own therapy. Involvement by the patient in decision-making and goal setting is important. Improving the patient’s physical and mental functioning is the ultimate goal.

The time allotted to each patient depends on the type of practice. A pain specialist may allot 40 to 90 minutes to assess a new patient; the busy primary care practitioner may only have 15 to 20 minutes. Alternatively, the assessment can be divided, and information can be completed over several different visits.

An initial comprehensive questionnaire can be sent to the patient via the post or via an e-mail link prior to the consultation (see Appendix 17.1 as
an example). If using an online questionnaire that is returned via e-mail, care should be taken to ensure it fulfills the health privacy regulations of the country.

Asking the patient to arrive 20 to 30 minutes early prior to the initial appointment enables any relevant paperwork and insurance verification, if necessary, to take place. It also gives time for the patient to complete the questionnaire, if not already done; have their blood pressure, etc., taken; and have a urine specimen collected for toxicology screening, if appropriate.

A companion, preferably a significant other, should accompany the patient when possible for the initial evaluation and when optimizing or initiating new therapies. By having this individual sit at the patient’s side, much information can be gathered about the couple’s relationship by body language as well as by visual and verbal expression. The companion may also contradict, or confirm, whether a therapy is working, either verbally or by gesture. As much of the therapeutic discussion is often missed by the patient, no matter how attentive he or she appears to be, having a second person there listening may help.

Outline of a Multidimensional Assessment Questionnaire for Persistent Pain History

It is important to assess the following:

- The pain history
- Medical and surgical history
- Mood
- Psychosocial comorbidities
- Sleep
- Cognitive impairment
- Vocational history and current disability
- Habits
- Risk of opioid misuse, abuse, or dependence
- Function
- Current and past treatments
- Current and past medications and supplements
- Allergies
- Previous investigations and consultations
- Goals
- Physical examination

Questionnaires used should ideally be
- Validated
- Simple and rapid to complete
- Valuable in identifying the problem and best therapy
- Allow functional outcomes to be followed
- Able to show health care benefits across a system and “follow” the patient between specialties

Davidson et al.\textsuperscript{2} suggested that seven factors accounted for 59\% of the total variance in outcomes of pain treatment. These were pain and disability, pain description, affective distress, support, positive coping strategies, negative coping strategies, and activity. A pain assessment should try to capture most of these factors.

Different practices will require different levels of questionnaire. Solo practitioners may differ in their need to validate their role in a health care organization. Other considerations are whether the questionnaire is proprietary, meaning its use for research in large organizations or in digital format on the web will need to be licensed. In the examples discussed in this chapter, most questionnaires are nonproprietary or available to be used freely. Most questionnaires may be used for individual practices and in paper format without licensing, as long as they are not going to be used in publications.

The Patient-Reported Outcomes Measurement Information System (PROMIS) initiative was a National Institutes of Health (NIH)-funded program to develop new ways to measure patient-reported outcomes (PROs), such as pain, fatigue, physical functioning, emotional distress, and social role participation. PROMIS has also created a psychometrically robust computer adaptive testing (CAT) system based on item response theory (IRT) to administer these items. Whether administered through the CAT system, or by paper version short forms, PROMIS questionnaires have been validated and have shown equal or even improved in efficiency and sensitivity in comparison with existing PROs.
SUMMARY OF SOME NONPROPRIETARY QUESTIONNAIRES

Depression: (Patient Health Questionnaire [PHQ] 2, PHQ 9, PROMIS Short Form Emotional Distress–Depression)
Anxiety: (General Anxiety Disorder [GAD] 7, GAD 2, PROMIS Short Form Emotional Distress–Anxiety)
Sleep: (STOP-Bang for sleep apnea, difficulty falling asleep, difficulty staying asleep; URGES for restless leg syndrome; PROMIS Short Form Sleep)
Mood: Interference with enjoyment of life, PROMIS Short Form
Function: Brief Pain Inventory, PEG, Interference with general activity, STarT Back, PROMIS Short Forms of Physical function, Pain Interference, Fatigue, Pain Behavior, Applied Cognition–Abilities, Global Health
Substance abuse: Alcohol Use Disorders Identification Test (AUDIT), PROMIS Short Form Alcohol Use
Opioid abuse: Opioid Risk Tool (ORT)

OTHER POTENTIALLY USEFUL QUESTIONS TO CONSIDER FOR GAUGING EFFECTIVENESS OF THERAPY

Difficulty with a specific activity, chosen by the patient
Goal identification and follow-up

SUMMARY OF PROPRIETARY QUESTIONNAIRES TO CONSIDER

Pain Catastrophization Scale—pain catastrophizing
Tampa Scale of Kinesiophobia (TSK)—fear of movement
 Screener and Opioid Assessment for Patients with Pain (SOAPP14)
Current Opioid Misuse Measure (COMM)
Screening Instrument for Substance Abuse Potential (SISAP)^{3}
CAGE-AID—screening tool to assess for risk of serious alcohol or drug problems

The following format for documentation of an initial multidimensional pain assessment is suggested. It encompasses the various dimensions of pain and should facilitate communication with other members of the health care team.

An excellent summary of measures to assess psychological, physical, emotional functioning, and disability as well as attitudes, beliefs, and coping are discussed by Turk et al.\textsuperscript{4} 

**The Pain History**

The history of each pain condition provides important clues to the underlying etiology and the chronicity of each condition. It is important to document the etiologies of all the patient’s pain diagnoses. The mechanism, if known, date of onset, overall severity, and factors that worsen or improve pain should be noted. It can be formally done during an interview by having a patient-completed history form. For children, or patients with cognitive impairment, a caregiver should be present to provide additional information.

A pain diagram can often provide a “quick look” picture and, when colored ones are used, can help to determine potential areas of neuropathic pain (see Appendix 17.4 or Fig. 17.3 as examples).
Summary and suggested questionnaires
O = Onset
P = Provocative/palliative
Q = Quality/character (Does it have neuropathic features?)
Colored pain diagram
McGill Pain Questionnaire Short Form
R = Region/radiation
Body diagram with shading or colors
S = Severity/intensity
Numerical Rating Scale (NRS)
Graded Chronic Pain Rating Scale
T = Timing of pain (Continuous or intermittent?)

**O: ONSET OF PAIN**
How pain began is often informative. In many cases, the initial acute cause of the pain may identify an understandable etiology. In other cases, there may not be an obvious organic initiating cause. In these cases, the practitioner has to be careful not to automatically ascribe the pain to psychogenic causes but to accept the patient’s description.
**P: PROVOCATIVE/PALLIATIVE**

Assessing what provokes or relieves the pain provides valuable clues to the diagnosis and treatment. Leg and back pain due to spinal stenosis has a characteristic pattern of worsening with walking or standing, with the pain being totally relieved with sitting or lying for a short time. Neuropathic pain can present with spontaneous pain or pain provoked by different stimuli such as cold, light touch, or the brushing of bedsheets. It is often improved with heat and worsened by cold, the opposite of inflammatory pain.

**Q: QUALITY OR CHARACTER**

Neuropathic pain is often described as burning, deep aching, shock-like, or shooting. Other associated sensations include numbness, tingling, pins, and needles. Patients may describe unusual sensations like cold water running down a leg or the feeling that they are walking on marbles. Patients with neuropathic pain may also have associated autonomic nervous symptoms including sweating, skin color, and temperature. Changes in hair and nail growth or swelling may also be present. The latter may be intermittent and not evident on the day of examination. They may be documented by photographs, as many patients now have a smartphone with a digital camera.

There are several neuropathic pain questionnaires which assess self-reported symptoms such as dysesthesias, electric shock-like qualities, numbness, temperature sensitivity, and allodynia. As many nonneuropathic pain syndromes may elicit positive responses, Mathieson et al. comment that these tools “should not replace a thorough clinical assessment.”

**R: REGION/RADIATION**

The different sites of pain and radiation patterns can be visually represented by having the patient draw the pain on a pain diagram. Neuropathic characteristics can be represented at the same time by using symbols or colors such as red for burning, green for tingling, and blue for numbness. Specific drawings for the head and face can be used to capture headache and orofacial pain (Fig. 17.4).
The pain diagram of a patient with bilateral peripheral neuropathy.

**S: SEVERITY/INTENSITY OF PAIN**

The NRS is the most commonly used method as it is easy to administer. It has been shown to have a higher compliance and ease of use than the Visual Analog Scale (VAS). The scale is from 0 = no pain to 10 = worst pain imaginable or worst possible pain. In children and those with limited cognitive ability, the Faces Pain Scale should be considered. The time scale varies from the last 24 hours to the last week. The Graded Chronic Pain Scale which asks the worst, least, and average pain over the same period of time can give an idea of the patient’s overall burden of pain.

Many physicians have difficulty when patients rate their pain score with a number that seems to be at odds with their demeanor and functionality. Acknowledging to the patient that you believe he or she must have significant pain and then offering further anchors to the scale often results in a different rating that may be more meaningful in follow-up. The following script may be helpful to consider in a patient who has rated the pain as 15/10:

“I believe you have pain that is severe, and it is obviously very
distressing to you, but I am not quite sure how to interpret your rating because I do need a number between 0 and 10. If I say 0 means absolutely no pain and 10 out of 10 pain would be severe burns to most of your body or the pain you would feel if your hand was caught in a meat grinder, where would you rate your pain?"

A patient who initially described the pain as 15/10 will often adjust the rating when belief, acknowledgment, and new anchors are provided. Remember, not all patients are able to separate the pain intensity from how much it bothers them and what it means.

**T: TIMING OF PAIN**
The timing of pain can provide diagnostic clues to pain etiology. Neuropathic pain is often spontaneous. Patients report episodes of severe pain without any provocation, although nociceptive pain, such as osteoarthritis of the hip, is usually not severe unless provoked by use. The typical timing of cluster headaches differentiates it from the ice-pick headache. The intermittent nature of trigeminal neuralgia would differentiate it from atypical facial pain.

**ALTERED PERCEPTION**
Many patients with persistent pain experience altered body perceptions. Hemi-attention (to both the affected, especially left-sided, body parts with associated mood change like depression) and hemi-neglect have been described in patients with some chronic musculoskeletal pain such as chronic low back pain and after limb amputation.7

Patients with complex regional pain syndrome (CRPS) may have subtle motor abnormalities. They may volunteer weakness but not mention tremor, dystonia, or motor incoordination unless specifically asked. They often have body perceptual distortions which are often not spontaneously reported. CRPS patients may feel like the affected limb does not belong to them and may want to amputate it because it feels alien. Ask how they feel emotionally about their limb, if it feels alien to them, and how aware they are of the physical position of the affected part. Consider asking them to close their eyes and describe how each affected part feels to them and draw it. In an affected foot, the calf may feel normal, but the foot feels
larger and the toes may not be distinct compared to the other side.

Questionnaires to consider: Widely used multiple-item questionnaires with a high reliability and validity include the McGill Pain questionnaire which has two validated short forms. These yield subscales which can assist in distinguishing between different types of clinical pain.8

Past Medical and Surgical History

Past medical conditions should be noted that could be an important cause of current or potential pain conditions (multiple sclerosis, prior cancer diagnoses, diabetes). The past surgical history should be obtained when relevant. Visceral dysfunctions such as renal or hepatic compromise or short gut syndrome that could affect absorption or metabolic function have an important role when considering pharmacologic treatments.

Dementia, depending on the severity, may affect how the pain is assessed and is discussed in a different chapter.

MOOD ASSESSMENT

The psychological state of the individual with chronic pain is an important determinant of pain, disability, and coping. The pain itself can lead to an altered psychological state, but previous traumatic psychological events can also alter pain perception. The goal of the initial assessment is not to clearly define all psychological risk factors, mood disorders, or coping strategies but to get a sense of areas of concern, so that they can be more fully evaluated in the future.

Summary with potential questionnaires

- Anxiety
  - GAD 7, GAD 2
  - PROMIS Short Form
- Depression
  - PHQ 9, PHQ 2
  - PROMIS Short Form
- PTSD
  - PTSD Civilian
- Bipolar disorder
Mood Disorder Questionnaire (MDQ)

Anxiety and depression are common and may decrease the patient’s tolerance to pain and reduce the coping ability. Major depression, anxiety disorders, PTSD, bipolar disorder, and suicidal ideation and plan should be identified and referred to the appropriate specialist.

A history of childhood traumatic events predicts an increased risk for the development of substance abuse, depressive disorders, and attempted suicides. Chronic pain creates an additional risk factor. Asking about childhood trauma can be difficult, especially in an initial interview, and the following question is suggested. “If you have a child, or imagine that you might, would you want them to have the same childhood you did?” Negative answers can be explored at a later time.

It is helpful to ask about current psychological states tactfully because many patients are sensitive to the idea that their pain, particularly pain that seems out of proportion to observable findings, is all in their head and become quite defensive when asked about how they are feeling. If the patient has completed a questionnaire, you should already know something about the mood and the way the patient thinks about the pain and coping strategies. You can use the patient’s answers to gently probe for more information. For example, “I see on this one questionnaire that you feel down or depressed most of the days. Can you tell me about that?”

PSYCHOSOCIAL FACTORS

Psychosocial factors are important variables in the comprehensive assessment of persistent pain. Numerous relevant factors have been described, and there are multiple assessment tools and measures to evaluate them.

Summary with potential questionnaires

- Pain catastrophizing
  - Pain Catastrophizing Scale (PCS)
  - Modified STarT Back tool
- Fear avoidance
  - TSK
  - Fear-Avoidance Belief Questionnaire
- Perceived injustice
Injustice Experience Questionnaire (IEQ)

Two key ways of thinking about pain that impact functionality include pain catastrophizing and kinesophobia or health-related anxiety.

Pain catastrophizing is defined as “an exaggerated negative mental set, brought to bear during actual or anticipated painful experience.”

Catastrophic thinking might contribute to the development or maintenance of anxiety, fear, or depression associated with pain. Life traumas such as major losses, severe accidents, and abuse experiences may sensitize individuals to distress reactions to future stressors.

Those who catastrophically misinterpret innocuous bodily sensations, including pain, are more likely to become fearful of pain. This may result in avoidance behaviors and the avoidance of movement and physical activity in particular.

Kinesophobia is defined as “an irrational and debilitating fear of physical movement and activity resulting from a feeling of vulnerability to painful injury or re-injury.” The TSK measures the belief that painful activity will result in damage and/or will increase suffering and/or functional loss. Avoidance also means withdrawal from rewarding activities such as work, leisure, and family.

Pain-related fear is associated with increased bodily awareness and pain hypervigilance. Hypervigilance, fear, and disuse are associated with increased pain levels and often interfere with successful completion of an active rehabilitation program and return to work programs.

Some patients who experience chronic pain as a result of, or the perception of, another’s error or negligence may suffer from the perception of injustice. This has been described as an appraisal cognition comprising elements of the severity of loss consequent to injury, blame, a sense of unfairness, and irreparability of loss. In a prospective study of individuals with mixed musculoskeletal pain, Sullivan et al. demonstrated that high scores on this measure predicted work disability at 1-year follow-up, even when controlled for depression, pain-related fear, catastrophizing, and pain severity.

Other psychosocial factors that may contribute to pain include the influence of others, for example, a spouse that is distant or even over solicitous; lack of family and/or community support; litigation issues;
previous sexual or physical abuse; financial security; and status of health care coverage.

**COPING STRATEGIES**
Of the seven factors that predicted most of the pain-related disability, Davidson et al.\(^2\) identified positive and negative coping strategies as being important.

Asking patients what coping strategies they use can help to identify their coping strengths and opportunities for future treatment strategies.

Some positive coping strategies include the following:
- Pacing
- Prioritizing and day planning
- Setting self-motivated goals and action plans
- Being patient and accepting small achievements over time
- Using relaxation skills such as reading, listening to music, meeting friends for coffee/tea or other social activity, practicing breathing, meditation skills, or walking
- Stretching and exercising regularly
- Keeping a diary to document progress
- Having a plan for when the pain flares

If available, a referral to a clinical psychologist specializing in pain should be made, especially if one or more of the following factors have been identified: pronounced emotional disturbance; pain behavior enabled by the family, possible secondary gain; failure to respond to several treatment modalities; reports of pain severity or functional impairment which seem inconsistent with disability; or excessive use of health care services.

**SLEEP DISORDERS**
The relationship between pain and sleep dysfunction can be complex, and up to 60% of patients with chronic pain report sleep disturbance.\(^3\) Most patients report that sleep is interrupted due to pain, many develop unhealthy sleep patterns, and up to 70% of patients with insomnia have chronic pain.\(^4\) A night continually interrupted by pain rather than reduced sleeping time may impair the endogenous pain-inhibitory function creating
spontaneous pain.\textsuperscript{15}  

Summary with potential questionnaires

- PROMIS Sleep Disturbance (four-, six-, or eight-question version items)
- PROMIS Sleep-Related Impairment (nine items) (measures the effects of poor sleep on daily function)
- STOP-Bang (for obstructive sleep apnea)

A sleep history should identify the type of sleep difficulty (getting to sleep or staying asleep); document the patient’s current sleep hygiene; and screen for possible sleep apnea, restless leg syndrome, and periodic limb movements. Patients may be unaware of either the leg jerking or apneic episodes but have associated partial awakenings that impair sleep and cause daytime fatigue. Bed partners may be able to give important information regarding leg jerking movements and apneic spells during the night. If they do not have a bed partner, overnight oximetry or a more formal sleep study may be necessary to make a diagnosis.

Patients with PTSD may have nightmares and flashbacks and often require specific therapies to ensure a restful sleep.

**COGNITIVE IMPAIRMENT**

Cognitive impairment in individuals with chronic pain has been widely described, and many patients report it has a marked effect on their quality of life. The relationship is not straightforward as pain can cause cognitive impairment, but increasing non–pain-related cognitive load (i.e., distraction) can reduce perceived pain.\textsuperscript{16}

One study of a multidisciplinary pain center population demonstrated 20% of patients underperformed on tests measuring working memory, verbal learning and memory, psychomotor speed, and attention.\textsuperscript{17}

Persistent pain moderately affects working memory in a consistent and significant manner and causes deficits in attentional control. Attention, which is linked closely with working memory, allows the brain to select the relevant inputs for storage and processing into working memory.\textsuperscript{18}

Many patients complain that pain is distracting.

Modeling the underlying causes of cognitive impairment in individuals with chronic pain has identified a few possibilities including pain
competing for attention in a brain with limited resources, neuroplasticity, and dysregulated neurochemistry. The effects of comorbid disease such as Parkinson and affective disorders such as anxiety or depression and the effects of age, sleep disturbance, and medication all play a role.

Medication has been shown to both increase and reduce cognitive impairment, the latter possibly due to the effects of tolerance to side effects and pain reduction.

Confirming cognitive impairment is an important element of the pain evaluation, but a detailed evaluation is better done by a qualified psychologist as there are many methodologic issues to consider including the exact nature of the deficits, comparison of objective and subjective complaints, control for effort, and covariates including pain severity, depression, and fatigue at the time of testing.

VOCATIONAL HISTORY AND CURRENT VOCATIONAL DISABILITY
A brief history of the patient’s schooling, vocational training, and recent employment or disability status should be obtained.

In 2009, a working group identified seven core factors affecting return to work in men with chronic low back pain where each of the core factors were at least supported by one review. The seven core factors were (1) heavy physical demands, (2) ability to modify work, (3) job stress, (4) social support, (5) job satisfaction, (6) return to work expectation, and (7) fear of reinjury. Although job satisfaction is often assumed to be highly predictive, a study of 574 individuals with chronic low back pain reported that a high expectation of return to work was the strongest predictor of return to work and high levels of job satisfaction was not predictive.

HABITS
Always ask about smoking history because this is something the patient has the choice to decide to quit, even though it is very difficult.

Also inquire about past attempts at quitting, alcohol use, diet, exercise, weight changes, the use of cannabis, and other nonprescribed or illicit drug use.
Risk of Opioid Misuse, Abuse, or Dependence

Opioid dependence exists as a spectrum disorder and can complicate the management of a patient with persistent pain. It is important to screen for opioid misuse and abuse and to reevaluate for all of these problems in each follow-up visit for patients who take these and other controlled substances.

There are several questionnaires that can screen for the risk of aberrant behaviors that may occur with opioid use or assess the risk of addiction to alcohol or other substances or behaviors.\textsuperscript{20}

Summary with potential questionnaires

- AUDIT
- SISAP
- PROMIS Short Form Alcohol Use
- CAGE-AID, screening tool to assess for risk of serious alcohol or drug problems
- ORT
- SOAPP14
- COMM

Urine toxicology testing can be done as a point-of-care test with the results available in as early as 5 minutes. This allows a discussion about potential aberrant results, either positive or negative, to be held at the time of the appointment. If no obvious explanation is forthcoming, without any accusation, the urine should be sent for more sensitive and specific laboratory confirmation. There are many medications that may give false positives on a clinic test, so laboratory confirmation and, if necessary, discussion with a forensic pathologist are important before potentially accusing the patient of aberrant behavior.

If available, a review of the local prescription monitoring program or pharmacy printout, to assess previous prescriptions of scheduled medications such as opioids and benzodiazepines, is important.

The prescription drug monitoring programs (PDMPs) are electronic databases run by all individual states in the United States except Missouri. They collect data entered by pharmacists on dispensed controlled medications. The data is housed by a specified statewide regulatory, administrative, or law enforcement agency.

The benefit is that they allow health care providers see patients’
prescribing histories which may influence their prescribing decisions. Unfortunately, as yet, there is no conformity among states on the time to enter data after the prescription has been filled. This ranges from monthly to daily or even in “real time”; that is, under 5 minutes. Timely data should maximize the utility of the prescription history data, with significant implications for patient safety and public health.

Partly because of poor utilization, some states have implemented policies that require providers to check a state PDMP prior to prescribing certain controlled substances. PDMPs can also be used to send “proactive” reports to authorized users to protect patients at the highest risk and identify inappropriate prescribing trends. One study reported on sending prescribers unsolicited reports about individuals on opioids who fulfil certain criteria such as multiple prescribers. Compared to a comparison group whose prescribers were not sent a report, the interventional group had significant decreases in number and dosage of opioids prescribed, number of pharmacies used, and number of prescribers visited.\(^{21}\)

States have taken a number of steps to make PDMPs easier to use and access. These include integrating PDMPs into electronic health record (EHR) systems, permitting physicians to delegate PDMP access to other allied health professionals in their office (e.g., physician assistants and nurse practitioners), and streamlining the process for providers to register with the PDMP. PDMPs are also used by state health departments to inform and evaluate interventions of perceived overprescribing of controlled substances. A 2017 study\(^{21}\) reported that states with a strong PDMP program, calculated using legal data compiled by the Prescription Drug Abuse Policy System (PDAPS), together with other covariates such as laws that regulate pain clinics, access to naloxone, use of emergency services (Good Samaritan laws), and medical marijuana, had a significantly lower opioid overdose rate than states with a less robust program.\(^{22}\)

PDMPs are playing an important role in evaluating the prescribing of controlled substances both for the prescriber and the regulatory authorities. Given the other general recommendations for careful charting of function and mood, opioid agreements, and random urine toxicology screens, PDMPs give the health care provider another objective way of assessing
patients. The concern about opioid knowledge and too much regulation was addressed in a study by Hwang et al.\textsuperscript{22} in 2016. Their conclusion was that “although physicians are unaware of some facets of prescription opioid-related morbidity, most support a variety of clinical and regulatory interventions to improve the risk-benefit balance of these therapies.” Only a third of physicians contacted believed that interventions to reduce prescription opioid abuse would have a moderate or large effect on preventing patients’ clinically appropriate access to pain treatment.\textsuperscript{23}

Assessment and treatment of addiction is covered in a separate chapter.

\textbf{Assessment of Function}

It is important to assess the functional impact of persistent pain by trying to quantify an individual’s ability to engage in a number of different activity domains. Function is one domain measured in quality-of-life assessments, so most questionnaires have overlapping questions that measure some aspects of both.

Three kinds of self-assessment questionnaires have been developed: general questionnaires applicable to all kinds of pain like the EuroQol, which is short, six questions but has complex scoring and weighting, or the four-, six-, or eight-item PROMIS Measures of Physical Function; disease-specific ones like the Fibromyalgia Impact Questionnaire; and regional ones, for example, the Oswestry Disability Index for back pain.

The questions should cover all of the relevant areas and usually include the impact of pain on domains such as employment, social, recreational, family, or home responsibilities. It should assess self-care and ideally evaluate the overall quality of life.

\textbf{Summary of potential questionnaires}

\begin{itemize}
  \item General questionnaires
    \begin{itemize}
      \item Brief Pain Inventory
      \item PEG: measures three items, average pain, interference with enjoyment of life, and general activity
      \item STarT Back: includes catastrophizing questions, useful to assess for potential chronicity
      \item EuroQol
    \end{itemize}
\end{itemize}
• PROMIS Short Form Physical Function
• PROMIS Global Health
• Work Productivity and Activity Impairment Questionnaire

• Specific questionnaires (there are many—these are just a few)
  • Oswestry Disability Index: specific for back pain
  • Neck Disability Index: specific for the neck

It is not uncommon in clinical practice to see a patient in follow-up who declares the pain to be much better, yet a review of the functionality questionnaire indicates a higher score than the previous visit.

For instance, on the Brief Pain Inventory, patients may rate their leg pain at 8/10 and the pain interference for walking at 6/10 one week and a month later rate their leg pain less at 5/10 yet rate their pain interference for walking at 9/10.

This may be because they are walking less due to depression, are not paying attention to the weighing scale, or have forgotten how bad their pain used to be (recall bias).

But pain interference scales also suffer from something called response drift, which involves reprioritization, recalibration, and reconceptualization.

A patient can reprioritize his or her disabilities depending on the current circumstances. The main problem may have been headaches, and if the patient substantially improves, now the leg pain becomes the biggest issue and so not walking seems more impairing.

They may recalibrate it. In this case, a 5/10 one day is different than a 5/10 the next day. In the last month, the patient may have had a fracture dislocation of his left elbow and has now decided, that what he thought was 8/10 leg pain, he would now rate at 5/10.

When a patient reconceptualizes his or her disability, he or she has changed the internal concept of what disability due to leg function is. So, in this case, before, the patient felt disabled if he could not get to the bathroom, and now, he feels disabled if he can not get to the store.24

**Current and Past Treatments**

The initial questionnaire should allow the patient to list all the therapeutic
modalities he or she is currently using and ones used in the past. This includes interventions such as biofeedback, physiotherapy, chiropractic, massage therapy, anesthetic pain blocks, or surgeries. It is important to determine which ones the patient felt were useful and how long they decreased the pain as well as which were ineffective or produced intolerable side effects.

**CURRENT AND PAST MEDICATIONS INCLUDING OVER-THE-COUNTER MEDICATIONS**

A complete list of the patient’s present medication should be recorded and any changes documented at each follow-up. This is especially important if the patient is seeing other providers who are prescribing medications, as this poses an increased risk for unsuspected drug interactions. Inquire about other alternative therapists prescribing nonprescription medications, herbs, or supplements. These may interact with prescribed medications or create other side effects and should be documented (for more specific information, go to the Memorial Sloan-Kettering Cancer Centre Web site at [http://www.mskcc.org/about/herbs](http://www.mskcc.org/about/herbs)). A list of previous medications tried and the results should also be obtained.

**ALLERGIES**

Allergies or sensitivities to medications, contrast dye, or latex should be identified.

**INVESTIGATIONS AND CONSULTATIONS**

A list of previous investigations should be obtained with the relevant results. Prior or upcoming relevant consultations should be listed and the outcomes, if known.

**Goals**

Summary
- Should be patient-determined and patient-specific for time and activity
- Need to reassess treatment and comorbidities if the patient is not
Goal setting seeks to determine which specific social, recreational, or occupational tasks or roles are important to the patient. Motivational interviewing is a skill that a provider can use to enable the patient identify a goal and set an expected date for change.

Examples of tasks in these categories include going out to see a movie (social), walking (recreational), decreasing or stopping smoking (health related), or being able to lift heavy objects (occupational).

Occupational task or roles could include active participation as a church volunteer, mentoring a student (social), or soccer or baseball coach (recreational).

Determining appropriate goals is an important part of the pain assessment as it will help to direct treatment. People resist coercion, so when getting the patient to identify achievable goals, it is important to influence and not control. (See Appendix 17.3 as an example.)

Goals need to be measurable, for example, “to walk three blocks,” not “exercise more.” They should reflect the patient’s current abilities. Numbers can be used; if the patient states he or she is at a 3/10 on the way to stopping smoking, the question can be asked: “What would it take to get to a 6/10?” That answer can be used as a goal to discuss at the next visit. The patient should be encouraged to assess how confident he or she is in achieving the goal in the time line chosen.

If a patient cannot achieve his or her goals, the practitioner should reassess the goals made, find out what barriers prevented the patient from completing the goal, and assist in reframing the goal to something more achievable in the short term. The goal, however, should always be one that the patient identifies. Evaluation by a psychologist may provide some helpful insights when constructing or reevaluating goals.

If patient-identified goals are not met and the function does not improve, it is reasonable to assume the current treatment is not effective and should be changed. Documenting that a patient has achieved or exceeded goals, and has achieved an improvement in functional scores corroborates treatment efficacy and is rewarding to both patient and provider.

Physical Examination
The examination is usually a focused examination based on the patient’s history. The goal is to determine the etiology of the pain (if possible) and to determine, if appropriate, the presence or absence of neuropathic pain and physical signs of substance abuse or misuse. The following evaluation outline for a comprehensive physical examination is suggested.

GENERAL EXAM: OBSERVE, IDENTIFY AND DOCUMENT

Mental status: Consider a mini-mental status exam if there are concerns about cognitive impairment; comment on mood, displays of emotion, or evidence of impairment (slurred speech, difficulty remaining alert) and any smell of substance of abuse on breath, body, or clothes
General appearance (whether it matches photo ID may be appropriate to comment on depending on the specific situation)
Blood pressure, heart rate, weight, and height
Stance and gait
Mobilization aids (what, how, and why they are used)
Signs of substance abuse including needle marks on lower arm, leg, or bottom of feet; rhinorrhea; red palms; spider veins on chest; and pupil diameter
Evidence of any tremors, muscle atrophy, trophic changes, or deformities

SITE OF PAIN
Perform a focused examination of the musculoskeletal system.

Observe
Positional relief postures (i.e., avoids weight bearing on one buttock, turns body instead of neck, prefers to stand and lean) or behaviors (wearing sunglasses inside in patients with chronic migraine and photosensitivity)
Pain distraction signs (i.e., permanent heating pad or ice burn marks, excessive teeth wear from clenching or grinding)
General posture (i.e., head forward posture, exaggerated lumbar
lordosis
Alignment of spine, shoulders, pelvis, and legs
Symmetry: deformities, visible muscle spasm, atrophy, hypertrophy, scars, tattoos and birthmarks
Leg length asymmetry
Evidence of damage to the local myotome segment which includes denervation sensitivity of the local spinal segment resulting in trophedema. Trophedema is nonpitting edema to digital pressure, but if the end of a matchstick is pushed into the skin, it will form a clear-cut indentation that persists for several minutes.

**Palpate**
Tenderness, swelling, crepitus, contour or bogginess of joint, muscle, ligament, bursa, or bone
Trigger points or taut bands

**Test**
Individual joints for swelling, crepitus, redness, warmth, and range of motion (active/passive)
Muscle tone
Muscle strength
Specific maneuvers (i.e., the impingement test to assess the shoulder, or the flexion adduction internal rotation [FAIR] test of the hip to assess for sciatic nerve impingement by the piriformis muscle)

**NEUROLOGIC EXAM**
**Observe or Ask About**
Signs of sensory avoidance (specific clothing to avoid clothes brushing, wearing dark glasses in the examination room, poor oral hygiene in patients with mouth pain)
Skin lesions (i.e., scarring from varicella zoster, foot ulcers with diabetic neuropathy)
Swelling of the painful area (neurogenic edema): Ask if this occurs as in many patients this can be an intermittent feature. Measure limb diameter or water displacement if in an area that is difficult to
Changes in skin color: Ask if this occurs as in many patients this can be an intermittent feature. A photo by the patient can provide documentation of this signs.

Altered sweating: Ask about if not present.

Trophic changes: loss of hair, thinning skin, cracked dry skin, altered nails (Fig. 17.5)

![Image](image.png)

**FIGURE 17.5** Late complex regional pain syndrome causing trophic changes in the left 4th and 5th fingers. (Photo from the author’s (PS) private collection. Used with permission from the patient.)

Secondary changes associated with chronic peripheral neuropathy (e.g., Charcot neuropathic foot destruction with necrotic arthropathy and chronic ulcers on the plantar surface)

Evidence of autonomic dysfunction, especially with CRPS or peripheral diabetic polyneuropathy

Involuntary movements: tremors, myoclonus, tics, dystonia, fasciculation, or others

Specific tests (i.e., upper limb tension test (ULTT) for “neurogenic” thoracic outlet syndrome, straight leg raise for lumbar radiculopathy)

**Palpate**

Temperature differences between affected and unaffected areas

Edema, swelling, tenderness

**Test**
Cranial nerves
Gait
Balance and coordination; finger tapping, rapid alternating movements; finger–nose and heel–shin testing; Romberg test
Tone
Spasticity: eliciting the “clasp knife phenomenon,” which predominates in the upper limb flexors and the lower limb extensors
Rigidity: uniform resistance that worsened during the range of movement; usually worsens with distraction
Paratonia: increased resistance because the patient has difficulty consciously relaxing the muscle. This usually improves with distraction.
Hypotonia: decreased tone
Motor function (Tables 17.1 to 17.4)

**TABLE 17.4 Upper and Lower Motor Neuron Dysfunction**

**Signs of Upper Motor Neuron Dysfunction**

- Hyperreactive reflexes
- Spasticity
- Positive Babinski sign
- Positive pronator drift sign
- Weakness that is predominant in the arm extensors and leg flexors

**Signs of Lower Motor Neuron Dysfunction**

- Absent or hyporeactive reflexes
Pronator drift: With the patient standing with both arms extended and palms up (supinated), look for one arm to drift downward and begin to turn palm down (pronate). A positive test is a subtle indicator of upper motor neuron weakness (in which supination is weaker than pronation)
Perceptual dysfunction: neglect
This may be detected by testing for extinction or double simultaneous stimulation. Patients may detect a stimulus on the affected side when presented alone, but when stimuli are presented simultaneously on both sides, only the stimulus on the unaffected side may be detected. In a patient with suspected motor neglect, normal strength or range of movement may be present, but the patient does not move the painful limb unless attention is strongly directed toward it. These individuals may benefit from specific physical therapy techniques.
Perceptual distortions: Many patients with chronic pain experience perceptual disturbances of the affected body part. The body part may feel bigger, smaller, or just different than the normal body part. Different examination techniques to evaluate for these disturbances are now being reported in the literature, and the reader is referred to individual chapters in this book for more detailed information.

**BEDSIDE METHOD FOR QUANTITATIVE SENSORY TESTING**
In patients with suspected neuropathic pain, the Quantitative Sensory Testing (QST) can be used as part of a routine neurologic exam to define the extent and pattern of sensory abnormalities and to characterize the sensory changes. QST does not seek to determine pain thresholds but to measure subjective experience (loss or gain of sensation) in response to particular thermal, mechanical, or vibratory stimuli. It also seeks to provide, indirectly, information used to evaluate underlying sensory
function and abnormalities.  
1. Have the patient complete a pain diagram with pain descriptors to identify affected areas and direct the physical exam.
2. Begin by mapping out the area of abnormality. This is most rapidly done with a toothpick or a cotton swab starting in a normal area (based on the pain diagram) and progressing toward the abnormal area, marking the area of skin where the sensation changed and moving in a radial pattern from normal to abnormal until the area of sensory change has been identified.
3. Establish a control site where the patient has no sensory abnormalities or pain, preferably on the opposite side of the body in a similar position. Use this as a reference for normal sensation.
4. For each stimulus, start in the normal area and then move to the abnormal painful area and ask after applying the stimulus, “Do you feel this more, less, or the same as the normal side?” Patients may experience sensory gain to one kind of stimulus and loss to another in the same area.

Patients are examined for the following modalities.

**Light Touch**
Lightly brush the skin. This can be performed at the bedside with a cotton wisp, cotton wool tip, Q-tip, foam brush, or paint brush. Testing should start over the normal skin and move toward the affected area. Once the patient feels any change in sensation, the point on the skin is marked.

Drawing the area of abnormality on the skin can help to determine the pattern of loss (single nerve territory, polyneuropathy, or nondermatomal). If light touch is normal, it is still important to test for pinprick and temperature, as these tests evaluate different small fiber components of the nerve.

**Vibration**
Vibration sense is usually tested with a 128-Hz tuning fork. Test over the bony prominences moving from distal to proximal. In subjects with distal symmetric polyneuropathy, the tuning fork is placed over the interphalangeal joint of the big toe. If no vibration is noted, move to the
medial malleolus and repeat the exam. If still unable to sense vibration, the test is repeated over the patella. For the hands, test over the second distal interphalangeal joint and move proximally to the ulnar styloid and lateral epicondyle, if no vibration is felt.

**Punctate/Pinprick**
This can be evaluated with a cocktail toothpick or a more standardized device such as a NeuroPEN. A safety pin should be avoided because with insensate skin, the skin may be damaged, and the safety pin may be inadequately sterilized. The size and angle of the sharp tool can significantly affect the intensity of the stimulus. The NeuroPEN has a standardized probe tip and is designed to allow production of a consistent stimulus. Perform the testing in the area with the abnormal positive or negative sensations.

**Warm and Noxious Heat**
For bedside testing, thermal evaluation can be done by heating the round end of a tuning fork in warm or hot water. There are no commercially available small devices for standard bedside testing of warmth or heat pain. Unfortunately, it is difficult to get the tuning fork to the correct temperature for heat pain testing. This test is most useful to confirm the involvement of small fibers when evaluating small-fiber neuropathy. This most often occurs in a patient whose pain drawing suggests a peripheral neuropathy but in whom sensation to vibration and light touch is normal.

**Cool and Noxious Cold**
For cool testing, a tuning fork is held under cool water and applied to the area of altered skin sensation. For cold pain, the tuning fork is immersed in ice water. Comparison is made with the established control site. Have the patient report on the sensation. (Does it actually feel cool? In some patients, it feels paradoxically hot.)

**Grading the Tests**
**Reduced sensation:** Have the patient express the degree of loss by utilizing the simple 1-to-100 scale of a dollar. Ask, “If this is a dollar
(stimulating the normal area), then how much is this worth? (stimulating the area of sensory loss).” A response of 90 cents reflects a very different degree of loss than a reply of 10 cents.

**Increased sensation:** In the case of a sensation that should have been painful (pinprick, noxious heat, or cold), have the patient grade the pain in the normal area first (0 to 100) and then grade the abnormal area.

Record dysesthesia if the nonpainful stimulus was felt as increased but not painful and write a description of the sensation (e.g., numb, pins, and needles).

Record hyperalgesia if the stimulus was a normally painful stimulus (pinprick, heat, or cold pain), but it produced more pain than the unaffected normal test site, and grade the intensity (0 to 100).

Record allodynia if the stimulus was nonpainful (brush, vibration, warm, cool) and either the threshold was normal or decreased (stimulus intensity reported as the same or more than the normal site) and the patient reported pain from the stimulus and grade the intensity (0 to 100).

Record hyperpathia if the stimulus threshold is increased (stimulus intensity reported as less than the normal site) and the patient reports it as painful. For example, you place a warm tuning fork on the affected area and the patient initially reports no warm sensation (because the threshold for feeling warm is increased) but then over the next 10 seconds gradually reports first a warm sensation and then reports it as painfully hot and grade the intensity (0 to 100).

The physical examination for central sensitization is not straightforward because central sensitization is a neurophysiologic term that can only be determined when both the input and output of the neural system are known. Practically, this means being able to measure both the stimulus (easily done) and the neural event that occurs after the stimulus (not easily done). Central sensitization can therefore only be inferred (but not proven) from the following physical signs:

**Widened receptor field.** Manifesting as an area of pain much larger than anticipated and affecting areas that do not have specific pathology

**Wind-up.** Manifested by repetitive activation of primary afferent C fibers leading to a synaptic strengthening of nociceptive transmission and measured by performing summation testing with a NeuroPEN or similar
standardized device (see the following discussion)

**Reduced thresholds.** Caused by facilitation of non-nociceptive Ab fibers manifested as dynamic mechanical allodynia and nociceptive Ad fibers manifested as pinprick or cold hyperalgesia

**After pain.** Following pinprick testing or temporal summation, it is normal for the sharp sensation to linger for 1 to 2 seconds; however, patients with this condition often report that they can still feel the sensation for several seconds occasionally minutes, after the stimulus has ended.

Summation testing for the presence of central sensitization

With the NeuroPEN, apply 10 stimuli to a single location at a rate of 1 per second (rate is important).

Ask, “Does the sensation change as I continue to stimulate it?” If the patient answers

- Yes, ask if the sensation was both painful and increased with each stimulus:
  - Yes: Record as summation and rate the first and final stimulus and have the patient describe the sensation. It is normal for the stimulus to increase by 1 to 2 on a numerical pain score (i.e., the first stimulus is rated at 3 and the last is rated at 5/10). In patients with central sensitization, the first stimulus is often high at 6 to 7/10, and if the patient can tolerate all 10 stimuli, the last stimuli may be rated at 10/10.
  - No: Record as nonpainful summation.

Note: While testing, if the first stimulus was recorded as either decreased or absent but as the stimuli continue the sensation changes to painful, record as hyperpathia.

**CAVEATS TO QUANTITATIVE SENSORY TESTING INTERPRETATION**

Pain related to muscle overuse is often described as burning. Loss of sensation to touch and pinprick can be reported with nonneuropathic pain (e.g., muscular pain). Patients with nociceptive pain may also report brush and warm allodynia and heat hyperalgesia, such as described with a sunburn. Pressure allodynia, in particular, is common in both nociceptive and neuropathic pain. Allodynia to brush, cold and heat, and temporal
summation to tactile stimuli, although not pathognomonic, are observed in a much higher frequency in patients with neuropathic pain. Bilateral sensory changes can occur in neuropathic pain conditions regarded as unilateral (e.g., postherpetic neuralgia), and cutaneous testing of deeper tissues (e.g., abdominal or pelvic tissues) has not been well validated in cases of nociceptive pain.

Although testing for hypoalgesia to pinprick, hypoesthesia to tactile stimuli, allodynia to brush and cold, and presence of temporal summation are highly reproducible, there is currently insufficient evidence for test–retest reliability and variance over time. Therefore, this examination cannot confidently be used as a monitoring tool to document changes over time.

Sensory testing is a psychophysical test, meaning a physical stimulus is applied, and the patient reports the elicited sensation. It is thus subject to reporting errors related to an individual’s attention and reaction time.

**FURTHER INVESTIGATIONS OR CONSULTS**
Other investigations may include specific radiologic or electromyography testing, a sleep study, specific or baseline laboratory investigations, or urine toxicology screening. Referral to appropriate specialists for further assessments should be requested as needed.

**Follow-up Visits**
Ideally, the first follow-up visit should be within a few weeks to allow assessment of treatment efficacy and tolerability and to review any tests taken, consults, or goal achievement. An example of a follow-up form given to the patient to complete prior to being seen may be helpful (see Appendix 17.2 as an example). Ideally, the follow-up questionnaire should use some of the same questions as the initial questionnaire to allow outcomes to be collected on such items as mood, sleep, function, and quality of life as well as pain. This will enable appropriate changes to be made in care and recommendations to the patient.

The five A’s have been suggested as a useful acronym to document follow-up visits and evaluate the efficacy of opioid therapy. These are
Adverse events (to treatment), Affect (mood), Activities (progress toward goals/functionality outcomes), Aberrant drug–related behavior if opioids are prescribed, and Action taken.31

Conclusion

Assessment and reassessment should be built into every treatment plan. Patients should leave each visit, whether an initial visit or a follow-up, with a definite and agreed plan. Ideally, this should be in a written/printed format the patients take with them. Patients should also be reminded that it will take engagement on their part to reach relevant goals.

Nonadherence, or questioning an agreed treatment plan, occurs in up to 50% of patients. Merely repeating the original reasoning will often be ineffective. Patients need to be involved in a discussion about any concerns or objections they may have to the treatment plan as it evolves. Motivational interviewing plays an important role in developing any treatment plan. For any trial of treatment, a reasonable time to expected improvement must be defined early on (e.g., up to 3 to 4 weeks for an antidepressant to work but within 2 weeks before improvement in pain may be felt with the same drug). With physical therapy or chiropractic care, it may take three to four sessions for ongoing improvement. If there are no recognizable improvements after the agreed on trial time, consider changing or stopping that particular therapy.

Working with a chronic pain patient can be immensely satisfying if the practitioner sees a patient begin to engage more in treating the often disabling, all-encompassing pain and improve the quality of life and function. Having an organized way of getting the patient to give a comprehensive history and validating the pain but not being drawn into the “stories” is a skill that takes time to develop. Being prepared by using some of the suggestions outlined in this chapter and appendices should speed up the “learning curve.” Equally important from the practitioner’s point of view is to not do it alone, but involve the patients, their significant other, and other community resources. An integrative, multidisciplinary approach will provide the best possible outcome for patients with chronic pain.
Appendix 17.1: Initial Visit Questionnaire

Name: ___________________________ Date of birth: ___________________________ Today’s date: ___________________________

We realize that some of the questions might not address your exact situation, but we encourage you to answer them to your best ability.

Approximately how many years have you had your pain? ________ years

How many areas of your body are now affected by chronic pain?

☐ 1 ☐ 2 to 3 ☐ 3 or more

Please indicate where your present pain is:

![Diagram of human body with pain areas indicated]

**Appendix 17.2: Pain Diagram**

Name Date ____________

Please color the areas where you experience pain. Use one of these five coloring pens to shade the specific type of pain that you are experiencing. Then circle with a pen all areas of pain and, starting with the worst, number the areas in order of severity.

Blue—numbness
Red—burning
Green—tingling
If you have other pain sensations, name them here and color as black or yellow
Yellow—
Appendix 17.3: Goal Setting

GOALS

Your ability to make a change in your life or achieve a goal depends largely on your attitude, commitment, and motivation to do something about your situation. Taking full responsibility to do something about it is the most empowering step you can take.

Taking responsibility does not mean blaming yourself for the problem. And it does not mean you have to do it alone. The big question is “Are you willing to change and to incorporate new habits into your daily routine?”

Considering the Right Goal for You

• What are the most positive changes you would like to see in your life?
• How would these changes affect your feelings and relationships?
• What new opportunities could you gain from making these changes?
• Visualize your goals.
• Setbacks are inevitable and so is the fact that you can figure a way out to solve them.
• Use setbacks as an opportunity to learn; do not view them as a failure.
• Reach out to your social support system for a “reality check” for your goals.
• Do not expect change to be rapid or to do any goal to perfection.
• Enjoy the process of change; the journey is important.
• Reward yourself for making gradual changes and achieving small steps leading to the goal.
• Be fair and kind to yourself.

Setting SMART Goals

Setting realistic and achievable goals will help bring order, success, and accomplishment back to your life. The criteria for setting achievable goals are the following:

• **Specific.** Does it involve specific behavioral actions or steps?
• **Measurable.** How will you know when the goal has been reached?
• **Attainable.** You are the one engaging in the actions or behaviors. Do you want the results enough to make the effort?
• **Realistic.** Is it possible to achieve?
• **Timely.** What is the time frame in which you expect to reach this goal?

Consider your goal and determine what your progress will look like in 2 weeks from now. Imagine yourself looking back, what did you have to do in 1 week in order to get there?

Think about how many goals are reasonable for you to accomplish before your next meeting with your provider. Typically one to three goals is manageable.

**Goal 1:**

Steps to take to reach this goal:

What could stop me from achieving this goal?

What can I do to prevent it from stopping me?

**Goal 2:**

Steps to take to reach this goal:

What could stop me from achieving this goal?

What can I do to prevent it from stopping me?

**Goal 3:**

Steps to take to reach this goal:
What could stop me from achieving this goal?

What can I do to prevent it from stopping me?

5. Mathieson S, Maher CG, Terwee CB, et al. Neuropathic pain screening questionnaires have

To effectively treat acute and chronic pain, the clinician must understand its causes. Electrodiagnostic testing (EDX) can significantly improve that understanding. It complements the history, physical examination, laboratory testing, and imaging studies by providing quantitative assessments of the health, integrity, and function of muscle and nerve. Thoughtful electrodiagnostic studies can help narrow a differential or confirm a diagnosis. They can clearly identify the extent, severity, and location of nerve injury, muscle damage, or disease of the neuromuscular junction. Serial examinations can track disease progression, provide prognostic information, and measure recovery.

Clinicians should consider EDX whenever they suspect focal or diffuse neuromuscular disease. In these conditions, weakness, numbness, tingling, and pain are the most frequent complaints. The physical examination may include alterations in sensation, strength, reflexes, muscle bulk, muscle tone, and/or coordination. Imaging and laboratory studies may be normal or abnormal, depending on the condition. Common indications for EDX include nerve entrapment, radiculopathy, plexopathy, and traumatic injuries as well as metabolic disorders (e.g., diabetes mellitus), peripheral neuropathies, myopathies, and diseases of the neuromuscular junction. Special tests can assess disorders of cranial, pharyngeal, and perineal structures.

This chapter will familiarize the reader with the basic principles of EDX, provide guidance on interpretation of test reports, and help caregivers make optimal use of EDX when assessing patients in acute and chronic pain.
A reputable electrodiagnostic laboratory employs consistent techniques and norms to ensure accuracy and reliability. Test data should be interpreted by a trained and experienced physician, and electromyographers should be readily accessible for questions and case discussions from referring providers. To determine abnormal results, the laboratory should compare its results to documented and standardized normal values and should use the same norms consistently. Examiners within a laboratory should use the same techniques so that the same norms apply to all cases.

The laboratory should have good climate control set at a comfortable room temperature, as an excessively cold environment may adversely affect results. Electrical circuitry supplying the room should be properly shielded and grounded to ensure patient safety and to reduce line–current interference from equipment such as fluorescent light fixtures. Commercial electrodiagnostic units have been designed and rigorously tested to ensure safety and reliability.

The electrodiagnostic unit or “EMG machine” is primarily composed of a sensitive differential amplifier (high signal-to-noise ratio) and an electrical stimulator with precise control of stimulus duration and intensity, coupled to a computer for ease of data acquisition, analysis, and storage (Fig. 18.1). An active electrode (G1) is placed over the desired recording location, and a reference electrode (G2) is placed nearby. The amplifier subtracts the reference signal from the active signal to remove elements common to both, leaving only the information unique to the active electrode. The resulting signal (G1 to G2) is amplified, displayed, and stored.
Electrodiagnostic Tests

Most patients referred for EDX will undergo both nerve conduction studies (NCS) and needle electromyography (EMG). The entire procedure (both EMG and NCS) is often referred to as “EMG” when ordering the test or describing it to patients.

NERVE CONDUCTION STUDIES

NCS use electrical stimuli over a selected nerve to produce an action potential, which is recorded using electrodes placed further along the course of the stimulated nerve or the muscle it supplies. The resulting waveforms are analyzed and compared to normal values derived from a database of healthy individuals. The electrical stimulus is usually administered transcutaneously, with the stimulator probe (Fig. 18.2 shows an example) positioned on the skin overlying the desired nerve. Recording electrodes are generally placed on the skin. In special circumstances (e.g., deep nerves, obesity, edema), stimulation and/or recording may be accomplished using needle electrodes advanced through the skin and placed adjacent to the desired structures. Patients should be warned before testing that the stimulated limb may twitch when the shock is delivered.
Electrical stimulation should not be performed over or near pacemakers, implantable cardioverter-defibrillators, spinal cord stimulators, or other implanted medical electronics. In most patients, stimulation distant from the implant and its electrodes can be safely accomplished, but if there is any doubt, check with the device manufacturer before proceeding.

Electrical stimulation is generally perceived as a brief (0.1 to 0.2 ms), mildly uncomfortable “static” shock, repeated as stimulus amplitude is gradually increased. Once a maximal response is elicited from the nerve being studied, stimulation is terminated and the action potential is analyzed.

Parameters recorded during NCS include action potential latency (time between stimulation and initiation or peak of action potential), action potential amplitude, and nerve conduction velocity (NCV). Latency and NCV reflect myelin health; demyelination will prolong the latency and slow the NCV. Amplitude reflects axonal integrity; axonal loss or injury may produce decreased amplitude and temporal dispersion of the action potential. The distribution of abnormalities can distinguish focal, segmental, and diffuse neuropathic processes. Stimulation at multiple points along the nerve allows measurement of NCV across different nerve segments. Where abnormal results are seen, comparison to a contralateral asymptomatic structure, where available, provides a valuable intra-individual control. Varieties of NCS are described in detail in the following text along with their specific applications.

**Sensory nerve conduction studies (SNCS):** SNCS provide detailed
assessment of sensory nerve function. Nerve stimulation produces a sensory nerve action potential (SNAP), which is recorded over the same peripheral nerve at a distance from the stimulation point. Figure 18.3 illustrates a standard setup for a median SNCS (Fig. 18.3A) and the resulting normal SNAP (Fig. 18.3B). Because nerves conduct bidirectionally from the point of stimulation, SNCS may be performed orthodromically (in the physiologic direction, stimulating distally, and recording proximally) or, as in this case, antidromically (stimulating proximally and recording distally).

**FIGURE 18.3**  A: Setup for median nerve antidromic sensory nerve conduction studies (SNCS). Stimulation is applied at the wrist and recorded over the digital nerves to the index finger. B: Median sensory nerve action potential (SNAP). Graph measures amplitude (y-axis) versus time (x-axis). Left edge of the diagram corresponds to the moment of electrical stimulation. Peak latency and amplitude of the SNAP are illustrated. GnD, ground electrode.

**Figure 18.4** shows an orthodromic SNCS comparing distal conduction of the median and ulnar nerves across the wrist (Fig. 18.4A). This study is highly sensitive and specific for the presence of carpal tunnel syndrome (median entrapment neuropathy at the wrist), which is demonstrated here (Fig. 18.4B). The two nerve segments are of equal lengths and should have
approximately the same latency and NCV. In this case, the median SNAP latency is appreciably prolonged, indicating conduction delay. Median amplitude is also lower than the laboratory’s norm of 51 µv. Values for the ulnar SNAP are normal.

SNCS results may be altered by cold skin temperatures, potentially leading to incorrect diagnoses. Warming the skin to ≥32°C will minimize this cause of error.

Like electrical cables, peripheral nerves are composed of numerous nerve fibers with varying functions, diameters, and degrees of myelination. The SNAP elicited during SNCS primarily reflects the response of faster conducting, more heavily myelinated afferent fibers. Responses from smaller diameter, less myelinated fibers (e.g., C and Aδ fibers transmitting pain and temperature signals) may not be detected. Standard SNCS therefore lack sensitivity for detecting small-fiber dysfunction in painful conditions. Alternate techniques, such as quantitative sensory testing (see

FIGURE 18.4  A: Setup for orthodromic median versus ulnar transcarpal sensory nerve conduction studies (SNCS). Palm is stimulated over median and then ulnar nerve. Sensory nerve action potentials (SNAPs) are recorded at the wrist. Distance (d) between G1 and the cathode is equal for median (med) and ulnar (uln) nerves. B: Results. In a normal study, median (med) and ulnar (uln) peak latencies are approximately equal. In this example, the ulnar SNAP is normal, but the median SNAP latency is prolonged and amplitude reduced, demonstrating conduction delay and axonal loss (or partial conduction block) from entrapment at the carpal tunnel. Gnd, ground electrode; Stim, stimulator position.

SNCS results may be altered by cold skin temperatures, potentially leading to incorrect diagnoses. Warming the skin to ≥32°C will minimize this cause of error.

Like electrical cables, peripheral nerves are composed of numerous nerve fibers with varying functions, diameters, and degrees of myelination. The SNAP elicited during SNCS primarily reflects the response of faster conducting, more heavily myelinated afferent fibers. Responses from smaller diameter, less myelinated fibers (e.g., C and Aδ fibers transmitting pain and temperature signals) may not be detected. Standard SNCS therefore lack sensitivity for detecting small-fiber dysfunction in painful conditions. Alternate techniques, such as quantitative sensory testing (see

915
the following text) and skin punch biopsy with nerve fiber staining, can augment the physical examination to help characterize small-fiber abnormalities.

**Motor nerve conduction studies (MNCS):** MNCS characterize the health of motor nerve fibers and the neuromuscular junction. Nerve stimulation produces a compound muscle action potential (CMAP), which is recorded over a muscle innervated by the stimulated nerve. Figure 18.5 shows the setup (Fig. 18.5A) and normal results (Fig. 18.5B) for an ulnar MNCS recording at abductor digiti minimi. The nerve is stimulated at multiple sites along its length; distances between stimulation points are measured and recorded. Onset latencies and CMAP amplitudes are measured. Motor NCV in meter per second (m/s) is calculated by dividing the distance between points (Δd, in millimeter) by the change in time between stimulation points (Δt, in millisecond).

![FIGURE 18.5 A: Setup for ulnar motor nerve condition studies (MNCS) recording at abductor digiti minimi. Stimulation is applied at the wrist (1), below the elbow (2), and above the elbow (3). B: Normal results, including onset latencies, amplitudes, and calculated motor NCV. Gnd, ground electrode; d, distance.](image_url)

**Repetitive nerve stimulation studies (RNS):** RNS are a variant of MNCS that can identify disorders of the neuromuscular junction. Rapid repetitive stimulation (usually 2 to 3 Hz) is performed, as illustrated in Figure 18.6A. A decrement in CMAP amplitude during RNS is abnormal and suggests a disorder of the neuromuscular junction. CMAP decrement with RNS is illustrated in Figure 18.6B. The response of CMAP amplitude to exercise can differentiate between neuromuscular disorders.
FIGURE 18.6  Motor nerve conduction studies (MNCS) (simulated) with repetitive nerve stimulation at ulnar nerve, recording at abductor digiti minimi, stimulation at wrist, frequency 2 Hz. A: Normal. Compound muscle action potential (CMAP) amplitude does not change with repetitive stimulation. B: Myasthenia gravis, preexercise. Decrement in CMAP amplitude with repetitive stimulation.

**H-reflex studies:** H-reflex studies are modified MNCS that help to identify some radiculopathies and peripheral neuropathies. The H-reflex is an analog of the muscle stretch reflex. Most commonly, the tibial nerve is electrically stimulated at the popliteal region (analogous to an Achilles tendon tap) and the reflex response (H-reflex) in the soleus muscle is measured. A unilaterally absent or delayed tibial H-reflex may reflect an S1 radiculopathy, tibial neuropathy, or sciatic neuropathy. Bilateral abnormalities may be seen in peripheral neuropathies and in older individuals. H-reflexes may also be found by stimulating the median nerve at the elbow and recording at flexor carpi radialis. They are more widespread in hyperreflexic conditions (e.g., myelopathy) and in infants.¹

Another modified MNCS, the F-wave study, allows indirect observation of nerve conduction between the dorsal root ganglion (DRG) and the spinal cord, permitting sensitive evaluation of polyneuropathies including Guillain-Barré syndrome (GBS), radiculopathies, and proximal nerve dysfunction.⁴ Upon peripheral nerve stimulation, the stimulus travels bidirectionally, producing (1) a CMAP and (2) a small, later potential (F-wave) from antidromic activation of a small pool of alpha-motoneurons. Their appearance and latency are variable (Fig. 18.7).
FIGURE 18.7 Ulnar motor F-wave study. The ulnar nerve is electrically stimulated, producing both orthodromic and antidromic action potentials. The orthodromic potential produces a compound muscle action potential (CMAP) (M-wave). The antidromic potential proceeds proximally via primary afferent neurons to the dorsal root ganglion, through the dorsal horn, and via reflex pathways activates a small pool of α-motor neurons in the ventral horn, producing a small motor response (F-wave).

**Cranial nerve studies:** The trigeminal nerve reflexes (blink reflex, jaw jerk, and masseter inhibitory reflex) can be studied using special EDX, providing valuable clues to lesions of cranial nerves and/or the brain stem. The blink reflex (corneal reflex) is the most often studied and can provide information regarding the integrity of the ophthalmic division (V1) of the trigeminal nerve, the facial nerve (efferent limb), and the brain stem. In the normal blink reflex study, electrical stimulation of the supraorbital nerve unilaterally is followed by a facial nerve blink response bilaterally.

**Sacral nerve studies:** Special techniques are used to examine sacral sensory and motor innervation, including studies of the bulbocavernosus and clitorocavernous reflexes (pudendal and perineal nerves). Along with EMG of pelvic floor muscles, these studies can help diagnose sacral nerve dysfunction due to cauda equina syndrome, peripheral neuropathy, focal neuropathies, pelvic pain syndromes, neurogenic erectile dysfunction, and Tarlov cysts. They may, however, be quite uncomfortable for the patient, so they are reserved for cases where the findings are crucial for treatment decisions.
NEEDLE ELECTROMYOGRAPHY

Needle EMG uses needle electrodes to directly assess the electrical activity of motor units, providing extensive information about their integrity, innervation, function, and recruitment. A skilled electromyographer can identify a broad range of disorders causing denervation, inflammation or other destruction, or failure of neuromuscular transmission.

EMG is indicated whenever muscular dysfunction is suspected. It can assist with the diagnosis of neuropathies, radiculopathies, or plexopathies; myopathies (inflammatory, congenital, or other); disorders of the neuromuscular junction; and motor neuron diseases. Where NCS has indicated abnormalities, EMG can help clarify their distribution and severity; also, EMG often detects significant abnormalities when NCS are normal (radiculopathy is a common example). Special electrodes and techniques permit the assessment of single muscle fibers, which can clarify diagnosis in some conditions, particularly neuromuscular junction disorders.9

The electromyographer chooses which nerves and muscles to examine, and which techniques to employ, based on the history and physical examination. A strong command of neuroanatomy is required. The electrodiagnostic exam will ideally screen for most conditions on the differential diagnosis. For example, when pathology in a nerve structure is suspected, the electromyographer will perform the appropriate NCS and then will use EMG to assess multiple muscles supplied by that structure. The choice of nerves and muscles will vary with suspicion of peripheral nerve, plexus, nerve root, muscle, or other neuromuscular pathology. Findings on earlier tests often change the choice of tests performed later as the differential is narrowed or widened.

Where it is important to diagnose a nerve lesion early, electrodiagnostic studies within 7 to 10 days of injury can localize nerve lesions and quantify the severity of nerve injury. Studies performed 3 to 4 weeks after injury provide information on muscle denervation and can help with surgical planning. Studies done 2 to 6 months after injury can quantify healing and provide prognostic information.10 In chronic illnesses such as motor neuron disease and peripheral neuropathies, serial studies document disease course, progression, and prognosis.
EMG should be performed with caution in patients with coagulopathies or who are taking anticoagulant agents. Bleeding with needle EMG is rare; anticoagulants should not routinely be discontinued, but caution is advised, particularly at higher levels of anticoagulation or where there are other reasons to suspect increased bleeding risk. Antiplatelet agents do not appear to significantly increase the risk of bleeding.

Once postoperative healing is complete, needle examination at or near prosthetic joints does not usually require prophylactic antibiotics. In cases of lymphedema, needle puncture may increase the risk of cellulitis and/or lymph leakage, so caution is advised when choosing to perform EMG in such situations. If a muscle may need to be biopsied, it should not be examined with needle electrodes, as the needle trauma may produce abnormalities in biopsy specimens.

Needle electrodes are most often monopolar (single conductor, requiring an external reference electrode) or concentric (active and reference electrodes within the same needle). As the distance between active and reference electrodes is much smaller using a concentric needle (Fig. 18.8), noise is minimized and signal clarity improves.

 Needle EMG can be uncomfortable, but the examiner can minimize the pain by positioning the patient comfortably, moving the needle only when the muscle is relaxed, using the smallest gauge needle necessary, and warning the patient to prepare him or her before insertion occurs. More anxious individuals may wish to employ relaxation techniques, have a
familiar person nearby, or take a mild prescribed anxiolytic before the procedure. As patients are asked to activate their muscles voluntarily during the procedure, it is important that they remain conscious and able to follow commands. Needle EMG can still be of value when conducted in heavily sedated or unconscious patients (such as in critical care situations), but analysis of voluntary motor unit activity is not possible in these circumstances.

The electromyographer chooses muscles for needle analysis according to the patient’s specific clinical situation, the reported symptoms, and the findings on physical examination. By careful muscle selection and observation of abnormalities, the skilled examiner can distinguish among plexopathies, myopathies, radiculopathies, and numerous other conditions.

The needle is typically inserted through the skin into a relaxed muscle. Following insertion, the needle is moved short distances within the muscle at intervals of about once per second while the electromyographer studies the display and listens to muscle activity. Healthy muscles are electrically quiet at rest. They produce short bursts of noise (insertional activity, or IA) during needle movements and silence between movements. In cases of muscle scarring or fibrosis, IA may be decreased or muted.

Potentials present between insertions in a resting muscle are known as spontaneous activity (SA) and reflect abnormalities of the neuromuscular junction. SA may be caused by denervation (as in neuropathies or radiculopathies), muscle membrane injury (as in myopathies), or other abnormalities affecting neuromuscular function. Each type of SA has a distinct waveform and sound that skilled electromyographers rapidly recognize. Common types of SA include fibrillation potentials, positive sharp waves, and complex repetitive discharges, as illustrated in Figure 18.9. Fasciculations (spontaneous discharges of single motor units) may indicate motor neuron disease or other neuromuscular disorders and may confirm a diagnosis of amyotrophic lateral sclerosis (ALS); distal limb muscles have the highest sensitivity for ALS-related abnormalities. The amount and frequency of SA provide information about the acuity and/or severity of a disease process. SA are summarized in electrodiagnostic reports using the grading system in Table 18.1.

Once the resting muscle is analyzed, the patient is asked to voluntarily contract the muscle being studied, producing motor unit potentials (MUPs). Normal MUPs have a characteristic amplitude, duration, and number of phases (crossings of the signal baseline). Low-amplitude muscle contractions engage one or a few MUPs, but more are recruited in frequency-dependent fashion as the force of contraction increases. Abnormalities of MUP morphology and recruitment provide clues to the type and chronicity of neuromuscular disease. Figure 18.10 illustrates MUPs seen in normal muscle (Fig. 18.10A) and in chronic radiculopathy (Fig. 18.10B). Table 18.2 summarizes the significance of various EMG parameters mentioned in electrodiagnostic reports.

MUP, motor unit potential.

**Somatosensory evoked potentials (SSEP):** SSEP are employed to measure nerve conduction between a peripheral nerve and the spinal cord.
and/or cerebral cortex. Interruptions in peripheral or central conduction are manifest as delayed or absent responses. SSEP can be helpful diagnostically in multiple sclerosis, spinal cord injury, and other central nervous disorders. SSEP are particularly useful in the diagnosis of cervical myelopathy; responses from tibial nerve stimulation are recommended. SSEP are frequently employed for intraoperative monitoring during neurosurgical procedures to assess continuity of nerve, root, and cord.

**Sympathetic skin response (SSR):** SSR measures tonic changes in skin conductance caused by changing sweat output, providing a measure of sympathetic efferent innervation. Increased sympathetic tone normally causes increased sweating and a corresponding drop in skin conductance. SSR may be useful in the diagnosis of generalized and localized neuropathies where small-fiber dysfunction is suspected and can help characterize peripheral efferent dysfunction in complex regional pain syndrome (CRPS).

SSR is generally performed using a 2- or 4-channel amplifier to record responses from multiple limbs simultaneously. A standardized stimulus, such as a small electrical shock, is delivered over a midline bodily structure, often the forehead. The SSR for each limb is recorded and differences between limbs are measured. Absence, delay, or decreased amplitude of SSR indicates abnormalities of sympathetic innervation.

**Surface electromyography (sEMG):** In sEMG, electrodes placed on the skin are used to detect skeletal muscle activity. sEMG acquisition is noninvasive and thus attractive. sEMG signals represent the summation of many CMAP. Although single motor units cannot be assessed, the technique is quite useful for specific applications. sEMG activity may reflect voluntary movement or hypertonic states such as muscle spasm. Trunk muscle sEMG activation patterns are altered in patients following low back injury, and these alterations may persist even after apparent recovery.

When converted to an audible or visual signal, sEMG may be used clinically in biofeedback training to treat pain conditions. Once patients are made aware of the degree of activity in a muscle or muscles, they can learn to reduce activity in overused muscles, lowering muscle pain and promoting relaxation. Conversely, patients may learn to strengthen
weakened or underused muscles. EMG biofeedback has been employed to treat low back pain with mixed results.\textsuperscript{20–22} Somewhat better success has been seen with arthritic knee pain,\textsuperscript{23} patellofemoral pain syndrome,\textsuperscript{24,25} and tension-type headache.\textsuperscript{26}

Spectral analysis of sEMG signals has led to additional applications; for example, the median frequency of sEMG signals from trunk muscles may be used as a real-time measure of muscle fatigue,\textsuperscript{27,28} permitting analysis of abnormal muscle activation patterns and targeted muscle training.\textsuperscript{29} sEMG biofeedback may be used to train computer users in maintenance of normal posture.\textsuperscript{30} sEMG is commonly used as a proportional control signal for operating powered myoelectric prostheses.\textsuperscript{31}

**Application in Selected Conditions**

**Carpal tunnel syndrome (CTS):** In this common neuropathy, the median nerve is entrapped by the transverse carpal ligament as it traverses the carpal tunnel. Pain, numbness, and tingling ensue, usually in a distribution corresponding to that of the median nerve. Weakness in median-innervated hand muscles may be present, especially in more severe cases. Nighttime exacerbations are common. The Tinel sign (percussion over the median nerve at the volar wrist) may be present but is neither sensitive nor specific for CTS. The Phalen sign (prolonged wrist flexion) is correlated with pain, paresthesia, and abnormal distal sensory and motor latencies.\textsuperscript{32}

EDX is widely used to aid in the diagnosis of CTS and has been found to be valid, reliable, and reproducible for this application.\textsuperscript{33} In their evidence-based clinical practice guideline, the American Academy of Orthopaedic Surgeons found moderate evidence for the use of EDX in diagnosing CTS.\textsuperscript{34} One well-designed prospective study found that EDX results significantly influenced patient selection for surgical management.\textsuperscript{35}

The sensitivity and specificity of EDX in CTS are difficult to determine precisely, as there are no firm criteria for diagnosing the syndrome. The diagnosis is best established by combining clinical symptoms and EDX findings.\textsuperscript{36} Median SNCS are more likely to be abnormal than median MNCS in cases of CTS. Ten percent to 15% of patients with clinical
symptoms of CTS will have normal NCS, so the sensitivity (true-positive rate) of NCS is 85% to 90%. The specificity of NCS has been estimated at 82% to 85% (i.e., a 15% to 18% chance of a false positive). Sensitivity and specificity may be improved by using multiple studies that compare median distal sensory latency to ulnar and radial distal sensory latencies.

EDX may be complemented by ultrasonography of the carpal tunnel, which permits measurement of median nerve cross-sectional area; as yet, there is no standardized protocol for carpal tunnel ultrasound. Ultrasonography may be most useful in patients with mild clinical CTS but negative EDX.

The value of thenar muscle EMG in the carpal tunnel screen has been extensively debated, and recommendations vary regarding when and whether to perform this test. Thenar EMG is quite uncomfortable for patients, but thenar EMG abnormalities are useful indicators of median motor axonal loss (and therefore severity of median nerve entrapment), and NCS results do not predict abnormal EMG on an individual basis. Most practitioners perform thenar EMG during all CTS screens; others limit it to cases where the results are likely to change a treatment decision. Chang et al. found that thenar EMG is most helpful when CMAP amplitude at abductor pollicis brevis is between 2.1 mV and normal; below 2.1 mV, SA is almost always present. SA is much less common when the CMAP is normal.

**Other entrapment neuropathies:** NCS and EMG can be useful in the diagnosis of compressive ulnar neuropathy at the elbow, especially to precisely localize the site(s) of nerve compression. EDX is effective and precise for the diagnosis of other ulnar and median neuropathies. Lower limb neuropathies are also readily diagnosed, including lesions of the tibial, peroneal, sciatic, saphenous, and other nerves. Patients with piriformis syndrome demonstrate a delay in the tibial and peroneal H-reflexes when the affected hip is flexed, adducted and internally rotated; needle EMG results in this disorder have been inconsistent.

**Painful polyneuropathies:** EDX can provide unparalleled insights regarding the type, distribution, and severity of neuropathic processes. Most polyneuropathies are length-dependent (affecting the lower limbs first) and symmetric bilaterally, following the classic “stocking-glove”
distribution of sensory disturbance. EDX can distinguish between axonal, demyelinating, and mixed polyneuropathies, each of which has its own potential causes. The distribution of abnormalities may suggest metabolic (e.g., diabetes mellitus, thyroid disease), toxic (alcoholic, chemotherapy, heavy metals), inflammatory (GBS, chronic inflammatory demyelinating polyneuropathy), hereditary (Charcot-Marie-Tooth disease), or other causes. Characterization of polyneuropathy can help determine further diagnostic workup and, where possible, specific treatment.

**Guillain-Barré syndrome:** Neuropathic pain is a common complaint of patients with this acute inflammatory demyelinating polyneuropathy. EDX is a valuable diagnostic and prognostic tool in GBS. Eighty percent of patients demonstrate conduction block and/or slowed NCVs during the illness. F-waves may be absent in cases of significant axonal involvement. Absence of the H-reflex is common. Proximal ulnar motor nerve conduction block (stimulating at Erb’s point) is highly predictive of GBS.

**Radiculopathies:** Needle EMG is the most useful test for diagnosing radiculopathy. MNCS are frequently normal, but more severe radiculopathies may result in temporally dispersed and/or low-amplitude CMAPs. SNCS are generally normal in radiculopathies because these studies assess the function of primary afferent neurons whose cell bodies reside in the DRG. Most radiculopathies are caused by compression within the spinal canal or neural foramen proximal to the DRG, sparing primary afferent neurons and thus causing no abnormality on SNCS.

Needle EMG is a highly specific but somewhat less sensitive measure for radiculopathy. Diagnostic yield is improved by careful selection of muscles for needle exam; a six-muscle screen (including paraspinal muscles) maximizes diagnostic yield. Abnormalities should ideally be present in at least two muscles sharing a single nerve root innervation but supplied by different peripheral nerves. If only one muscle tested shows abnormalities suggesting radiculopathy, additional muscles should be studied. SA is the primary clue to acute or subacute radiculopathy; positive waves and fibrillation potentials develop over the first few weeks following root injury. An examination performed too soon after injury may show little or no abnormality. SA may disappear within a few months of
injury, but symptoms can persist. Abnormalities of motor unit recruitment and morphology (decreased recruitment, high-amplitude and/or polyphasic MUPs) indicate more chronic radiculopathy.

EDX and magnetic resonance imaging (MRI) are complementary tools for the diagnosis of radiculopathy. If radiculopathy is clinically suspected but MRI findings are nondiagnostic, or if the presentation is complex, adding EDX can significantly improve diagnostic precision. EMG may also be useful prognostically. Abnormal needle EMG predicts long-term pain relief after lumbar interlaminar or translaminar epidural steroid injection in the treatment of lumbosacral radiculopathy. Similarly, EMG-confirmed radiculopathy predicted >50% pain reduction and decreased opioid use following cervical and lumbar transforaminal epidural steroid injections.

**Complex regional pain syndrome:** This severe neuropathic pain condition usually produces severe allodynia over multiple nerve root and peripheral nerve territories. EDX is not useful in the majority of CRPS patients. EDX is generally avoided in CRPS because patients find it too painful to tolerate. In cases where a specific nerve injury is suspected (i.e., CRPS “type 2” or causalgia) and intervention is being planned, EDX may help to isolate the site of nerve injury.

**Conclusion**

EDX provides a wealth of information about neuromuscular function, and every pain care practice should have ready access to a skilled electromyographer. Properly applied, EDX helps pain care providers diagnose painful conditions, localize nerve injuries, design treatment plans, target injections, measure treatment outcome, and monitor disease recovery. It increases our understanding of the patient, opening a clearer path to pain relief and improved function.

929

Pain is one of the most common indications for clinical imaging examinations. Pain could be an indicator of imminent tissue damage, such as ischemia, direct injury, malignancy, inflammation, and infection. It could also be due to peripheral or central nervous system diseases. Imaging protocols are tailored based on acuteness, character, and location of the pain and the working diagnosis. In case of acute pain, life-threatening and surgical emergency can be in the differential. Therefore, often imaging for acute pain is to confirm or exclude the presumed ominous diagnosis in doubt, such as acute fracture and associated tissue damage, intracranial hemorrhage, aortic dissection, pneumothorax, pneumoperitoneum, etc., based on history, labs, and physical exam findings. Even when the presumed urgent diagnosis is excluded, imaging exams are often useful in delineating the cause of pain.

For patients with recurrent or persistent pain whose diagnosis remains obscure after routine imaging workup, it might be challenging to make a diagnosis or find the cause of pain. Specialized imaging techniques such as magnetic resonance (MR) neurogram, discogram, and imaging-guided injection should be chosen depending on the careful review of the clinical scenarios. American College of Radiology (ACR) Appropriateness Criteria are a useful resource when the next imaging tool is uncertain. It consists of evidence-based guidelines to assist decision making for specific clinical conditions. In some institutions, it is incorporated into electronic medical records and ordering systems.

A comprehensive discussion of radiographs, computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, and radionuclide examinations (such as bone scan) for evaluation of pain should include almost all radiologic subspecialties. This is beyond the scope of this
chapter and can be found in most general diagnostic imaging textbooks. This chapter is dedicated to the evaluation of pain related to the nervous system and reviews the imaging approach to several regional pain syndromes. It discusses imaging techniques that can be used to select surgical candidates among patients with back pain, tic douloureux, and peripheral nerve entrapment syndromes. Techniques and indications for MRI of the cranial nerves and posterior fossa vasculature, and high-resolution MRI of the brachial plexus and peripheral nerves are also discussed.

Headache

Headache is a common symptom. The lifetime prevalence of any form of headache is 93% in men and 99% in women. Unless acute findings such as hemorrhage, tumor, and meningoencephalitis are of clinical concern, choosing the patient who should have a cranial imaging study can be challenging (see Chapter 62). The diagnostic yield of neuroimaging examinations in patients with headache and a normal neurologic examination, or in patients with typical migraine, is low (Table 19.1). For example, in adult and pediatric patients with known migraine and no change in symptoms, routine neuroimaging is discouraged.

Specific clinical features associated with significant intracranial abnormality, however, should prompt neuroimaging. Acute onset of an extremely severe headache (often described as “thunderclap” or “sudden worst headache of life”) should be treated as an emergency, due to increased positive predictive value for subarachnoid hemorrhage (SAH) from intracranial aneurysms in adults, and arteriovenous malformation.
(AVM) or other vascular malformations in children.\textsuperscript{2,4–7} Other imaging-appropriate clinical scenarios include worsening subacute headache, headache associated with focal neurologic signs or cognitive impairment (in patients without a history of migraine), new headache in patients older than age 50 years, and headache in immunocompromised patients or patients with known malignancy.\textsuperscript{2,4,5,8} Patients over the age of 65 years with new onset of pathologic headache have a 15\% incidence of serious intracranial disease, including temporal arteritis, tumor, and infarct. In contrast, patients younger than age 65 years (other than the acute SAH subset) have only a 1.5\% incidence of detectable underlying pathology.\textsuperscript{9}

**ACUTE HEADACHE**

Sudden onset of severe headache—especially if associated with neurologic abnormality or depressed sensorium—suggests possible acute SAH from an aneurysm or other vascular malformation. The devastating consequences of untreated, ruptured aneurysm require prompt exclusion of SAH in this setting: Patients who survive their initial hemorrhage have a 50\% chance of a fatal rehemorrhage within 1 year, with the highest risk in the immediate postbleed period.\textsuperscript{10,11} Rapid diagnosis with high sensitivity is best made by CT demonstration of hyperdense blood in the subarachnoid space.\textsuperscript{12}

If SAH is found on initial noncontrast head CT, subsequent magnetic resonance angiography (MRA), computed tomography angiography (CTA), or catheter angiogram is directed at detecting and localizing an aneurysm (Fig. 19.1) or AVM (Fig. 19.2). Venous sinus thrombosis (Figs. 19.3 and 19.4),\textsuperscript{13,14} benign perimesencephalic SAH,\textsuperscript{15} and arterial dissection (Fig. 19.5)\textsuperscript{16,17} may also result in SAH in the absence of an aneurysm or vascular malformation on CTA. In addition, migraine, and bacterial meningitis (in the proper clinical setting, e.g., stiff neck and fever) can also present as severe acute headache but without presence of SAH on acute CT.
FIGURE 19.1  Subarachnoid hemorrhage caused by ruptured terminal internal carotid artery aneurysm. A: Nonenhanced computed tomography shows hyperdense aneurysm (arrow) and blood within interhemispheric and sylvian fissures (arrowheads). The ventricles are mildly enlarged and clot is present within the third ventricle. B: Left internal carotid artery arteriogram shows a 2-cm aneurysm arising from the termination of the internal carotid artery. C: A second, unruptured aneurysm is seen at the junction of the left anterior cerebral artery and the anterior communicating artery (arrow).
FIGURE 19.2  Arteriovenous malformation. A 39-year-old man with several days’ headache. 
A: Noncontrast computed tomography shows enlarged, slightly hyperdense vessels in the sylvian fissure (arrow).  
B: Hyperdense, dilated veins at the parietal vertex (arrow).  
C: Computed tomographic angiography shows the arteriovenous malformation nidus (arrow), as well as dilated feeding arteries and peripheral draining veins.
FIGURE 19.3 Venous sinus thrombosis with cortical infarct. A 26-year-old postpartum woman with headache and left hemiparesis. A: Axial fluid attenuation inversion recovery (FLAIR) image at level of centrum semiovale shows increased signal in precentral gyrus, indicating cortical infarct. B: Nonenhanced computed tomography shows high attenuation in vein of Galen and straight sinus (arrow). C: Magnetic resonance venogram shows absence of flow through straight sinus (arrow) with patent sagittal and transverse sinuses.
FIGURE 19.4  Venous sinus thrombosis with bilateral thalamic infarcts in a 24-year-old woman with 4 days of headache followed by several hours of nausea and depressed consciousness. Nonenhanced computed tomography shows low attenuation changes in both thalami, with increased attenuation in the internal cerebral veins (arrow) and straight sinus (arrowhead).

FIGURE 19.5  Internal carotid artery dissection in a 37-year-old man with headache and left pupillary constriction. A: Computed tomographic angiography at skull base shows decreased caliber of left internal carotid artery (white arrow) at the skull base. Intramural hematoma surrounds the narrowed lumen (black arrow). Normal right internal carotid artery (arrowhead). B: Left internal carotid arteriogram shows smooth narrowing of distal cervical internal carotid with near
complete occlusion at the skull base (arrows).

As noted earlier, imaging the patient with suspected SAH should begin with nonenhanced CT. Cisterns and sulci must be carefully examined for hyperdense acute blood, which can be subtle if the amount of hemorrhage is small, or if the study is performed more than 24 hours after the bleed occurred. Nonenhanced CT has a sensitivity of 98%\textsuperscript{18} for detection of acute SAH within 12 hours of onset (in fact, 100% on emergency CTs has been reported).\textsuperscript{19} CT sensitivity for detection of SAH is reduced as the time interval from hemorrhage increases.\textsuperscript{2}

A lumbar puncture (LP) may be considered in the possible—but uncommon—scenario of a patient for whom there is a bona fide high clinical index of suspicion for acute SAH and a negative head CT.\textsuperscript{18,20} Detection of xanthochromic cerebrospinal fluid (CSF) on LP remains the “gold standard” for sensitivity in detecting SAH in this setting.\textsuperscript{21,22} In patients for whom an LP is truly indicated to assess for occult SAH, care must be taken for pristine technique: ideally a one-pass, atraumatic tap, with small caliber (25G or 22G) spinal needle. No xanthochromia and red blood cell count <2000 × 10\textsuperscript{6}/L reasonably excludes aneurysmal SAH.\textsuperscript{23}

In the absence of SAH, nonenhanced CT can detect signs of other pathologies, including increased density within a thrombosed dural venous sinus, venous infarction, and edema associated with intracranial mass lesions. If subtle abnormalities are found on nonenhanced CT, further imaging evaluation may include contrast-enhanced CT or (preferably) MRI. In the absence of SAH, MRI is a more sensitive technique to evaluate the patient for other causes of headache, including dural venous sinus occlusion, infarct, mass lesion, or intracranial infection. If SAH is detected, CTA and/or catheter angiography with digital subtraction angiography (DSA) is generally used to further evaluate the location and features of an aneurysm, pial AVM, dural arteriovenous fistula (DAVF), or other vascular malformation. Dural venous sinus thrombosis is better evaluated by computed tomography venogram (CTV) rather than magnetic resonance venogram (MRV) with contrast MRA/MRI because MRI and MRV may be affected by flow artifact resulting in false-positive appearance.
Computed Tomography Angiography and Magnetic Resonance Angiography

MRA and CTA are useful for rapid, noninvasive diagnosis of intracranial vascular lesions. CTA is a dynamic technique in which thin-slice, contiguous images are rapidly obtained during the first pass of an intravenous bolus injection of iodinated contrast. Through proper timing, the images are acquired as the bolus of contrast fills the intracranial arteries and provides high-resolution images of the intracranial vessels. This provides a sensitive, rapid, and relatively noninvasive means to detect aneurysms, AVMs and arteritis, which can be seen as vessel wall irregularities.

Using state-of-the-art multidetector CT, axial images covering the entire cerebral vasculature can be acquired in a few seconds. Using rapid computer processing, multiplanar and three-dimensional (3D) reconstructions can be created to display the enhanced blood vessels in a manner analogous to the projection images from catheter angiography. When indicated, CTA can be easily performed immediately following the initial noncontrast CT while the patient is still on the CT table. MRA is a possible alternative technique, but it is more time-consuming and may not be suitable in the setting of acute intracranial hemorrhage, when the patient may be unable to hold still and requires close monitoring. Whereas conventional MRA visualizes flow-related signal within the vascular lumen, CTA depicts the surrounding structures with better spatial resolution, such as vascular calcification, plaque formation, and extrinsic compression. The quality of CTA in detecting aneurysms is comparable to DSA. However, DSA is still considered by many to be the “gold standard” for aneurysm assessment and may be superior to CTA for surgical treatment planning.\textsuperscript{24–29}

CTA or MRA can provide rapid diagnosis or exclusion of aneurysms and AVMs in the patient with severe acute onset headache. These images are also used to clarify subtle findings in patients with questionable abnormalities on noncontrast CT. For example, carotid or vertebral artery dissection can be detected by imaging the upper cervical vasculature with the earlier described imaging techniques (see Fig. 19.5).\textsuperscript{30,31} Supplemental MRI with axial fat-saturated T1-weighted sequences in addition to MRA is
also highly sensitive for detection of small, focal mural thrombus seen in carotid or vertebral dissections.\textsuperscript{32,33}

**CHRONIC HEADACHE**

Image findings are unrevealing in most cases of uncomplicated chronic headache. Intracranial lesions often present with headache but usually are associated with other neurologic signs or symptoms.\textsuperscript{34} When headaches are caused by underlying pathologic disorders, the differential diagnosis is broad. Serious primary conditions include intraparenchymal, dural, or skull base tumors\textsuperscript{35}; unruptured aneurysms\textsuperscript{36,37}; abscesses; arterial dissection\textsuperscript{38,39}; venous sinus thrombosis; vasculitis\textsuperscript{40}; and AVMs.\textsuperscript{41} A normal CT or MRI without intravenous contrast excludes most intracranial masses to reassure the clinician and justify continued clinical observation and symptomatic treatment. If the clinical evaluation points toward neoplasm, abscess, or a vascular process, then contrast-enhanced CT or, preferably, contrast-enhanced MRI is appropriate next study. As already discussed, if there is a high clinical index of suspicion for vasculitis, CTA or MRA is useful technique to explore further.\textsuperscript{42} So-called “black-blood” postcontrast MRA is a newer highly specialized MRI technique that may be used to better assess vessel wall abnormalities, such as vessel wall enhancement that occur in cases of inflammatory vasculitis or prior hemorrhage (Figs. 19.6 and 19.7).\textsuperscript{43,44}
FIGURE 19.6  Vasculitis. Young patient who presented with aphasia and bilateral middle cerebral artery (MCA) territory infarcts. Cerebrospinal fluid analysis indicated the presence of anti-varicella zoster virus (anti-VZV) antibodies, confirming a diagnosis of VZV vasculitis. Three-dimensional reconstruction of the posterior circulation from time-of-flight (TOF) magnetic resonance angiography (MRA) (A) shows high-grade stenosis of the right P2 posterior cerebral artery (short arrow). There were additional stenoses involving the inferior division of the bilateral M1 MCA and bilateral A2 anterior cerebral artery (not shown). On T1 postcontrast intracranial vessel wall imaging (IVWI) (B), there is a circumferential enhancing lesion involving the stenotic segment (long arrow), compatible with inflammatory vasculopathy. On follow-up IVWI and TOF MRA performed 2 months (C and D) and 4 months (E and F) later, there is progressive improved luminal patency (short arrow, C and E) and diminished wall enhancement (long arrow, D and F), which corresponded with clinical improvement. (Reprinted from Mossa-Basha M, Alexander M, Gaddikeri S, et al. Vessel wall imaging for intracranial vascular disease evaluation. J Neurointerv Surg 2016;8[11]:1154–1159, with permission from BMJ Publishing Group Ltd.)
Noncontrast CT scanning of the craniofacial region is the study of choice for the imaging evaluation of acute and chronic inflammatory diseases of the sinonasal cavities. Conventional plain film radiography is no longer utilized for this purpose due to its low sensitivity and specificity. Acute sinusitis is a common cause of headache or facial pain. Sinus CT is performed as a rapid, high-resolution, thin-section CT examination targeted to include the paranasal sinuses. Because the information is primarily related to bone detail, these scans can be acquired with lower radiation dose levels. The axial thin-section, high-resolution data can be reformatted into coronal, sagittal, or any other desired imaging plane. CT has the additional advantage of enabling evaluation of the middle ear and mastoid air cells. Possible findings include observation of air–fluid levels that are associated with acute sinusitis. An additional finding suggestive of
acute inflammatory sinusitis in the appropriate clinical setting is the presence of “frothy” material within one or more sinus cavities. Findings of mucosal thickening and subtle bony wall thickening reflect changes associated with chronic sinusitis and osteitis. When surgery is indicated for repetitive, recurrent, or intractable chronic sinusitis, thin-section, 3D CT technique with multiplanar viewing also assists in operative planning for endoscopic sinus surgery (Fig. 19.8).

**FIGURE 19.8** Chronic sinusitis. Coronal, nonenhanced screening sinus computed tomography through the face shows opacification of the left maxillary sinus caused by chronic inflammation (long arrow). The ostiomeatal unit (short arrow) and uncinate process (arrowhead) are clearly demonstrated on the opposite side.

**INTRACRANIAL HYPOTENSION**

The syndrome of intracranial hypotension is often characterized by positional headache. Presenting signs and symptoms are variable and may include nausea/vomiting and visual, auditory, or vestibular disturbances. CSF hypotension can be caused by development of a CSF leak due to head or spinal trauma or secondary to skull base surgery. It can also develop spontaneously, likely arising from dural thinning/erosion from adjacent inflammation or infection. Intracranial hypotension may also result from slow, persistent CSF leakage following a spinal puncture or from a spontaneous dural defect, or from overshunting of CSF after placement of a ventriculoperitoneal shunt.

Findings associated with CSF hypotension are best demonstrated on cranial MRI with gadolinium enhancement. This demonstrates a “pachymeningeal” pattern of smooth, continuous, enhanced dural thickening. In some cases, this may be associated with small subdural
effusions and/or downward vertical displacement of the brainstem and cerebellar tonsils (Fig. 19.9). These are generally reversible and disappear with resolution of CSF hypotension after successful treatment by blood patch, epidural saline injection, or surgical repair of the defect.\textsuperscript{49–51} Headache with MR findings of diffuse enhanced dural thickening, not explained by prior surgery or infection, should prompt a diligent search for possible site of an occult CSF leak. This can be done with MRI using a heavily fluid-weighted 3D sequence such as Constructive Interference in Steady State (CISS, Siemens trade name), Balanced Fast Field Echo (BFFE, Philips) or Fast Imaging Employing STeady-state Acquisition (FIESTA, GE) to provide an MR cisternogram or MR myelogram type of image.\textsuperscript{52–55}

\textbf{FIGURE 19.9} Cerebrospinal fluid hypotension caused by overshunting. A 54-year-old woman with ventriculoperitoneal shunt. Diffuse dural thickening and enhancement (arrow) caused by shunt valve with insufficient resistance. Similar findings may be seen in patients with postlumbar puncture, dural tears, or posttraumatic cerebrospinal fluid leaks.

\textbf{INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI)}

On the other hand, increased intracranial pressure could cause moderate to
severe headache, vision change, nausea, and vomiting. Papilledema can be seen on funduscopic evaluation, which eventually leads to loss of vision if left untreated. After excluding secondary intracranial hypertension such as mass lesion, dural venous sinus thrombosis, systemic diseases, and medication, idiopathic intracranial hypertension should be considered. It is more common among overweight females. Increased intracranial pressure is confirmed by measuring opening pressure during LP. On imaging, prominent CSF in tortuous optic sheaths, empty sella turcica, and slit-like ventricles are supportive findings.

Facial Pain

Intractable trigeminal neuralgia (tic douloureux) can be caused from irritation of the nerve from a vascular loop that contacts the cisternal portion of the fifth cranial nerve near its exit from the pons. The vessels most responsible for this often arise from a branch of the superior, anterior-inferior, or posterior-inferior cerebellar arteries (see Chapter 67). Surgical intervention with placement of a small Teflon prosthetic “pad” or “spacer,” to separate the offending vessel from the root entry zone of the cranial nerve, is often effective in relieving symptoms. Diagnosis of vascular loops in the prepontine cistern and cerebellopontine angle was difficult before the development of high-resolution MRI. Thin-section heavily fluid-weighted steady-state, free precession, gradient echo techniques (BFFE, CISS, FIESTA) provide a cisternogram image of the basal cisterns that outline the cranial nerves and vessels in the area. This technique can effectively display the offending vascular loop in relation to the cranial nerve. The diagnosis of vascular loop syndrome is made by demonstration of a blood vessel contiguous with, or actually distorting, a cranial nerve close to its origin from the brainstem at the root entry zone in correlation with the appropriate clinical symptoms. This portion of the nerve lacks a full nerve sheath and thus is sensitive to irritation from pulsations from the contacting artery. The diagnosis must be based on appropriate correlation with clinical symptoms because up to 49% of asymptomatic patients may show similar vascular imaging findings. These MR studies not only aid in identification of surgical candidates but
also serve as a roadmap for surgical treatment planning (Fig. 19.10).58–63

![Image](99x361 to 496x735)

**FIGURE 19.10** Vascular loop compression of the trigeminal nerve. Axial balanced fast field echo (BFFE) image (A) and coronal BFFE image (B) demonstrate the left superior cerebellar artery branch runs immediately inferior to the cisternal segment of the left trigeminal nerve (arrows) with possible compression. C: Diffusion tensor imaging (DTI) clearly delineates the asymmetry of the trigeminal nerves (arrows) with decreased anisotropy on the left (right arrow), which is suggestive of vascular compression.

Other structural causes of trigeminal nerve dysfunction include mass lesions near the trigeminal nerve such as meningioma, schwannoma, arachnoid cyst, cholesteatoma, and epidermoid cyst.64,65 These can be diagnosed by conventional cranial MRI and CT studies.

In addition to trigeminal neuralgia, vascular loops can compromise other cranial nerves along the brainstem. Thus, chronic vertigo can be caused by posterior fossa vessels contacting the root entry zone of the eighth cranial nerve (Fig. 19.11) and compression of the intracisternal seventh nerve can result in hemifacial spasm. Similar high-resolution MRI techniques are
used to identify potential vascular loop syndromes causing these symptoms. Of note, vascular loops contacting seventh and/or eighth cranial nerves are also common, and the finding of a vascular loop needs to be carefully interpreted.  

**FIGURE 19.11** Vascular loop compression of the eighth nerve. A: Anteroposterior projection of a magnetic resonance angiography (MRA) of the vertebral basilar arterial system shows a good demonstration of a prominent right anterior inferior cerebellar artery (arrowheads). However, this standard MRA display does not allow one to determine the relationship of the looping portion of the vessel to the underlying neural structures. B: Axial source image of the MRA now shows a good demonstration of a vascular loop (arrow), which lies contiguous with the eighth nerve (arrowhead) near its origin from the brainstem. C: Coronal reformatted image from the MRA data set confirms the contiguous position of the vascular loop with the eighth nerve near its root entry zone (arrow).

**Spinal Pain**

**OVERVIEW**

Technical advances in surgical fusion of lower lumbar vertebrae have resulted in safer, less invasive operations and have generated renewed interest in diagnostic tests that might predict a favorable surgical outcome for the back pain patient. Conventional MRI, CT, and CT myelography can accurately evaluate central spinal canal or neuroforaminal stenosis. MR of the lumbar spine, in particular, is very sensitive for the detection of lumbar disk protrusion, extrusion, or sequestration in the patient with pain and radiculopathy. Also, facet arthropathy in patients with nonradicular back pain is readily assessed with CT or MRI (Fig. 19.12). Gadolinium-enhanced MRI is useful in evaluation of patients with failed back surgery syndrome because it aids in distinguishing between postsurgical scar and recurrent disk herniation.
Postoperative scar tissue has a blood supply and thus demonstrates contrast enhancement, whereas a herniated disk fragment does not have a direct blood supply and does not exhibit significant enhancement on postcontrast MRI.\textsuperscript{72}

![Image of lumbar magnetic resonance imaging]

**FIGURE 19.12** Lumbar magnetic resonance imaging. **A:** Sagittal T1-weighted image without contrast demonstrates a sequestration at L2–L3 level extending superiorly (arrow). **B:** Axial T2-weighted image demonstrates abnormal high signal in the sequestrum (arrow). The right lateral recess is compressed. **C:** Intense surrounding enhancement is present (arrow). The exiting right L2 nerve is compressed (arrowhead).

CT and MRI are very sensitive imaging techniques that accurately depict spinal degenerative changes and disk pathology. However, it must be recognized that because of the prevalence of degenerative changes in the adult population, imaging findings such as annular tears, disk bulge, and even focal disk protrusion commonly occur in asymptomatic patients. Therefore, these imaging findings alone do not prove a causal effect in an individual patient with back pain.\textsuperscript{73} Indeed, it is prudent to have a healthy
Awareness of potential overreliance on using imaging findings alone to guide treatment decisions.\textsuperscript{74} Rather, correlation of the patient’s pain pattern and clinical findings with the imaging findings is needed to assess whether or not any observed abnormalities are likely to be the cause of a patient’s pain. Only when such correlation is positive is it appropriate to proceed with invasive treatment planning. The natural history of acute back pain without fracture, infection, or malignancy is most often spontaneous resolution following primary conservative treatment (rest, physical therapy, exercise).\textsuperscript{75} Indeed, in acute atraumatic low back pain without a “red flag” such as history of malignancy, weight loss, immunocompromise, etc., imaging is not indicated (ACR). Surgery should be reserved for cases with intractable pain, rapidly progressive symptoms, or patients with neurologic compromise.\textsuperscript{76–79}

**COMPRESSION FRACTURES**

Workup of vertebral body compression deformity may include initial plain films, followed by MRI to assess for marrow edema if the acuteness of a lesion is in question. In cases of acute traumatic injury, CT can best assess extent of fracture planes and stability, along with presence and amount of posterior endplate retropulsion, whereas MR can best evaluate possible presence of associated intraspinal hemorrhage, nerve root/cauda equina compromise, and posterior ligamentous complex injury. If MRI is contraindicated, a nuclear medicine bone scan may also demonstrate marrow edema.

**BENIGN VERSUS MALIGNANT; INFECTION/INFLAMMATION**

Water/fat MR images obtained in-phase and opposed-phase (using gradient recalled-echo MRI sequences) are useful for differentiating pathologic compression fracture from benign compression fracture.\textsuperscript{80} With this method, signal intensity ratio on opposed-phase (water − fat) images compared to in-phase images (water + fat) of >0.8 suggests malignancy because malignant processes tend to infiltrate and replace normal fatty marrow, whereas benign compression fractures displace fat to a much lesser degree.
If an infectious or inflammatory process such as discitis/osteomyelitis is suspected, MRI with pre- and postcontrast fat-saturated T1-weighted sequences are most helpful. These show enhancement of bone and marrow space involvement accompanied by contiguous disk space inflammation (discitis) and uniform paraspinous enhancement of varying thickness. This complex of findings is generally absent with pathologic tumor or benign compression fractures.

Differentiating discitis/osteomyelitis from Modic type 1 degenerative edematous change can be challenging. Lack of paraspinal soft tissue abnormality and normal or dark signal of the intervening disk are suggestive findings for degenerative changes. Diffusion-weighted imaging sequences (DWI), if obtained, may demonstrate well-marginated linear high signal between normal and edematous marrow (“claw sign”) which is highly indicative of degenerative changes; conversely, diffuse abnormal high signal on DWI in the edematous region (absence of claw sign) is highly suggestive of discitis/osteomyelitis (Figs. 19.13 and 19.14).  

**FIGURE 19.13** Diffusion magnetic resonance imaging “claw sign.” The claw sign is identified on trace/combined diffusion-weighted imaging sequences (DWI) as well-marginated, linear, typically paired, regions of high signal situated within adjoined vertebral bodies at the boundaries between the normal bone marrow and vascularized bone marrow. (Republished with permission of American Society of Neuroradiology from Patel KB, Poplawski MM, Pawha PS, et al. Diffusion-weighted MRI “claw sign” improves differentiation of infectious from degenerative modic type 1 signal changes of the spine. AJNR Am J Neuroradiol 2014;35[8]:1647–1652; permission conveyed through Copyright Clearance Center, Inc. Copyright © 2014 by American Journal of Neuroradiology.)
FIGURE 19.14  Gradation from positive to negative “claw signs.” 1 = definite, 2 = probable, 3 = questionable, 4 = negative (diffuse signal). (Republished with permission of American Society of Neuroradiology from Patel KB, Poplawski MM, Pawha PS, et al. Diffusion-weighted MRI “claw sign” improves differentiation of infectious from degenerative Modic type 1 signal changes of the spine. AJNR Am J Neuroradiol 2014;35[8]:1647–1652; permission conveyed through Copyright Clearance Center, Inc. Copyright © 2014 by American Journal of Neuroradiology.)

Nuclear medicine gallium scan may also be considered for imaging in this setting, if MRI is contraindicated.

DISCOGENIC PAIN
Before the advent of spinal CT and MRI, discography was the only radiologic technique for directly assessing the anatomy and integrity of the intervertebral disk. Discography involves injection of radiographic contrast material into a suspected abnormal disk and one or two normal (control) disks while monitoring the patient’s subjective reported pain (Fig. 19.15). A positive test result is indicated by reproduction of the patient’s
symptoms during injection of the involved abnormal disk level, without similar symptoms on injection of control disk levels.\textsuperscript{83}
FIGURE 19.15 Discogram. A 34-year-old man with chronic lower back pain with radiation to left leg. **A:** Sagittal T2-weighted lumbar magnetic resonance imaging examination demonstrates an annular tear at L4–L5 as well as mild disk desiccation at L3–L4 and L5–S1. **B:** Lateral fluoroscopic spot film showing placement of 25G Chiba needles within the intervertebral disks at L3–L4, L4–L5, and L5–S1. **C:** Anteroposterior (left) and lateral (right) fluoroscopic images after injection of contrast material. During contrast injection, the patient reported no pain at L3–L4, mild (2/10) pain similar to clinical symptoms at L4–L5, and minimal (1/10) pain unlike clinical symptoms at L5–S1. **D:** Postdiscography axial computed tomography (CT) through L3–L4. Internal fissures and small central annular tear (arrow). **E:** Axial CT through L4–L5. Internal fissures. **F:** Axial CT through L5–S1. Internal fissures and annular tear with focal herniation (arrows). Discography is a unique provocative test for discogenic pain, but its major limitation is the fact that it is highly subjective. Patient reliability in accurately reporting symptoms during disk injection can be affected by psychological factors as well as the interview technique.\(^{84,85}\) The discographic identification of a painful disk also does not guarantee that the patient will respond to surgical fusion at that level.\(^{86,87}\) Concordant pain could be present in patients with mild low back pain who do not seek treatment.\(^{88}\)

Because ongoing controversy exists regarding the accuracy and reliability of discography\(^{89–91}\) as well as the potential for sustained trauma
to the disk by discography, its utilization has steeply declined in recent years coinciding with concurrent improvement in noninvasive MRI techniques. From an anatomic standpoint, CT and MRI have mostly replaced discography.\textsuperscript{92} Currently, there is a limited role for discography as a provocative test in selected patients with persistent and presumed disk abnormalities but negative on imaging, with the aim of selecting patients with a greater likelihood of improvement after spinal fusion procedures.\textsuperscript{93} Indeed, in many centers, it is no longer performed and has been supplanted by modern MRI spinal imaging techniques.

**Limb Pain and Magnetic Resonance Neurography**

**MAGNETIC RESONANCE NEUROGRAPHY**

Magnetic resonance neurography (MRN) involves high-resolution imaging of peripheral nerves to confirm pathologic involvement of a nerve and to localize the site and extent of a pathologic process. It is targeted to specific peripheral nerves based on symptom pattern and neurologic exam. It should not be considered a screening technique and is ineffective as such. The primary purpose of MRN is to confirm presence of a suspected abnormality involving a specific nerve based on clinical neurologic signs and symptoms. It is also useful to localize the site and extent of pathology to help in assessing the need for surgical intervention and to aid in surgical treatment planning should intervention be indicated. MRN indications include evaluating a mass lesion, compressive neuropathy, nerve entrapment syndromes, unexplained focal neuropathy or plexopathy, and traumatic nerve injury. It is also useful in the posttreatment setting for evaluation of nerve response to invasive therapy.

With the advance of available surgical techniques, accurate presurgical evaluation of a nerve abnormality is becoming more and more important. MRN of the brachial or lumbosacral plexuses and major peripheral nerves permits direct visualization of the nervous structures and can visualize the presence of abnormalities associated with perineural irritation, edema, or compression.\textsuperscript{94–98} Pathologic states caused by variant anatomy (such as compressive fibrous bands or offending bony spurs), prior trauma, scar tissue or mass lesion, and musculoskeletal causes of pain can be detected
or excluded (Figs. 19.16 to 19.18). MRI of distal musculature can provide evidence of denervation in the distribution of a given peripheral nerve and provide further evidence of neuropathy (Figs. 19.19 and Fig. 19.20). In rat models, increased T2 signal has been shown in the denervated muscles as soon as 48 hours following a denervation event and peaks at about 2 to 4 weeks. If there is nerve regeneration and reinnervation, the abnormal muscle signal resolves as reinnervation progresses in about 6 to 8 weeks in the rat model. But without regeneration of the nerve, denervation changes of the muscle progresses and eventually causes muscle atrophy with fatty infiltration several months later.

FIGURE 19.16  C5 schwannoma. An 81-year-old man with 4 years of left upper extremity pain and dysesthesia. Axial and coronal short tau inversion recovery images reveal a dumbbell-shaped high signal intensity extradural mass involving the left C4/C5 neural foramen (arrows).
FIGURE 19.17 Nerve root avulsion. A 25-year-old man with traumatic injury to the right brachial plexus following a motorcycle accident that resulted in a flail upper extremity. After the accident, he suffered from daily, intermittent, lancinating pain. Electromyography demonstrated absent cortical and brainstem response to stimulation of median and ulnar nerves and upper trunk of brachial plexus (C6–C8 roots). Coronal T1 and short tau inversion recovery images show proximal meningeal diverticula at C6, C8, and T1 (arrows, arrowhead) as well as abnormal signal in the right brachial plexus.

FIGURE 19.18 Pancoast tumor. A 42-year-old man with mild cough. Posterior superior mediastinal mass was identified on plain radiograph. Sagittal T2 images demonstrate the pulmonary
apex mass (long arrow) that abuts but does not surround the subclavian artery (small arrowhead). At surgery, the mass was found to be a lung cancer. Small arrow, anterior scalene muscle; large arrowhead, brachial plexus.

**FIGURE 19.19** Subacute denervation in the distribution of the peroneal nerve. This axial short tau inversion recovery image of the proximal calf at the level of the fibular head (F) and the tibial metaphysis (T) demonstrates markedly hyperintense signal intensity within the anterior compartment muscles (asterisk). Note the muscles of the posterior calf for comparison, which show normal signal intensity. This illustrates the typical appearance of acute and subacute denervation that in this case followed severe injury to the left common peroneal nerve.

**FIGURE 19.20** Ulnar and radial nerve injury. This patient suffered a severe left brachial plexus injury, with radial and ulnar neuropathy. A: T1-weighted axial image through the left upper arm showing location of the radial (arrow) and ulnar (arrowhead) nerves. T1 sequences generally demonstrate anatomic relationships better than corresponding short tau inversion recovery sequences. B: Short tau inversion recovery image showing increased signal in radial and ulnar nerves (arrows) as well as increased signal in triceps muscle (asterisk).

Neurogenic pain involving the neck, shoulder, and the upper extremity can result from cervical nerve root compression, brachial plexopathy, thoracic outlet syndrome (TOS), ulnar nerve entrapment at the
elbow, or median nerve compression at the carpal tunnel.

Neurogenic pain involving the lower back, hips, and legs can result from lumbar nerve compromise, lumbosacral plexopathy, and an abnormality in or along the sciatic nerve (see Chapters 40, 69, and 72). MRN is particularly useful for patients with unexplained neuropathy, for whom surgical intervention is considered, or when the exact anatomic site of abnormality remains unclear after clinical examination and electrodiagnostic studies. However, because only a relatively small field of view (FOV) can be imaged with high spatial resolution, it is necessary to clinically approximate the site of a suspected neuropathic lesion as closely as possible before performing MRN. Imaging is then focused on the site of maximum clinical suspicion with optimal high-resolution imaging technique.

High magnetic field strength (3T) is preferred, although adequate studies can often be performed at 1.5T. T1-weighted images obtained parallel and perpendicular to the nerve of interest provide superb anatomic definition. Frequency selective fat saturation fast spin echo (FSE) T2 and/or short tau inversion recovery (STIR) sequences are sensitive to changes in normal signal intensity within a nerve. The roots, trunks, and cords of the brachial plexus can be shown for evaluation of possible pathology. Imaging of the lumbosacral plexus is done within the pelvis and upper thigh to follow the course of the sciatic or femoral nerves. In the case of bilateral nerve representation in the plexuses, it is often helpful to image both sides of the patient for comparison with the asymptomatic side.

Optimal MR neurography at the elbow, wrist, and arm in the upper extremity and the thigh, knee, and ankle in the lower extremity requires even higher resolution imaging to enable visualization of these very small nerves that are of the order of 1.5 to 3 mm in cross-sectional size. However, similar T1, FSE T2, and STIR sequences are employed for imaging; in the extremities, these are generally conducted in the axial plane perpendicular to the nerve and in the coronal plane parallel to the nerve.

MRN appearance of normal nerves demonstrates iso- or slightly increased T2-weighted signal compared to muscles. Fascicles are easily
seen within larger nerves such as the sciatic nerve but can often be seen even in smaller nerves including ulnar, median, and radial nerves in the upper extremity and the sciatic, tibial, and peroneal nerves in the lower extremity. Abnormal changes in peripheral nerves identified by MR neurography include focal or generalized enlargement of the nerve, increased signal on T2 and STIR sequences, and swelling or loss of fascicular architecture. Enhancement after administration of gadolinium contrast is generally only seen with tumors of the peripheral nerves or with infection, and thus, for most MRN studies done for other indications, contrast enhancement is not used.\textsuperscript{97,98,108} Direct imaging of peripheral nerves at common sites of entrapment can confirm the location of repetitive stress injury or tumor and help clinicians select patients who might benefit from decompressive surgery (see Figs. 19.20 and Figs. 19.21).\textsuperscript{108}

A secondary sign of peripheral neuropathy may include acute and subacute denervation of musculature supplied by the involved peripheral nerve. This consists of increased signal on T2 and STIR sequences, sometimes accompanied by postcontrast enhancement of the denervated muscle in the acute phase. On the other hand, chronic denervation results in marked loss or atrophy of muscle mass, together with fatty infiltration. At the same time, the increased T2 signal seen in acute and subacute denervation disappears, and the muscle returns to a normal T2 signal.

\textbf{FIGURE 19.21} Ulnar entrapment. Axial T1 (A) and short tau inversion recovery (STIR) (B) images of the right elbow taken at the level in which the ulnar nerve passes through the cubital tunnel. A: On this T1-weighted image, a normal sized right ulnar nerve is nicely demonstrated surrounded by perineural fat (arrow). B: The STIR image, however, demonstrates abnormally increased hyperintensity within the nerve that is abnormal (arrow) and that, in the presence of appropriate symptoms, is an indication of ulnar nerve entrapment.
intensity. Thus, the specific pattern of abnormal muscle denervation defines the involved peripheral nerve or nerves as well as providing a rough estimate of chronicity and is an effective means of confirming the affected nerve (see Figs. 19.19 and 19.20).\textsuperscript{94,109}

**THORACIC OUTLET SYNDROME**

TOS is a group of disorders associated with impingement of the nervous or vascular structures during egress/ingress from the base of the neck to the axilla (see Chapter 40). Most patients have a controversial syndrome characterized by variable supraclavicular and upper extremity pain, dysesthesia, and weakness in the absence of a definitive etiology such as anomalous cervical rib.\textsuperscript{110} Because musculoskeletal inflammatory conditions, complex regional pain syndromes, and distal compressive neuropathies can have similar symptoms, the diagnosis of TOS can be extremely difficult. Although decompression of the inferior brachial plexus and subclavian vessels by transaxillary resection of the first rib has been successful in management of some patients with intractable TOS after a failed trial of physical therapy, the decision to operate is rarely straightforward.

There are three forms of TOS: arterial, venous, and neurogenic. Neurogenic TOS is considered to be most common, consisting of more than 90\% of all TOS cases.\textsuperscript{111} Neurogenic TOS is difficult to diagnose. Patient symptoms are subtle and confusing but generally show chronic progression. It is usually considered to be associated with chronic compression and entrapment. Primary use of EMG is to exclude other peripheral neuropathies, rather than to rule in TOS.

A minority of patients (fewer than 10\%) have a predominantly vascular form of TOS (arterial or venous). Arterial TOS symptoms result from subclavian or axillary artery compression, whereas venous TOS arises from venous insufficiency and/ or thrombosis.\textsuperscript{112} Arterial TOS typically presents with upper extremity arterial insufficiency symptoms or embolic episodes. Ultrasound and/or arteriography may help to demonstrate subclavian artery compression, arterial thrombosis, or distal emboli. Venous TOS (Paget-Schroetter syndrome) is due to thrombosis caused by compression of the subclavian or axillary vein and typically presents with
upper limb swelling, pain, and cyanosis. It is significant in that it can result in pulmonary embolism.

The role of imaging in suspected TOS is not clearly established at present, and more investigation is required to evaluate the validity of imaging.\textsuperscript{113} If cervical radiographs visualize the cervical ribs, the diagnosis is easily made. However, most cases of neurogenic TOS are not associated with cervical ribs. Neurogenic TOS may be imaged with MR neurography of the brachial plexus; the diagnosis may be made through identification of an angular deformity of the brachial plexus trunks as they pass through the scalene triangle (interscalene triangle), especially when there is abnormal insertion of the anterior scalene muscle. There may be accompanying increase in T2 signal of the affected nerve(s). Other potential compression sites are the costoclavicular space and the subpectoral space.

MRI is an emerging modality in evaluation of TOS.\textsuperscript{114,115} It is noninvasive, does not require radiation, and demonstrates good soft tissue delineation. Panegyres and colleagues\textsuperscript{114} reported sensitivity of 79\% and specificity of 87.5\% for the detection of distortion or displacement of the brachial plexus or subclavian vessels. Contrast-enhanced MRA is also useful to evaluate vascular compression,\textsuperscript{116} especially with abducted arm position.\textsuperscript{117–119} However, arterial compression can also be seen in the normal population (0\% to 1.39\%), and venous compression is seen more frequently in normal populations (41.7\% to 47\%); therefore, clinical correlation is extremely important.

**PIRIFORMIS SYNDROME**

Piriformis syndrome is radiating leg pain from a non disk origin caused by compression or irritation of the sciatic nerve as it courses anterior/inferior to or through the piriformis muscle. On MR, abnormal high T2-weighted signal can be present in the affected sciatic nerve.\textsuperscript{120,121} Filler et al.\textsuperscript{121} reported that piriformis muscle asymmetry and sciatic nerve hyperintensity at the sciatic notch exhibited a 93\% specificity and 64\% sensitivity on MR, in distinguishing patients with piriformis syndrome from those who had similar symptoms but not attributable to piriformis entrapment.
PERIPHERAL NERVE ENTRAPMENT SYNDROMES

Carpal tunnel syndrome is the most common form of nerve entrapment and is the result of median nerve compression at the carpal tunnel (see Chapter 72). Clinical features are usually sufficient for diagnosis. Frequent signs and symptoms include paresthesia and hyperesthesia in the median nerve distribution, radiation of pain along the volar aspect of the forearm, nocturnal pain, exacerbation with repetitive movements, and atrophy of the thenar muscles. Carpal tunnel syndrome is most often caused by repetitive injury of the median nerve within a tight carpal tunnel volume. Other possible etiologies include focal space-occupying lesions, local inflammatory processes, or metabolic derangements related to systemic illness.122,123

Proximal nerve entrapment can mimic carpal tunnel syndrome; potential sites of impingement are the cervical spine, thoracic outlet, and along the course of the median nerve. The pronator syndrome and the anterior interosseous syndrome are distal median nerve compression syndromes. In the former, the median nerve is compressed by the two heads of the pronator teres muscle. In the latter, the anterior osseous nerve is entrapped as it courses along the interosseous membrane. Both of these syndromes can produce symptoms identical to carpal tunnel syndrome.97

Although ultrasound and CT have been used to evaluate anatomy of the carpal tunnel and visualize the median nerve,124 MR is superior to these technologies in confirming the diagnosis due to its sensitivity for detection of abnormal T2/STIR signal within a compressed median nerve. Axial T1 and STIR images are obtained from the distal radiocarpal joint to the metacarpal bases. High-resolution imaging with high field strength 3T MR systems are valuable in providing good image quality to optimally demonstrate these small structures (Fig. 19.22).94
Findings in carpal tunnel syndrome include increased cross-sectional size reflecting swelling of the median nerve proximal to the carpal tunnel, flattening of the nerve within the tunnel, increased palmer bowing of the flexor retinaculum, and increased median nerve T2 signal intensity on STIR sequences. Ganglion cysts, lipomas, and other soft tissue tumors and posttraumatic or degenerative bony deformities may result in similar symptoms. These abnormalities are easily identified and differentiated on MRI. Thickening or separation of tendons with increased signal changes on T2 or STIR sequences indicates tenosynovitis, often idiopathic. Amyloid, gout, acromegaly, hypothyroidism, and other systemic diseases associated with carpal tunnel syndrome are generally diagnosed on the basis of clinical, laboratory, and plain film findings.\textsuperscript{125–128}

Additional entrapment syndromes are also found with ulnar nerve entrapment either in the cubital tunnel at the elbow or in Guyon’s canal in the wrist.\textsuperscript{129} Common symptoms include tingling sensation in the ring and little fingers. On MRN of the elbow or wrist, respectively, abnormal signal and enlargement of the ulnar nerve can be seen.\textsuperscript{130} In the leg, common peroneal nerve entrapment may occur as it passes around the fibular head and can be recognized by abnormal high T2 signal within the nerve.\textsuperscript{101} MRN diagnosis of these various entrapment syndromes requires careful attention to the anatomy of the particular nerve involved.\textsuperscript{94}

**Imaging Guided Injection**

Imaging studies play an important role in the facilitation of diagnostic and
therapeutic nerve blocks, vertebroplasty, and kyphoplasty (see Chapters 100 to 104). Accurate placement of needles for the injection of local anesthetic or neurolytic substances is confirmed with image guidance that may utilize fluoroscopy, ultrasound, or CT scanning. These imaging techniques can assist with safe and accurate placement of a needle at the specific nerve, nerve root, or facet that is being blocked. The injection of a contrast agent with a local anesthetic solution can reveal the distribution of the agent used and confirm which nerve or facet has been exposed to the anesthetic solution. This is particularly important when a surgical decision is based on the responses to the blocks. These techniques are particularly useful in patients whose anatomy has been distorted by disease processes or prior surgical procedures.

Fluoroscopy is also used in the placement of epidural electrodes or catheters. Surgical procedures such as gangliolysis of the trigeminal nerve or radiofrequency rhizolysis of spinal nerves are performed with fluoroscopy or with intraoperative CT. CT scans are commonly used for celiac plexus block.

These procedures are discussed in more detail in other chapters of this textbook.

**Future Application of Pain Imaging**

Pain is subjective and affected by emotional and psychological factors. Recent advances in functional and volumetric anatomic brain imaging have started to reveal the complex processes involved in central pain mechanisms. Patterns of brain activation with various pain syndromes are being explored, and the responses of individuals with chronic pain versus control subjects undergoing identical painful stimuli are beginning to reveal interesting findings (e.g., in evaluation of cluster headaches) (Fig. 19.23).
Neuroimaging of cluster headache. Schematic brain representation summarizing the findings of neuroimaging studies of cluster headache (CH): (1) CH appears to involve structural and functional changes in the pain matrix, especially in the descending pain modulation network; (2) disordered frontal top–down pain modulation is dynamically altered between in-bout and out-of-bout periods; (3) the anatomic and functional links between the hypothalamus and forebrain as well as cerebellar and occipital areas are altered in CH and may underlie its pathophysiology and clinical characteristics; and (4) the hypothalamus is likely involved in acute attacks, with a possible tendency to reverse outside acute attacks. The blue circles indicate the anatomic locations with structural and functional changes during in- or out-of-bout (without acute attacks) episodes. The yellow circles indicate the anatomic locations with structural and functional changes between in- and out-of-bouts. The red circles indicate the anatomic locations with structural and functional changes during acute attacks. ACC, anterior cingulate cortex; Amyg, amygdala; Cereb, cerebellum; Hyp, hypothalamus; Insula, insular cortex; PAG, periaqueductal gray; PFC, prefrontal cortex; PPC, posterior parietal cortex; SMA, supplementary motor area; S1, primary sensory cortex; Th, thalamus. (Adapted and revised from May A. Structural brain imaging: a window into chronic pain. Neuroscientist 2011;17[2]:209–220. Copyright © 2011 SAGE Publications; From Yang FC, Chou KH, Kuo CY, et al. The pathophysiology of episodic cluster headache: Insights from recent neuroimaging research. Cephalalgia 2018;38[5]:970–983. Copyright © 2018 SAGE Publications.)

Pain-related activity and the areas in the brain that subserve pain are complex and is termed the pain matrix. These evolving brain maps offer hope for understanding how pain relates to emotions, memory of pain, anticipation, personality, and other contributors. Imaging is used in investigating pain types, pursuing suppression mechanism of pain, and prevention of transition from acute pain to chronic pain. Chronic pain is now known to be associated with reduction of gray matter density and altered network connectivity. How these will influence diagnosis and management of patients with chronic pain is yet to be defined but offer exciting possibilities and hope.
Conclusion

Diagnostic imaging in patients with acute pain has a clearly defined role in establishing or confirming a pathologic diagnosis and directing medical, surgical, or radiologic intervention. Imaging for patients suffering from chronic or recurrent pain plays a significant role in detecting degenerative disease, anatomic variations, chronic inflammatory conditions, neoplasm, and postoperative or posttraumatic scarring. In selective cases, targeted and specialized imaging examinations may be of benefit for the determination of etiology, treatment planning, and prediction of the outcome of directed therapy.

CHAPTER 20
Measurement of Pain
MARK P. JENSEN

Introduction

Valid and reliable pain assessment is essential for successful pain care. Adequate assessment is also necessary to determine the efficacy of pain treatments in clinical trials and for understanding the mechanisms of those effects. The clinician or researcher who wishes to use the most useful measures and strategies for pain assessment is faced with a large, and growing, number of options and decisions. The purpose of this chapter is to make those decisions easier.

Of course, in clinical settings, pain assessment in a broader sense should involve a detailed psychological and medical exam and often also involves the administration of general measures of physical and psychological function. These issues are addressed in detail in other chapters of this volume on different pain conditions. The focus of this chapter is on self-report and observational measures that are specific to the experience and impact of pain.

The chapter begins with a brief discussion of several important issues that clinicians and researchers need to consider when choosing from among pain measures and designing pain assessment procedures, including (1) evaluating the reliability, validity, and utility of pain measures; (2) determining the number of pain problems to assess; (3) choosing the pain domain(s) to assess; and (4) selecting the time period of assessment (e.g., current pain experience vs. recall of pain over the last day, week, or longer). The bulk of the chapter then reviews the available psychometric information regarding measures of six pain domains: pain intensity, pain affect, pain quality, pain site, pain’s temporal characteristics, and pain interference. Next, the chapter briefly discusses strategies for assessing pain in special populations (e.g., infants and young children or other
patients who might have difficulty expressing themselves verbally). It ends with a summary of recommendations.

VALIDITY, RELIABILITY, AND UTILITY IN THE CONTEXT OF PAIN ASSESSMENT

No measure is perfect. No one measure assesses all pain domains, nor is any single measure useful in all settings and with all populations. Moreover, because of the imperfection of available instruments, it is theoretically possible to modify any existing measure to improve it further or to develop new and better measures to replace existing ones. As a result, new pain assessment procedures and measures are constantly being developed and published. Thus, the clinician or researcher seeking to find the best measure for his or her needs should not only be aware of the existing pain assessment literature but should also know how to evaluate new measures as they are published.¹ The following section seeks to facilitate this task by briefly summarizing the three key issues that should be considered when evaluating any pain measure: validity, reliability, and utility.

Validity
Validity refers to the appropriateness, meaningfulness, and usefulness of a measure for a specific purpose. It is generally seen as the most important consideration in the evaluation of a measure.² Validity always needs to be evaluated with respect to the specific purpose a measure or instrument will be used for; measures are not inherently “valid” or “invalid” in and of themselves. For example, a hammer is not inherently valid. It is valid (useful) for driving nails into wood but invalid for washing dishes.

Rarely, if ever, can the validity of a measure be determined with a single study. Rather, support for the validity of a measure is usually established over time and with a series of studies. When evaluating the validity of a potential measure, the clinician or investigator should consider content, construct, and criterion validity.

Content Validity
Content validity concerns the degree to which the items of a measure
represent a defined universe or domain of interest. For example, if a measure of a patient’s usual pain or average pain over the last month is needed, then a single rating of current pain would not usually be considered to have content validity for assessing this construct because pain can vary so much from one moment to another. Similarly, if a measure of the impact of pain on a patient’s life is needed, and a measure includes items that ask only about pain’s impact on sleep and mobility (but not other important daily activities), the measure would not generally be viewed as adequately representing the domain of pain interference. Thus, a critical question that every test user should ask is whether or not a potential measure assesses or represents all of the key components of the domain of interest. If the measure does not meet this standard, it does not have content validity.

Construct Validity
Construct validity refers to how well the items of a measure perform as measures of the domain or construct of interest. Two measures can have similar content validity—that is, both may contain items that assess the critical components of some pain construct—but have different construct validity. For example, if two measures ask about pain interference with the same set of activities, yet respondents are asked to indicate the extent of interference with each activity using different response levels (e.g., yes/no response in one measure vs. 0-to-10 scales in the second), the latter measure may evidence more precision than the former. The more precise measure may represent the construct better and have more construct validity than the less precise one, despite the fact that the two measures have the same content validity.

Similarly, if the language used in the items of one measure is clear and succinct and the language used in another measure is confusing and complex, the former measure would likely contain less error than the latter measure, and the scores from the former measure would therefore be more likely to better represent the construct of interest. Thus, factors other than content validity will impact how the scores obtained from different measures behave, especially with respect to their associations with other important pain-related measures and the precision with which they represent the domain of interest. Evidence for the construct validity of a
measure generally comes from studies that demonstrate strong associations between a measure’s score and other measures of the same construct or related constructs and weak to moderate associations with measures of other constructs.

Criterion Validity
Criterion validity refers to a measure’s associations with one or more key outcome criteria. Usually, the most important criterion of a pain measure is the responsivity of the measure to the effects of a pain treatment, or to changes in pain over time, because pain measures are most often used for detecting these differences and changes. Pain measures that are proposed to be used as outcome measures in clinical trials should therefore have evidence that they are able to detect treatment effects or show expected changes in pain over time.

But not all pain measures are designed to assess treatment efficacy. A number of measures of pain quality, for example, and as described later in this chapter, were designed to distinguish from among different types of pain (e.g., neuropathic vs. nociceptive). The validity of such measures should be determined by their ability to perform the task they were designed for or that they will be used for; their validity as measures of treatment efficacy need only be of concern when or if they are being considered for that specific purpose.

Reliability
Reliability refers to the extent to which the score from a test is free from errors of measurement. Many factors, other than a patient’s experience of pain, could potentially influence his or her response to a pain measure or scale. Such factors could include the specific assessment setting (e.g., home vs. clinic), assessment burden (e.g., single assessment vs. a daily diary), the person administering the measure (e.g., research assistant, nurse, spouse, primary health care provider), other subjective experiences and feelings (e.g., being more or less fatigued or upset), motivational factors (e.g., desiring to appear stoic, wanting a prescription for a specific medication), ethnicity or culture, and previous learning experiences (e.g., the consequences of reporting of higher vs. lower pain levels), among many others. The variability in a pain score (the “variance”) that is
associated with these other factors, and that is not associated with the specific domain of interest, is considered error variance. Although no measure is 100% reliable, the best measures demonstrate relatively little influence of these other factors and potential sources of error.

Higher error variance means lower reliability. Unlike validity, which is considered with respect to the proposed use of the measure, and therefore varies depending on context, reliability is usually considered to exist within a measure. However, it is also possible for a measure to be more reliable in some settings or with some populations then in others. For example, as described in more detail later in this chapter, Visual Analogue Scales (VASs) of pain intensity (where the respondent is asked to make a mark on a line that represents the perceived magnitude of pain) have been found to be more difficult for patients with cognitive deficits than with patients who do not exhibit cognitive deficits. VAS measures, then, are now considered to be inadequately reliable in populations at risk for cognitive deficits, although evidence indicates that they may be adequately reliable in otherwise healthy adults. Thus, it is important that the reliability of any measure be established for the specific population with whom the measure will be used or at least in samples of individuals who are similar to the population with whom the measure will be used.

Utility
Finally, issues of reliability and validity need to be considered in light of a measures’ utility, given that there is often a trade-off among these. For example, to maximize the content validity of a measure of pain interference, one would want the measure to assess the pain interference of all, or nearly all, of the possible (100s? 1,000s?) activities a person could engage in. Such a measure, although it would have clear content validity, would not be practical; no one would use it. Similarly, to maximize the content validity of a measure of a patient’s usual pain over the course of the last month, one might ask the patient to report on his or her current pain every hour for 30 days and then average those responses into a single index of average pain. But few patients would be willing to perform this assessment task, and the costs of ensuring complete data for such a measure would be prohibitively expensive for most clinicians and many
researchers. Deciding on which measure(s) to use for a particular application often comes down to selecting the measure that is both adequately valid and practical.

**HOW MANY PAIN PROBLEMS SHOULD BE ASSESSED?**

Patients often have more than one pain problem. For example, the majority of individuals with spinal cord injury have chronic pain, and the majority of these report pain at more than one site. Clinicians and those researchers who do not limit their sample to the (few) patients with only one pain problem are faced with the difficult task of determining the number of pain problems to assess in any one patient or study participant. If only one “primary” pain problem is assessed at a clinic visit, but on the next visit, a different “primary” pain problem emerges as the most distressing, then it would be very difficult to track the effects of pain treatment from one clinic visit to the next.

Similarly, researchers who limit the number of pain problems assessed to just one primary problem run the risk of underestimating the magnitude of pain and its impact in their research findings. On the other hand, it is not practical to assess every pain problem in every patient seen in the clinic or in every participant of a research study. These considerations suggest that, in many situations, patients should have the opportunity to report on more than one pain problem but not necessarily be required or expected to report on every pain problem that they have at every assessment point.

But how many pain problems should be assessed? Two? Five? More? One approach to deal with this issue is to begin by assessing pain “in general”; for example, asking patients to consider all of their pain problems together when rating the overall average magnitude or intensity of their pain and the impact of pain on their lives. This is a practical solution, especially for assessing pain interference, because it may be very difficult for patients to identify the unique contribution of each different pain problem to interference with different activities. Moreover, assessing global pain intensity and interference allows the clinician or researcher to have a single primary measure of these two key pain domains, making analyses and tracking over time easier.
However, limiting assessment to only pain “in general” may oversimplify assessment and also interfere with determining the true effects of pain treatment. For example, if a pain treatment reduces the pain associated with one pain problem (e.g., headache) but not another (e.g., low back pain or a neuropathic pain condition), the specific effect of the treatment on headache pain might be less noticeable or even lost altogether if a measure of “general” pain intensity is used. So, in many situations, allowing for the assessment of more than one pain problem would be useful.

Unfortunately, however, there is not yet a clear consensus in the field concerning the best number of pain problems to assess. In the clinical setting, it probably makes sense to assess as many of the pain problems that are of concern to the patient. If the patient experiences eight unique pain problems and views each as a significant problem that contributes to dysfunction, then perhaps each of these should be assessed, at least at the initial evaluation, and then tracked at subsequent clinic visits as appropriate.

When determining how many pain problems to assess in a research study, the number of problems that should be assessed would vary as a function of the research question(s) being asked and the specific population being studied. One reasonable option would be to select the number of pain problems to assess that would capture the majority of patients in the population. For example, in persons with spinal cord injury, it has been recommended that investigators should consider assessing basic information (such as pain location and intensity) for up to three presenting pain problems. In this instance, three was chosen as a way to balance the need for a thorough assessment against the need to minimize assessment burden, keeping in mind that the majority of persons with spinal cord injury and pain report three or fewer pain problems. Although it is unlikely that a single upper limit of pain problems can be identified that should be assessed in every research project and with every patient population, each investigator would do well to consider this issue when developing assessment protocols.

**WHICH PAIN DOMAIN(S) SHOULD BE ASSESSED?**

980
Clinicians and researchers have long recognized that pain is a multidimensional experience that includes a number of measurable qualities such as intensity, affect (global bothersomeness of the pain experience as well as the impact of pain on emotional functioning), sensory quality, spatial quality (location), temporal quality, and impact on or interference with daily activities. Although the focus of pain assessment in many clinical and research settings has often been, and continues to be, on pain intensity, there is now a well-established recognition and interest in the assessment of pain’s other domains.

It is important that clinicians and investigators consider assessing more than just pain intensity for a number of important reasons. First, limiting assessment to only pain intensity leaves clinicians and researchers in the difficult position of having limited information about the presenting pain problem(s). In a clinical situation, changes in a pain domain not assessed might end up being critical for understanding the effects of a pain treatment (e.g., if pain qualities are not assessed, and a treatment reduces the “aching” and “deep” qualities of a pain problem, but perhaps not average pain intensity overall, or if a treatment produces a decrease in the impact of pain on sleep or other areas of functioning, even when there has been a minimal impact on pain intensity). For this reason, clinicians and researchers interested in assessing pain should at least consider all of the pain domains when determining which ones to assess and perhaps only avoid those domains they are certain will not be important to treatment (for clinicians) or understanding (for researchers).

One of the factors that might determine the selection of fewer domains and measures (e.g., perhaps choosing to assess just pain intensity and pain quality) over a more comprehensive assessment (e.g., including measures of pain site, pain interference, and the temporal qualities of pain as well as perhaps more general measures of psychological and physical functioning) is whether the pain problem being assessed is more acute or chronic. Acute pain, which may be defined as pain resulting from current or very recent damage to tissue, includes pain from medical procedures (e.g., injections, lumbar punctures, surgery) as well as both major and minor physical injuries. Because acute pain problems tend to resolve quickly in most individuals, their impact tends to be transitory. In this situation, and if the
focus of treatment is on just one or two pain domains (e.g., pain intensity, mood), then it may be appropriate to assess only one or two pain domains. Chronic pain, on the other hand, tends to be more complex than acute pain. It also tends to influence a large variety of quality of life domains (e.g., employment status, sleep quality, psychological status, social functioning). Patients’ responses to chronic pain can also be quite variable, as can its impact. For chronic pain, then, in both clinical and research settings, and in order to ensure a thorough understanding of the pain problem, more pain domains, and perhaps more measures that assess these domains, are often required.

RECALL RATINGS VERSUS SUMMARY SCORES FROM MULTIPLE RATINGS USING DIARIES

Often, the clinician or researcher wishes to have a measure of a patient’s usual pain during a specific period of time. A single measure or rating of current pain is not likely going to be an adequate index of usual pain, given that pain can vary from one moment to another. So what is the best way to assess usual pain? The three most common methods to assess pain intensity in clinical trials are (1) ask respondents to provide multiple ratings of current pain on pain diaries during the epoch of interest (e.g., four times per day for 7 days) and then compute the arithmetic mean of the ratings obtained, (2) assess pain once per day on several days, asking respondents to provide a recall rating of their average pain in the previous 24 hours and then computing the arithmetic mean of these 24-hour recalled average pain ratings to create a composite score representing usual pain, or (3) assess pain just once but ask respondents to provide recall ratings of their average pain over the entire epoch of interest. Each approach has strengths and weaknesses. In addition, pain assessment experts have not yet reached a clear consensus on which option should be recommended.

Support for the first approach, using multiple ratings of current pain from daily diary data (most often obtained electronically by asking patients to access a Web site to provide ratings or via automated telephone calls to patients) comes from studies that have demonstrated (1) a biasing impact of recent pain and worst pain (also known as “end” and “peak” effects) on recall ratings\textsuperscript{10–12} and (2) access to computer-based and electronic diary
technology which facilitates data collection.\textsuperscript{13,14} When diaries are required, electronic, Web-based, or phone diaries are preferred over paper-and-pencil ones, given the common finding that respondents use paper-and-pencil diaries inappropriately.\textsuperscript{15,16} Because of the strengths of diary approaches, there has been an increase over time in the use of this approach to collect data in clinical trials.\textsuperscript{17–20}

However, there are also good reasons which make some investigators hesitant to embrace an approach that requires multiple daily diary entries to compute pain intensity scores, especially for use in clinical trials. First, as a practical issue, daily diary data can be expensive to collect. The financial cost of the hardware and software management associated with data collection via electronic diaries may be beyond the means of some investigators. Related to this, there is also a cost in terms of patient assessment burden. Some procedures ask respondents to provide only one assessment per day,\textsuperscript{15,21–23} but it has been more common to ask patients to provide three\textsuperscript{23} or even more (4 to 6 times\textsuperscript{17,18,24}) ratings per day. This requires a significant effort on the part of patients, which may lower compliance with the task. To the extent that less costly recall ratings (that require just a few or even just one assessment) may be adequately valid, investigators may save substantial resources and significantly decrease the patient assessment burden if recall ratings are used instead of diary ratings.

A second problem with diary data requiring many ratings is that using this approach will result in missing data. The reported percentages of missing data points from electronic diary studies range from 6\%\textsuperscript{16} to 25\%.\textsuperscript{25} The reported rates of study participants who provide incomplete data (i.e., at least some missing data during the study period) can range from 17\%\textsuperscript{15} to 46\%.\textsuperscript{21} The primary reason reported for missing electronic data is that the patient did not hear the alarm or cue asking for the assessment.\textsuperscript{26} Other reasons given include the alarm going off at an inconvenient time, the participant being too busy to respond, technical difficulties with a computer, emotional reasons, and pain being too severe at the time of assessment.\textsuperscript{26} When data are missing, investigators need to either remove subjects from the analyses (which limits the generalizability of the findings and runs the risk of resulting in findings that overstate the impact of treatment) or use some approach to impute the missing data (i.e.,
estimate what the missing ratings might have been, had all subjects provided complete data). A variety of data imputation procedures can be used for clinical trial data, such as “last observation carried forward” which involves taking the most recent rating obtained and replacing all missing values with that rating. A more conservative approach is to replace missing values with pretreatment ratings. However, if the treatment being examined is effective, this approach can underestimate the treatment effect size. Regardless of the approach used, however, data imputation adds error; imputed data are estimates only. In fact, the error added by the need to impute missing scores could potentially be greater than that associated with recall bias, so the use of diary data over recall ratings could potentially result in a more costly and effort-intensive assessment procedure that is ultimately also less accurate.

A third issue is that the use of electronic diaries limits the subjects who can participate in a study. For example, in one electronic diary study that approached 52 possible participants, 6 refused participation outright, 1 did not have the motor ability to hold the computer stylus, and 5 had visual problems that interfered with their ability to read the computer display. By limiting the participants in clinical trials to those who are able and willing to use electronic diaries, their use in these trials limits the generalizability of the study findings.

Perhaps, the strongest argument against the strategy of computing average pain from multiple ratings of current pain over time is that research increasingly supports the conclusion that recall ratings of pain intensity are adequately valid for most research purposes. Although research does indicate that there can be both peak and end effects that bias recall ratings, these effects tend to be small. Moreover, research indicates that the correlations between recalled average pain (in the previous 7 days) and actual average pain during that same period (as assessed by diaries) are strong (correlation coefficients range from 0.68 to 0.99)—well within a range that indicate they carry valid variance as measures of average or usual pain. In short, recall ratings reflect actual average pain and are therefore valid indicants of that pain. In addition, and perhaps most critically, the research finding that provides the most support for the validity of recalled pain ratings as outcome measures in pain
clinical trials is indisputable: Recall ratings are responsive to the effects of pain treatments known to impact pain. Hundreds, if not thousands, of clinical trials have shown that effective treatments for chronic pain result in reductions in recall ratings of average pain. Thus, there is adequate evidence to support the use of recall ratings as valid measures of pain intensity in clinical and research settings.

That said, two important questions remain unresolved. First, if a researcher chooses to obtain multiple ratings of recalled pain over a relatively small recall period (e.g., daily ratings of average pain in the past 24 hours) and compute the arithmetic mean of these ratings to create a composite score representing usual pain, how many of these recall ratings are needed to create an adequately valid measure of a patient’s average pain? Second, might a single rating of recalled pain over a relatively larger recall period (e.g., a single rating of recalled average pain in the past week) be as adequately valid as a composite score made up of multiple 24-hour recall ratings?

Unfortunately, to date, relatively little research has been performed to address these two questions, despite the significant implications of the answers for designing and conducting pain clinical trials. Only three studies were identified which address the first question. In the first of these, investigators compared the reliability and sensitivity (i.e., ability to detect significant treatment effects) of pain intensity scores made up of one to nine 24-hour recall ratings of pain intensity using data from a clinical trial evaluating the efficacy of oxymorphone extended-release for the treatment of low back pain. As would be expected based on psychometric theory, the reliability of the outcome measure reflecting average pain intensity increased as the number of ratings used to compute that measure increased from one to nine. However, and unexpectedly, this increase in reliability was not associated with improvements in the ability of the composite score to detect treatment effects. In fact, the first single 24-hour recall rating was about as sensitive for detecting treatments effects as the composite scores made up of 2 to 9 ratings. In a commentary on this finding, other researchers noted that these results may have been due to the unusually strong test–retest reliability of the 24-hour recall ratings in the study sample. To address this question further, these other
investigators performed a similar set of analyses using data from a clinical trial evaluating the efficacy of a behavioral intervention for pain associated with osteoarthritis. They found that the individual 24-hour recall ratings of average pain intensity evidenced a great deal of variability in their ability to detect treatment effects, with effect sizes ranging from medium ($d = .34, P = \text{NS}$) to large ($d = .88, P < .001$). Thus, had only a single 24-hour recall rating been used, the actual treatment effect might have been under- or overestimated and deemed either significant or nonsignificant, depending on the single rating used. On the other hand, the effect sizes for composite scores—which were .51, .55, and .66 for composites made up of two, three, and seven ratings—were more stable. Also, all of the composite scores were statistically significant ($P = .0005 \text{ to } .007$). The third study that addressed this question was a secondary analysis of a pilot study (N = 10 individuals with spinal cord injury and chronic pain) which examined the ability of pain intensity scores to detect changes in pain intensity from before to after 12 sessions of neurofeedback treatment. In this study, the single-item ratings (of current pain and 24-hour recalled least, average, and worst pain) also evidenced a great deal of variability in effect sizes (ranging from 0.08 to 1.03). They also became more stable when two ratings were averaged (range, 0.16 to 0.38) and were not that much more stable than this when four ratings were averaged (range, 0.17 to 0.42). These investigators concluded that just two ratings (e.g., two ratings of 24-hour recalled average pain) may be adequate for assessing pain in outcome trials in clinical trials. However, they also noted that it is possible that in some populations—especially populations where pain can vary markedly from 1 day to the next, such as in individuals with chronic headache—more than two ratings might be needed to ensure adequate reliability and validity.

With respect to the second question, regarding the potential of a 7-day recall rating for providing valid ratings of average pain during the previous 7 days, although there are findings showing a tendency for people to overestimate recalled pain over the past week, no study was identified which directly compared the validity of a single 7-day recall rating with composite scores made up of multiple diary ratings. Thus, this critical question remains unanswered at this point in time.
Given the current state of knowledge, what can or should researchers do with respect to assessing average or usual pain intensity? The answer probably depends on the resources available to the researcher. Certainly, there is evidence that a single 7-day recall rating of pain intensity can be sensitive to changes in pain with treatment (e.g., Hans et al., Branco et al.). Therefore, 7-day recall ratings can be considered when resources are limited. However, given that psychometric theory predicts greater reliability (and therefore, ultimately, validity) when more measures are combined into composite scores, and until research is performed to compare single 7-day recall ratings with various combinations of 24-hour recall ratings, it would probably be wise for investigators to consider obtaining more than one rating (e.g., three or four 24-hour recall ratings obtained within a specified number of days) and combining these recall ratings into a single composite score.

Measuring Pain’s Domains

MEASURING PAIN INTENSITY

The single pain domain assessed most often in clinical and research settings is pain intensity, or the magnitude of felt pain. The three most commonly used scales to assess pain intensity are (1) the VAS, (2) the Numerical Rating Scale (NRS), and (3) the Verbal Rating Scale (VRS) (Fig. 20.1). The results from research across many different pain populations yield fairly consistent findings concerning the psychometric properties of these measures and may be summarized as follows:

1. Each of these measures is adequately valid and reliable as a measure of pain intensity in most settings.

2. For both VAS and 0-to-10 NRSs, changes (decreases) between 30% and 35% appear to indicate a meaningful change in pain to patients across patient populations.

3. For 0-to-10 NRSs, the rating chosen has a specific meaning in terms of the impact of pain on function. In most samples, ratings in the 1 to 4 range have a minimal impact on function and can be viewed as representing “Mild” pain. Once ratings reach 5 or 6, patients report that pain has a greater impact on function; these ratings can be
viewed as “Moderate” pain. Ratings ranging from 7 to 10 have the greatest impact on function and can be viewed as representing “Severe” pain.

4. When examined, single-item measures of pain intensity appear to have adequate test–retest stability (often, but not always, greater than 0.80) over short periods of time.

5. There are fairly consistent differences between available measures in terms of their failure rates. VASs usually show higher failure rates than NRSs and VRSs, and NRSs tend (when differences are found) to show slightly higher failure rates than VRSs, probably related to the increased complexity of matching a sensation to a line length versus a number or verbal descriptor.

6. In terms of preferences, patients in Western countries tend to prefer VRSs and NRSs over VASs. Patients from China prefer VRSs over NRS. Whether this finding replicates to populations of patients in other non-Western countries remains to be seen.

**FIGURE 20.1** The Visual Analogue Scale, Numerical Rating Scale, and Verbal Rating Scale.

**Recommendations for Assessing Pain Intensity**

Given the empirical support for the validity and reliability of VASs, NRSs, and VRSs as measures of pain intensity, any of these could reasonably be considered as options in most clinical settings or as outcome measures in clinical trials. Primarily because of (1) differences in failure rates between
these measures in some populations (supporting NRSs and VRSs over VASs),\(^1\) (2) the evidence that some people can differentiate between more than just four or five levels of pain between from “No pain” and “Extreme pain,”\(^{43,44}\) and (3) the potential benefits of standardizing pain intensity assessment to allow for increased comparisons between studies, the field has recently moved toward recommending that clinicians and researchers consider first using the 0-to-10 NRS (see Fig. 20.1) over other pain intensity measures, at least in Western countries and cultures.\(^9\)

Of course, there may be times when the 0-to-10 scale may not be appropriate. This scale requires the respondent to match his or her pain experience to a number, a task that may not be that easy for the very young, the extremely elderly, or individuals who are very ill. In these cases, and perhaps others, alternative pain intensity measures may be needed (see “Measuring Pain in Special Populations” section). Moreover, research suggests that 0-to-10 scales are not preferred by patients in China, as these individuals tend to describe their pain severity using verbal descriptions.\(^42\) Additional research in non-Western countries regarding the utility and validity of the different pain intensity measures is needed to help determine which scale(s) might be most appropriate for cross-cultural research.

**MEASURING PAIN AFFECT**

The affective quality of pain includes both the general unpleasantness and/or bothersomeness of the pain sensation as well as the many varieties of affect (fear, anger, sadness, frustration, feelings of hopelessness) that pain can produce—especially as it becomes chronic. The most common measures of general, global pain unpleasantness are single-item rating scales (VASs, NRSs, and VRSs) that use endpoints that reflect extreme levels of unpleasantness (e.g., for a 0-to-10 NRS or 100 mm VAS, “not bad at all” for the 0 rating or 0-mm mark and “the most unpleasant feeling possible for me” for the 10 rating or 100-mm mark).\(^45\) In general, these measures have proven useful in highly controlled laboratory studies that seek to differentiate intensity from affective components of pain.\(^45,46\)

On the other hand, outside of the laboratory setting, patients appear to treat single-item VAS, NRS, and VRS measures of pain unpleasantness
much like measures of pain intensity so that the two are often indistinguishable from one another in clinical populations.\textsuperscript{47,48} Moreover, one might question the content validity of single-item measures of affect, given the complex and multidimensional nature of emotional experience.

Pain affect can also be assessed using multiple-item scales, the most common of which are the Affective subscale of the McGill Pain Questionnaire (MPQ)\textsuperscript{49} and its associated short form, the Short-Form McGill Pain Questionnaire (SF-MPQ)\textsuperscript{50} (Fig. 20.2). The original MPQ contains 78 descriptors that are categorized into 20 subgroups, 5 of which assess the impact of pain on affect. The five affective domains are tension (assessed using “tiring” and “exhausting” descriptors), autonomic (assessed using “sickening” and “suffocating” descriptors), fear (assessed using “fearful,” “frightful,” and “terrifying” descriptors), punishment (assessed using “punishing,” “grueling,” “cruel,” “vicious,” and “killing” descriptors), and affective miscellaneous (assessed using “wretched” and “blinding” descriptors).\textsuperscript{49} Within each domain, when administered the MPQ, respondents are asked to circle or mark the single descriptor within each group that most accurately reflects or describes their pain. Descriptors are then ranked according to their position in the word set. The Pain Rating Index (PRI), which can be computed for each of the four primary MPQ subscales, including the Affective subscale, is the sum of the rank values of these descriptors.
The short form of the MPQ (SF-MPQ) contains 15 descriptors, four of which come from the MPQ Affective subscale ("tiring-exhausting," "sickening," "fearful," and "punishing-cruel"). However, unlike the MPQ, which requires respondents to select a single descriptor from each category list that best describes their pain, respondents to the SF-MPQ are
allowed to rate the severity of each item individually on a 4-point Likert scale (0 = None to 3 = Severe). A severity or intensity score can then be calculated for the Affective subscale (as well as for Sensory and Total scale scores; see “Measuring Pain Quality” section). Research has shown that the correlations between the corresponding scales on the MPQ and SF-MPQ are high (rs range, 0.68 to 0.92).  

There is a substantial amount of data supporting the validity of the MPQ and SF-MPQ Affective subscales. First, like the other MPQ and SF-MPQ scales, the Affective subscale has been shown to be responsive to pain treatment. Additional support for the validity of the MPQ Affective subscale as a measure of the affective component of pain, specifically, was reported by Ahles and colleagues, who found that this scale was more strongly associated with measures of psychological distress than with measures of pain intensity. Also, Kremer and colleagues reported that patients with cancer report a greater affective component of their pain on the MPQ Affective subscale than patients with low back pain, consistent with the hypothesis that cancer pain may be associated with higher levels of affect (e.g., be more worrisome and cause more fear) than low back pain.

**Recommendations for Assessing Pain Affect**

Although single-item measures of pain affect or pain bothersomeness have demonstrated validity in highly controlled laboratory studies, supporting their use in this setting, they have shown less discrimination (from single-item measures of pain intensity) in clinical populations. Thus, with clinical populations, when an index of pain affect is needed, clinicians and researchers should strongly consider administering the MPQ or SF-MPQ Affective items. The MPQ Affective subscale, having a longer history than the SF-MPQ, has more empirical support for its reliability and validity. However, given the strong associations between the MPQ and SF-MPQ scales, their high degree of item overlap, and the relative brevity and greater simplicity of the SF-MPQ for scoring, adequate evidence exists to support the use of the SF-MPQ as well.

**MEASURING PAIN QUALITY**
The experience of pain consists of much more than its magnitude or intensity and affective components. Pain is also often described using a number of different qualities, such as “burning,” “aching,” and “tender,” among many others. Although historically, clinicians and researchers have focused on pain intensity as the single most important pain domain to assess, there has been an upsurge of interest in the assessment of pain qualities. The two primary purposes of such measures are (1) to help diagnose the pain problem and (2) to more thoroughly describe the pain experience and determine the effects of pain treatments on that experience.

Using Pain Quality Measures as Diagnostic Aides

A growing body of research supports the conclusion that different pain qualities are associated with different causes, sources, or types of pain. In one study supporting this conclusion, Chang and colleagues induced skin pain and muscle pain in human subjects through the use of intracutaneous and intramuscular injection of capsaicin into the left forearm, respectively. Although ratings of global pain intensity were very similar for both the skin and muscle pain, capsaicin injection into skin and muscle produced distinctly different pain qualities, as described by the subjects. When capsaicin was injected into the skin, subjects described their pain as sharp, cutting, and burning; pain induced by intramuscular capsaicin injection was described as throbbing, pulsing, and tingling. The results of this study support the idea that different pain mechanisms or sources of pain produce different pain sensations and that these differences can be reliably assessed through the assessment of specific pain qualities. Also, it is generally thought that different nociceptors and fibers underlie different pain sensations, with the myelinated Aδ delta fibers responsible for localized “sharp,” “stinging,” and “shooting” pain, and the unmyelinated C fibers responsible for less localized dull pain sensations.

The four most commonly used measures of pain quality that have been developed specifically to assist in the diagnosis or classification of pain include the (1) Leeds Assessment of Neuropathic Symptoms and Signs (LANSS), (2) Self-Report Leeds Assessment of Neuropathic Symptoms and Signs (S-LANSS), (3) Neuropathic Pain Diagnostic Questionnaire (DN4), and (4) painDETECT.
DN4) have both patient self-report and clinician examination items, and two (the S-LANSS and painDETECT) include only patient self-report items.

Leeds Assessment of Neuropathic Symptoms and Signs
The LANSS\textsuperscript{63} was the first measure designed specifically to distinguish neuropathic from nociceptive pain. The self-report component of the measure consists of five items that ask respondents to indicate, yes or no, if their pain could be described as (1) “[consisting of] strange, unpleasant sensations . . . like pricking, tingling, pins and needles”; (2) “[making] . . . the skin in the painful area look different from normal . . . like mottled or looking more red . . .”; (3) “[making] . . . the affected skin abnormally sensitive to touch . . .”; (4) “[coming] . . . on suddenly and in bursts for no apparent reason . . . like electric shocks, jumping and bursting . . .”; and (5) “[feeling] . . . as if the skin temperature in the painful area has changed abnormally . . . like hot and burning. . . .” The sensory testing component asks a clinician to test for allodynia (by lightly stroking a nonpainful and the painful area with cotton wool) and to test for altered pinprick threshold (by comparing the patient response to a 23G needle mounted inside of a syringe barrel placed gently on the skin in a nonpainful area and then in the pain area). Each response is weighted, and the weights of all positive responses are summed to create a total score, with a score of less than 12 indicating an unlikelihood that neuropathic mechanisms are contributing to the patient’s pain, and a score of 12 or greater (out of a total possible score of 24) indicating that neuropathic mechanisms are likely to be contributing to the patient’s pain.

Self-report Leeds Assessment of Neuropathic Symptoms and Signs
One potential drawback to the LANSS, that could limit its use in some clinical and research settings, is that it requires a trained clinician to administer. To address this limitation, a self-report version of the LANSS (S-LANSS) has been developed.\textsuperscript{64} The S-LANSS includes the same five pain quality items of the LANSS. However, the sensory items were modified to allow patients to self-administer them by gently rubbing the painful and a nonpainful area with their index finger for the allodynia item and gently pressing the painful and a nonpainful area with a fingertip to
assess static allodynia.

Neuropathic Pain Diagnostic Questionnaire
The 7-item Neuropathic Pain Diagnostic Questionnaire (DN4)\textsuperscript{65} was designed to discriminate between neuropathic and nonneuropathic pain. It is administered by a clinician and begins by asking patients if they do or do not experience their pain as having burning, painful cold, or electric shock qualities. Patients are then asked to indicate if they do or do not experience tingling, pins and needles, numbness, or itching in the same area that they experience pain. Finally, and similar to the LANSS, the evaluating clinician determines if hypoesthesia (decreased sensitivity) to touch or to pinprick exists in the painful area, and whether lightly brushing the area elicits pain. The items are weighted to yield a score that can range from 0 to 10. A score of 4 or greater is used to classify the respondent as having possible neuropathic pain.

painDETECT
The painDETECT (PD)\textsuperscript{66} consists of nine self-report items assessing seven sensory qualities (burning, tingling, sensitivity to light touch, electrical, sensitivity to temperature changes, numbness, sensitivity to light pressure), the temporal pattern of pain (e.g., persistent with slight fluctuations), and the spatial pattern of pain (i.e., if it does or does not radiate). The responses are scored and weighted to yield a score that can range from 0 to 38. Scores of 19 or more are used to classify the respondent as being likely to have a neuropathic component to their pain, scores of 12 or less as being indicative of being unlikely to have a neuropathic component to their pain, and scores from 13 to 18 are used to indicate an ambiguous result.

**Strengths and Weaknesses of Pain Quality Measures as Diagnostic Aids**
A growing body of research has examined the metrics of the LANSS, S-LANSS, DN4, and painDETECT, which has been summarized in review articles.\textsuperscript{67,68} These reviews have noted that evidence supports the ability of each one of these measures to distinguish neuropathic from nonneuropathic pain in many patient groups, but that their accuracy (including sensitivity, or ability to identify someone as having neuropathic
pain, and specificity, or ability to identify someone as not having neuropathic pain) can vary a great deal as a function of the clinical population being considered. Among the measures that include clinician’s ratings, the DN4’s overall accuracy has been shown to be the best on average (with sensitivity ranging 76% to 100% and specificity ranging from 45% to 92%) for many populations (see Canadian Agency for Drugs and Technologies in Health\textsuperscript{67}). As indicated by these ranges, specificity tends to be lower than sensitivity with the DN4 and has been reported to be particularly low in individuals with leprosy (45%), patients with mixed chronic pain conditions (57%), and patients with a history of breast tumor resection (60%), even when sensitivity is good to excellent in these same conditions (100%, 87%, and 90%, respectively) (see Canadian Agency for Drugs and Technologies in Health\textsuperscript{67}). In addition, the DN4 lacks accuracy for individuals with failed back syndrome (sensitivity: 62%; specificity: 44%; see Canadian Agency for Drugs and Technologies in Health\textsuperscript{67}). On the other hand, the DN4 was reported to be superior to the LANSS and painDETECT for classifying patients with cancer and spinal cord injury as having neuropathic pain or not (see Canadian Agency for Drugs and Technologies in Health\textsuperscript{67}). The tendency for the DN4 to be more accurate for classifying patients was also noted in a review by Mathieson and colleagues.\textsuperscript{68}

The available research evidence does not provide strong support for the use of one of the self-report measures (i.e., S-LANSS or painDETECT) over the other, when a self-report measure is needed\textsuperscript{67}; either could be selected and used. However, it is important to remember that all of these measures are screening questionnaires only and should not be used in an attempt to provide a definitive diagnosis of neuropathic pain.\textsuperscript{69}

**Pain Quality Scales as Descriptive and Outcome Measures**

Pain quality measures may also be used to describe the pain associated with different pain conditions as well as to identify the effects of pain treatments on various qualities of the pain experience. To the extent that different pain qualities are linked to different pain mechanisms, then understanding the effects of treatments on those qualities may be used to better understand the mechanisms of those treatments. In addition, given
the evidence (reported later) that different pain treatments have different effects on various pain qualities, pain clinicians could potentially use pain quality assessment for helping to select from among different treatment options. For example, clinicians may offer patients reporting their pain as primarily “aching” those treatments shown to impact “aching” pain most effectively, while providing patients who describe their pain as “electrical” with treatments that have been shown to reduce “electrical” pain sensations.\textsuperscript{70,71}

To date, six measures have been developed to assess pain quality and have been used as outcome measures in clinical trials. They include (1) the MPQ,\textsuperscript{49} (2) the SF-MPQ,\textsuperscript{50} (3) the Revised Short-Form McGill Pain Questionnaire (SF-MPQ-2),\textsuperscript{72} (4) the Neuropathic Pain Symptom Inventory (NPSI),\textsuperscript{73} (5) the Neuropathic Pain Scale (NPS),\textsuperscript{74} and (6) the Pain Quality Assessment Scale (PQAS)\textsuperscript{75} and its slight modification, the Revised Pain Quality Assessment Scale (PQAS-R).\textsuperscript{76}

McGill Pain Questionnaire
The MPQ was introduced previously in the context of assessing pain affect. In addition to assessing the affective component of pain, the 78 MPQ descriptors can be scored to assess sensory pain (10 sensory categories, such as temporal, punctuate pressure, and thermal pain, assessed using 42 descriptors), evaluative pain (one category, assessed using 5 descriptors), and miscellaneous pain (four categories that do not clearly fall into sensory or affective components, assessed using 17 descriptors).\textsuperscript{49}

As described previously, respondents are asked to select the single descriptor from each of the 20 categories (the number of descriptors listed per category varies from 2 to 6) that best describes his or her pain and the rank order of the descriptors in each category are summed to compute sensory, affective, evaluative, miscellaneous, and total scores.

Support for the usefulness of the MPQ comes from the fact that it has been used in hundreds of studies and has been translated into at least 20 languages.\textsuperscript{77} Moreover, a three-factor (sensory, affective, and evaluative domains) structure of the MPQ has been confirmed in two studies,\textsuperscript{78,79} although the high degree of association among these subscales suggests
some limitations in discriminative validity of the different MPQ scales. In support of the measure’s validity, the MPQ scales have demonstrated validity as outcome measures given their responsivity to changes produced by pain treatments.

A number of studies have examined the reliability of the MPQ. In populations of patients with cancer pain, studies have found that responses to the MPQ are generally consistent over the time span of several days. In a study with patients with low back pain, Love and colleagues found adequate test–retest stability for the MPQ scale scores (Total: $r = 0.83$; Sensory: $r = 0.76$; Affective: $r = 0.78$) over the course of several days.

Despite the many strengths of the MPQ, it also has some important limitations. First, although it has been reported to take only 5 minutes to complete by someone who is very familiar with the measure, the MPQ includes a large number of descriptors that are rarely used by individuals with pain; 78 descriptors suggests a very high degree of content validity, but so many descriptors may not be needed to adequately describe pain quality in many populations.

A second limitation of the MPQ concerns the way it is scored. Although it probably makes sense to combine multiple affective responses into a composite Affective subscale, there are limitations in combining a large number of different sensory descriptors into a composite Sensory subscale. Primary among these is the possibility that such a procedure does not allow investigators to detect the impact of treatments on specific unique pain quality domains or descriptors. Thus, a significant effect of a pain treatment on the MPQ Sensory subscale could have been due to its modest effects on many different pain qualities, or a large effect on just a few. One of the important reasons to assess pain quality in clinical trials is to determine the effects of treatment on specific pain qualities; scoring the MPQ descriptors into composite scales does not allow for this.

Also, because it is unlikely that pain treatments impact all pain qualities in the same way, the use of composite pain quality scores, based on many different items (recall that the MPQ Sensory subscale assesses 10 quality domains using 42 descriptors), runs the risk of reducing one’s ability to detect significant effects. When using composite measures in clinical trials...
that include items that are not affected by treatment, or are affected only minimally, the effect size for the total scale is reduced. Indeed, when differences in responsivity to treatment are found, the MPQ scale scores tend to be less responsive to treatment effects than single-item pain intensity ratings.\textsuperscript{85–87}

Short-Form McGill Pain Questionnaire
The SF-MPQ was developed in order to balance the need for pain quality data against the need to minimize assessment burden (see Fig. 20.2).\textsuperscript{50} As previously mentioned in the “Measuring Pain Affect” section, the SF-MPQ consists of 15 descriptors, each of which can be rated on a 4-point severity scale from none to severe. Eleven of the descriptors assess sensory pain (throbbing, shooting, stabbing, sharp, cramping, gnawing, hot-burning, aching, heavy, tender, and splitting), and, as described previously, four items assess affective pain.

Evidence supporting the validity of both SF-MPQ scales includes data showing a strong association between the Sensory and Affective subscales scored from the SF-MPQ and the original MPQ Sensory and Affective subscales.\textsuperscript{50–52} Also, a number of studies have demonstrated that the SF-MPQ is responsive to pain treatments, providing additional support for the validity of the SF-MPQ as an outcome measure.\textsuperscript{88–90} Finally, because each of the SF-MPQ items is rated, SF-MPQ responses could theoretically be used in clinical trials to look at the specific effects of pain interventions on particular pain qualities, although this strength of the SF-MPQ has yet to be capitalized on.

Limitations of the SF-MPQ include the fact that some descriptors common to neuropathic pain (e.g., electrical, tingling) are not included in the measure, limiting its content validity for assessing neuropathic pain. An additional limitation of the SF-MPQ concerns scoring. As discussed previously with respect to the MPQ, if the sensory pain quality items are combined into composite scale scores, these scores may be less sensitive to treatment effects than are individual ratings of pain intensity or individual descriptor ratings. This makes the SF-MPQ scale scores, perhaps, less useful than global pain intensity ratings or even the individual SF-MPQ items as outcome measures.
Revised Short-Form McGill Pain Questionnaire

A revised version of the SF-MPQ (the SF-MPQ-2)\textsuperscript{72} was developed with a goal of addressing the content validity problems of the SF-MPQ for assessing neuropathic pain and also to expand the severity response options for the items from 4 to 11 levels (i.e., to a 0 = “None” to 10 = “Worst possible” NRS) to increase measure responsiveness. The descriptor items that were added were “electric-shock pain,” “cold-freezing pain,” “piercing,” “pain caused by light touch,” “itching,” “tingling or ‘pins and needles,’” and “numbness.” Exploratory and confirmative factor analyses indicated that the items can be scored into four reliable subscales assessing continuous pain, intermittent pain, predominantly neuropathic pain, and affective pain domains, all of which have been shown to be sensitive to the effects of a topical combination of amitriptyline and ketamine for painful diabetic peripheral neuropathy.\textsuperscript{72} The reliability of the SF-MPQ-2 scale scores has been replicated in a large sample of US veterans with chronic pain, although the very strong associations among the subscales in this sample, ranging from $r = 0.74$ to 0.91 and subsequent confirmatory factor analysis, supported the conclusion that although the SF-MPQ-2 items can be scored to assess four different domains, they also reliably assess a single global construct.\textsuperscript{91} In addition, two studies have been published which have shown the SF-MPQ-2 subscales to be responsive to pain treatments.\textsuperscript{92}

However, research suggests that even the SF-MPQ-2 may not be content valid in some samples of patients. Three different studies have sought to identify the most commonly used pain descriptors in patients with chronic pain.\textsuperscript{93–95} Fourteen descriptors were found to be commonly used by patients with spinal cord injury and multiple sclerosis,\textsuperscript{93} and 15 descriptors were found to be commonly used by patients with low back pain, fibromyalgia, and headache.\textsuperscript{94} Both of these studies used participants with chronic pain from the United States. An additional study using individuals with chronic musculoskeletal pain problems from Nepal found that nine pain quality domains were used most often.\textsuperscript{95} Based on the pain qualities spontaneously used by the participants in these studies, the SF-MPQ-2 might be considered to have mostly adequate content validity for assessing pain quality in patients with spinal cord injury or multiple sclerosis.
However, it has somewhat less content validity for assessing pain quality in patients with musculoskeletal patients from Nepal (assessing 7 of 9 pain qualities) and has marginal content validity for assessing pain in patients with low back pain, fibromyalgia, and headache (assessing only 12 of 15 descriptors).

Neuropathic Pain Symptom Inventory
The NPSI includes 12 items that were selected to assess four global domains of neuropathic pain (spontaneous ongoing pain, spontaneous paroxysmal pain, evoked pain, and paresthesias/dysesthesia). Respondents rate the severity or intensity of each descriptor item on 0-to-10 NRSs. Two additional items assess the temporal qualities of pain (number of hours of spontaneous pain in the past 24 hours, number of paroxysms during the last 24 hours).

As reported in the initial development study, short-term (3 hours) and longer term (1 month) test–retest stability of the NPSI items were shown to be very high (intraclass correlation coefficients range 0.78 to 0.98). Also, validity for the evoked pain items was evidenced through their significant associations (rs range 0.66 to 0.73) with related clinician scores of pain evoked by brushing, pressure, and cold stimuli. Changes in the NPSI total score have been found to be associated significantly with patient and provider ratings of global improvement over a 1-month period. The NPSI scales have also been shown to be sensitive to the effects of lidocaine medicated plaster and pregabalin and ultramicronized palmitoylethanolamide in samples of patients with postherpetic neuralgia. The evoked pain NPSI score, but not the total score, was shown to be sensitive to the effects of a thoracic sympathetic block in a sample of patients with complex regional pain syndrome, supporting the potential utility of the NPSI subscale scores for examining different pain qualities as distinct outcome domains.

Crawford and colleagues examined the cross-cultural content validity of the NPSI items by asking 132 individuals with neuropathic pain from six different countries to describe their pain on a written questionnaire and describe their pain in focus groups. Twenty descriptors were used by the participants to describe their pain in response to the questionnaires. As the
NPSI only includes 12 items, then it clearly lacks content validity for assessing the descriptors used by these patients with neuropathic pain. This finding is consistent with the results of the studies, cited previously, which also evaluated the content validity of pain quality measures with respect to the descriptors patients actually use to describe their pain. Specifically, the NPSI only assesses 7 of 14 descriptors used by patients with chronic pain and spinal cord injury or multiple sclerosis, and 5 of 15 descriptors used by patients with low back pain, fibromyalgia, or headache.

In addition, questions remain regarding the number of underlying factors assessed by the NPSI items and how those items should be best scored. One factor analysis performed in 2008 in a large sample of patients with neuropathic pain yielded five factors (assessing evoked, paraesthesia/dysesthesia, deep pain, paroxysmal pain and burning pain). A factor analysis of the NPSI items in a different sample yielded three factors which the authors labeled pinpointed pain, deep pain, and provoked pain. These differences in how the NPSI items should be scored into multi-item subscales have not yet been resolved.

One of the important strengths of pain quality measures, such as the NPSI, is that it is possible to evaluate the effects of treatment on specific pain quality items (also see how the NPS and PQAS/PQAS-R items have been used in this way later in this section). By analyzing the items individually, it is possible to identify the specific pain qualities that may be more or less responsive to different treatments. A study published by Cocito and colleagues illustrated how the NPSI items could be used in this way. They found that an add-on treatment to patients with neuropathic pain (palmitoylethanolamide ultramicronized) was more effective for reducing paresthesia/dysesthesia pain qualities as measured by the NPSI than it was for reducing burning, pressing, paroxysmal, or evoked pain. Similarly, Freeman and colleagues found that combination therapy (duloxetine with pregabalin) was more effective than duloxetine alone for reducing pain described as squeezing and pressure and pain increased by brushing and pressure than other pain qualities.

Neuropathic Pain Scale
The NPS, having been introduced in 1997, is the first measure developed
to assess neuropathic pain qualities and probably for this reason has the most research supporting its reliability and validity for this purpose. The NPS includes 10 items, 2 that assess global pain intensity and unpleasantness, and 8 that reflect specific pain domains (6 pain qualities and 2 spatial characteristics) likely to be reported by patients with neuropathic pain syndromes.

Respondents rate each item on a scale from 0 to 10, with 0 being “no ___” or “not ___” and 10 corresponding to “the most ___ sensation imaginable.” An 11th item allows patients to report the temporal nature of their pain (constant with intermittent increases, intermittent, or constant with fluctuation). The NPS items were intended primarily to be used for assessing distinct pain qualities, which could then be used to create a profile of a person’s pain quality experience. A large body of research supports the validity of the NPS for describing neuropathic pain conditions, distinguishing between pain diagnoses, predicting treatment outcome, and other symptoms, and detecting treatment effects. The NPS has also shown utility for identifying the pain qualities affected by different pain treatments. For example, one study examined the effectiveness of the NPS for assessing changes in pain qualities in three groups (peripheral neuropathic pain, low back pain, and osteoarthritis) of patients treated with open label lidocaine patch 5%. Although significant changes in almost all NPS pain qualities were found, significantly larger changes were seen for NPS items measuring sharp and deep pain than for items measuring cold, sensitive, or itching pain. In another study, controlled-release oxycodone was found to be associated with decreases in sharp, dull, deep, and surface pain but had little impact on hot, cold, itchy, or sensitive pain in patients with painful diabetic neuropathy. In a sample of patients with mixed neuropathic pain conditions, intravenous lidocaine and phentolamine were found to have similar effects on 8 of 10 NPS items, although lidocaine had a greater effect on global pain unpleasantness and deep pain. Finally, one study showed that tizanidine for neuropathic pain impacted the hot, cold, and sensitive NPS items (as well as global intensity and unpleasantness) after 2 weeks of treatment and then impacted sharp, dull, and deep pain NPS.
items after 8 weeks, indicating that the NPS may be used to show how treatments impact various pain qualities over time.\textsuperscript{113}

Another strength of the NPS is its brevity, which makes it potentially useful in survey research and in settings where assessment burden may be a significant issue. Also, the NPS has been translated into 36 languages and so is useful for cross-cultural research comparing neuropathic pain conditions and treatments across cultures.

Although the NPS was originally designed to be scored to create a “profile” of sensation severity across different pain qualities, it is possible to combine the items into composite scores. Galer and colleagues,\textsuperscript{108} for example, created four different NPS composite scores when examining the effects of a lidocaine patch 5\% in a sample of patients with postherpetic neuralgia: an average of all 10 items (NPS10), an average of the 8 specific descriptors excluding the global ratings of pain intensity and unpleasantness (NPS8), an average of the 8 items that do not reflect allodynia (i.e., excluding the “sensitive” and “surface” items; NPS NA), and an average of 4 items thought to reflect nonperipheral pain mechanisms (“dull,” “deep,” “sharp,” and “burning” items; NPS4). However, concerns about the use of composite scores from pain quality measures, raised earlier with respect to the MPQ and the NPSI, are also relevant here; use and interpretation of composite pain quality scores, regardless of the measure used for item selection, needs to proceed with caution.

The primary limitation of the NPS is associated with its brevity. Because it has only 10 items, the NPS has limited content validity for assessing pain across different diagnostic conditions. For example, the NPS items assess only 5 of 14 of the most commonly used pain descriptors in samples of patients with spinal cord injury and multiple sclerosis\textsuperscript{93} and only 6 of the 15 most commonly used pain descriptors in samples of patients with low back pain, fibromyalgia, and headache.\textsuperscript{94} Thus, although there is a great deal of research supporting the reliability and validity of the NPS for assessing treatment effects in patients with neuropathic pain, there is limited content validity for assessing pain quality in populations of individuals with nonneuropathic pain conditions.
Pain Quality Assessment Scale

The PQAS\textsuperscript{75} was developed to make available a measure that had the strengths of the NPS but that would also be content valid for assessing both neuropathic and nonneuropathic pain. The PQAS used the original 10 NPS items as a starting point and then added 10 additional items to create a measure capable of assessing the most common pain qualities seen across a variety of chronic pain conditions.\textsuperscript{75} Like the NPS, the PQAS also includes an item to differentiate between three primary temporal patterns of pain: intermittent (i.e., variable pain with some pain free periods), variable (variable pain without pain-free periods), and stable (i.e., constant pain with little variation). The PQAS instructions and items have also been cognitively tested to ensure that they were maximally clear and understandable to patients. This resulted in minor word modifications to the instructions and some of the items (but no changes in the specific pain quality domains assessed), creating the PQAS-R (Fig. 20.3).
PAIN QUALITY ASSESSMENT SCALE (PQAS)

Instructions: There are different aspects and types of pain that patients experience and that we are interested in measuring. Pain can feel sharp, hot, cold, dull, and achy. Some pains may feel like they are very superficial (at skin-level), or they may feel like they are from deep inside your body. Pain can also be described as unpleasant.

The Pain Quality Assessment Scale helps us measure these and other different aspects of your pain. For one patient, a pain might feel extremely hot and burning, but not at all dull, while another patient may not experience any burning pain, but feel like their pain is very dull and achy. Therefore, we expect you to rate very high on some of the scales below and very low on others.

Please use the 19 rating scales below to rate how much of each different pain quality and type you may or may not have felt OVER THE PAST WEEK, ON AVERAGE.

Place an “X” through the number that best describes your pain. For example:

All of the extensive data that support the validity of the NPS also support both versions of the PQAS because the NPS items are included in the PQAS. Research also provides support for the validity of the new items. For example, all of the new items have been found to be responsive to the effects of both lidocaine patch 5% and a corticosteroid injection in a sample of patients with carpal tunnel syndrome. A factor analysis of the PQAS items yielded three factors labeled paroxysmal sensations (shooting,
sharp, electric, hot, radiating), superficial pain (itchy, cold, numb, sensitive, and tingling), and deep pain (aching, heavy, dull, cramping, and throbbing). A large and growing body of research supports the sensitivity of the PQAS and PQAS-R scales and items for detecting treatment effects.

The PQAS and PQAS-R items have also been shown to be useful for identify the “response profiles” of different pain treatments. For example, oxymorphone was shown to have the larger effect on deep, aching, and sharp qualities than other pain qualities. In addition, the PQAS/PQAS-R items and scales are able to predict who responds to pain treatments. For example, in a sample of 50 patients with neuropathic pain, the PQAS-R items were able predict who did and did response to pregabalin with 85% sensitivity and 76% specificity.

The PQAS and PQAS-R have been shown to be the most content valid of all of the available pain qualities measures. All of the most common pain qualities spontaneously used by individuals with spinal cord injury and multiple sclerosis and all of the most common pain qualities spontaneously used by individuals with low back pain, fibromyalgia, and headache are assessed by the PQAS. Also, the PQAS assess eight of the nine most common pain qualities spontaneously used by individuals with musculoskeletal pain in patients from Nepal.

Strengths and Weakness of Descriptive and Outcome Measures of Pain Quality

The original MPQ is the most established measure of pain quality and has been used in more research studies than any other pain quality measure combined. However, the length of the original MPQ—which includes a large number of items that are rarely endorsed—and its complicated scoring procedure has led researchers to develop new measures, including a short-form version of the MPQ (SF-MPQ). However, the SF-MPQ was subsequent found to have very limited content validity. Although the SF-MPQ-2 was developed to address the content validity problems of the SF-MPQ, recent research indicates that it too does not adequately assess some of the most common pain qualities reported by individuals with chronic pain.
The NPS was the first measure developed to assess neuropathic pain qualities specifically. It has a great deal of research supporting its validity for this purpose. It is particularly useful for assessing the effects of pain treatment on a variety of specific neuropathic pain quality domains. However, the NPS is not content validity for assessing pain quality in populations of patients with nonneuropathic pain.

The NPSI is the most recent addition to field. However, the NPSI has significant limitations with respect to its content validity (i.e., it does not measure many pain quality domains common to individuals with neuropathic and nonneuropathic pain conditions) and questions remain regarding how the items should be scored into composite scale scores.

The PQAS was developed to improve on the strengths and empirical foundation of the NPS by adding items to improve content validity for assessing pain in a variety of patient populations. The available research indicates that the PQAS—and by extension the PQAS-R—was successful in achieving this goal, having demonstrated 100% content validity for assessing pain in populations of patients with chronic pain in the United States\textsuperscript{93,94} and demonstrating adequate content validity for assessing pain quality in a sample of patients with chronic pain from Nepal.\textsuperscript{95}

Given the similarity between the existing measures (i.e., all of the viable measures, including those that were revised from earlier measures, emulate the format of the original NPS, by asking respondents to rate the severity of different pain qualities on 0-to-10 rating scales), the primary difference among them is their content validity. Based on this criterion, it would appear that the PQAS and PQAS-R would be the most valid for assessing pain quality in a variety of pain populations.

**MEASURING PAIN’S SPATIAL CHARACTERISTICS**
Pain can occur both at different body locations (e.g., head, leg) or at different depths (e.g., “surface” or “deep” pain). The two most common strategies used for assessing the body location of pain are the pain drawing and the pain site checklist. A pain drawing consists of an outline of a human form, and respondents are simply asked to mark or shade in the areas on the drawing which correspond to pain they are currently experiencing. Pain drawings are included in a number of standard pain
questionnaires, such as the MPQ, the LANSS, and the original (non-short form) Brief Pain Inventory (BPI) scale. One published pain drawing allows the assessor to use a template to score the patient’s response, both for the specific area that has been shaded as well as for “pain extent” (which reflects the total number of areas that have been shaded). Pain drawings can also be administered electronically, with respondents indicating the area(s) of pain on a computer or electronic tablet screen, and the specific body areas shaded (e.g., Barbero et al.).

A site checklist is a simple list of possible sites for pain, and the respondent is asked to indicate which site(s) are currently painful. Like pain drawings, site checklists can be scored for both the specific site(s) chosen as well as for “pain extent” (total number of sites chosen). The presence and severity of “deep” and “surface” pain can be determined by asking respondents to rate each (see the PQAS-R reflecting these in Fig. 20.3).

Research shows that pain drawings are reliable, regardless of the methods used to score them (e.g., Barbero et al., Ohnmeiss, MacDowall et al., Hayashi et al.). Research also shows that scores from pain drawings can be used as outcome measures in clinical trials, given evidence that they are sensitive to effective pain treatment (e.g., Voorhies et al., Marcus et al.).

Scores derived from measures of pain site (i.e., “pain extent” as represented by the number or percent of body area involved) also predict, in some patients, important domains of patient function, including disability, pain interference, medication use, return to work, and psychological functioning. However, these associations are not consistent or strong enough to warrant the use of pain’s spatial characteristic as proxy measures of psychopathology or disability.

In addition, pain drawings, pain site checklists, and measures of the relative depth of pain are well suited for descriptive purposes. For example, research in patients with spinal cord injury has used pain drawings and pain site to describe the frequency of pain experienced at different body sites, as well as the relationship between pain location or number of pain sites and other related variables.
Recommendations for Assessing Pain Site

Pain drawings, pain site checklists, and severity ratings of pain’s perceived depth have all been used successfully to help patients describe their pain experience. These measures have also demonstrated responsivity as outcome measures in clinical trials. Decisions about which to use in any one setting or with any one population will largely depend on the preference of the assessor and practical issues concerning how the data will be used. Clinicians often prefer pain drawings, given that they provide a global overview of how patients experience the location(s) of their pain. However, when used in research, pain drawings require an additional step (usually with the aid of a template or software) to objectively determine the specific site(s) selected and the amount of body area with pain (i.e., pain extent). Pain site checklists may be more practical for the researcher, given that coding for the specific sites (e.g., legs, low back, head) is completed by the respondent once the checklist has been administered and completed.

MEASURING PAIN’S TEMPORAL CHARACTERISTICS

The temporal aspects of pain, such as its variability, frequency, and duration as well as its pattern across time (over minutes, hours, days, or months) can be assessed by asking patients to rate their pain on multiple occasions over time using pain diaries. The specific temporal domains of interest can then be operationalized by computing scores from the diary ratings. Based on diary data, pain variability can be operationalized as the standard deviation of pain intensity ratings during a specific epoch, frequency of “breakthrough” pain as the number of times pain reached and exceeded a specific cutoff (e.g., 7 or more on a 0-to-10 scale for severe breakthrough pain, or 5 or more for moderate to severe breakthrough pain), and pain duration as the number of hours that pain was rated as being above a specific cutoff; for example, 5 or more on a 0-to-10 scale for duration of “moderate to severe” pain.

Diary data can also be used to identify temporal patterns. Jamison and Brown, for example, identified six different temporal pain pattern types (e.g., steady increase over the course of a day, steady decrease, curvilinear pattern, no consistent pattern) based on diary data. They found that the
group of patients that showed no clear consistent pattern from one day to the next also reported the greatest emotional distress.\textsuperscript{133} van Grootel and colleagues\textsuperscript{134} identified two primary patterns of pain intensity from diary data in a sample of patients with temporomandibular disorders: (1) those reporting higher levels of pain later in the day and (2) those reporting higher levels of pain in the morning; with the former group reporting higher overall levels of pain intensity, more difficulty falling asleep at bedtime, more widespread pain, and greater endorsement about the role of a physician in managing their pain problem. These findings suggest the possibility that the time pattern of pain experience may play a role in how patients think about or manage their pain.

Pain diaries may be particularly important when assessing patients with pain problems that show marked variations in pain over time, such as patients with headaches.\textsuperscript{135} The many strengths of diaries for this purpose include their utility in (1) identifying different headache diagnoses when they occur in the same patient, (2) identifying possible factors that trigger a patient’s headaches, and (3) evaluating the efficacy of treatments used by patients over time.\textsuperscript{135} Their ability to help identify triggers for pain flare-ups, in particular, makes diaries particularly useful clinically for enabling secondary prevention of the disabling effects of these flares (e.g., being unable to function, leaving work early, sleep interference) with appropriate behavioral, physical (e.g., ice and stretch), or pharmacologic (e.g., NSAIDs) interventions.

However, such diaries are not without limitations. They involve significant assessment burden and can be associated with low compliance rates and inaccurate reporting. They also carry the risk of sensitizing the patient to health problems and—at least temporarily—increasing the patient’s focus on pain and its negative effects.\textsuperscript{135}

Another way to assess pain pattern is to describe different temporal patterns to patients and allow them to select the description that best describes their pain. For example, an item from the PQAS-R (see Fig. 20.3) asks patients to indicate which of the following best describes their pain: (1) I have intermittent pain (I feel pain sometimes but I am pain-free at other times), (2) I have variable pain (“background” pain all the time, but also moments of more pain, or even severe “breakthrough” pain or
varying types of pain), and (3) I have stable pain (constant pain that does not change very much from one moment to another, and no pain-free periods). One study found that these temporal characteristics differed as a function of neuropathic versus nonneuropathic pain, with patients rated by physicians as having “possible” neuropathic pain being more likely to endorse having variable pain than patients rating as being “unlikely” to have neuropathic pain. The painDETECT also has a temporal item, which asks the respondent to select one from a selection of illustrations that depict four temporal patterns (i.e., persistent pain with slight fluctuations, persistent pain with pain attacks, pain attacks without pain in between, or pain attacks with pain between).

Recommendations for Assessing Pain’s Temporal Characteristics
Either diary-based measures or categorical scales may be used to assess pain’s temporal characteristics. Categorical scales require less investigator and patient effort than diary-based measures, but diary-based measures allow for greater flexibility in coding different temporal patterns than categorical scales. Diary-based measures may be particularly useful for helping clinicians and researchers understand pain problems that are highly variable over time, such as headaches.

MEASURING PAIN INTERFERENCE
Pain interference refers to the extent to which pain interferes with day-to-day functioning. The two most commonly used measures of pain interference are the BPI Pain Interference scale (see Fig. 41.3) and the Patient-Reported Outcomes Measurement Information System (PROMIS) Pain Interference item bank.

Brief Pain Inventory Pain Interference Scale
The BPI Pain Interference scale includes seven items that assess the extent to which pain has interfered with: general activity, mood, walking ability, normal work (including both work outside the home and housework), relations with other people, sleep, and enjoyment of life. Respondents are asked to rate the degree of pain interference with each activity on 0 (does
not interfere) to 10 (completely interferes) numerical scales. The responses to the seven items are then averaged to form the Pain Interference scale score.

Factor analyses of responses show that the seven interference items often but not always (see discussion of alternative scoring methods of the BPI Pain Interference scale items in the following paragraph)—load together onto a single factor and that the scale has excellent internal consistency (with αs ranging from .78 to .91) when scored in this way.

One early study used multidimensional scaling to determine the factors underlying the BPI Pain Interference scale items in a large sample of 1,843 persons with metastatic cancer. These analyses yielded two underlying interference dimensions: interference with activity- (walking, work, general activity, sleep) and affectivity-related interference (relations, mood, enjoyment of life), suggesting the possibility of alternate scoring and use of the BPI Pain Interference scale. Support for scoring the BPI Pain Interference scale items into two distinct scales comes from a large-scale Rasch analysis study, using data from 1,000 patients from an ambulatory patient database. These investigators found support for a two-factor model in which three of the activity interference items (walking, work, general activity) and the three affective items (relations, mood, enjoyment of life) were scored as distinct subscales. They recommended that the sleep item be removed or interpreted separately. However, findings from another study using four different samples of individuals with pain provided more support with a single-factor model for BPI Pain Interference scale items, consistent with the many factor analyses, cited previously, that are also consistent with this model.

The BPI Pain Interference scale has been increasingly used as an outcome measure in clinical trials, and evidence demonstrating changes in the BPI Pain Interference scale score supports its validity for this purpose.

The BPI Pain Interference scale has also been slightly modified (with permission from the copyright holder) to increase its utility for assessing pain interference in persons with physical disabilities. Perhaps the most important modification was to change the wording of the interference
with walking item to ask respondents to rate the degree of interference with “mobility (ability to get around).” This change makes it possible for individuals who have mobility restrictions unrelated to pain (i.e., who are wheelchair users) to rate the impact of pain on their mobility. Because many of these individuals would be unable to walk even if they had no pain, the original wording of this item would not be appropriate.

The other modification made was to increase the content validity of the scale by including items asking about pain interference with self-care, recreational activities, and social activities\(^{159}\) as well as items asking about interference with communication and learning new information or skills.\(^{158, 160}\) These five activity domains are important to many individuals with disabilities and also reflect functioning domains defined as relevant and unique by the WHO’s International Classification of Functioning, Disability, and Health.\(^{161}\) Given the psychometric strength of the original BPI Pain Interference scale items, it is perhaps not surprising that the 10- and 12-item modified scales also have strong psychometric properties. First, the internal consistency of the modified scales are uniformly high (range, 0.89 to 0.96) in three samples of persons with disabilities, including individuals with cerebral palsy,\(^{159}\) spinal cord injury,\(^{160}\) and multiple sclerosis.\(^{158}\) Second, like the original BPI Pain Interference scale, the modified and expanded scales show strong associations with measures of pain intensity (correlation coefficients range, 0.61 to 0.66), consistent with what would be expected if they measured the extent to which pain interfered with functioning.\(^{159, 160}\) Finally, factor analyses of the modified and expanded items show that new items all load strongly on a pain interference factor that is not only related to but also distinct from a pain intensity factor.\(^{158}\)

However, although the modification of the original walking BPI item makes it possible for individuals who have difficulties walking for reasons other than pain to respond to that item, and the addition of items increases the content validity of the BPI, it is not clear that these modifications substantially improve other psychometric properties of the scale. For example, the internal consistency of a scale made up of 10 items (\(\alpha = 0.95\) to 0.96)\(^{158, 160}\) is not that much larger than the original 7-item scale (\(\alpha = 0.92\) to 0.93)\(^{158, 160}\) in these same samples, suggesting that if scale brevity
is important, the original 7-item BPI may provide as good a measure of pain impact as the expanded 10- or 12-item version. Indeed, if a single score representing the domain of pain interference is needed, more than three pain interference items may not be needed to detect significant changes with treatment.\textsuperscript{155}

**Pat\-\textsuperscript{ient-Reported Outcomes Measurement Information System Pain Interference Item Bank and Short Forms**

A recent measure of pain interference introduced to the field is the 41 items from the PROMIS Pain Interference item bank.\textsuperscript{137} Like all of the PROMIS measures (http://www.healthmeasures.net/explore-measurement-systems/promis), the PROMIS Pain Interference items were developed and calibrated using item response theory (IRT). The focus of an IRT-based item banking approach is on the final score rather than on the items that make up that score, which can be computed as a t-score from any number or any combination of items from the item bank. This score has mean of 50 and standard deviation of 10 in the normative sample. As a result, scores created from different items from the item bank can be directly and meaningfully compared.

PROMIS Pain Interference item scores have demonstrated validity through their associations with measures of other pain-related constructs (e.g., physical function, depression, anxiety, pain intensity, other measures of pain interference).\textsuperscript{137,162,163} A PROMIS Pain Interference short form has also demonstrated responsivity to pain treatment.\textsuperscript{163} In addition, a subset of items from the Pain Interference item bank have been identified as being appropriate for use with individuals with spinal cord injury and chronic pain.\textsuperscript{164} Thus, there is not necessarily a need to “adapt” the items from the PROMIS scales for any one special population as there was with the BPI Pain Interference scale. Because PROMIS scores can be computed by using any one or more items from the item bank (of course, the more items used, the more precise the score) any “adaptation” needed can be performed by selecting the specific items most appropriate for the population to be studied. Also, the item bank approach allows for the administration of the PROMIS scales (including the PROMIS Pain Interference item bank items) using computer adaptive testing, in which a
program selects the next item for the respondent based on the responses provided so far. With such an approach, it is possible to assess the domain of interest with very few items (e.g., often, with as few as four items) with as much precision that usually requires many more items.

**Recommendations for Assessing Pain Interference**

Both the BPI Pain Interference scale and PROMIS Pain Interference item bank items were developed using sound scale development strategies, and each has support for its reliability and validity as a measure of pain interference. Also, each measure is easy to administer and score. However, although both measures have been shown to be responsive to pain treatments, one study—the only one identified which compared the two measures directly—found that the BPI Pain Interference scale was more responsive as an outcome measure than the PROMIS Pain Interference short form was.\textsuperscript{165}

Each measure also has its own unique strengths and weaknesses. The primary strength of the BPI Pain Interference scale is that it has a longer history and therefore has the most empirical support for its reliability and validity. Moreover, it has been translated into more languages that the PROMIS scale has (so far), making it more useful for comparing pain interference scores across different cultures. The BPI items can also be scored into two subscales (assessing interference with activity and social/affect interference domains), although in some populations, these two interference domains are strongly associated with one another and so may not always operate as distinct domains. Another strength of the BPI Pain Interference scale, as mentioned previously, is that one study found it to be more responsive to pain treatment than the PROMIS Pain Interference short form.

The strengths of the PROMIS item bank include those associated with item banking, which allows for a great deal of flexibility in administration (e.g., use of static short forms, use of computer adaptive testing, use of custom items most appropriate for the population, selection of items most appropriate for a specific population). In addition, the National Institutes of Health (NIH) in the United States is strongly advocating for the use of PROMIS measures in NIH research, which will result in a continued
growth in their use and a likely explosion of additional knowledge regarding their psychometric properties over the next decade. Also, at least two consensus groups are recommending use of the PROMIS Pain Interference scales over other measures, including the BPI Pain Interference scale.\textsuperscript{166,167}

Given the available data, and especially given the fact that algorithms exist for computing PROMIS Pain Interference scores from BPI Pain Interference scale scores,\textsuperscript{168,169} an edge might be given to selecting the BPI over the PROMIS scales at this point in time, if the plan is to use the measure as an outcome in clinical trial. For other purposes (e.g., in research seeking to understand how pain interference is associated with other pain-related factors), either measure would appear adequate.

**Measuring Pain in Special Populations**

Although the measures described and recommended for use in this chapter can be used by many patients in most settings, there are special populations that may require different measures or approaches. These include patients that are at risk for cognitive deficits (e.g., patients with head injuries, the very elderly, the very ill) or who may not yet have reached an adequate developmental stage to understand the measure or the tasks that the measure requires (e.g., infants and toddlers). A detailed review of the many measures and procedures for assessing pain in special populations is beyond the scope of this chapter, and the interested reader is referred to other more detailed reviews to obtain information concerning the available options (for children,\textsuperscript{170–172} for the elderly,\textsuperscript{173–176} for individuals with limited communication abilities,\textsuperscript{174,177} for individuals with cancer\textsuperscript{178}). In general, when assessing pain in special populations who are unable to provide valid responses to standard measures, the clinician and researcher has two options: (1) to simplify the assessment strategy to a level that can be understood by the patient or (2) to depend on observation of behaviors known to reflect pain experience.

**SIMPLIFIED MEASURES OF PAIN**

Simple Pain Measures to Consider
Of the two options to consider when selecting a pain assessment approach for special populations, the first option, using a simplified measure of pain, may be considered a better option to select whenever possible and practical given the facts that (1) only patients have direct access to their pain experience and so are in the best position to describe this experience and (2) observational measures of pain behaviors show, at best, only moderate associations to patient reports of pain experience.\textsuperscript{179,180}

Of the three primary pain intensity measures used most often in pain research and clinical settings, evidence indicates that VRSs tend to be easier for patients to understand and use than NRSs, and that NRSs are easier for patients to understand and use than VASs,\textsuperscript{48,181–186} making simple VRSs (e.g., “None,” “Mild,” “Moderate,” “Severe”) a natural choice to consider when a simple measure of pain is needed.

Another measure to consider in this situation is a face scale. Face scales consist of line drawings of faces, each of which represent expressions that communicate different levels of pain and distress. Although a number of such scales have been developed, one that has many strengths is the Faces Pain Scale–Revised (FPS-R, Fig. 20.4).

\textbf{FIGURE 20.4} The Faces Pain Scale–Revised (FPS-R). Instructions to the respondent: “These faces show how much something can hurt. This face [point to left-most face] shows no pain [or hurt]. The faces show more and more pain [point to each from left to right] up to this one [point to right-most face]—it shows very much pain. Point to the face that shows how much you hurt [right now].” Do not use words like “happy” or “sad.” This scale is intended to measure how the respondents feel inside, not how their face looks. Numbers are not shown to the respondent; they are shown here only for reference. The instructions for administration are currently available in over 31 languages from \url{www.painsourcebook.ca}. (From Hicks CL, von Baeyer CL, Spafford PA, et al. The Faces Pain Scale–Revised. Toward a common metric in pediatric pain measurement. Pain 2001;93:173–183. This Faces Pain Scale-Revised has been reproduced with permission of the International Association for the Study of Pain®[IASP]. The figure may NOT be reproduced for any other purpose without permission.)

There is ample evidence supporting the reliability and validity of the FPS-R as a measure of pain intensity (see review\textsuperscript{174}). For example, the
FPS-R of pain intensity is strongly associated with other measures of pain intensity\textsuperscript{187,188} and shows adequate test–retest stability over a 2-week interval ($r = 0.76$).\textsuperscript{187} Also, the FPS-R shows responsivity to treatments known to impact pain, including in a clinical trial involving children as young as 4 to 6 years old,\textsuperscript{189} a trial involving children 5 to 12 years old,\textsuperscript{188} and one that used the FPS-R in children aged 3 to 12 years old.\textsuperscript{190}

An earlier version of the FPS-R\textsuperscript{191} as well as the FPS-R have been shown to be easier to comprehend by older patients and patients with dementia than either a VRS or a VAS.\textsuperscript{185,187,192,193} Interestingly, although the NRS tends to be preferred over other scales by older patients who are not cognitively impaired, in one study, the FPS-R was shown to be preferred over other pain measures by elderly patients who have cognitive impairments.\textsuperscript{187} Thus, the FPS-R appears to be the best measure to when even simple VRSs are too complex for the patient or population being studied. Also, the instructions for the FPS-R are available in many languages (currently 64), and information about the FPS-R is readily available and kept updated on a Web site (https://www.iasp-pain.org/Education/Content.aspx?ItemNumber=1519).

However, one study reported that over half of a sample of 6-year-olds had difficulty understanding and using the FPS-R,\textsuperscript{194} suggesting that when designing a pain trial with very young children, either (1) adequately large numbers of participants may be needed to overcome possible unreliability of the measure or (2) if limited numbers of possible participants are available, an alternative measure or procedure (such as a pain behavior observation procedure) may be needed.

**Selecting the Best Measure for a Patient or Population**

One way to determine which measure to use in any one patient in the clinical setting would be to begin by asking him or her to provide pain ratings using a number of different measures (e.g., a NRS, a VRS, or the FPS-R) for six domains of pain intensity: his or her own current pain; his or her own worst, least, and average pain during a specific period of time (e.g., the past 24 hours); the rating he or she would make on the scales that would represent mild pain; and the rating he or she would make on the scales that would represent severe pain. The patient’s responses to the
measures could then be examined to determine which scales show the most consistent responses; that is, the scales for which his or her own least pain is rated lower than worst pain, ratings of his or her own current and average pain ratings fall within the least-worst range, and the ratings they selected as representative of “mild” and “severe” pain fall within an expected range (e.g., severe pain is rated higher than mild pain, and both are rated higher than the lowest possible response on the scale). Evidence indicates that even among individuals with severe dementia, the majority can provide a valid response to at least one type of scale, although the scale that is most useful for any one patient may differ between individuals. Thus, by first trying different scales with patients who are at risk for having difficulties with standard measures, the clinician can determine for each patient that measure or scale that provides the most consistent response and that the patient indicates is easiest for him or her to use. This is the scale that could then be used with that patient in future clinical encounters.

Selecting a measure to use in a clinical trial involving populations of patients who may have difficulty comprehending or using pain measures is more challenging, given that there is no single measure that will be universally valid for every individual. In this situation, it probably makes the most sense to (1) select the single measure that is most likely to be valid for the most study participants (e.g., either a simple VRS or the FPS-R), (2) ensure that the measure is adequately explained to all study participants, (3) ensure adequate power (e.g., large sample sizes) to deal with possible decreases in reliability of assessment due to possible difficulties with the measure in some study participants, and (4) consider using ability to comprehend and use the measure (as determined, e.g., by an ability to provide a consistent response when asked to rate current, least, average, most, “mild” and “moderate” pains, see previous discussion) as an eligibility criterion for participation in the study. If the study population of interest is known to include at least some participants who will not be able to provide a valid response on a self-report pain measure, and adequate sample sizes are not available to address possible increased unreliability in assessment because of this potential problem (or there is a need to determine the effects of the treatment even among those
who are unable to validly describe their pain), then the use of pain behavior observation scales or procedures may be indicated.

**BEHAVIOR OBSERVATION MEASURES**

A large number of pain behavior observation scales and measures have been developed for use as proxy measures of pain when self-report scales cannot be used, for example, in preverbal children or in nonverbal adults. The field has not yet come to a consensus regarding which one of the available measures is the most valid and reliable in most populations. The interested reader is referred to the published reviews for the most up-to-date summary of the state of the science concerning these measures.\(^{171,174,175,195–197}\)

Briefly, all of the available measures contain a list of behaviors commonly thought to be associated with the experience of pain, such as moaning, crying, furrowing one’s brow, grimacing, and rubbing a body part, among many others. The scales often score the behaviors as being present or absent, but they sometimes ask the observer to rate the behaviors along a continuum of frequency or intensity. Item responses are then summed to create total pain behavior scores or subscales for specific classes of behaviors, such as vocal, social, and activity pain behavior subscales. One earlier review of pediatric measures\(^{171}\) recommended two scales for assessing pain intensity associated with medical procedures: the Face, Legs, Activity, Cry, and Consolability, or FLACC scale\(^{196}\) and the Children’s Hospital of Eastern Ontario Pain Scale, or CHEOPS,\(^{197}\) one for assessing postoperative pain in the hospital (FLACC), one for assessing postoperative pain at home (Parents’ Postoperative Pain Measure or PPPM),\(^{198}\) one for assessing pain in critical care (the COMFORT scale),\(^{199}\) and two for assessing pain-related fear or anxiety (the Procedure Behavior Checklist or PBCL\(^{200}\) and the Procedure Behavior Rating Scale–Revised\(^{201}\)). Consistent with this, a more recent paper noted that in 12 published reviews of behavioral observational scales, of 65 existing measures, the scales that were recommended most often were the FLACC or Revised FLACC (rFLACC),\(^{202}\) CHEOPS, and COMFORT scales.\(^ {197}\) A review of pain behavior measures in elderly individuals with dementia\(^ {175}\) concluded that two scales appear most valid and useful in these
populations: the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC)\textsuperscript{203} and the DOLOPLUS 2.\textsuperscript{204} Finally, a review of pain observation measures for potential use in critical care patients who are otherwise unable to communicate about their pain\textsuperscript{195} recommended the Critical-Care Pain Observation Tool.\textsuperscript{205}

**Measuring Pain in Busy Clinical Settings**

Of course, in many busy clinical settings, it may only be possible to administer just a very few scales. Two newer very brief multidomain pain measures that have been developed for this situation are the Defense and Veterans Pain Rating Scale (DVPRS)\textsuperscript{206} and the PEG (assessing pain intensity [P], interference with enjoyment of life [E], and interference with general activity [G]).\textsuperscript{207} The DVPRS is a 5-item questionnaire assessing pain intensity and pain interference with usual activity and sleep, impact on mood, and contribution to stress, all using 0-to-10 scales with additional cues (e.g., color shading from yellow to red) to make understanding easier. The PEG items assess average pain intensity and pain interference with enjoyment of life and general activity, also using 0-to-10 NRSs. Not surprisingly, as these measures are based in large part on existing measures with proven reliability and validity, research findings support the validity and reliability of both the DVPRS (and the even more recent DVPRS-2) and PEG items.\textsuperscript{206–210}

**Summary and Conclusions**

When considering which pain domains to assess for research or clinical purposes, investigators and clinicians must balance the need for a thorough assessment against the needs of the patient for minimal assessment burden. When determining this balance, all of the possible pain domains (intensity, affect, quality, temporal characteristics, and impact or interference) should at least be considered. Moreover, it is important to remember that many patients with pain often report more than one pain problem.

The ideal assessment, even when assessment needs to be brief, would probably involve assessing up to at least three “primary” or “most bothersome” pain problems, and include an evaluation of their intensities.
and locations. For assessing intensity of each pain problem or pain site, the data from a large number of studies in persons with chronic pain suggest that 0-to-10 Numerical Pain Scale of pain intensity (with 0 = “No pain” and 10 = “Pain as bad as you can imagine”) have the most strengths and fewest weaknesses of the available measures in many populations. Four-point VRSs or the FPS-R would be most appropriate in populations who might struggle with the 0-to-10 NRS, such as the elderly or individuals who have cognitive impairment.

To assess pain site, pain drawings have been used more often than site checklists in published research. However, pain site checklists are easier to score, given that pain drawings require a second step of scoring to determine the location(s) and extent of pain, and there is no evidence to suggest that patients’ responses to site checklists are any less valid than their responses to pain drawings. For these reasons, a site checklist, provided that the sites listed are adequately comprehensive, may be more practical in many research situations, although clinicians may prefer pain drawings for the overall gestalt that such measures can provide concerning how the patient views pain in his or her own body.

Whether or not to assess the temporal pattern(s) of the different pain problems would be important (1) if altering the temporal pattern of pain is a goal of treatment or (2) if knowledge about the temporal pattern is needed to help diagnose the pain problem. The available data indicate that pain’s continuous versus intermittent nature can predict important functional outcomes, with continuous pain associated with poorer outcomes, suggesting that some assessment of this aspect of pain may be useful. A simple categorical question (e.g., such as that included on the PQAS-R or the painDETECT) appears to be adequate for assessing this characteristic of pain. More research is needed to determine the relative validity and utility of assessing other temporal characteristics of each pain problem.

Although pain does have an affective component, pain affect is not frequently measured in pain research. This may be due, in part, to the strong associations found between measures of pain intensity and pain affect; pain that is more severe usually bothers people more. There are, however, a number of situations in which it may be appropriate to assess
pain affect in addition to pain intensity, for example, when evaluating the effects of treatments, such as cognitive-behavioral therapy or mindfulness-based interventions, that might have a greater impact on the affective or suffering component of pain than on pain intensity. In these situations, because of its brevity and demonstrated validity, the Affective subscale of the SF-MPQ would appear to be the best choice.

Although more research is needed to identify the pain quality scales (and items) that best classify pain types (e.g., neuropathic vs. nonneuropathic), at this point, the DN4 has the most empirical support for this purpose. When a self-report measure that can be used to classify patient pain is needed, both the S-LANSS and painDETECT could be used, with neither one evidencing stronger empirical support than the other at this point in time. To assess pain qualities for describing pain or determining the effects of treatment on pain qualities, the PQAS-R has the most empirical support for its content validity and ability to detect changes in distinct pain qualities with pain treatments.

Research has confirmed what many clinicians and patients with chronic pain already know; pain can have a significant negative impact on important activities. Assessing the critical domain of pain interference should be strongly considered by both clinicians and researchers. Clinicians can use this information to help target treatments (e.g., substantial impacts on mood might suggest the need for treatments that could address mood disturbances, whereas substantial impact on sleep would suggest the need for treatments that could help the patient sleep better) as well as track the efficacy of different pain treatments that are provided. Researchers could, and in many cases probably should, assess pain interference as a primary or secondary outcome in clinical trials in order to determine whether or not the treatment being examined has benefits on the patient’s life beyond its effects on pain. For assessing this domain, the seven BPI Pain Interference scale items (with the “walking” item modified in samples of patients with physical disabilities so these patients can rate the interference of pain on “mobility [ability to get around]”) and the PROMIS Pain Interference scales appear to have the most strengths of the available measures.

In populations of patients who might have limited ability to
communicate or to use the measures recommended in the preceding text, clinicians can select from among the simpler measures, such as simple verbal categorical scales (i.e., “None,” “Mild,” “Moderate,” or “Severe”) or the FPS-R. Among patients who demonstrate an inability to understand or use these measures, then a very simple dichotomous question (“Do you have bothersome pain?”) or some of the validated pain behavior observation scales may be needed.

One final point can be made concerning the pain assessment: In any setting, it is critical to remember that we are ultimately assessing individuals who have specific pain conditions as well as pain-related and non–pain-related comorbidities, which affect treatment choices and treatment outcomes. We are not only assessing their pain. Many of the measures that we use have extensive support for their reliability and validity and can provide numbers and ratings that can be used to help determine the efficacy of pain treatments, the need to continue or discontinue those treatments, and the possible need to provide additional treatments. But all of the numbers and ratings provided by patients and research subjects come from people, many of whom may be suffering a great deal. Measures, surveys, and questions can never replace the need to listen with compassion to the people we serve, in order to ensure the appropriate evaluation and treatment of their pain condition. The experience of a person reporting a pain level of “7” (out of 10) will rarely, if ever, be the same as the experience of another person reporting that same pain level. Much more important than obtaining a pain rating or score is an understanding of patients and their experience. We serve our patients best when we remember to take the time to listen.

112. Moseley GL. Graded motor imagery is effective for long-standing complex regional pain

Biopsychosocial approaches posit that biologic, psychological, and social factors interact to shape the overall experience of pain.\(^1\) This relationship is exemplified by the negative impact on psychological well-being that results from the lack of definitive cure for many chronic pain conditions\(^2\) and the ensuing development of a vicious cycle in which physical pain and emotional distress exacerbate each other. Psychosocial variables are also known to play a predictive role in medical intervention outcomes\(^3\); thus, assessing and addressing these risk factors can maximize treatment efficacy. Although the history and physical exam completed during a medical appointment may touch on psychosocial factors as they relate to pain, a full pain psychology evaluation provides a more comprehensive perspective regarding how past and current stressors, emotional functioning, sociocultural variables, and health behaviors may be influencing the etiology and maintenance of underlying pain conditions.

The current chapter provides an overview of the various components of a psychological evaluation, the rationale for their inclusion, and briefly discusses several assessment devices that can be used to facilitate this process. A more thorough review of instruments that can be used to measure pain and its associated features can be found in the previous chapter. Just as the data from clinical interviews and objective assessment devices are used in a complementary fashion in pain evaluation, the information contained in the previous and current chapters should be used in a similarly integrative fashion.

**Psychosocial History**

Psychosocial factors evolve over the course of the life span have been
associated with pain and pain outcomes. A full psychosocial history should include information about early life experiences, academic history, and vocational functioning.

**EARLY LIFE EXPERIENCES**

Awareness the role that early life events play in the human experience—namely, adverse childhood experiences (ACE)—is fundamental to understanding how patients relate to their internal world and outside environment. ACE include verbal abuse, physical abuse, sexual abuse by an adult/or someone 5 years older, neglect, witnessing domestic violence, parental divorce, substance use in home, mental illness of someone in the home, and/or history of prison sentence of someone in the home. ACEs have been associated with a myriad of adverse health and behavior outcomes, including the development of pain conditions. The negative impact of ACE is believed to occur through increased pituitary adrenal and autonomic nervous system reactivity, as evidenced by increased reactivity when compared to counterparts who have not experienced significant adverse events. The relational strength seen between ACEs and the development of negative health outcomes can be mediated by a combination of psychological and physiologic factors such as negative schemas, decreased mood, decreased positive health behaviors, suppressed immunologic function, and increased stress reactivity. Given the role that early life experiences can play in the development of pain conditions over time, it is important to assess this aspect of patients’ personal history in the clinical interview. This process can be facilitated by use of the Adverse Childhood Experience Questionnaire, a free, 10-item measure in which a score of 4 and above that indicates a higher likelihood of negative health outcomes.

**VOCATIONAL HISTORY**

Past and current vocational functioning provides perspective regarding patients’ activity patterns and is also predictive of the development of and prognosis for pain-related issues. A prospective study of 3,020 volunteers assessing risk factors associated with later back injury claims found that job dissatisfaction was the most predictive individual factor for reporting
work-related low back pain over the course of time. Subsequent studies of job satisfaction have further reinforced its predictive value in pain-related disability. It has been postulated that work satisfaction may serve as a protective factor for adverse pain outcomes across different work environments and socioeconomic groups. The postinjury work environment itself also plays a role in pain outcomes. The lack of work place modifications to accommodate the limitations caused by the injury and the inability to modify the pace at which one completes job-related tasks are both predictive of chronic pain-related disability.

All of the aforementioned underscores potential secondary gain variables that may influence response to treatment and should thus be explored in greater detail. It is imperative to note that these variables are not limited to the vocational environment: factors that can reinforce maintenance of impaired functioning should be assessed across all domains of patients’ lives. If such influences are detected, it is useful for clinicians to delineate the mechanism by which they may be shaping response to treatment rather than merely identifying a clinical situation as having potential for secondary gain, as the latter can have negative ramifications for patients. Finally, although it is important to assess for its presence, it is also incumbent on the clinician to ensure that a lack of response to treatment is not inappropriately attributed to secondary gain.

EDUCATIONAL HISTORY
Educational history is another patient variable that is known to influence chronic pain. A study examining correlates of back pain in German patients found that level of education significantly predicted low back pain and accounted for a large majority of the variance in the differences across age and gender. Large-scale studies in other countries have also found links between education and pain. In a study of 17,543 adults from Australia, lower levels of completed education, unemployment benefits, and being unemployed for health reasons were all associated with having chronic pain. A study of 8,970 individuals from Finland found an “educational gradient” for both chronic and disabling chronic pain, where lower levels of education were associated with a higher prevalence of chronic pain and disability. Low educational attainment is strongly
associated with low back pain, and this is believed to function primarily through psychological factors and health behaviors such as smoking, diet, exercise, and obesity. An analysis targeting the link between education and pain found that individuals with lower levels of education achievement were more likely to report pain as a signal of harm and had increased self-reported disability, potentially explaining the mediating psychological factors between level of education and pain. There is also evidence that the course of back pain is less successful for individuals with lower levels of education. Level of education is of particular importance in understanding psychological and health literacy barriers that can impact pain treatment. Information related to education can be obtained by assessing level of academic preparation (e.g., less than high school, high school, college, and graduate school).

Current Functioning

An assessment of current status should delineate patients’ daily activity patterns and the extent to which physical pain and pain-related beliefs affect functioning. Attention should focus on the presence or absence of adaptive coping skills and health behaviors such as time-based activity pacing, consistency in dietary and sleep habits, and engagement in activities that promote physical and psychological wellness (e.g., physical exercise, meditation). Tension in interpersonal relationships, finances, and/or work should also be noted, as studies have found an association between stress and pain. The pain experience and response to treatment is ultimately a product of the interaction among all of the aforementioned variables, belief structures, social relationships, and cultural factors. As the latter three categories are more nuanced, they will be discussed in greater detail in the following text.

BELIEF STRUCTURES

Individuals’ belief structures about their pain can influence their overall adjustment to the condition itself. Pain catastrophization is characterized by maladaptive, exaggerated thoughts, and emotions about actual or anticipated pain. It is strongly associated with poor treatment outcomes.
across the life span and is predictive of function, opioid use, and pain intensity. Individuals who engage in high levels of pain catastrophization are often somatically hypervigilant at baseline which can lead to both increased pain perception and affective distress. Activity reduction is frequently employed as a coping strategy to escape pain, but this approach can result in the development of a fear avoidance cycle. The latter construct refers to avoidance of activity secondary to fear of reinjury, pain, or worsening of the underlying condition. Over the course of time, the avoidance of activity contributes to emotional distress and declining physical functioning which further reinforces the fear. Fear avoidance beliefs are self-perpetuating in nature and are predictive of functional limitations and perceived disability.

In addition to data gleaned from the clinical interview, there are a number of devices available to assist with the assessment of catastrophic and fear avoidance beliefs. The Pain Catastrophizing Scale (PCS) is a commonly used device composed of 13 items rated on a Likert scale. In addition to general tendencies toward catastrophization, subscales indicate the extent to which the respondent’s cognitions are characterized by magnification, rumination, and helplessness. The Fear-Avoidance Beliefs Questionnaire (FABQ) and the Pain Anxiety Symptoms Scale (PASS-20) specifically developed to assess patients’ beliefs as they relate to low back pain. It is composed of 16 items scored on a 7-point Likert scale and yields scores on two subscales: Scale 1 assesses fear-avoidance beliefs about work and Scale 2 assesses fear-avoidance beliefs about general physical activity. The PASS-20 is composed of 20 items on a 6-point Likert scale. It measures pain-related anxiety across four subscales: cognitive, escape/avoidance, fear, and physiologic anxiety.

Beyond interpretation of pain, it is also useful to assess patients’ beliefs regarding the role that they play in their own care. There are differences in how treatment is approached in acute versus chronic pain: Patients often assume a more passive role in the former, whereas the latter requires active self-management. Assessing patients’ understanding of this process and providing appropriate education can facilitate their ability to become active participants in their treatment plan.
Assessment for alignment in treatment expectations is also important. Clinicians and patients may have different perspectives regarding what constitutes a successful outcome: A clinician may perceive improvement in physical functioning despite the presence of pain as fitting in this category, whereas a patient may view this as unsuccessful due to the ongoing nature of the pain symptoms. The potential for such a discrepancy highlights the importance of ensuring that patients understand the treatments in which they will participate and that they have realistic expectations of outcomes they may experience.41

SOCIAL SUPPORT

Social support factors relate to chronic pain conditions in a bidirectional fashion. Experiencing pain and resulting disability can further stress one’s family system and may create conflict, particularly if one is no longer able to complete their expected family responsibilities.42–44 Supportive family systems can also reinforce disability as they may engage in overly solicitous behavior, which can lead to further disability and passivity in the patient.45–47 This is evidenced through operant models of conditioning, where increased reinforcement of pain-related behavior translated to increased pain intensity and disability.48 There is evidence to support further pain and disability with communal catastrophizing as well, where increased expression of distress can lead to exhaustion of social support.49 At the same time, a dysfunctional family can further exacerbate patients’ conditions. Studies show that individuals who felt invalidated by a partner experienced more marital conflict, which in itself is associated with increased negative pain outcomes.50 A longitudinal study assessing the impact of social support on pain outcomes found that immediately after a motor vehicle accident, social support did not relate to perceived pain ratings; however, at 6-week follow-up, individuals with less perceived social support had higher pain ratings than those with elevated social support, and this relationship was more significant for men than women and for those with depression.51 Assessing the level of social support is particularly relevant in chronic pain management, and evidence supports the need for assessment in acute instances as well. Depleted levels of support can predict negative outcomes; yet, overly solicitous social support
can also be as deleterious. Evaluation in this arena should include information about the quantity, quality, and stability of the full range of past and present interpersonal connections, including marital, family, work, and other social relationships. The Social Provisions Scale is a free, 24-item, self-report questionnaire that has been validated across several samples that can provide useful data that complements information obtained from the clinical interview.\textsuperscript{52}

\textbf{CULTURAL FACTORS}

In its seminal report Relieving Pain in America, Institute of Medicine\textsuperscript{2} specifically highlighted the importance of addressing cultural factors in the delivery of pain care. The literature has demonstrated variability across gender, ethnicity, race, and age influences the pain experience and patients’ responses to treatment.\textsuperscript{53–55} Clinical interview questions should therefore focus on gathering information on the sociocultural background of patients, their families, and communities, including assessment for disparities that may affect access to care.

\textbf{Substance Use}

Substance use behaviors are consistently identified as factors that can influence pain and pain treatment.\textsuperscript{56} The mere presence of substance use does not necessarily indicate the presence of a problem; however, continued use of a substance despite the presence of adverse outcomes, failed attempts at abstinence, and the experience of clinically significant impairment in daily functioning are hallmark characteristics of a substance use disorder (SUD).\textsuperscript{57}

Concurrent diagnoses of pain and SUDs are of particular significance given the influence they can have on one another. Veterans who are diagnosed with hepatitis C and have a history of an SUD display an increased likelihood of having a pain diagnosis versus patients who have no SUD history.\textsuperscript{56} One cross-sectional analysis of chronic pain prevalence among patients in current substance abuse treatment programs found that 37\% to 60\% reported experiencing chronic pain.\textsuperscript{58} Within this sample, significant predictors of both pain and substance use included younger age,
chronic illness, lifetime psychiatric illness, drug craving, and current psychiatric illness. Persistent pain has also been associated with continued substance abuse after detoxification.

There is a relative scarcity of randomized controlled trials assessing the variations in pain treatments for patients with chronic noncancerous pain (CNCP) and comorbid substance use; however, existing studies emphasize the effectiveness of psychological interventions in improving pain-related function while reducing the risk of relapse for patients with concurrent CNCP and SUDs. Effective reduction of aberrant medication use behaviors among patients with comorbid CNCP and SUDs can be achieved through use of a multidisciplinary care framework, creating treatment plans with high levels of specificity, increasing visit frequency, utilizing urine drug screens, and limiting opioid supply.

A large review of comorbid SUD in patients with CNCP found estimates of current SUD ranging between 3% and 43% and a lifetime prevalence ranging from 16% to 74%. Of note, the highest rate of comorbid SUD with CNCP patients was found in those attending emergency rooms for opioid refills with 74% meeting criteria for lifetime SUD. The data remains mixed on predictive value of demographic variables such as age, employment, race, gender, ethnicity, marital status, and years of education rates of comorbid SUD and CNCP.

There is a wide array of evidence supporting the need to evaluate and consider previous and current substance use and SUDs as a means of improving outcomes and performing risk stratification. The specific pathway to evaluate substance use risk in patients with chronic pain is often multimodal: More specifically, a combination of clinical evaluation, formal instruments, and review of adjunctive methods of evaluation (e.g., urine drug screens, prescription drug monitoring) is suggested. Assessment in this arena should include exploration of nicotine, alcohol, and prescribed and nonprescribed (e.g., medications obtained illegally, illicit substances) drug use patterns.

**NICOTINE**
The prevalence of nicotine use in individuals living with chronic pain is higher than what is found in the general population: The Centers for
Disease Control and Prevention identifies approximately 15.6% of the US adult population as current smokers, whereas a recent analysis of 5,350 chronic pain patients found approximately 23.5% identify as active nicotine users.\textsuperscript{71,72} Zvolensky and colleagues\textsuperscript{73} found that individuals with a lifetime history of neck or back pain were significantly more likely to meet criteria for current or historical nicotine dependence. In their study of 9,282 participants, those with a lifetime history of medically unexplained chronic pain were more likely to be current smokers.\textsuperscript{73} It has been proposed that these variables interact with one another in a feedback loop in which smoking behavior increases pain and the presence of pain motivates smoking behavior.\textsuperscript{74} Pain-induced motivation to smoke is likely related to withdrawal-based learning and patients’ expectations of the effects of smoking in improving mood.\textsuperscript{75} Nicotine’s relationship with health outcomes is quite broad: It negatively impacts cardiovascular and pulmonary functioning, is associated with increased mortality, and can adversely influence the experience of pain.\textsuperscript{76} The global negative effects of nicotine on health—particularly its impact on pain—highlight the importance of assessing for the use of this substance as a coping strategy.

**ALCOHOL**

Alcohol consumption can interfere with successful pain management and have adverse effects on psychological functioning.\textsuperscript{77} Similar to other variables discussed in this chapter, pain and alcohol use have a bidirectional relationship. Pain has been identified as a situational factor that motivates alcohol use and excessive use of alcohol can complicate pain treatment.\textsuperscript{78} Furthermore, alcohol can also play a causal role in the development of painful conditions such as peripheral neuropathy and pancreatitis. Individuals with lower socioeconomic status are more likely to report increased alcohol consumption and experience higher levels of alcohol use disorder.\textsuperscript{79,80} Other factors have also been found to be related to increased likelihood of alcohol use disorder such as obesity, symptoms of anxiety and depression, family history of alcohol use disorder, other SUDs, and tobacco smoking.\textsuperscript{79,81–85} The assessment of alcohol use among pain patients is particularly relevant given the potential dangers that exist when it is combined with prescribed pharmaceuticals (e.g., nonsteroidal
anti-inflammatory medications, acetaminophen, opioids, and benzodiazepines). In addition to verbal inquiry, alcohol use can be assessed using the Alcohol Use Disorders Identification Test (AUDIT). The AUDIT is a free, reliable, valid, self-administered, 10-item questionnaire, where scores above 8 are associated with negative health outcomes. It has been validated in multiple languages within primary care, rural, and college populations. A shortened version, the Alcohol Use Disorder Identification Test Consumption Questions (AUDIT-C), has been validated for use in screening for alcohol use disorder in primary care samples. 

**PRESCRIBED AND NONPRESCRIBED DRUG USE**

The rate of emergency department visits involving prescription drug misuse doubled from 2004 to 2011 and fatal prescription drug overdoses involving opioids roughly quadrupled from 1999 to 2011. The sharp rise in opioid-related issues led to the development of clinical guidelines for opioid therapy in CNCP. Included in the guidelines is the importance of assessing for aberrant drug-related behaviors as a part of ongoing treatment.

A large review study involving two large health plans found that prescribing of long-term used opioids for CNCP increased from 11.6% to 17% for those with SUD histories. Additionally, those with prior substance use history received higher doses of opioids, were more likely to use other schedule II drugs, and were more often using sedative-hypnotic medications in conjunction with opioids. Prior use of cocaine and cannabinoids, previous drug convictions including driving under the influence, and alcohol abuse histories are identified as predictors of opioid misuse above and beyond self-reported pain scores.

A thorough assessment of prescribed and nonprescribed drug use includes current and previous use of such substances, personal and family histories of SUDs, and prior participation in substance abuse treatment programs. Social, legal, and/or occupational impairment secondary to use of these substances should be noted, as should lack of compliance with prescription instructions.
Prescription drug monitoring programs (PDMPs) are state-level databases that track prescribing and dispensing of controlled substances. They help characterize patients’ use of such substances and are thus useful tools to use when planning pharmacologic treatment. Use of PDMPs has been associated with a reduction in drug-related deaths, but the laws and guidelines surrounding their use vary across states. Although access to such databases is not readily available to nonprescribing clinicians such as psychologists, information from the medical record that comments on PDMP findings should be included in evaluations when available.

The Opioid Risk Tool (ORT) is a free, 10-item self-report measure that provides some identification around individuals who may develop aberrant behaviors when prescribed opioids for chronic pain symptoms. It includes items related to personal and family history of substance use, age, history of preadolescent sexual abuse, and some psychological factors related to chronic pain and opioid use. Score interpretations include a score of 0 to 3 representing a low risk of aberrant behaviors, 4 to 7 representing a moderate risk, and greater than 8 representing a high risk of such aberrant behaviors. This assessment had previously been identified as having a high degree of sensitivity and specificity in identifying which patients are at greater risk of aberrant opioid use behavior. More recent studies, however, have found that the ORT’s utility has diminished. It is mentioned here due to its high prevalence in clinical practice; however, caution should be exercised when using this or any other questionnaires that rely on self-report as they have a high risk of response bias. Use of self-report tools should thus be supplemented with collateral information from the clinical interview, medical record review, urine drug screens, and PDMPs.

Psychiatric Functioning

Evaluation of psychiatric functioning should include information about personal and family histories of psychiatric disturbances; lifetime history of involvement in formal mental health treatment (e.g., individual therapy, pharmacologic management of moods, and psychiatric hospitalization); and past, current, and imminent ideation, intent, or plan to harm self or
others. Information regarding symptoms of psychosis, mania, panic, learning disabilities, obsessive-compulsive disorder, and other forms of psychopathology can initially be obtained through general queries as it is not practical to walk patients through the diagnostic criteria for all psychiatric disorders. Positive endorsement of any such inquiries should be followed by more thorough assessment. As depressive and anxious disorders have a higher societal prevalence, their diagnostic criteria should be reviewed in more detail. Given the association between ACE and health and behavior outcomes, trauma history also warrants more focused attention. Lastly, all of the aforementioned forms of psychological distress have the potential for somatic manifestations; thus, understanding somatic disorders and their associated symptoms is also a critical part of the evaluation. Psychiatric impressions and recommendations are based on a combination of information obtained through behavioral observations, the clinical interview, and objective assessment devices.

**BEHAVIORAL OBSERVATIONS**

Objective observations on cognitive, emotional, and behavioral domains characterize the disposition of patients during the evaluation itself. Cognitive functioning is assessed via orientation to time, person, place, and situation; content and linearity of thought processes; and speech and patterns. Mood, affect, insight, and judgment should be commented on, including their congruence with the situation. The presence of verbal (e.g., vocal complaints, moaning, sighing) and nonverbal (e.g., shifting position, wincing, taking medication) pain behaviors should also be noted, as they also play a role in the overall experience of pain.

**DEPRESSION**

Depression is a mood disorder characterized by pervasive sadness and anhedonia that causes clinically significant impairment in daily functioning. Associated symptoms may also include changes in sleep patterns, diet, weight, attention, concentration, energy, and motivation. Individuals with chronic pain are 3 times more likely to meet criteria for depression, and symptoms of pain and depression vary directly with each other. Some prospective studies have shown that a history of
depression may predispose a person to develop pain,\textsuperscript{109,110} whereas others have postulated that the consequences of the pain experience result in the formation of depression.\textsuperscript{111} Regardless of the causal direction of the relationship, 65% of individuals with depression report pain symptoms and depression is present in 5% to 85% (varies by setting) of patients with pain conditions.\textsuperscript{112} More importantly, the presence of pain leads to decreased identification of depression, resulting in it being undertreated.\textsuperscript{112} As untreated/undertreated psychological distress can impact pain, this underrecognition can trigger a self-perpetuating cycle in which pain and depression adversely impact each other.

Screening for depression can occur with use of the Patient Health Questionnaire-9 (PHQ-9). This brief assessment device is composed of 9 items plus a qualitative functional deficit item and helps to identify depressive symptoms and their severity.\textsuperscript{113} Clinical interview questions should focus on Diagnostic and Statistical Manual of Mental Disorders (5th ed.; DSM-5)\textsuperscript{57} diagnostic criteria for depression and must also include specific suicide risk assessment.

**ANXIETY**

Anxiety is characterized by excessive fear or worry that is intrusive and has a significant negative impact on a person’s daily functioning.\textsuperscript{57} Anxiety-related disorders and chronic pain can have reciprocating relationships that are similar to those observed between depression and pain. Anxious interpretations of pain stimuli can result in decreased functionality and increased pain. More specifically, novel pain symptoms can trigger fear of their underlying meaning resulting in pain being viewed as a threatening stimulus. This cognitive appraisal can then lead to decreased engagement of activities for fear of worsening pain or causing further damage, thereby completing a positive feedback loop by further increasing avoidance, inactivity, and disability. This process concurrently results in overstimulation of physiologic arousal leading to lower pain thresholds, increased pain sensitivity, and sustained pain.\textsuperscript{114,115} Other studies have found that individuals with elevated trait anxiety report higher levels of pain intensity compared those who score lower on this construct.\textsuperscript{116} Anxiety has also been found to negatively affect health
outcomes, as it has been associated with increased surgical complications and prolonged hospital stays.\textsuperscript{117,118}

The Generalized Anxiety Disorder-7 (GAD-7) assesses symptoms of generalized anxiety disorder.\textsuperscript{119} Somatic, cognitive, and affective clusters of symptoms are assessed on a 4-point Likert scale with scores of 5 or greater considered mild elevation in symptoms. The GAD-7 can serve as an effective screen for anxiety, but further delineation of symptoms is necessary to assist with diagnosis and formulation of a specific treatment plan.

**POSTTRAUMATIC STRESS DISORDER**

Posttraumatic stress disorder (PTSD) may develop after experiencing or witnessing a traumatic event. It is often associated with reexperiencing the event, hypervigilance, avoidance, and emotional reactivity.\textsuperscript{57} Approximately 30\% to 80\% of individuals with PTSD also report the presence of chronic pain.\textsuperscript{120} It is believed that individuals with anxiety are more vulnerable to develop PTSD as a result of neurobiologic predispositions to negative reactivity to stimuli, maintenance of symptoms secondary to continued avoidance of associated stimuli, attentional biases to trauma-related cues, and reduction of pain thresholds and pain tolerance due to increased anxiety-related physiologic processes.\textsuperscript{120} Although some degree of clinical specificity exists among symptoms of depression, anxiety, and PTSD, there seems to be overlap between neurobiologic processes underlying these disorders that explains their relationship with pain and pain-related outcomes.

The Primary Care-PTSD (PC-PTSD) scale is a 4-item screening instrument that assesses symptoms associated with traumatic stress conditions as defined by DSM diagnostic criteria.\textsuperscript{121} There are four symptom cluster items that patients respond to in a dichotomous fashion. Although the original development of the scale identified the possibility of PTSD symptoms with 3 out of 4 items endorsed, later research has suggested that just 1 out of 4 items may indicate the presence of an underlying trauma condition. As with the GAD-7, this tool should be used as a screening device only and not as a tool to formally diagnose PTSD. Information gleaned from a throughout clinical interview is necessary for
SOMATIZATION
Psychological distress can often manifest in the form of physical symptoms, a process referred to as somatization. The DSM-5 identifies a number of somatic symptom disorders that are often seen in pain settings: (1) Somatic symptom disorder is marked by ruminations of thoughts about the seriousness of the symptoms or excessive anxiety or time and energy spent related to symptoms; (2) illness anxiety is characterized by high level of anxiety, preoccupation, and behaviors associated with possibly getting or having a medical or physical health condition; (3) functional neurologic symptom disorder is marked by motor, cognitive, or sensory symptoms that are largely medically unexplained; (4) psychological factors affecting medical conditions centers around emotional, behavioral, cognitive, or psychiatric factors that impact treatment of medical condition or the course of medical treatment; (5) factitious disorder is the intentional exaggeration of injury or medical condition for the sake of maintaining a patient role; and (6) malingering disorder is also the exaggeration of injury or medical condition but specifically for the purpose of some sort of secondary gain. Understanding the mentioned disorders and the differences among them is fundamental for diagnostic accuracy.

Psychological Screening for Advanced Interventional Procedures
Some insurance carriers require a pain psychology evaluation prior to undergoing implantable therapy trials (e.g., neurostimulation, intrathecal pump). Although this is not always mandated, it is useful to include such screening to maximize the benefit that patients may receive from the intervention itself, as psychological factors have been demonstrated to impact treatment outcome. Preprocedure psychology evaluations do not merely provide dichotomous responses regarding whether or not a patient is a decent candidate for a particular medical intervention; rather, they help identify
risk factors that may contraindicate a treatment pathway and provide recommendations for how to address them. In addition to obtaining information from all of the domains outlined in this chapter, evaluations in these situations also assess patients’ understanding of the procedure including risks and benefits and establishes that they have appropriate treatment expectations and an ability to cope with an unsuccessful trial. They further assess for psychological stability, the presence of chemical dependency issues, social support, and historical compliance with medical care. If deficits are noted in any of the aforementioned areas, recommendations may be made for behavioral preparation to optimize patients’ overall pain management care.123

Conclusion

The pain psychology evaluation is a critical component of multidisciplinary approaches to pain treatment. It is rooted in biopsychosocial models of pain and provides useful information regarding psychosocial factors that can contribute to the onset, maintenance, and exacerbation of pain conditions. Most importantly, it helps inform the creation of comprehensive treatment pathways that can maximize patients’ overall physical and emotional functioning.

Issues related to the evaluation of work disability claims by patients with chronic pain have been considered in the third and fourth editions of Bonica’s Management of Pain. The purpose of this chapter is to build on the concepts and data provided in the earlier chapters. In particular, we hope to shed light on issues related to the evaluation of disability in chronic pain patients by contrasting the approaches to the problem taken by two disability agencies—the Social Security Administration (SSA) and the Washington State Department of Labor and Industries (DLI).

Basic Concepts

Many societies have programs of financial support for individuals with medical conditions that render them incapable of working. The agencies that administer these programs differ in many respects, but their broad mandate is to evaluate claims for disability benefits made by their constituents and decide whether to accept or reject the claims.

Agencies that administer disability benefits in the United States include the SSA, the Department of Veterans Affairs, the Department of Defense, the Office of Personnel Management, the Department of Labor, workers’ compensation carriers, welfare programs, and private disability insurance companies. These agencies have somewhat different eligibility criteria, but they all must answer the following questions when evaluating someone who applies for work disability benefits.

1. Does the applicant have a medical condition that might interfere with his or her ability to work? If so, what is the diagnosis?
2. How severely impaired is the body part or organ due to the person’s
medical condition?
3. What kinds of activity limitations might the person reasonably be expected to have because of his or her impairment?
4. How do these expected activity limitations compare with the essential activities required by various jobs?

In addressing these issues, disability agencies generally emphasize the significance of objective medical evidence. They apply their conclusions regarding the facts of a case to the rules in their respective jurisdictions to determine whether a claimant is actually disabled. The basic challenge in the evaluation of chronic pain patients is that incapacitation that may be alleged is at least in part inherently subjective. This challenge was succinctly summarized in a monograph about the evaluation of pain for purposes of the SSA:

The notion that all impairments should be verifiable by objective evidence is administratively necessary for an entitlement program. Yet this notion is fundamentally at odds with a realistic understanding of how disease and injury operate to incapacitate people. Except for a very few conditions, such as the loss of a limb, blindness, deafness, paralysis, or coma, most diseases and injuries do not prevent people from working by mechanical failure. Rather, people are incapacitated by a variety of unbearable sensations when they try to work.\textsuperscript{1}(p28)

Thus, the challenge for disability agencies is to reliably and consistently determine the extent to which “unbearable sensations” affect individuals who apply for benefits. If they discount “unbearable sensations” completely, they are likely to deny benefits to applicants who are actually unable to maintain employment. If they rely too heavily on statements of “unbearable sensations,” they might encounter two adverse outcomes: First, they might give preference to patients who communicate their struggles very effectively over more stoic patients who actually have more severe medical conditions. Second, because it is possible to feign severe pain, the agencies might award disability benefits to individuals with completely fraudulent claims.\textsuperscript{2–5}

**Conceptual and Empirical Issues**
In order to study the role that chronic pain plays in work disability awards, observers and researchers must consider several issues. These were discussed in detail in the fourth edition of Bonica’s Management of Pain and will be summarized only briefly here.

**IMPAIRMENT AND DISABILITY**

Two concepts that are central to the functioning of agencies that administer disability programs are “impairment” and “disability.” Unfortunately, these terms do not have unique definitions because different disability agencies define them in slightly different ways.

**Impairment**

The definition of impairment given by the SSA is “anatomical, physiological, or psychological abnormalities that can be shown by medically acceptable clinical and laboratory diagnostic techniques.”

This definition captures essential features of the concept. A key point is that impairments are construed as biomedical abnormalities that can be analyzed at the level of organs or body parts. In fact, a critical distinction between impairment and disability is that they address limitations at different levels of analysis. Impairment refers to a limitation in the function or structure of an organ or body part, whereas disability refers to a limitation in the behavior of a person. This distinction is reflected in the syntax used to describe impairments and disabilities. For example, one would say “Ms. Smith’s right leg is weak because of her polio” to describe her impairment and “Ms. Smith is unable to walk up stairs” to describe her consequent disability. In summary, impairment can generally be considered to be a medical issue—typically, the presence of an abnormality that interferes with an individual’s normal functional ability.

**Disability**

In its broadest meaning, disability refers to an inability to carry out necessary tasks in any important domain of life because of a medical condition. Several distinctions need to be made regarding it.

First, a distinction needs to be made between self-reported disability and disability as a social construct. In medical research, it is common for
investigators to use self-reported disability as an outcome variable. For example, patients might be asked to complete the Roland-Morris scale, which assesses the extent to which they are limited in activities of daily living (ADLs) because of low back pain. In this sense, disability is specific to the individual and is often closely linked to impairment: “Because of her knee injury, Ms. Smith is unable to walk up stairs.” In contrast, “disability” for insurance purposes reflects a very different meaning. Government-regulated disability insurance systems, including workers’ compensation and Social Security, all to a greater or lesser degree reflect a societal view of what benefits should be awarded to an individual: “Because she cannot walk up stairs, Ms. Smith should be awarded X dollars.” This linkage of a term that refers at one level to something very specific to an individual, but at another level to a societal determination that is applied to all covered individuals, is often not fully recognized and is often the source of great consternation. Moreover, two different government systems, which may exist in the same geographical area, which offer benefits to the same covered populations, but whose benefits flow from decisions made by two separate and distinct legislative bodies, may offer greatly distinct benefits for what at the individual level may be the same disability.

If a disability agency determines that a patient is eligible for benefits, he or she is granted the social status of being disabled. As a consequence of this determination, he or she is exempted from selected customary societal obligations. If the type of disability in question is work disability, the individual may receive financial support to compensate for lost income.

An obvious but important point regarding disability as a social construct is that the process of disability evaluation starts when a person applies to an insurance company or disability agency. That is, the person alleges that he or she is disabled. The insurance company or disability agency then has the task of evaluating the claimant and deciding whether to accept or reject the allegation of disability.

A second distinction relates to the domain(s) in which activities are limited. For example, a C5 quadriplegic is disabled in the sense of being unable to carry out many basic ADLs. Such an individual might need an attendant to assist in the performance of ADLs. A person with early
Alzheimer might be unable to manage financial affairs responsibly and thus might need a relative or friend to assume power of attorney. Individuals with a wide range of medical conditions might be disabled from work. Different disability agencies may include or exclude benefits for disability in these domains, depending on their legislative or contractual mandates.

Finally, there is a distinction between short-term and long-term disability. For example, injured workers who believe they are unable to work due to symptoms they consider to be work-related typically apply for benefits under a workers’ compensation claim. Most of these “time loss” claims are resolved within a matter of a few weeks because most workers return to work after a short period of disability.8 In contrast, some medical conditions produce limitations that continue for an individual’s entire life, so that the disability agencies to which they apply must decide whether to grant permanent disability benefits.

This chapter focuses on long-term or permanent work disability as a social construct.

ASSOCIATIONS BETWEEN IMPAIRMENT AND DISABILITY

Disability agencies typically require objective medical data that demonstrate that an applicant has a medical condition that causes impairment. They develop schedules and procedures that allow adjudicators to create linkages between applicants’ medical data and activity limitations that the applicants might reasonably be expected to have. In order to follow these procedures, they rely on the assumption of a strong linkage between impairment and disability. First, they construe impairment as a necessary condition for disability. The logic underlying this requirement is straightforward, especially in relation to work disability. Disability programs are designed to assist individuals who are unable to compete in the workplace because of a medical condition. In essence, disability programs attempt to partition individuals who fail in the workplace into two large groups: those who fail because of a medical condition and those who fail for nonmedical reasons. The distinction is necessary because there are many potential nonmedical reasons that may
restrict employment, including a lack of demand for an individual’s skills or lack of motivation on the part of the individual. Disability programs require evidence that an applicant has a medical problem underlying his or her workplace failure. Impairment provides the needed evidence because it can be viewed as a marker that an individual has a medical problem, which diminishes his or her capability. Conversely, if an individual has no identifiable impairment, this implies that employment limitations are not due to a medical condition.

Second, disability agencies typically assume that the severity of a patient’s impairment correlates with the degree and/or probability of his or her being disabled from work. Even when an agency compensates for work disability and not for impairment, it will often seek information about the severity of a patient’s impairment to rationalize its decision about whether or not to award disability benefits.

Despite the administrative need of disability agencies to assume a tight relationship between impairment and disability, there is reason to doubt the strength of the relationship, at least when it comes to work disability. Observers over at least the past 75 years have noted that the ability of an individual to work depends on a host of factors, only some of which are medical. The widely held belief that work disability is a product of both medical and nonmedical factors implies that statistical associations between results of medical evaluations and severity of work disability would be expected to be modest.

**THE “EMBEDDEDNESS” PROBLEM**

One conceptual problem in any discussion of pain-related impairment is that pain is not completely distinct from medical conditions that cause organ/body part dysfunction. Rather, it is usually most appropriate to construe pain as a “component” of a medical disorder. From this perspective, it is arbitrary to examine the significance of pain in isolation from the medical condition underlying the pain, just as it would be arbitrary to evaluate shortness of breath in isolation from congestive heart failure. It would be seem conceptually appropriate to evaluate a medical disorder as an entity with characteristic signs, symptoms (e.g., pain), and pathophysiology. An impairment rating based on such an evaluation would
take into account all manifestations of the disorder, including pain. Many disability agencies follow this logic; that is, they construe pain as one of many manifestations of injuries or diseases. This conceptualization involves the implicit and, in some cases, explicit assumption that impairment ratings based on objective evidence of derangement of organs or body parts capture the burden of illness borne by an individual, including the burden imposed by pain.

Unfortunately, this apparently plausible approach to the assessment of pain in the context of impairment ratings can run into either of two complications. First, pain severity may not (and often does not) correlate well with objective indicators of organ/body part dysfunction. In fact, empirical evidence has consistently demonstrated a low concordance between self-reports of pain and behavioral functioning (such as ADLs) or physiologic indices. In such situations, impairment ratings based strictly on objective findings are likely to fail to capture the burden of illness of the disorder.

A second and even more difficult situation involves conditions that are associated with severe pain but are not amenable to conventional impairment ratings because they are not associated with unequivocal objective findings. In these conditions, it is not possible to make impairment ratings on the basis of such findings. Common examples include headache disorders and fibromyalgia (FM).

**PRACTICAL PROBLEMS IN IDENTIFYING THE ROLE OF PAIN IN DISABILITY DETERMINATIONS**

In order for an investigator to determine the role that pain plays in the decisions that a disability agency makes, it is necessary to consider a few basic questions. First, what benefits does the disability agency offer and to what individuals? Second, what methods do adjudicators for the agency follow when they evaluate a disability claim? Third, what are the outcomes of the evaluations? That is, claimants with which types of medical conditions typically receive benefits? Some disability agencies treat both their evaluation methods and the results of the evaluations as proprietary, so that investigators do not have access to either kind of data. Other agencies publish information about their evaluation methods; those used
by two disability agencies (DLI and SSA) are discussed in the following text.

Even when information about the methods adjudicators use is available, it is often difficult to obtain and interpret data regarding the results of the evaluations. As discussed earlier, the problem is that pain is embedded in medical disorders in complex ways. For example, a patient with a chronic lumbar radiculopathy might have atrophy and weakness in one lower extremity, along with severe pain. If such a patient were awarded disability, it might not be clear whether the award was made on the basis of the objective evidence of lower extremity dysfunction or on the basis of chronic pain.

In some medical conditions, incapacitation may occur primarily because of pain, so that if disability is attributed to the conditions, it is likely that pain, rather than objectively measurable organ impairment, is the basis for the calculation of the disability. Examples of such conditions include most spine disorders (unless there is evidence of spinal cord injury or cauda equina syndrome), most sprains and strains (unless there is clear evidence of major ligamentous or muscle injury), and complex regional pain syndrome. Moreover, there are at least a few disorders in which pain is the dominant feature, and there is no definable associated organ impairment. The most prominent example of this is FM. A disability agency that allows self-reported pain to serve as a basis for concluding that an impairment exists may conclude that, in a given case, the impairment is of sufficient magnitude to warrant a declaration of disability. The same patient in a system that mandates the presence of a condition that can be verified objectively as a foundation for a declaration of disability may, in the absence of such evidence, be denied such a declaration.

In the following discussion, the aforementioned conditions are considered proxies for disorders in which pain is the major driver of impairment. But seeking such proxies does not necessarily make the role of pain in disability awards fully apparent. Disability agencies may provide only very general information about the medical conditions of claimants who are awarded disability. For example, data from the SSA indicate that 31.7% of Social Security Disability Insurance (SSDI) awards were given for conditions labeled as “Diseases of the musculoskeletal
system and connective tissue” (2015 Statistical Report, Table 21). No
details are given within this broad category, and it is virtually impossible
to determine the role that claimants’ pain played in the decisions that the
SSA made. For example, a claimant with severe loss of function in both
hands due to rheumatoid arthritis is lumped together with a claimant with
chronic low back pain.

Somewhat more useful data are available from the Bureau of Labor
Statistics (BLS). Data from 2015 reveal that 37% of all work injury claims
leading to time off work were coded as “sprains, strains, or tears,” and that
an additional 16% were coded as “soreness, pain.” If we accept the
premise that most of the patients diagnosed with “sprain” or “strain”
receive the diagnosis when they present to health care providers with
musculoskeletal pain but do not have clear-cut objective findings, it would
appear that about 50% of the injuries that lead workers to take time off
work involve pain as the major driver of incapacitation. The BLS also
provides at least some data on the frequency with which spinal disorders
lead to time off work. For example, in 2015, 31% of all time loss claims
nationally were coded as musculoskeletal, and at least in Arkansas, 46%
of musculoskeletal conditions were coded as “back” conditions. These
data suggest that approximately 14% of claims leading to work disability
are attributable to disorders of the spine. These figures are crude and
address only short-term work disability. However, they strongly suggest
that painful conditions are a major cause of time lost from work and may
in many instances serve as the basis for declarations of disability.

Methods for Evaluating Chronic Pain in Applicants
for Disability Benefits

The following discussion addresses the methods that adjudicators in two
agencies use when evaluating pain in disability applicants—the SSA and
the Washington State DLI.

EVALUATION METHODS IN THE SOCIAL SECURITY
ADMINISTRATION
The U.S. SSA manages two disability programs—Social Security
Disability Insurance (SSDI) and Supplemental Security Income (SSI). The programs use the same medical criteria when determining whether a claimant is in fact disabled from work but differ in their nonmedical eligibility requirements.

Adults who become disabled after working long enough to meet the SSA’s “work credits” criterion\(^{15(p4)}\) are eligible to apply to the SSDI program. The SSI program is available to individuals who do not meet the work credits criterion for SSDI eligibility and have very limited financial resources. It pays substantially less than the SSDI program. Many SSI recipients are children or adults who have been disabled since childhood.\(^{16}\)

The present discussion focuses on adults applying for benefits under the SSDI program. For these claimants, disability is defined as “inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months.”\(^{15(p2)}\) “Substantial gainful activity (SGA)” is defined in terms of the amount of money the claimant is making or could make—in 2015, SGA was defined as making more than $1,090 per month.

The SSDI program is construed as a permanent (or at least long-term) disability program, and there is evidence that individuals who have been awarded SSDI rarely return to work.\(^{17,18}\)

The SSDI and SSI programs represent the largest disability programs in the United States by a wide margin. More than 2.5 million Americans apply for benefits under one of the programs each year, and as of 2013, 12.71 million were receiving disability benefits.\(^{19}\)

Adjudicators for SSA use the following five-step process in determining whether an applicant is to be awarded SSDI/SSI benefits (Fig. 22.1).\(^{20,21}\)
1. Is the claimant currently engaged in SGA as defined earlier? If the claimant is engaged in SGA, he or she is not eligible for SSDI or SSI.

2. If not, does the claimant have a medically determinable impairment (or a combination of medically determinable impairments) that is severe and either has lasted for more than 12 months or is expected
to last that long? If not, the claimant is not eligible.

3. If the criterion in step 2 is met, does the claimant’s impairment meet a “listing,” or is it medically equivalent to a listing? If yes, the claimant is awarded SSDI/SSI. If not, the evaluation proceeds to step 4.

4. Given the claimant’s impairment, does he or she have sufficient residual functional capacity to perform work that he or she has actually performed in the past or that is similar to that work? If yes, the claimant is not eligible.

5. Given the claimant’s residual functional capacity and other factors such as age, education, and work experience, does he or she have the ability to do any other kind of work? If yes, the claimant is not eligible.

The SSA provides detailed discussions of each of the steps.\textsuperscript{20,21} For purposes of this chapter, several points need emphasis.

1. Adjudicators are instructed to consider both signs and symptoms of claimants. Pain is specifically mentioned as a symptom that should be considered. In theory, symptoms such as pain would make a claimant eligible for disability only if they were associated with signs and were considered secondary to a medically determinable impairment that is severe. The importance of signs is emphasized in “Disability evaluation under Social Security,”\textsuperscript{6} which states that SSA regulations require “objective medical evidence” of impairment. Although this verbiage appears to require the presence of objective evidence of dysfunction of an organ or body part, a close examination reveals something more subtle. For example, SSA defines signs as “anatomical, physiological, or psychological abnormalities established by medically acceptable clinical diagnostic techniques that can be observed apart from individual’s symptoms.”\textsuperscript{22} It is plausible to construe signs as akin to the objective medical findings mentioned earlier in this chapter. However, it appears that the SSA definition of “signs” basically acquiesces to the judgments of physicians regarding the findings that qualify as signs of a disease or injury. It does not specify that the findings must be ones that are not under the voluntary control of the claimant.\textsuperscript{23}
Essentially, the same logic applies to “medically determinable impairments.” Again, the SSA defers to the opinions of physicians regarding what represents a medically determinable impairment—it does not require that such impairments be based on findings that cannot be influenced voluntarily by claimants. The evaluation of patients with FM highlights these issues. Because many patients with FM are awarded SSDI benefits,\textsuperscript{24} it is clear that the SSA accepts either the diagnostic criteria articulated by the American College of Rheumatology in 1990 for diagnosing FM,\textsuperscript{25} or the 2010, 2011, or 2016 modified criteria.\textsuperscript{26–28} The latter three sets of criteria permit a diagnosis of FM without any clinical signs. The 1990 criteria include the responses of patients during tender point examinations, in which the examining practitioner palpates 18 designated sites on the body of a patient with approximately 4 kg of force and asks whether the palpation is painful. Patients are described as having positive tender point findings if they report pain in 11 or more of the 18 sites. The findings on a tender point examination could be viewed as a sign of FM, but it is obvious that a patient’s responses during the examination are to some extent under voluntary control.

2. Step 2 of the evaluation protocol specifies that the medically determinable impairment must be severe. An impairment is described as severe if it has more than a minimal effect on an individual’s physical or mental ability or abilities to do basic work activities.\textsuperscript{29} Text in “Disability Evaluation under Social Security”\textsuperscript{6} states, “Once the existence of an impairment is established, SSA considers all evidence from all medical and nonmedical sources to assess the extent to which a claimant’s impairment(s) affects his or her ability to function in a work setting; or in the case of a child, the ability to function compared to that of children the same age who do not have impairments. Nonmedical sources include, but are not limited to: the claimant, educational personnel, public and private social welfare agency personnel, family members, caregivers, friends, neighbors, employers, and clergy.” Thus, symptoms reported by a claimant, as well as descriptions provided by her physician, friends, coworkers, etc., can influence an adjudicator to determine that a medically
determinable impairment is severe.  
3. Once a claimant has been found to have a medically determinable impairment that is severe, the subsequent steps in the decision-making algorithm center on the severity of the associated incapacitation. In evaluating severity, adjudicators are instructed to consider not only signs such as laboratory or imaging findings but also claimants’ symptoms and their statements about the impact of their impairments on their ability to function. SSA specifies that pain and other symptoms should be considered when adjudicators determine whether an impairment is severe in step 2 of the evaluation process and also during steps 3 and 4 of the process. Although SSA rulings indicate that adjudicators should look for consistency among medically determinable impairments, symptoms, signs, and various types of collateral data, the criteria for determining consistency are not well defined. The Program Operations Manual System (POMS) does specify that there should be qualitative congruence between a claimant’s symptoms and his or her impairment. Thus, for example, if a claimant were undergoing evaluation of a lumbar spine condition, her statement that she cannot raise her right arm above shoulder height would not be considered as evidence regarding the severity of her impairment. But the POMS is silent about the more difficult issue of how adjudicators might assess claimants’ statements about the severity of limitations that are qualitatively congruent with their medical conditions. For example, it is not clear how an adjudicator evaluating a claimant with a lumbar spine condition would factor in the claimant’s statement that she experiences unbearable pain if she sits for more than 15 minutes or walks more than one block.

In summary, the SSA considers pain and other symptoms throughout its five-step evaluation process. Although it nominally emphasizes signs at step 2, the fact that many FM patients receive SSDI or SSI awards strongly suggests that the SSA’s requirements regarding signs include physical exam findings that are to some extent under the control of a patient.

OUTCOMES OF SOCIAL SECURITY
ADMINISTRATION EVALUATIONS
Regardless of the procedures that SSA nominally follow when considering applicants for permanent disability, consideration of the types of claimants who actually receive disability awards could in principle provide important insights into the decision making of the agency. Unfortunately, data regarding the medical conditions of SSDI and SSI beneficiaries are difficult to obtain largely because the SSA classifies beneficiaries into very large diagnostic groups. For example, as noted earlier, 31.7% of SSDI beneficiaries in 2015 were classified as having “diseases of the musculoskeletal system and connective tissue.” The problem with this broad category is that it does not differentiate between conditions that we consider proxies for chronic pain disorders from other musculoskeletal conditions.

There are a few publications from outside the SSA that do provide hints about chronic pain patients who are receiving SSDI or SSI benefits. For example, Meseguer provided data indicating that about 11% of all SSDI awards are given to claimants with a diagnosis of “Disorders of the back (discogenic and degenerative).”

Walittt et al. identified FM patients based on responses to the 2012 National Health Interview Survey. They found that 30% of individuals so identified reported that they had received “SS disability payments” during the previous years. The authors did not distinguish between SSDI and SSI recipients. These data are fragmentary but clearly support the conclusion that large numbers of people with at least two conditions which we consider proxies for chronic pain disorders—low back pain and FM—receive SSDI or SSI benefits.

DISABILITY EVALUATION AND DISABILITY MANAGEMENT IN THE WASHINGTON STATE DEPARTMENT OF LABOR AND INDUSTRIES
The Washington State DLI is the sole source of workers’ compensation insurance for nonfederal employees in Washington State. (Companies of sufficient financial capability can elect to be self-insured, although they must provide the same benefits offered by DLI through its insurance program.) DLI serves as a funder of medical services and disability
payments for injured workers. It provides additional services and has regulatory responsibilities that are not relevant to this chapter.

If a worker covered by DLI sustains an injury at work, he or she must file a claim in a timely manner in order to receive workers’ compensation benefits. A health care professional typically files the claim on the worker’s behalf. To be accepted by DLI, the claim must be supported by a licensed health care professional and submitted to DLI on a Report of Accident form. A claim for benefits will generally be allowed when the claim manager concludes that the worker has had an injury in the course of employment or has incurred an occupational disease in the course and scope of employment. The allowance determination is generally made by the claim manager based on the information provided by the worker and the health care professional on the Report of Accident. About 80% of claims do not involve more than 3 days of lost time from work. For these claims, DLI pays for medical services only. However, if the work injury or occupational disease causes the worker to miss more than 3 days from work, the worker is designated as being temporarily totally disabled from work and is eligible for wage replacement benefits from DLI. DLI proceeds on several fronts simultaneously in managing claims associated with wage replacement payments:

1. As described in the following discussion, DLI has instituted several programs to reduce the occurrence and duration of work disability associated with claims.

2. Repeated assessments of the worker’s ability to work are made. Often, the attending provider for the worker’s claim is asked to assess whether the worker has recovered well enough to return to work. DLI also has the option of referring the worker to an independent medical examination to get an opinion from physicians not involved in the injured worker’s care.

3. Vocational rehabilitation services are often provided for the injured worker. Depending on the nature and extent of a worker’s condition, the counselor who provides these services may help guide the injured worker back to the type of work that the worker did at the time of injury or may provide guidance about other kinds of work that the worker might do.
4. Toward the end of a claim, DLI determines whether a worker’s condition qualifies him or her for a permanent partial impairment award or a pension. A worker who is awarded permanent partial impairment receives a cash award from DLI that is determined by rules that relate to an assessment of the severity of the worker’s impairment. Typically, the workers’ compensation claim is closed following such an award. If it is determined that the worker is permanently disabled from reasonably consistent gainful employment and that the worker is not a candidate for vocational rehabilitation, the worker is deemed permanently totally disabled and is awarded a pension. In such cases, the claim is closed when the pension is awarded. Pensions in the DLI system are analogous to SSDI/SSI awards in the SSA system because they embody the premise that the worker is totally and permanently disabled and therefore eligible for wage replacement payments in perpetuity.

There are significant differences between the SSDI/SSI system and the DLI system. Some of the differences are the following:

1. As described earlier, and as more fully described in the following text, DLI interacts with injured workers in a variety of ways and over extended periods of time. In contrast, SSA makes only one determination regarding a claimant—whether he or she is eligible to SSDI/SSI benefits.*

2. DLI not only evaluates the impairment and disability status of injured workers but also utilizes multiple strategies to reduce the likelihood that injured workers will develop long-term disability (see the following discussion). In contrast, the mandate of SSA is strictly to make disability determinations.

3. Causation of a worker’s inability to engage in employment is central to the DLI system. As a workers’ compensation system, DLI is responsible only for injuries and occupational diseases that are proximately caused by workplace exposures. Therefore, when DLI adjudicators evaluate the reports of claimants’ conditions, they consider both the severity of the workers’ incapacitation and the causal relationship between the incapacitation and workplace exposures. In contrast, causation is irrelevant in the SSDI/SSI
programs, so that the only task for adjudicators is to determine the severity of a claimant’s incapacitation.

4. Information from nonmedical sources, such as friends of a claimant, is considered by adjudicators in the SSA system but generally not in the DLI system.

WASHINGTON STATE DEPARTMENT OF LABOR AND INDUSTRIES PROGRAMS TO REDUCE DISABILITY

Pain that interferes with or prevents employment may have ramifications at many levels:

- It most obviously affects the individual, potentially adversely, in many ways.
- It will likely affect the individual’s family—also adversely—in many ways.
- It may significantly impact the individual’s employer through lost productivity and the need to hire and train a replacement worker. This is a special concern for small businesses for which the increased cost of DLI insurance because of an employee’s work-related injury can force the closing of a business.
- It may affect coworkers through work redistribution and, potentially, in indirect ways secondary to financial impacts on the employer.
- It may affect society as a whole should its treatment be reflective of unsafe or ineffective practices, such as the use of high doses of opioids to treat chronic noncancer pain.

This section summarizes some of Washington State’s efforts to minimize the potentially broad, adverse impact that pain can have on individuals, families, employers, coworkers, and society. Although this section focuses principally on workers’ compensation matters, it will touch on Washington State’s efforts to ensure that the pain-related health care services for which it pays are safe and effective.

Since 2006, it has been the intent of the Washington State legislature that health care programs for which state agencies pay will deliver care that is based “to the extent possible, upon the best available scientific and medical evidence.” The legislature has passed a number of bills over the years to facilitate the implementation of its intent. For example, it passed
legislation that created the Health Technology Clinical Committee (HTCC) and gave that committee the authority to determine, after an evidence-based review, whether a given health technology will be included as a covered benefit in health care programs of the participating state agencies.\textsuperscript{34} The HTCC has assessed, among others, technologies used to treat pain, such as spinal cord stimulation and spinal injections. Based on its evidence reviews, the committee has determined that certain pain-related technologies should be covered, others covered with conditions, and certain others not covered. Its determinations bind all state agencies that purchase health care services.

Separately, the legislature mandated that all state-purchased health care programs, with minor exceptions, implement evidence-based best practice guidelines or protocols applicable to advanced diagnostic imaging services.\textsuperscript{35} Such imaging studies are commonly used by health care providers in the diagnosis and treatment of pain-related conditions.

The Washington legislature created the Robert Bree Collaborative\textsuperscript{36} and gave the Collaborative the charge of identifying health care services in the state that meet the following criteria:

- The services are associated with substantial variation in practice patterns, or
- The services are associated with high utilization trends in Washington State, but
- The services do not produce “better care outcomes for patients, that are indicators of poor quality and potential waste in the health care system.”

When the Collaborative identifies such a service, it is charged with several responsibilities that are intended to potentially lead to improved services. The Collaborative must, among other responsibilities,

- Analyze and identify evidence-based best practices and guidelines that are relevant to the issue,
- Identify data collection and reporting that is necessary to develop baseline health service utilization rates, and
- Identify strategies to increase the use of evidence-based best practice approaches among those providing the services.

The aforementioned, and other actions of the Washington State
legislature with regard to evidence-based medicine, inform and give
direction to the development of programs by which state agencies fund
services that diagnose and treat pain and other conditions. Among others,
these programs affect prisoners, Medicaid recipients, retirees covered by
state pensions, and injured workers. The following paragraphs focus on the
panoply of services potentially available to Washington State’s injured
workers who present with pain.

With the exception of employment that falls under federal jurisdiction,
all workers’ compensation insurance in Washington State is sold by the
state’s DLI. An employer with a sufficiently large economic base may be
allowed to self-insure, but all other employers must purchase insurance
through the state fund run by DLI. Self-insured employers are required to
follow the same policies that DLI mandates in state fund claims.

DLI has sought to create an environment in which workers with pain
can be successfully and efficiently diagnosed and treated. In significant
part, DLI has endeavored to positively incentivize physicians (medical
doctors, doctors of osteopathic medicine, physician assistants, advanced
registered nurse practitioners, dental surgery doctors, and others who can
serve as attending health care providers) to follow occupational medicine
best practices and relevant evidence-based guidelines. These efforts on
DLI’s part have included the following:

• Modest financial incentives for following certain best occupational
  medicine practices. For example,
  • In Washington State, it is the physician who first sees the worker
    who files the Report of Accident. Because DLI cannot pay for
    benefits until a claim is filed, DLI has authorized an incentive
    payment for physicians to file the Report of Accident within two
    business days of its creation.
  • Similarly, because long-term disability can be minimized in many
    cases by an employer keeping an injured worker in the workplace,
    DLI created an incentive payment for physicians to telephone the
    employer if the worker is to be removed from employment or
    placed on restricted activities. Physicians are able to advise
    employers about restrictions and can help employers define work
    activities that will not adversely affect the injured worker.
A modest payment was created to incentivize the health care provider to see the patient at least every 2 weeks and to complete an Activity Prescription Form at each visit.

A payment was also created to incentivize disability assessment at 4 weeks’ postinjury if the worker is not back to work, in the absence of a clear medical explanation for the worker’s inability to engage in employment. An example of such an explanation might be a pending surgery.

It is noteworthy that these four modest incentive payments, after 1 year of implementation, produced the following results, among others:

- There was a 30% reduction in disability claims for back injuries.
- Disability days per claim were reduced by 4.1 days (P = .004).
- Disability costs were reduced by $347 per claim, and medical costs were reduced $245 per claim, after subtracting the program costs (each P ≤ .001).
- There was a 20% reduction in the likelihood of 1-year disability.

- The creation of Centers for Occupational Health and Education (COHE). DLI contracts with organizations that provide health service coordinators (HSCs) who facilitate injured workers’ medical needs by interfacing on the care providers’ behalf with DLI. These coordinators function as an aid to the providers and injured workers, not as an agent of the insurer. For example, should a patient be given return-to-work restrictions, which occurs in about 30% of industrial injury cases, an HSC can interface on the physician’s behalf with both the claim manager and the employer to assure that the restrictions are understood and to explore their impact on the patient’s return to work.

- The piloting of a three-question Functional Recovery Questionnaire (FRQ) to guide care coordination and treatment decision making. DLI has found that the answers to three questions in its FRQ can help predict long-term disability. With that understanding, DLI authorizes payments to COHE HSCs to assist workers’ caregivers in devising treatment approaches that may reduce the risk of long-term disability. Functional recovery interventions (FRIs) that follow FRQ-related disability concerns may include the following:
- Addressing biopsychosocial considerations, including recovery expectations, activity avoidance, and concerns about work activities potentially aggravating the industrial condition;
- Addressing returning to work, including speaking with the employer, assessing the availability of modified work, and using the services of an HSC, or DLI staff, to assist the patient in returning to work;
- Incrementally increasing activity, potentially monitored by review of a weekly activity diary with appropriate follow-up and a physical therapy or occupational therapy referral if needed;
- Emphasizing and tracking functional improvement, including setting specific functional improvement targets and timelines and potentially using a validated instrument to track functional progress;
- Should an employer not be able to offer modified duty to an injured worker, involvement of an HSC to explore whether there are other return-to-work options that may be available;
- If the patient is awaiting surgery or a specialty consultation, reinforcing the need for the patient to be an active participant in his or her recovery, addressing concerns that the patient about discomfort or aggravation while becoming or staying active; and
- Offering a structured program in which a trained activity coach who combines skill development to address biopsychosocial factors with sessions that focus on progressive increases in activity.

- The creation of Centers of Excellence for Burns and Amputations. Not uncommonly, catastrophic injuries result in severe pain, at times from major burns, and not uncommonly associated with limb compromise. Such injuries require considerable expertise and multidisciplinary health care services. To assure that the risk of harm from such injuries is minimized and to facilitate the best possible outcomes from those injuries, DLI has contracted with a tertiary care facility to provide the health care services needed by such catastrophically injured workers.39
- The creation of a Center of Excellence for Chemically Related illnesses. DLI has contracted with a tertiary care facility to provide the necessary multidisciplinary care to address the needs of workers who
have been chemically injured.

• Providing a process to assess return-to-work for workers who have been given restrictions. DLI’s computer system flags claims in which restrictions have been placed and brings them to the attention of COHE-employed HSCs. Acting as resources for workers’ providers, HSCs contact injured workers, answer (or find answers to) questions that the workers may have, assess return-to-work issues, and have such discussions with employers and providers as may be helpful in assuring the safe and efficient return to the highest reasonably attainable functional level.

• Providing access to activity coaching resources. A treating provider may request that DLI provide funding for activity coaching. DLI can fund such coaching for workers who have not been able to return to work by 4 weeks following injury, who are not making progress with early interventions such as physical or occupational therapy, and who are not being considered for surgery. The coaching that is funded by DLI involves 10 weekly 1-hour sessions that may be in-person or telephonic.

• Providing, in a pilot program, incentive payments to surgeons who demonstrate and document high-quality and efficient patient care. The performance of surgeons seeking such payments is measured against their compliance with six specified quality indicators. Payments are tiered. To receive Tier 1 pay, a surgeon must demonstrate compliance with three specified quality indicators. Surgeons who qualify for Tier 1 incentive payments will receive payments at the Tier 2 level if they are additionally in compliance with one or two of three other quality indicators. Surgeons who are in compliance with all six quality indicators receive payments that are at the Tier 3 level.

• In collaboration with Washington State’s Industrial Insurance Medical Advisory Committee (IIMAC), developing guidelines that are applicable to the diagnosis and treatment of industrial injuries and occupational diseases. In 2007, the legislature mandated that DLI establish an industrial insurance medical advisory committee, and it specified the duties and the composition of the committee. In collaboration with the IIMAC and subject matter experts selected by
the IIMAC, in an open and transparent process that includes opportunities for public comment, DLI has developed guidelines related to the diagnosis and treatment of multiple body regions and conditions that commonly present as pain or paresthesia. The guidelines combine medical literature evidence as developed by a master’s-level epidemiologist with input from subject matter experts from the medical and surgical communities. These guidelines serve as the basis for utilization review recommendations to claim managers.

- Making a best effort attempt to assure that injured workers are not further harmed by the treatment they receive for their industrial injuries and occupational diseases. In addition to the guideline development process described earlier, DLI has addressed the public health crisis of accidental deaths involving prescribed opioids in a variety of ways. These have included development of an online opioid dose calculator so prescribers can easily calculate the morphine equivalent dose (MED) of prescribed opioid medications and efforts to educate prescribing doctors in the potential harms that opioids can cause. Additionally, DLI has adopted stringent administrative regulations that include the following:
  - Mandatory prescriber checking of the prescription monitoring program database, if available
    - Before opioids are prescribed in the subacute phase of an injury
    - At risk-related intervals if chronic opioid therapy is prescribed
  - Recommended prescriber checking of the prescription monitoring program database for first-time prescriptions and for preoperative evaluation for surgery
  - Mandatory administration of a urine drug test, followed by appropriate documentation of the results, during the subacute phase of an injury, and at repeated risk-related intervals if prescribing chronic opioid therapy
  - Mandatory use of validated instruments to track pain and function when prescribing opioids during the acute and subacute phase of an injury and regularly at not greater than 90-day intervals when chronic opioid therapy is prescribed
  - For workers who were on opioid therapy prior to their work injury,
nonpayment of opioids beyond the acute phase, except for catastrophic injuries, and for other severe injuries for which payment may extend to the subacute phase of the injury

- If opioids are to be prescribed during the acute phase of the injury (0 to 6 weeks)
  - Mandatory assessment and documentation of baseline pain and function measurements

- If opioids are to be prescribed during the subacute phase (6 to 12 weeks of the injury)
  - Mandatory verification of clinically meaningful improvement in function and pain with the use of opioids during the acute phase;
  - If indicated, mandatory use of a validated instrument to screen the worker for comorbid psychiatric conditions, such as depression or anxiety;
  - Verification of the absence of contraindications to the use of opioids;
  - Mandatory checking of the prescription monitoring program database, if it is available, to verify that the controlled substance history is consistent with the prescribing record and with the worker’s report;
  - Mandatory use of a validated screening instrument to verify the absence of any current substance use disorder (except nicotine) or a history of opioid use disorder;
  - Mandatory administration of a baseline urine drug test to verify the absence of cocaine, amphetamines, alcohol, and nonprescribed opioids; and
  - Verification that the worker shows no evidence of, and is not at high risk for, serious adverse outcomes from opioid use.

- If opioids are to be prescribed during the chronic phase (beyond 12 weeks of the injury)
  - Documentation that clinically meaningful improvement in function has occurred with opioid therapy during the acute or subacute phases of the injury;
  - Reasonable alternatives to opioids have been tried and have failed;
A pain treatment agreement has been agreed on and signed by the worker and the prescribing physician;

Documentation of a consult with a pain management specialist if the opioid dose is to exceed 120 mg per day MED (with certain narrow exceptions);

Documentation of the absence to any contraindication to the use of opioids;

Documentation of the absence of the worker being at high risk of serious adverse outcomes from opioid use;

Documentation of the absence of more than one episode of aberrant behavior identified by the prescription monitoring program database, by urine drug testing, or by some other source; and

The creation of a time-limited treatment plan that documents how opioid therapy is predicted to improve the worker’s work capacity, or the ability to progress in vocational rehabilitation.

If chronic opioid therapy is to be prescribed

The prescribing doctor must, at risk-based intervals not to exceed 90 days, review the effects of opioid therapy and document the following best practices:

- Clinically meaningful improvement in function is maintained with stable dosing;
- If the opioid dose is increased, clinically meaningful improvement in function must be demonstrated in response to the dose change;
- There must be a current signed pain treatment agreement;
- The worker has no contraindication to opioid use, including substance use disorders (excluding nicotine), or a history of opioid use disorder;
- The worker is not at high risk for serious adverse outcomes from opioid use;
- There must be a consultation with a pain management specialist before the opioid dose is increased above 120 mg per day MED (with minor exceptions); and
- The worker has not had more than one episode of aberrant
behavior identified by the prescription monitoring program database, by urine drug testing, or by some other source.

- If opioids are to be prescribed to treat catastrophic injuries
  - There must be a current signed pain treatment agreement;
  - There must be a consultation with a pain management specialist before the opioid dose is increased above 120 mg per day MED (with minor exceptions);
  - The worker has not had more than one episode of aberrant behavior identified by the prescription monitoring program database, by urine drug testing, or by some other source;
  - The dose is stable; and
  - The worker is not at high risk for serious adverse outcomes from opioid use.

- Discontinuation of opioids
  - Opioid therapy must be discontinued if
    - The worker requests discontinuation; or
    - Out of concern for potential adverse outcomes the attending provider (who may not in all circumstances be the prescribing physician) requests opioid discontinuation; or
    - After 3 months of opioid maintenance therapy, there is no sustained clinically meaningful improvement in function, as measured by validated instruments; or
    - Risk of further treatment outweighs the potential benefits; or
    - The worker experienced an opioid overdose event related to
      - Aberrant behavior, or
      - Substance use disorder other than nicotine, or
      - A prescribing pattern that is not in compliance with applicable rules or guidelines, or
    - The worker has experienced any other severe adverse outcome; or
    - There has been more than one aberrant behavior, including, but not limited to
      - Inconsistent urine drug test results
      - Lost prescriptions
      - Multiple requests for early refills
Multiple prescribers
Unauthorized dose escalation
Apparent intoxication
The use of opioids is not in compliance with applicable rules or guidelines.
Under certain circumstances, DLI may pay for weaning, detoxification, and/or addiction treatment.

In summary, DLI, acting as a state agency that administers a monopolistic workers’ compensation insurance system, has used financial incentives, guidelines, and regulations that have the force of law in its efforts to assure that pain arising from industrial injuries is treated timely, safely and effectively.

METHODS USED BY WASHINGTON STATE DEPARTMENT OF LABOR AND INDUSTRIES TO EVALUATE INJURED WORKERS FOR PERMANENT DISABILITY BENEFITS

In determining whether an injured worker is entitled to a permanent disability award (also called a pension), the DLI adjudicator must determine, when the worker is at maximum medical improvement, whether a permanent impairment exists and, if so, its nature and extent. Whether a permanent impairment exists is determined by assessing information provided by health care professionals. Typically, treating providers or independent medical examiners identify the presence of any such impairment and describe its nature. If the adjudicator concludes that, on a more likely than not basis, a permanent impairment exists as the result of an industrial injury or occupational disease, the adjudicator must determine the extent of the impairment. Two principal inquiries are made; one relates to the extent of physical or mental impairment per se, and the other relates to the impact of the impairment on employability. To determine the extent of a physical or mental impairment for rating purposes, the adjudicator applies relevant medical information in the claim file to either the American Medical Association’s Guides to the Evaluation of Permanent Impairment (5th edition) (AMA Guides) or to a statutory rating system that applies to certain types of cases. The adjudicator must
also determine whether the worker is employable given the worker’s preinjury status and the effect that any impairment-related restrictions may have on his or her ability to return to employment. A discussion of the various factors that an adjudicator must take into consideration in making this determination is beyond the scope of this chapter, but the issue can be summarized as follows: If the worker can, given the restrictions that have been placed on him or her, return to a type of employment for which he or she is otherwise qualified, or if the worker has been successfully retrained for employment, the demands of which are consistent with his or her impairment-related restrictions, the worker is deemed employable. An employable worker receives a payment for the permanent impairment that has been calculated using the AMA Guides or the statutory rating system. A worker who is not employable due to the effects of an industrial injury or occupational disease may be awarded a pension. A pension from DLI is analogous to an SSDI/SSI award by SSA because they both require that a claimant be totally and permanently disabled from work.

The role that pain plays in DLI pension decisions can be seen by examining: (1) the AMA Guides handling of pain-related impairment and (2) policies that DLI has developed in relation to the evaluation of pain. The AMA Guides focuses on impairment rather than work disability. Thus, it addresses only some of the issues that SSA and DLI adjudicators address during disability evaluations. For the most part, the AMA Guides emphasizes objective assessment of organ/body part dysfunction and asserts that effects of pain can be assessed by determining the severity of organ/body part dysfunction with which the pain is associated. Thus, it states in Chapter 1, “ Physicians recognize the local and distant pain that commonly accompanies many disorders. Impairment ratings in the AMA Guides 5th already have accounted for commonly associated pain, including that which may be experienced in areas distant to the specific site of pathology.” Chapter 18 of the AMA Guides, which was coauthored by one of us (JPR), gives a very different message. It asserts that the impact of pain cannot always be determined by assessing objective indicators of organ/body part dysfunction and therefore needs to be directly assessed. However, Chapter 18 was written after all the other chapters of the AMA Guides had been completed, and the concepts
outlined in it were never integrated into the rest of the book.

DLI’s policies emphasize the importance of objective factors in its disability evaluations. DLI has determined that pain has been incorporated into both its statutory rating system for specified disabilities and into the ratings in the AMA Guides. Because pain is a subjective symptom and because a worker’s report of pain cannot be objectively measured, DLI has determined that there is no valid, reliable, or consistent means to segregate the worker’s subjective complaints of pain from the pain already rated and compensated for in the conventional rating methods.45 In providing self-insured employers with claims adjudication guidelines, DLI has written, “The AMA Guides to the Evaluation of PPD and the category system both incorporate subjective complaints. Subjective complaints, such as pain, cannot be objectively validated or measured. When rating PPD, reliance is primarily placed on objective findings.”46 Also, DLI has explicitly rejected the use of Chapter 18 of the AMA Guides in evaluations of injured workers in Washington State.47

OUTCOMES OF WASHINGTON STATE DEPARTMENT OF LABOR AND INDUSTRIES EVALUATIONS

DLI does not have fields in its claim-related databases that allow it to determine whether pain was a significant symptom leading to the filing of any given claim. Anecdotally, the great majority of injuries and most of the musculoskeletal occupational disease presentations involve pain or paresthesias. As discussed earlier, DLI generally does not accept liability for “pain” per se—accepted conditions typically are diagnoses that indicate the medical conditions that are thought to underlie workers’ reports of pain.

In summary, DLI and SSA differ significantly in the ways they incorporate pain into disability awards. The differences in approach between the two systems to pain beg a question: Is it possible to determine which system is working better in distinguishing between chronic pain patients who are truly work disabled and ones who are capable of working? Unfortunately, we are not able to provide an answer to this question. We are not aware of any research that compares the outcomes of DLI versus SSA evaluations and believe such comparative research would
be extremely difficult because of a host of methodologic problems.

**Conclusion**

This chapter has briefly discussed general conundrums related to disability awards for chronic pain and has discussed in detail the manner in which two disability systems that provide benefits in the same area, not uncommonly to the same individuals at the same time for the same medical condition have addressed these conundrums. The DLI and SSA systems were chosen in part for the practical reason that the authors are familiar with them. But there was another reason for choosing them: If chronic pain could easily be assessed and incorporated into disability evaluations, we would expect different disability agencies to use similar methods to evaluate it. In fact, though, the distinctly different legislative mandates under which DLI and SSA operate have resulted in very different approaches to the assessment of chronic pain. In our opinion, the differences between the two systems highlight differing societal views regarding disability in the context of chronic pain and also the challenge faced by any disability system in the evaluation of chronic pain.

*In some instances, SSA makes a rapid decision to grant SSDI/SSI benefits to a claimant so that the claimant’s interactions with SSA occur over only a short period of time. But if a claim for disability is rejected, the claimant has the option of going through a series of appeals leading up to a face-to-face hearing with an administrative law judge. Thus, an application for SSDI/SSI benefits can drag on for years. Also, if the applicant is finally denied SSDI/SSI, he or she can start the evaluation process all over again by filing another claim for disability benefits. Finally, although SSDI/SSI awards typically end up being permanent, SSA is required by law to review the eligibility of beneficiaries on a periodic basis. This responsibility starts with a letter or similar communication to the beneficiary. It asks about the beneficiary’s work status and medical treatment. This usually ends the reevaluation process, but in about 2.5% of instances, SSA officials refer the beneficiary’s file for a more thorough evaluation after reviewing his or her responses to the mailing. This is carried out by agents of the Office of Continuing Disability Reviews and can lead to termination of the beneficiary’s disability award.†

†Revised Code of Washington 51.36.140 states, “(1) . . . The industrial insurance medical advisory committee shall advise the department on matters related to the provision of safe, effective, and cost-effective treatments for injured workers, including but not limited to the development of practice guidelines and coverage criteria, review of coverage decisions and technology assessments, review of medical programs, and review of rules pertaining to health care issues. . . . (2) The industrial insurance medical advisory committee is composed of up to fourteen members appointed by the director. The members must not include any department employees. The director shall select
twelve members from the nominations provided by statewide clinical groups, specialties, and associations, including but not limited to the following: Family or general practice, orthopedics, neurology, neurosurgery, general surgery, physical medicine and rehabilitation, psychiatry, internal medicine, osteopathic, pain management, and occupational medicine. At least two members must be physicians who are recognized for expertise in evidence-based medicine. The director may choose up to two additional members, not necessarily from the nominations submitted, who have expertise in occupational medicine. . . .”

46. Washington State Department of Labor and Industries. Permanent partial disabilities. Available at:
This chapter deals with the multidisciplinary assessment of patients with chronic noncancer pain. In order to be specific, especially with regard to the medical evaluation of chronic pain patients, we organize the discussion around a typical and common chronic pain problem (e.g., persistent cervical spine pain). We note, though, that many of the concepts in the chapter are relevant to the assessment of virtually any chronic pain patient. In particular, concepts related to the assessment of psychological factors, social factors, and functional limitations have wide applicability.

A key premise in this chapter is that multiple factors influence the symptoms and functional limitations of patients with chronic pain. As a consequence, we believe that evaluation along multiple dimensions, performed by professionals with a variety of skills, provides important insights into the factors governing the reports of these patients and assists in treatment planning.

Conceptual Issues

CONUNDRUMS IN THE ASSESSMENT OF PAIN
How we think about symptoms such as pain influences the way in which we go about evaluating patients. Physicians and the lay public alike tend to assume that some underlying pathology is both a necessary and a sufficient cause of the symptoms reported and experienced by patients. Consequently, medical assessment usually begins with taking a thorough history and performing a physical examination, followed by, when deemed appropriate, laboratory tests and diagnostic imaging procedures in an attempt to identify or confirm the presence of an underlying pathology that
A CONCEPTUAL MODEL FOR ASSESSING PAIN
The conundrums described suggest that multiple factors likely contribute to persistent pain and related disability. There is a growing consensus that

causes the symptom (see later). However, over the years, research has revealed puzzling observations that challenge the presumed isomorphism between pain and organic pathology. For example, the exact pathophysiology underlying some of the most common and recurring acute (e.g., primary headache) and chronic (e.g., back pain, fibromyalgia [FM]) pain problems is largely unknown. Thus, it is common for patients to have pain that cannot be attributed unambiguously to an organic pathologic process. Conversely, many people have abnormalities on diagnostic tests but no pain. For example, studies using plain radiography, computed tomography (CT), and magnetic resonance imaging (MRI) reveal that more than 30% of asymptomatic individuals have structural abnormalities such as herniated disks, spinal stenosis, joint space narrow in degenerative knees, and torn rotator cuffs that would be accepted as valid explanations of pain if the individuals had been symptomatic. Thus, we are confronted with a rather strange set of circumstances: people with no identified organic pathology who report severe pain and, conversely, others with significant pathology who are apparently pain-free.

When health care providers are unable to identify organic pathology that reasonably accounts for a patient’s reports of pain, they may assume that the reports reflect psychological factors such as personality characteristics, psychopathology, and malingering. A psychological evaluation may be requested to detect the psychological factors that underlie the patient’s reports. Thus, there is a duality where the report of symptoms is attributed to either somatic or psychogenic mechanisms. This dualistic perspective dates back at least to the 17th century and the philosopher René Descartes. The assumption that symptoms that cannot be explained by medical findings must originate from psychological distress is, albeit unfortunately common, overly simplistic and inconsistent with current scientific understanding. The dichotomous view is incomplete and, as described throughout this chapter, is not compatible with available research evidence or the current understanding of chronic pain.

A CONCEPTUAL MODEL FOR ASSESSING PAIN
The conundrums described suggest that multiple factors likely contribute to persistent pain and related disability. There is a growing consensus that
these consist of (1) genetic composition; (2) physical pathology associated with trauma or disease; (3) alterations in the peripheral and central nervous system (CNS) attributable to the initial insult (peripheral and central sensitization); (4) psychological contributors including various types of psychopathology, prior learning history, and available coping resources (e.g., emotional support, financial resources, acquired coping skills); and (5) environmental influences (e.g., response by significant others, disability compensation, features inherent in the workplace) that all likely interact. A comprehensive evaluation should provide information about each of these factors. Examination of unique genetic contributions is in its infancy at this time and is generally not performed in clinical settings, although it will likely be gaining attention in the coming years. Thus, in this chapter, we describe a general strategy for assessing factors 2 to 5.

Pain Behavior

It is useful to begin a discussion of assessment of patients with chronic pain with the concept of pain behaviors. Pain is a subjective perception, and there is currently no objective way to know about the experience of pain other than by patients’ behavior. Pain behaviors include verbal behaviors (i.e., statements about pain). They also include nonverbal behaviors such as limping or wincing. These pain behaviors are sources of communication; they convey to others the presence and severity of pain.

The challenge for an examiner is how to interpret patients’ pain behaviors. Although these behaviors are sometimes determined entirely by an abnormal biologic process in the area of injury, they are typically also influenced by changes in nervous system encoding and processing of nociceptive signals; by a patient’s beliefs and appraisals, emotional status, and coping strategies; and by the social environment.

Classes of Variables Underlying Pain Behavior

We will return to more formal assessment of pain behaviors later in this chapter. For now, a useful way to conceptualize this challenge is to think of a prediction equation with multiple unknowns: \( PB = f(X_{a1}, X_{a2}, \ldots, X_{an}, X_{b1}, X_{b2}, \ldots, X_{bn}, X_{c1}, X_{c2}, \ldots, X_{cn}, X_{d1}, X_{d2}, \ldots, X_{dn}) \).
Where PB = the pain behavior that a patient demonstrates, and predictor variables are organized into four categories, such that $X_{a1}, X_{a2} \ldots X_{an}$ refer to biomedical factors at the end organ where the patient reports pain; $X_{b1}, X_{b2} \ldots X_{bn}$ refer to alterations in nervous system function (especially CNS sensitization [CNSS]) that perpetuate pain after nociceptive impulses from the end organ have diminished or ceased; $X_{c1}, X_{c2} \ldots X_{cn}$ refer to psychological variables; and $X_{d1}, X_{d2} \ldots X_{dn}$ refer to social or contextual variables that influence pain behavior.\(^7\)

The prediction equation emphasizes the multiplicity of factors that influence patients’ expressions of pain and highlights the dilemma facing an evaluating clinician. The dilemma is that it is extremely difficult to determine the weights that should be assigned to various factors for an individual patient. To make matters even worse, there is no consensus about what the possible variables within various categories are (e.g., to specify the types of psychological factors that may affect a patient’s pain behavior).

In accordance with the model, the discussion is organized around the assessment of medical factors, CNSS, psychological factors, and social factors in chronic pain patients. We also consider the assessment of the severity of functional incapacitation in these patients.

## Assessment of Medical Factors

A careful medical evaluation is a basic element in a multidisciplinary evaluation of a patient with chronic pain. The general goals of such an evaluation are to (1) make a medical diagnosis, (2) determine whether additional diagnostic testing is needed, (3) make a judgment about the extent to which medical data regarding a patient adequately explain his or her symptoms and the severity of his or her apparent incapacitation, (4) determine whether there is any medical or surgical treatment that has a reasonable chance of reversing the pathophysiologic processes underlying the patient’s pain, (5) determine whether there are any symptomatic treatments that should be prescribed if a reversal of pathophysiology is not possible, and (6) establish the objectives of treatment.

The specific procedures that physicians perform and the differential
diagnostic possibilities they entertain vary enormously with patients’ symptoms and presumed medical disorders. For example, the medical evaluation of a patient with pelvic pain is entirely different from the evaluation of a patient with neck pain. Also, the medical evaluation of a pain patient depends on the chronicity of the patient’s symptoms and the physical evaluations and diagnostic testing that the patient has already undergone.

In order to be reasonably specific, the discussion here focuses on the medical evaluation of patients with persistent neck pain, especially in the aftermath of a “whiplash” injury.

There is no uniformly accepted algorithm for evaluating neck pain patients. In fact, as will be discussed, clinicians differ sharply about some aspects of such evaluations. The approach discussed in the following section is summarized in Figure 23.1, which identifies key questions that should be asked in the evaluation of a patient with persistent neck pain.

![Diagram](image-url)

**Step 1. Are there “red flags” to suggest symptoms are secondary to a disease process rather than an injury?**

- **YES**
- **NO**

**Step 2. What is the nature of the injury?**

- **Neurologic Injury**
- **Major Skeletal Injury** (fracture; instability)
- **Musculoskeletal—Axial Spinal Pain**
  - a. Discogenic
  - b. Ligamentous
  - c. Facet joint
  - d. Myofascial
  - e. Widespread “nonanatomic” pain

**Step 3. Are there risk factors for delayed recovery?**

- a. Systemic musculoskeletal disorder (e.g., rheumatoid arthritis)
- b. Relevant general medical conditions (e.g., stroke)
- c. History of prior spinal injuries
- d. Evidence of severe spondylosis
- e. High pain intensity
- f. Severe functional limitations on exam
- g. Chemical dependency
- h. Sleep disturbance
- i. Evidence of severe emotional distress
- j. Disability and/or litigation issues
FIGURE 23.1  Key issues to address in the medical evaluation of chronic pain patients.

ARE THERE RED FLAGS?

Although the assumption in this section is that the patient is undergoing evaluation for residuals of a neck injury, occasionally, the physician will find that the patient has misattributed his or her symptoms and is actually symptomatic because of a disease rather than because of any injury.

A general medical history that addresses issues such as weight loss or fevers should alert the physician to the possibility that a patient is symptomatic because of a disease such as a neoplasm or infection.\(^8,9\)

If symptoms appear to be the result of injury, what is the nature of the injury?

1. Neurologic injuries. The physician needs to be alert to clinical evidence of a cervical radiculopathy or a myelopathy. Evidence for these possibilities is obtained from the patient’s history (e.g., pain and paresthesias into an extremity in a segmental distribution) and a careful neurologic examination. Electrodiagnostic studies can provide additional evidence regarding the presence of a cervical radiculopathy\(^10\), MRI scans can provide evidence of anatomic compromise of nerve roots or the cervical spinal cord\(^11–14\).

2. Major skeletal injuries. When a history of significant trauma is elicited, radiologic studies are needed to rule out the possibility that a patient has a spinal fracture or a ligamentous injury severe enough to yield instability.\(^14–16\) Although these major skeletal injuries are often accompanied by spinal cord injury or radiculopathy,\(^17\) they may occur among individuals who are neurologically intact.\(^18\)

3. Other musculoskeletal injuries (axial spinal pain). The overwhelming majority of patients with chronic neck pain do not have evidence of a neurologic injury or a major skeletal injury but present with localized axial cervical spine pain that suggests a musculoskeletal injury or with pain in a pattern suggesting referral from a joint in the cervical spine.\(^19,20\) These patients are often very difficult to evaluate medically because there are no physical examination findings or diagnostic tests that unequivocally identify the structural basis of axial cervical spine pain. In this ambiguous situation, it is important
for the examining physician to be aware of the structures that might underlie a patient’s symptoms.

a. Ligamentous injuries. Ligaments abound in the cervical spine, so pain felt to be ligamentous in origin could stem from various structures. The ligaments most often proposed as causes of axial cervical spine pain are the alar ligament, the posterior longitudinal ligament, and the facet joint capsular ligaments. Because ligaments are critical to the stability of the cervical spine, severe damage to them is often assessed by looking for instability. Most commonly, this gross instability is associated with major skeletal injuries and is diagnosed in emergency room settings. A more subtle type of ligamentous abnormality has been postulated to be identifiable based on an abnormal MRI signal from ligaments, such as high signal intensity on proton attenuation–weighted high-resolution MRI. In principle, these signal abnormalities could reflect ligamentous injuries that cause pain but are not severe enough to cause instability. Some investigators have reported that ligamentous injuries identified by abnormal MRI signals play a significant role in whiplash injuries and that the severity of self-reported disability among people with these injuries correlates with the severity of the MRI signal abnormalities. However, longitudinal studies on whiplash patients as well as research on asymptomatic people and ones with neck pain secondary to cervical degenerative conditions rather than injury suggest that the MRI signals that some investigators have interpreted as indicators of ligamentous injuries should actually be considered normal variants or indicators of cervical degenerative disk disease.

b. Disk pathology. It is widely accepted that cervical disk herniations can cause radiculopathies. But a more controversial issue is whether pathology of cervical disks can cause axial cervical spine pain and, if so, how such discogenic pain can be diagnosed and treated. Some investigators have proposed that cervical discogenic pain does occur and that it can be diagnosed via discography—a procedure in which imaging is performed after injection of contrast dye into a cervical disk and the pain
response of the patient is assessed during injection of the dye and just after follow-up injection of a local anesthetic. The presence of an abnormal discogram, defined on the basis of some combination of the morphology of a disk and the pain responses of a patient during the procedure, is viewed as an indication that the disk accounts for the patient’s pain and that a cervical spinal fusion is the appropriate definitive treatment. The evidence supporting discography as a means of identifying cervical discogenic pain is weak, with some reviews concluding that there is no compelling evidence to support its use and others specifically recommending against its use. Skepticism regarding cervical spine discography is bolstered by research on lumbar spine discography. This research has demonstrated a high false-positive rate for discography, a tendency for psychosocially stressed people to have an especially high false-positive rate, and failure of spinal fusion based on discography results to produce satisfactory results. Although dueling literature reviews make it somewhat difficult to reach any definite conclusions about cervical discogenic pain, a reasonable conclusion is that although discogenic pain is biologically plausible, no technology currently exists to demonstrate its presence in an individual patient or to provide treatment based on its suspected presence.

c. Facet joint injury. Bogduk and colleagues have asserted that facet joint injuries often underlie persistent cervical pain and have pioneered techniques for identifying painful facet joints on the basis of patients’ reports of symptoms during injection procedures designed to provoke or palliate pain. Using these techniques, they have reported that approximately 70% of individuals with persistent neck pain following motor vehicle collisions have pain mediated by one or more of the cervical facet joints. Equally important, they have demonstrated that when patients diagnosed with facet joint–mediated pain receive injections (facet neurotomies) designed to denervate the affected facet joint, approximately 70% experience prolonged symptom relief. More recent research has supported the importance of facet joint
pathology in whiplash pain, although the frequency was reported as 29% rather than 70%. As with discography, prominent teams of reviewers have reached opposite conclusions about the prevalence of facet joint–mediated pain, the validity of the diagnostic procedures used to diagnose this kind of pain, and the efficacy of invasive therapies to treat it. It is beyond the scope of this chapter to try to resolve the discrepant assessments of facet joint–mediated whiplash pain, although we believe the evidence supporting it is more impressive than the evidence supporting discogenic pain.

d. Muscle pain. Opinions about the prevalence and significance of muscle pain in chronic axial neck pain are, if anything, more divided than opinions about discogenic pain or pain associated with facet joint or ligamentous injury. Most investigators of muscle pain use the language and concepts developed by Travell and Simons, who popularized the term myofascial pain and emphasized its importance as a cause of persistent musculoskeletal pain. Proponents of myofascial pain have argued that this is extremely common in patients with persistent neck pain. For example, one recent study found evidence of myofascial pain in 100% of a cohort 224 patients treated for chronic neck pain by primary care providers. But the quality of the data supporting the importance of myofascial pain in spinal disorders is questionable, and the term myofascial pain is not even mentioned in comprehensive reviews of neck pain (e.g., Côté et al., Hogg-Johnson et al., Holm et al.). Again, it is beyond the scope of this chapter to resolve the conflicting views regarding the importance of myofascial problems among patients with chronic neck pain. But a few observations are worth making. First, there are no accepted diagnostic tests for myofascial pain. Clinicians rely on the history and physical examination to make the diagnosis. Second, clinicians should be aware that many neck pain patients will describe pain that suggests irritation of muscles and will report tenderness to palpation of neck and shoulder girdle muscles. Third, there is uncertainty about the appropriate
interpretation of these symptoms and reports during physical exams. Because pain that seems to be muscular is typically widespread and because CNS hypersensitivity is now recognized as at least one contributor to the pathophysiology of myofascial pain,\textsuperscript{46} symptoms that some physicians construe as indicators of myofascial pain could instead be construed as widespread “nonanatomic” pain, or as pain secondary to CNSS rather than peripheral nociception.

4. Widespread “nonanatomic” pain. As described earlier, physicians who practice musculoskeletal medicine try to explain symptoms following a musculoskeletal injury in terms of some structural lesion in joints, periarticular tissues, muscles, and nerves in the body region where the patient is symptomatic.\textsuperscript{47} The first step in this approach is to elicit a patient’s symptoms and consider pathophysiologic processes that might reasonably account for them. But this approach founders when the symptoms of patients do not fit a pattern that suggests some discrete injury to a musculoskeletal structure. For example, Figure 23.2 is a pain drawing provided by a chronic pain patient who reported that she initially hurt her lower back pain when she lifted a heavy box on her job. Although the patient denied injuries other than her low back injury, the figure indicates that she was now experiencing widespread pain. In interpreting such figures, it is important to note that research has demonstrated that irritation of intervertebral disks and facet joints produces characteristic patterns of referred pain\textsuperscript{48,49} and that experts in myofascial pain have proposed characteristic patterns of referred pain from affected muscles. Thus, it is sometimes possible to explain widespread symptoms as indications of referred pain. However, the drawing shown in Figure 23.2 does not lend itself to such an interpretation because it does not conform to any known pattern of referred pain from an intervertebral disk, a facet joint, a ligament, or a muscle in the cervical region. The most plausible interpretation of such widespread pain is that it is a manifestation of altered perception based on CNSS (described later) or psychological factors.
ARE THERE RISK FACTORS FOR DELAYED RECOVERY?

It is important to evaluate risk factors for delayed recovery in a patient with chronic neck pain. Unfortunately, research on the validity of many potential indicators is lacking. Thus, the following list of indicators should be viewed as plausible candidates for consideration during the medical evaluation of a chronic pain patient rather than as proven predictors. Another caveat is that although some of the potential indicators refer to medical variables, others refer to psychosocial variables that might be evaluated better by a psychologist than by a physician.

- Presence of a systemic disorder of the musculoskeletal system, such as
as rheumatoid arthritis or one of the muscular dystrophies

- Presence of general medical conditions that influence prognosis. For example, if a patient has severe cardiovascular disease, this may have implications for his or her ability to function in a physical therapy program. A patient who has had a stroke may have difficulty following medical directions.
- History of prior spinal injuries or of significant prior symptoms in the absence of injury
- Evidence of severe spondylosis
- High pain intensity
- Severe functional limitations on examination

• Chemical dependency. The patient’s history in this domain is important because it may bear on the appropriateness of prescribing opioids or sedatives.

• Sleep disturbance. Disturbed sleep is a common symptom reported by chronic pain patients, and most clinicians who treat these patients accept the premise that disordered sleep plays a role in perpetuating symptoms and disability. Thus, if a patient reports significantly disturbed sleep, a treatment plan for him or her should include interventions to promote normalization of sleep.

- Evidence of severe emotional distress
- Disability and litigation issues

**SPECIFIC EVALUATION PROCEDURES**
The physician should gather at least some information on most or all of the issues outlined earlier. For factors that are not biomedical, it is important for the physician to at least identify areas of concern, so that follow-up evaluations can be provided by the appropriate specialists. Broadly speaking, the information will come from three sources: the patient’s history, the physical examination, and ancillary studies.

**History**
It is beyond the scope of this chapter to discuss the elements of a thorough history. It is worth noting, though, that in evaluating a chronic pain patient, the physician should pay careful attention to certain historical items that
are considered only cursorily in other clinical settings. In particular, the physician should be careful to assess the patient’s history with respect to chemical dependency, sleep disturbance, apparent severity of incapacitation, and his or her status with respect to litigation and compensation.

**Physical Examination**

A neurologic and musculoskeletal examination should be performed on all patients with chronic cervical spine pain. In a patient with a normal neurologic examination, a musculoskeletal evaluation of the neck (including assessment of soft tissue hypersensitivity and range of motion) is often not especially revealing.\(^{19}\) In particular, it is virtually impossible to identify a distinct pain generator on the basis of a physical examination of such patients. But some useful information can be gleaned from a musculoskeletal examination. First, the physician can determine the severity of the patient’s functional limitations, especially restricted motion of the spine and pain-inhibited weakness of neck and extremity muscles. Second, the physician can check for hyperalgesia over muscles of the neck and shoulder girdle as well as more widespread hyperalgesia involving remote sites. Third, the physician can determine whether the patient demonstrates significant apprehension and “nonorganic signs.”\(^{51,52}\) Research indicates that patients with nonorganic signs usually have significant somatic anxiety. This emotional distress may impair their recoveries and may be a focus of treatment.

One caution about physical examination concerns the reliability of the assessment of factors such as range of motion. Evidence suggests that the interrater reliability of commonly performed physical examination tests is limited,\(^{53,54}\) and thus, it is important to determine whether findings on a single examination are consistent with a patient’s history, previous examination findings, and diagnostic tests.

**Ancillary Studies**

Although laboratory studies and electrodiagnostic evaluations are occasionally helpful in the assessment of patients with chronic neck pain, imaging studies are the procedures that are done the most frequently.
There is significant controversy about how and when imaging should be done on chronic pain patients. When judged against guidelines, one-third to two-thirds of spinal CT and MRI imaging may be inappropriate. High imaging rates can be problematic because irrelevant but alarming findings, including herniated disks, are common in asymptomatic people. Without attempting to resolve these controversies in any systematic way, we suggest the following: (1) for pain involving a trauma, it is reasonable to check for the possibility of a fracture or significant spinal instability using plain x-rays of the spine; (2) additional imaging is generally not needed for such a patient, unless there is clinical evidence of a neurologic injury. In that case, an MRI scan is generally indicated; and (3) CT scans and bone scans usually have a limited role—they can be obtained to identify an occult fracture or an inflamed facet joint.

Another type of diagnostic test for patients with chronic neck pain is one that uses local anesthetic blocks of structures thought to be the pain generators. The logic underlying this approach is that if a patient reports dramatic relief following a local anesthetic injection of a structure in his or her neck, it is reasonable to assume that the structure is functioning as a pain generator for the patient. The most widely used procedures of this kind are nerve root blocks, medial branch blocks, and discography. As discussed earlier, there is controversy about how valuable local anesthetic blocks are in the diagnosis of patients with chronic neck pain. We believe that nerve root blocks can play an important role in identifying the structural basis of radicular symptoms and are often used to guide surgical decision making. We believe that medial branch blocks should be used selectively but can be helpful in the management of patients who do not have evidence of nervous system sensitization or psychological or social processes that might interfere with their recovery. We are skeptical of the value of discography in neck pain patients.

CONCLUSION

The previous discussion addresses the medical evaluation of chronic pain within the context of patients with cervical spinal pain. We have gone into some detail in order to make the point that medical decision making in relation to cervical spine pain is far from simple. It is our opinion that in
order for pain patients to participate fully in evaluations of nonmedical factors contributing to their pain, they need to be confident that their problem has been evaluated thoroughly from a medical perspective. Thus, it is important for physicians participating in a multidisciplinary team either to have a lot of expertise in medical aspects of the problems that afflict their patients or to consult with colleagues who have this expertise.

**Assessment of Central Nervous System Sensitization**

During the past 35 years, CNSS has emerged as an important phenomenon in chronic pain.\(^{58,59}\) Early research on nonhumans demonstrated that they predictably developed CNSS in response to tissue injury and that the CNSS was manifested by characteristic changes in the behavior of dorsal horn neurons in the spinal cord, including a lowered response threshold and an expansion of receptive fields.\(^{59}\) Expansion of receptive fields was postulated to correlate with referral of pain and lowered response threshold with hyperalgesia.\(^{60,61}\)

Several methods have been developed to assess CNSS in humans. Among them is quantitative sensory testing, which has shown that people with chronic pain demonstrate reduced thresholds to multiple modalities of sensory stimulation, including pressure, thermal, and electrical stimuli.\(^{62,63}\) These abnormalities occur when stimuli are applied to the specific location of the reported pain and even to body regions where patients do not experience clinical pain.

Another approach has been to study withdrawal reflexes in response to potentially noxious stimuli. Relevant studies have shown that these reflexes can be elicited among chronic pain patients at lower stimulus intensities than the ones required to elicit the reflexes in healthy people.\(^{64,65}\)

Still another promising method for assessing CNSS is functional MRI (fMRI). Several investigators have used fMRI methodology to identify brain areas associated with processing of noxious stimuli and have found that patients with chronic pain (e.g., FM, chronic low back pain, and chronic pelvic pain) demonstrate more dramatic activation of these areas than healthy controls.\(^{66,67}\)
Findings from the aforementioned lines of inquiry have been interpreted by several researchers as evidence of CNSS among people with persistent pain and as a central feature in the development of neuropathic pain. Although these proposals have not been conclusively proven, the widespread belief among many neuroscientists and pain specialists that CNSS is a major factor in chronic pain has implications for the evaluation of the condition. At a conceptual level, CNSS challenges the simple dichotomy between organic pain and psychogenic pain that held sway in the orthopedic literature of a generation ago. At the level of clinical evaluation of an individual patient, the absence of definitive tests to determine the presence of CNSS makes it difficult for a clinician to rule in or out the hypothesis that it is affecting symptoms. The ambiguity introduced by CNSS is increased by the fact that although it is usually identified during an examination by a physician, it is not a medical diagnosis in the usual sense. For example, the International Classification of Disease, 10th edition, does not include any codes that can be used to designate that a patient’s pain is a reflection of CNSS. Also, no clear delineation has been drawn between CNSS versus psychological factors as a cause of persistent symptoms. The evaluation of CNSS is given a separate section in this chapter because of its ambiguous middle ground status between traditional medical processes and psychological processes. At a practical level, clinicians who treat chronic pain patients need to be aware that CNSS may be playing a role in the reports of their patients. One reason for this is that in the presence of CNSS, many of the inferential rules followed by clinicians when they interpret reports of pain are invalid because the rules are based on a simple model of an isomorphic correspondence between symptoms and dysfunction of tissues (nerves, joints, periarticular tissues, muscles) in the region where the patient indicates pain. The inferential rules are simply not valid when CNSS has occurred. For example, stocking glove numbness has long been considered a nonphysiologic complaint, but it can logically be interpreted as a result of CNSS. Another practical issue is that clinicians should not expect to find a one-to-one relation between symptoms and a definable structural lesion in a patient whose pain is mediated by CNSS rather than by ongoing nociceptive input from specific body locations. Finally, clinicians need to
be cautious about invasive therapies for patients whose pain is mediated by CNSS. The problem is that the pain of such patients may be generated primarily by spontaneous activity within the nervous system rather than by ongoing nociception from peripheral tissues, so that surgical alterations of tissues have little impact on it.

Given the potential importance of CNSS in the symptoms and functional limitations of pain patients, it would be highly desirable to have sensitive and specific tests to determine whether it is occurring in individual patients. Unfortunately, although the methods described earlier and several others have been examined in research on CNSS, no definitive test for its presence is available for clinical use. In clinical settings, practitioners usually rely on various indirect indices to decide whether CNSS is playing a major role in their patients’ symptoms.

Assessment of Psychosocial Factors

A comprehensive psychological evaluation of a pain patient is a fundamental component of a multidisciplinary evaluation. It addresses the specific psychosocial, behavioral, cognitive, and contextual factors such as current mood (anxiety, depression, anger), interpretation of the symptoms, expectations about the meaning of symptoms, and the responses to the patient’s symptoms by significant others (e.g., family members, coworkers), each of which contributes to the subjective experience of pain. This type of information should be included in the development of a comprehensive treatment plan.

PSYCHOLOGICAL FACTORS AS CAUSES VERSUS CONSEQUENCES OF CHRONIC PAIN

Psychological Factors as Causal Agents in Development of Chronic Pain

Patients often resist psychological evaluations because they intuitively sense that the outcome of such evaluations might be the conclusion that their pain is a result of psychological dysfunction rather than the injury to which they attribute their symptoms. Indeed, early reports suggested that preexisting psychopathology or neurotic traits might be the underlying
mechanisms for unremitting chronic pain. As early as 1953, Gay and Abbot mentioned “neurotic reactions,” noting that particular psychological factors predisposed an individual to chronic problems after an injury. In 1982, Blumer and Heilbronn postulated that patients with chronic symptoms had a distinct personality type that predisposed them to developing chronic pain—“pain-prone personality.” They specifically suggested that persistent symptoms offered a solution for their preexisting neurosis. There has been little empirical support indicating that the majority of chronic pain patients manifest character traits comprising a common and unique disposition. However, some studies have noted the high lifetime prevalence of psychiatric diagnoses observed in chronic pain patients, and prospective studies that followed healthy individuals who subsequently develop back pain and from acute injuries to the presence of disabling pain have observed that premorbid psychological factors were the best predictor of persistent pain chronicity.

Psychological Consequences of Chronic Pain

Psychological symptoms following the onset of pain have also been thoroughly documented. Acute and long-lasting psychological symptoms following symptom onset are prevalent. Disabling emotional symptoms have been observed in as many as 59% of people following initial pain onset.

A number of studies have implicated the role of the patient’s idiosyncratic appraisals of his or her symptoms, expectations regarding the cause of the symptoms, and the meaning of the symptoms, in addition to organic factors, as essential in understanding the individual’s report of pain and subsequent disability. Moreover, the patient’s current mood, ways of coping with symptoms, and responses by significant others including physicians may modulate the experience of pain, particularly chronic or recurrent pain. Failure to address these factors can result in poor response to treatments that focus exclusively on somatic causes.

The results of many studies implicate psychological symptoms as concomitants rather than precursors to chronic symptoms after chronic pain. Initial reaction to an injury, rather than the preexisting psychological status, has been shown to predict chronicity. It seems
reasonable that preexisting psychological status may predispose some individuals to chronic emotional disturbances following an injury. For example, acute emotional distress has been shown to be related to pain severity 1 month following a motor vehicle collision. The correct answer is probably somewhere in the middle where preexisting psychological disturbances, immediate emotional reaction, coupled with medical complications contribute to chronicity of pain, at least for some people. In either case, these studies underscore the importance of evaluating psychological factors for all chronic pain patients.

ELEMENTS OF THE PSYCHOLOGICAL EVALUATION
Table 23.1 contains a brief set of salient issues with the acronym ACT-UP (Activity, Coping, Think, Upset, People’s responses) that can be used as a guide for interviewing patients who report persistent or recurring symptoms. Generally, a referral for evaluation may be indicated where disability greatly exceeds what would be expected based on physical findings alone, when patients make excessive demands on the health care system, when the patient persists in seeking medical tests and treatments when these are not indicated, when patients display significant emotional distress (e.g., depression or anxiety), or when the patient displays evidence of addictive behaviors or continual nonadherence to the prescribed regimen. Table 23.2 contains a detailed outline of the areas that should be addressed in a more extensive psychological interview for pain patients.

### TABLE 23.1 Brief Psychosocial Screening: ACT-UP

Perception of cause (e.g., trauma, virus, stress)
What has the patient been told about the symptoms and condition? Does the patient believe that this information is accurate?
Exacerbating and relieving factors (e.g., exercise, relaxation, stress, massage)
Pattern of symptoms (e.g., worse certain times of day or following activity or stress)
Sleep habits (e.g., difficulty falling to sleep or maintaining sleep, sleep hygiene)
Thoughts, feelings, and behaviors that precede, accompany, and follow fluctuations in symptoms

Treatments Received and Currently Receiving
- Medication (prescribed and over-the-counter). How helpful have these been?
- Pattern of medication use (as needed, time-contingent), changes in quantity or schedule
- Physical modalities (e.g., physical therapy). How helpful have these been?
- Exercise (e.g., Do they participate in a regular exercise routine? Is there evidence of deactivation and avoidance of activity due to fear of pain or exacerbation of injury?). Has the pattern changed (increased, decreased)?
- Complementary and alternative (e.g., chiropractic manipulation, relaxation training). How helpful have these been?
- Which treatments have they found the most helpful?
- Compliance (adherence) with recommendations of health care providers
- Attitudes toward previous health care providers

Compensation and Litigation
- Current disability status (e.g., receiving or seeking disability, amount, percentage of former job income, expected duration of support)
- Current or planned litigation

Responses by Patient and Significant Others
- Typical daily routine
- Changes in activities and responsibilities (both voluntary and obligatory) due to symptoms

Educational and Vocational History
- Level of education completed, including any special training
- Work history
- How long at most recent job?
- How satisfied with most recent job and supervisor?
- What like least about most recent job?
- Would the patient like to return to most recent job? If not, what type of work would the patient like?
- Current work status, including homemaking activities
- Vocational and avocational plans

Social History
- Relationships with family or origin
- History of pain or disability in family members
- History of substance abuse in family members
- History of or current, physical, emotional, and sexual abuse. Was the patient a witness to abuse of someone else?
- Marital history and current status
- Quality of current marital and family relations

Alcohol and Substance Use
- Current and history of alcohol use (quantity, frequency)
- History and current use of illicit psychoactive drugs
- History and current use of prescribed psychoactive medications
- Consider the CAGE questions as a quick screen for alcohol dependence. Depending on response, consider other instruments for alcohol and substance abuse.

Psychological Dysfunction
- Current psychological symptoms/diagnosis (depression including suicidal ideation, anxiety disorders, somatization, posttraumatic stress disorder). Depending on responses, consider conducting structured interview such as the Structured Clinical...
| Changes in significant other’s activities and responsibilities due to patient’s symptoms |
| Patient’s behavior when pain increases or flares up |
| Significant others’ responses to behavioral expressions of pain |
| What does the patient do when pain is not bothering him or her (uptime activities)? |
| Significant other’s response when patient is active |
| Impact of symptoms on interpersonal, family, marital, and sexual relations (e.g., changes in desire, frequency, or enjoyment) |
| Activities that patient avoids because of symptoms |
| Activities continued despite symptoms |
| Pattern of activity and pacing of activity (can use activity diaries that ask patients to record their pattern of daily activities [e.g., sitting, standing, walking] for several days or weeks) |

Interview for Diagnostic and Statistical Manual of Mental Disorders (4th ed., text rev.; DSM-IV-TR) (SCID).\(^c\)

- Is the patient currently receiving treatment for psychological symptoms? If yes, what treatments (e.g., psychotherapy or psychiatric medications)? How helpful are the treatments?
- History of psychiatric disorders and treatment including family counseling
- Family history of psychiatric disorders

**Concerns and Expectations**

- Patient concerns/fears
- Explanatory models of pain held by the patient
- Expectations regarding the future and treatment (will get better, worse, never change)
- Attitude toward rehabilitation versus “cure”

**Treatment Goals**

---

**Interviews**

A psychological interview with chronic pain patients is typically semi-structured. A structured format of psychiatric interview\(^82\) can be incorporated as a tool to examine psychopathology. However, a psychological interview with pain patients’ needs to go beyond an assessment of psychopathology because its main purpose is to assess a wide range of psychosocial factors (not just psychopathology) related to a patient’s symptoms and disability.

When conducting an interview with chronic pain patients, the health care professional should focus not only on gathering information provided by the patient but also on observing patients’ pain behaviors and the manner in which they convey information (e.g., facial expressions,
movement patterns). We discuss some specific measures that have been proposed to systematically assess pain behaviors later.

Chronic pain patients’ beliefs about the cause of symptoms, their trajectory, and beneficial treatments will have important influences on emotional adjustment and adherence to therapeutic interventions. A habitual pattern of maladaptive thoughts may contribute to a sense of hopelessness, dysphoria, and unwillingness to engage in activity. These reactions, in turn, deactivate the patient and severely limit his or her physical and emotional adaptation. The interviewer should also determine both the patient’s and the significant other’s expectancies and goals for treatment. An expectation that pain will be eliminated completely may be unrealistic and will have to be addressed to prevent discouragement when this outcome does not occur. Setting appropriate and realistic goals is an important process in pain rehabilitation as it requires the patient to attain better understanding of chronic pain and goes beyond the dualistic, traditional medical model—somatogenic versus psychogenic.

In order to help chronic pain patients understand the psychosocial aspects of pain, attention should focus on the patients’ reports of specific thoughts, behaviors, emotions, and physiologic responses that precede, accompany, and follow pain episodes or exacerbation as well as the environmental conditions and consequences associated with their responses in these situations. During the interview, the clinician should attend to the temporal association of these cognitive, affective, and behavioral events; their specificity versus generality across situations; and the frequency of their occurrence to establish salient features of the target situations, including the controlling variables. The interviewer should seek information that will assist in the development of potential alternate responses, appropriate goals for the patient, and possible reinforcers for these alternatives.

Patients with chronic pain problems typically consume a variety of medications to alleviate their symptoms. It is important to discuss a patient’s medications during the interview, as many pain medications (particularly opioids) are associated with side effects that may mimic emotional distress and can have deleterious adverse effects. A clinician, for example, should be familiar with side effects that result in fatigue,
sleep difficulties, and mood changes to avoid misdiagnosis of depression. A general understanding of commonly used medications for chronic pain is important, as some patients also may use opioid analgesics to manage dysphoric mood that accompanies pain and its impact. During the interview, potential psychological dependence and aberrant drug-seeking behaviors on pain-relieving medications should be evaluated. In the majority of states in the United States, a physician is able to obtain a record of prescriptions of controlled substances. When in doubt, a psychologist may recommend that such a record be obtained and request urine toxicology screening to rule out aberrant opioid-taking behaviors.  

**Self-report Inventories**

In addition to interviews, a number of standardized assessment instruments designed to evaluate patients’ attitudes, beliefs, and expectancies about themselves, their symptoms, and the health care system have been developed and published. One survey of clinicians who treated pain indicated that the five most frequently used instruments in the assessment of pain, in order of frequency, were the McGill Pain Questionnaire, Beck Depression Inventory (BDI), Multidimensional Pain Inventory (MPI), Coping Strategies Questionnaire (CSQ), and the Oswestry Low Back Pain Disability Questionnaire.

Standardized instruments have advantages over semi-structured and unstructured interviews. They are easy to administer, require less time, assess a wide range of behaviors, obtain information about behaviors that may be private (sexual relations) or unobservable (thoughts, emotional arousal), and, most importantly, have been submitted to analyses that permit demonstration of their psychometric properties (e.g., reliability and validity). These instruments should not be viewed as alternatives to interviews; rather, they are complements that may suggest issues to be addressed in more depth during an interview or investigated with other measures.

There is an important caveat when interpreting the results of patient self-report inventories. Studies of the psychometric properties of these inventories typically involve data collection from a large number of patients. As reliability estimates are influenced by sample size, it follows
that the measurement error of questionnaire data from one person should be expected to be much greater than that found in reports based on group data.

**PROBLEM AREAS TO ASSESS**

**Assessment of Pain**

**Pain Intensity**

Self-report measures of pain often ask patients to quantify their pain by providing a single, general rating of pain: “Is your usual level of pain ‘mild,’ ‘moderate,’ or ‘severe’?” or “Rate your typical pain on a scale from 0 to 10 where 0 equals no pain and 10 is the worst pain you can imagine.” There are a number of simple methods that can be used to evaluate pain intensity—Numerical Rating Scale (NRS), Verbal Ratings Scale (VRS), and Visual Analog Scale (VAS) using different variation. For example, the Brief Pain Inventory (BPI) includes four individual questions using NRSs—right now, pain on average, pain at worst, and pain at least.\(^{92,93}\)

Each of the commonly used methods of rating pain intensity, NRS, VRS, and VAS, appear sufficiently reliable and valid, and no one method consistently demonstrates greater responsiveness in detecting improvements associated with pain treatment.\(^{94,95}\) However, there are important differences among NRS, VRS, and VAS measures of pain intensity with respect to missing data stemming from failure to complete the measure, patient preference, ease of data recording, and ability to administer the measure by telephone or with electronic diaries. NRS and VRS measures tend to be preferred over VAS measures by patients, and VAS measures usually demonstrate more missing data than do NRS measures. Greater difficulty completing VAS measures is associated with increased age and greater opioid intake, and cognitive impairment has been shown to be associated with inability to complete NRS ratings of pain intensity.\(^{95}\) Patients who are unable to complete NRS ratings may be able to complete VRS pain ratings (e.g., none, mild, moderate, severe). Other measures are available to assess pain in children and those who are unable to verbally communicate (e.g., stroke patients, mentally impaired).\(^{96,97}\)

There has been some concern expressed that retrospective reports may not be valid, as they may reflect current pain severity that serves as an
anchor for recall of pain severity over some interval.\textsuperscript{98,99} More valid information may be obtained by asking about current level of pain, pain over the past week, worst pain of the last week, and lowest level of severity over the last week (e.g., BPI). This has also led to the use of daily diaries that are believed to be more accurate as they are based on real time rather than recall. For example, patients are asked to maintain regular diaries of pain intensity with ratings recorded several times each day (e.g., at meals and bedtime) for several days or weeks. One problem noted with the use of paper-and-pencil diaries is that patients may not follow the instruction to provide ratings at specified intervals. Rather, patients may complete diaries in advance (“fill forward”) or shortly before seeing a clinician (“fill backward”).\textsuperscript{99,100} These two reporting approaches undermine the putative validity of diaries. As an alternative to the paper-and-pencil diaries, a number of commentators have advocated for the use of electronic devices that can prompt patients for ratings and “time stamp” the actual ratings, thus facilitating real-time data capture.\textsuperscript{100–102} Although there are numerous advantages to the use of advanced technology to improve the validity of patient ratings, they are not without potential problems, including hardware problems, software problems, and user problems.\textsuperscript{103} These methods are also costly, and although they may be appropriate for research studies, their usefulness in clinical settings may be limited.

Pain Quality
Pain is known to have different sensory and affective qualities in addition to its intensity, and measures of these components of pain may be used to more fully describe an individual’s pain experience. It is possible that the efficacy of pain treatments varies for different pain qualities, and measures of pain quality may therefore identify treatments that are efficacious for certain types of pain but not for overall pain intensity. Assessment of specific pain qualities at baseline also makes it possible to determine whether certain patterns of pain quality moderate the effects of treatment. The Short-Form McGill Pain Questionnaire (SF-MPQ)\textsuperscript{86} assesses 15 sensory and affective pain descriptors, and its sensory and affective subscales have demonstrated responsivity to treatment in a number of
clinical trials. More recently, a revision of the SF-MPQ (SF-MPQ-2) was developed to increase the range of items (rated on a 0-to-10 scale) and items added to assess characteristics of neuropathic pain that have been not been adequately assessed in the SF-MPQ.

Pain Modifiers
For the majority of people with chronic pain, pain severity varies. Thus, it is useful to inquire as to what the patient believes makes his or her pain worse. For example, are their specific activities that result in increase in symptoms? Are their certain circumstances that contribute to exacerbation of pain such as stress including interpersonal conflicts? Does pain vary with time of day? For example, does the patient notice that his or her pain is worse in the morning or later in the day? In the same way, it is important to identify factors that magnify or initiate pain episodes; it is important to ask about what factors result in reductions of pain. For example, does medication, rest, heat or cold, distraction, or exercise result in reductions of pain severity or even elimination of symptoms for some period? Pain may be influenced by the context or activities being undertaken. For example, pain intensity when an individual is at rest may differ substantially from pain experienced during movement. Thus, it is important to address what factors modify pain such as the nature of different activities.

Assessment of Overt Expressions of Pain
As noted previously, patients display a broad range of responses that communicate to others that they are experiencing pain, distress, and suffering. Some of these pain behaviors may be consciously controllable by the person, whereas others are not. Informally, a health care provider can observe patients’ behaviors during their interviews and examinations. It is useful to observe patients in multiple contexts when possible (e.g., waiting room, ambulating to an exam room, during interview with clinician, during physical examination). When patients know they are being observed and are presenting information to a health care provider, they may use behavior to convey information in ways most likely to support the impact of their symptoms. They may feel a need to convince
the health care provider of the severity of their symptoms, functional limitations, and distress. Thus, observation of the patient in the waiting room, when ambulating to the examination room, and when departing may allow the clinician to establish the stability and consistency of pain behaviors. We have also found it useful to observe patients in the presence of a significant other to note differences in behaviors when the significant other is present and absent and also how the significant other responds to the patient’s pain behaviors.

A number of different observational procedures have been developed to identify and quantify pain behaviors. Structured methods that require patients to engage in a set of behaviors during which their behavior is observed and rated have been proposed by Keefe and colleagues.\textsuperscript{106,107} Such structured approaches may be useful in research studies but can be cumbersome in clinical settings. Several investigators have developed observational Pain Behavior Checklists\textsuperscript{108,109} that can be used in any setting. Although they have the advantage of efficiency, these methods may be less appropriate to compare among patients who are viewed in different contexts (e.g., during a physical examination or interview). As noted, the context may influence the behaviors observed. For example, the nature of pain behaviors observed might be quite different during a physically demanding examination compared to an interview. The number and nature of pain behaviors might be influenced by the presence of significant others during the observation period. At a minimum, it is important to note the context in which the behaviors were observed. Studies using Pain Behavior Checklists have found a significant association between these self-reports and behavioral observations. A variant of this observational procedure was developed by Kerns and colleagues\textsuperscript{110} who developed a self-report version in which patients endorsed specific behaviors that they engaged in when they were experiencing pain.

Facial expressions and muscle patterns can provide objective, fine-grained analysis of the subjective experience of pain.\textsuperscript{111} Formal assessment of facial expression has been found to be valuable in research but may be too complex for use in a clinical setting.

Uses of the health care system and analgesic medication are other ways
to assess pain behaviors. Patients can record the times when they take
medication over a specified interval such as a week. Despite the cautions
regarding patient diaries noted, diaries can not only provide information
about the frequency and quantity of medication but may also permit
identification of the antecedent and consequent events of medication use.
Antecedent events might include stress, boredom, or activity. Examination
of antecedents is useful in identifying patterns of medication use that may
be associated with factors other than pain per se. Similarly, patterns of
response to the use of analgesic may be identified. Does the patient receive
attention and sympathy whenever he or she is observed by significant
others taking medication? That is, do significant others provide positive
reinforcement for the taking of analgesic medication and thereby
unwittingly increase medication use?

Assessment of Emotional Distress
The results of numerous studies suggest that chronic pain is frequently
associated with emotional distress, particularly depression, anxiety, anger,
and irritability. The presence of emotional distress in people with chronic
pain presents a challenge when assessing symptoms such as fatigue,
reduced activity level, decreased libido, appetite change, sleep disturbance,
weight gain or loss, and memory and concentration deficits. These
symptoms are often associated with pain and have also been considered
“vegetative” symptoms of depressive disorders. Improvements or
deterioration in such symptoms, therefore, can be a result of changes in
either pain or emotional distress.

The BDI and BDI-2,\textsuperscript{87,88} the Profile of Mood States (POMS),\textsuperscript{112} the
Hospital Anxiety and Depression Scale (HADS),\textsuperscript{113,114} and Patient Health
Questionnaire (PHQ-9)\textsuperscript{115} have well-established reliability and validity in
the assessment of symptoms of depression and emotional distress, and they
have been used in numerous clinical trials in psychiatry and an increasing
number of studies of patients with chronic pain.\textsuperscript{116} In research in
psychiatry and chronic pain, the BDI provides a well-accepted criterion of
the level of psychological distress in a sample and its response to
treatment. The POMS\textsuperscript{112} assesses six mood states—tension–anxiety,
depression–dejection, anger–hostility, vigor–activity, fatigue–inertia, and
confusion–bewilderment—and also provides a summary measure of total mood disturbance. Although the discriminant validity of the POMS scales in patients with chronic pain has not been adequately documented, it has scales for the three most important dimensions of emotional functioning in chronic pain patients (depression, anxiety, and anger) and also assesses three other dimensions that are very relevant to chronic pain and its treatment, including a positive mood scale of vigor–activity. Moreover, the POMS has demonstrated beneficial effects of treatment in some (but not all) chronic pain trials.\textsuperscript{117,118} The HADS include seven items assessing anxiety and depression. One advantage of the HADS is that it was developed and standardized with medical patients rather than psychiatric patients. Shorter measures of anxiety (Generalized Anxiety Disorder [GAD]-7)\textsuperscript{119} and depression (PHQ-9)\textsuperscript{115} have been reported to provide reliable and valid assessments and might also be considered for research as well as clinical use. Any of these measures reasonable choices as brief measures of emotional distress.

As noted previously, various symptoms of depression—such as decreased libido, appetite or weight changes, fatigue, and memory and concentration deficits—are also common. It is unclear whether the presence of such symptoms in patients with chronic pain (and other medical disorders) should nevertheless be considered evidence of depressed mood or whether the assessment of mood in these patients should emphasize symptoms that are less likely to be secondary to physical disorders.\textsuperscript{111,120}

**Assessment of Fear**

Many patients with chronic pain, especially those who attribute their symptoms to trauma, are fearful of engaging in activities that they believe may either contribute to further injury or exacerbate their symptoms. Avoidance of activities may, in the short term, lead to symptom reduction. But over time, restriction of activities is likely to lead to decreased functional capacities as a result of deconditioning. Also, avoidance of activity has the unfortunate consequence of preventing corrective feedback where patients can learn about their erroneous beliefs. Health care providers may inadvertently contribute to avoidance of activity by
providing patients with cervical collars that restrict neck movements and advising them to avoid activities that hurt (i.e., hurt = harm). They may contribute to patients’ anxiety that something is seriously wrong with their bodies by continuing to order sophisticated diagnostic tests in search of occult physical pathology. Self-report measures of fear of movement that might increase pain or physical damage are available (e.g., Tampa Scale of Kinesiophobia [TSK], Fear Avoidance and Beliefs Questionnaires [FABQ]).

Assessment of Beliefs, Coping, and Psychosocial Adaptation to Pain

Historically, psychological measures designed to evaluate psychopathology have been used to identify specific individual differences associated with reports of pain, even though these measures were usually not developed for or standardized on samples of medical patients. Because disease status and medication can affect responses to such items, patients’ scores may be elevated, thereby distorting the meaning of their responses. As a result, a number of measures have been developed for use specifically with pain patients. Instruments have been developed to assess psychological distress; the impact of pain on patients’ lives, feeling of control, coping behaviors, and attitudes about disease, pain, and health care providers; and the patient’s plight.

Two particularly potent beliefs (i.e., self-efficacy and catastrophizing) held by patients have been demonstrated to play important roles in chronic pain. Self-efficacy is the conviction that one can successfully perform a certain task or produce a desirable outcome. A major determinant of self-efficacy is prior mastery experience. In chronic pain patients, self-efficacy positively affects physical and psychological functioning, and improvements in self-efficacy after self-management and cognitive-behavioral interventions are associated with improvements in pain, functional status, and psychological adjustment. Self-report instruments to assess self-efficacy with chronic pain patients have been developed and have been used in both clinical research and practice.

Pain catastrophizing can be defined as an exaggerated negative orientation toward actual or anticipated pain experiences. Current
conceptualizations most often describe it in terms of appraisal or as a set of maladaptive beliefs. It is a cognitive and emotional process that involves magnification of pain-related stimuli, feelings of helplessness, and a negative orientation to pain and life circumstances. It includes obsessive rumination about pain, and its meaning and magnification of symptoms also are associated with decreases in pain severity ratings and functional disability. Catastrophizing has been shown to be an important predictor of response to both acute and chronic pain. Catastrophizing have been associated with increased perceptions of pain severity in both acute and chronic pain severity and disability among groups with diverse pain diagnosis.

Several self-report measures of catastrophizing have been developed and shown to have good psychometric properties (Coping Strategies Questionnaire [CSQ], Pain Catastrophizing Scale [PCS]). These measures have been used in both clinical research and contexts and have shown to have predictive validity for disability and response to various treatments. A brief, two-item measure of catastrophizing have been shown to have a high correlation with the longer form and may be useful as a screening device.

Assessing Functional Impact

A major focus of the discussion earlier has been on the identification of factors underlying the symptoms of a chronic pain patient. It is important to note, though, that the identification of factors that qualitatively play a role in a patient’s symptoms is not the same as an explanation of the severity of these symptoms or the extent to which the patient is disabled by them. Thus, we recommend that an evaluation of any chronic pain patient should include an assessment of the extent to which the patient is affected by his or her symptoms. When a multidisciplinary evaluation is conducted, physical therapists, vocational rehabilitation counselors, physicians, and psychologists may participate in the evaluation of function among pain patients. Conceptually, the impact of chronic pain on function can be subdivided into (1) the ability of patients to function in the sense of performing activities of daily living, (2) their physical capacities as
demonstrated in a structured setting, and (3) their ability to function in adult roles such as work.\textsuperscript{137}

Physical functioning and activity can be considered from three complementary perspectives, namely, the patient’s perspective on his or her functioning (self-report), observation during performance on structure tasks in a clinical or laboratory setting (e.g., timed walking, gait pattern), and objective assessment of activity in the natural occurring environment (e.g., using technical instruments and devices such as accelerometry).\textsuperscript{138,139} Each of these perspectives will provide different information about performance and are complementary. Objective assessment of physical functioning will depend to some extent on the nature of the physical capacity and diagnostic condition being assessed, and detailed discussions are beyond the scope of this chapter (see Taylor et al.\textsuperscript{139} for a comprehensive review).

**SELF-REPORT MEASURES OF FUNCTION**

Self-report measures have been developed to assess people’s reports of their abilities to engage in a range of functional activities such as the ability to walk up stairs, sit for specific periods of time, lift specific weights, and perform activities of daily living as well as the severity of the pain experienced upon the performance of these activities.\textsuperscript{139} There are a number of well-established, psychometrically supported generic (e.g., Short-Form 36 [SF-36]),\textsuperscript{140} pain-specific (e.g., BPI Interference Scale,\textsuperscript{92} Pain Disability Index [PDI],\textsuperscript{141} MPI Interference Scale), and diagnosis back pain–specific (Oswestry Low Back Pain Disability Questionnaire [OLBPQ],\textsuperscript{91} Western Ontario McMaster Assessment of Knee and Hip Osteoarthritis [WOMAC])\textsuperscript{142} measures of functional status (for a review, see Taylor et al.\textsuperscript{139}).

The OLBPQ is a widely used, 10-item scale that asks patients about disability associated with back pain.\textsuperscript{91} It has the advantage of being a disease-specific instrument. In general, disease-specific measures are designed to evaluate the specific effects of a disorder that may not be assessed by a generic measure.\textsuperscript{138,139} In addition, responses on disease-specific measures will generally reflect the effects of comorbid conditions on physical functioning, which may confound the interpretation of change
occurring over the course of a trial when generic measures are used. Disease-specific measures may be more sensitive to the effects of treatment on function, but generic measures provide information about physical functioning and treatment benefits that can be compared across different conditions and studies. Each of these approaches has strengths. Decisions regarding whether to use a disease-specific or a generic measure, or some combination, will depend on the purpose of the assessment. For individual patients in clinical practice, it would be most appropriate to use measures developed on samples with comparable characteristics. If the clinician wishes to compare across a group of patients, then one of the broader based pain-specific measures should be considered. If the assessment is being performed as part of a research study, some combination might be appropriate to compare chronic pain samples with a larger population of people with diverse medical diseases (e.g., SF-36).

A particularly important aspect of physical functioning that is particularly important to those with chronic pain is sleep. Pain is frequently reported as have a significant impact on sleep quality as well as duration. Patients being evaluated should be asked about their sleep, and depending on the information acquired during an interview, more detailed methods are available to assess sleep objectively using formal sleep laboratory evaluation, accelerometry, and self-report measures (e.g., Medical Outcomes Study [MOS] Sleep Scale).

Assessment of Physical Capacity

The physical capacities of pain patients are typically assessed by physical and occupational therapists. In some clinical settings, evaluation protocols are developed informally by individual therapists, sometimes in conjunction with a physician. In other settings, formal assessment protocols are used. Although the validity of such protocols has been questioned, they are frequently used—particularly when injured workers are being evaluated. The purpose of such evaluations is to obtain objective information about the capabilities of patients. In clinical settings, this information is used in the planning of rehabilitative treatment. In more
adversarial settings (e.g., workers’ compensation), physical capacities data are used when adjudicative decisions about claims are made.

Ideally, a multidisciplinary evaluation would include having a vocational rehabilitation counselor perform a comprehensive evaluation of the work status of pain patients and their potential for vocational rehabilitation. In many situations, though, the job of assessing vocational disability falls on the physician or psychologist on the multidisciplinary team. We are not aware of standardized instruments to assess the vocational status of pain patients. In the absence of a standard instrument, we recommend that clinicians assessing these patients address the following issues: (1) Is the patient currently working? (2) If the patient is not working, is this related to his or her health? (3) How long has the patient been out of the workforce? (4) Is he or she receiving any kind of work disability benefits? Which ones?

Assessment of Social Factors

Social factors are construed as factors in the social environment that influence people independent of their individual psychological characteristics. A good example is the receipt of workers’ compensation benefits.

Social factors include demographic variables that influence the presentation and clinical course of people with painful conditions. In particular, research indicates that an individual’s clinical presentation is associated with his or her age, sex, ethnicity, and education level.

The social factors that have attracted the most research attention in relation to chronic pain are participation in work (including household activities), interpersonal interactions, litigation, and participation in a workers’ compensation system.

Important social factors also include influences from an individual’s immediate social environment. For example, there is good evidence that pain patients generally demonstrate more dramatic pain behaviors when they are in the presence of solicitous spouses.

A significant proportion of individuals involved in injuries file personal
injury claims. There is some evidence that injured workers with workers’ compensation claims respond more poorly to a variety of treatments compared to individuals with these same medical conditions but without workers’ compensation claims.\textsuperscript{150} Research on the relation between litigation and clinical course, however, has been contradictory. For example, whereas several studies have reported a negative effect of attorney involvement and litigation on recovery from whiplash disorders,\textsuperscript{69,152} Others have not supported the prognostic role of these factors.\textsuperscript{153} It is beyond the scope of this chapter to review the often contentious literature on the effect of litigation/attorney involvement on outcomes of chronic pain.\textsuperscript{154–158}

**Organization of Multidisciplinary Evaluations**

As discussed previously, the clinicians who might participate in multidisciplinary evaluations include physicians, psychologists, vocational rehabilitation counselors, physical and occupations therapists, and perhaps other professionals. An obvious question is “How do these clinicians orchestrate their evaluations and communicate with each other?”

The model that has received the most attention in research literature has been multidisciplinary intensive pain rehabilitation.\textsuperscript{159} In the United States, the multidisciplinary pain centers and functional restoration programs that provided intensive pain rehabilitation began in the late 1960s, flourished during the 1980s and early 1990s, and more recently have been in decline.\textsuperscript{160}

Given the decline in intensive pain rehabilitation programs, it will probably be necessary in the future for professionals involved in the evaluation of patients with chronic pain to develop a number of informal strategies for working together. There are almost certainly a variety of models that can succeed. The key issue is for professionals to work together in acquiring data on the multiple dimensions that affect chronic pain patients and to communicate with each other so that the patients benefit from the data that are gathered.

**Conclusion**
Pain and associated symptoms are the results of a complex interplay of factors. Assessment and treatment of patients with chronic pain can be complicated by the web of influential factors that modulate the overall pain experience and associated disability. Furthermore, traditional biomedical approaches with diagnostic tests are often not helpful because structural damage and persistent pain reports do not necessarily coincide. Pain research in the last half century has repeatedly shown that pain is not just a physiologic phenomenon and that a range of “person variables,” such as psychosocial, environmental, and behavioral factors, play a significant role in determining the occurrence, severity, and quality of pain. Given the multifactorial nature of chronic pain, adequate assessment requires an interdisciplinary team approach. In this chapter, we discussed the assessment of medical factors, altered CNS processing, psychological factors, and social factors in patients with chronic pain. We introduced a number of self-report inventories that can be used in conjunction with interviews and medical examinations. As we have repeatedly stressed, an adequate assessment of patients with chronic pain means the evaluation of the person with the symptoms. We must not just focus on the pathology or symptom report but must reach out to understand the person and his or her well-being. Although there is no shortcut in this, the delineation of relevant medical, psychosocial, and behavioral factors contributing to pain in a patient is critical in planning and executing a successful treatment plan.

A number of national and international efforts have recommended minimal data sets composed of standardized measures that should be considered for use in clinical practice as well as research on specific pain disorders. These efforts include many of the multidimensional concepts and constructs reviewed in this chapter. The adoption of these recommendations would permit the aggregation of assessment information across studies and advance the understanding of individuals with chronic pain and the evaluation of treatments.

Pain as a Symptom of Neuropathy

Neuropathy is a common clinical problem. Pain merits attention in any discussion of neuropathy for several reasons. First, insofar as pain varies among neuropathy etiologies, the presence, absence, and type of pain when present can contribute to the diagnostic process. Second, for many people with neuropathy, pain is the chief complaint and the only cause of disability. The traditional neurologic focus on deficits rather than positive sensory phenomena does not serve these patients well. Finally, and perhaps most importantly, pain is a neurologic symptom. The study of pain due to nerve disorder or injury is providing essential insights into the function of the nervous system, as has the study of other neurologic symptoms in the past.

The Evaluation and Diagnosis of Neuropathy

NEUROPATHY CLASSIFICATION

The approach to the diagnosis of neuropathy is fully covered in textbooks devoted to this topic. The present section is a conceptual overview to
allow readers unfamiliar with neuromuscular practice to better understand the balance of this chapter. Throughout this section, specific neuropathies are named for the purpose of illustration only. More comprehensive and detailed information about specific types of neuropathy can be found later in this chapter under “Painful Neuropathies.”

The four principal questions to address in the etiologic classification of neuropathy are the time course of symptoms, the distribution of neuropathy symptoms and signs, the modalities affected (motor, small fiber sensory, large fiber sensory, and autonomic), and the primary locus of pathology (axon or myelin). Answers to these four questions will narrow the differential diagnosis substantially.

**Time course:** Many common neuropathies, particularly those due to metabolic or genetic conditions, progress insidiously over years. Some, such as chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), can progress over a period of weeks to months, often with unpredictable relapses or remissions. Relatively few neuropathies present acutely over days to weeks; among these are Guillain-Barré syndrome (GBS), toxic neuropathies, and peripheral nerve vasculitis.

**Distribution:** The distribution of neuropathy symptoms and signs can be identified by the history and confirmed by the examination and electrophysiologic studies. Most neuropathies conform to one of two patterns: symmetric, length-dependent versus asymmetric, multifocal, nonlength-dependent. The symmetric, length-dependent pattern begins with symptoms in both feet and progresses rostrally in a symmetric fashion. Symptoms usually do not appear in the hands until lower limb symptoms have progressed to the proximal calves or thighs. Symptoms appear last in the trunk and face. The term length dependent refers to the fact that nerve dysfunction in these patients begins in the longest axons and progresses rostrally. The implicated pathophysiology is that all nerves are exposed in equal measure to a systemic stressor and that the effect of this stressor on nerve function is closely correlated to the distance of the nerve terminal from the cell body. Many metabolic, toxic, and genetic disorders of nerve present in this fashion.

Asymmetric, nonlength-dependent neuropathies can affect proximal and distal nerve segments concomitantly in an unpredictable manner.
Examples of those include CIDP, necrotizing vasculitis, granulomatous disorders such as sarcoidosis and leprosy, hereditary neuropathy with liability to pressure palsies (HNPP), and lymphomatous or carcinomatous infiltration of peripheral nerves.

**Modality:** The modalities affected refer to motor axons, large fiber (Aβ myelinated) sensory axons, small fiber (Aδ and C) sensory axons, and autonomic (cardiorespiratory, vasomotor, and visceromotor) axons. As with distribution, the involvement of these fiber classes can be identified by the history and confirmed by the neurologic examination and electrophysiologic studies; in addition, numerous clinical tools have been developed in recent decades to assist in the confirmation of small fiber sensory and autonomic involvement. Most symmetric, length-dependent metabolic or toxic neuropathies are clinically sensory-predominant until they are relatively advanced. The relative involvement of large and small sensory axons varies among, and in some cases within, etiologies. Patients with clinical findings isolated to small fiber modalities are often referred to as having small fiber neuropathy (SFN), although there is evidence that this progresses over time to involve large fibers as well. Etiologies of SFN are discussed in subsequent paragraphs. Large fiber sensory symptoms predominate in those neuropathies in which the primary pathology is a disorder of myelin, such as Charcot-Marie-Tooth (CMT) type I or CIDP. Necrotizing vasculitis, CMT, and CIDP demonstrate prominent motor and sensory involvement. Motor neuropathies without discernible sensory or autonomic involvement are uncommon in general clinical practice. They include multifocal motor neuropathy (MMN) and toxic neuropathy due to lead or dapsone exposure. Because pain is not a prominent feature of those, they are not discussed further. Diabetic, uremic, amyloid, paraneoplastic, and certain hereditary neuropathies can have clinically significant autonomic involvement.

**Locus of pathology:** The primary locus of pathology (axon or myelin) may be inferred by clinical examination. For example, demyelinating neuropathies are often characterized by early loss of stretch reflexes even before the development of substantial muscle weakness, and by relatively preserved muscle bulk, because demyelination alone does not result in denervation, and therefore, denervation atrophy does not develop unless or
until there is secondary axonal injury. By contrast, axonal neuropathies result in relative preservation of reflexes and early atrophy of clinically affected muscles. Nevertheless, these clinical clues require confirmation by nerve conduction studies which, if interpreted correctly, provide reliable information about the primary pathologic substrate. For this reason, nerve biopsy is rarely needed to determine whether the primary pathology is axonal or demyelinating. The only common disorders of peripheral myelin are GBS, CIDP, and CMT type I.

Pain is common in some neuropathies and uncommon in others. Pain commonly manifests in neuropathies which have a predominance of small fiber involvement. There are pain descriptors that are common in painful neuropathies and less common in other painful conditions. This clinical observation has led to the development of several neuropathic pain questionnaires.\textsuperscript{3–6} The process of validating such questionnaires has resulted in the identification of several symptoms that correlate well with the presence of neurologic pathophysiologic processes that lead to pain. These symptoms include paresthesias; spontaneous ongoing pain most frequently described as burning, numbness, and shooting; and tactile allodynia.\textsuperscript{7}

The presence or absence of pain and characteristics of neuropathic pain can help the clinician identify the most likely type and etiology of a patient’s neuropathy. For example, neuropathic pain is one of the defining characteristics of SFN. Allodynia is almost universally present in postherpetic neuralgia (PHN). Severe, aching, boring pain is an essential feature of neuralgic amyotrophy (NA) and a common complaint in necrotizing vasculitis. By contrast, CMT may be associated with musculoskeletal pain, but the presence of prominent neuropathic pain would put this diagnosis in doubt. One of the neuropathic pain symptom questionnaires, whether structured or unstructured, should be included in every diagnostic evaluation for neuropathy.

**HISTORY, EXAMINATION, AND DIAGNOSTIC STUDIES**

The medical history of a patient with neuropathy should include a systematic assessment of positive and negative sensory, motor, and
autonomic symptoms. The neuropathy symptom profile instrument includes all of these. As noted previously, neuropathic pain questionnaires allow systematic and comprehensive assessment of spontaneous and stimulus-evoked positive sensory symptoms, as well as pain descriptors, in patients with neuropathic pain.

The examination of the patient with neuropathy must include bedside assessments of both large and small fiber sensory modalities.

In addition to the standard neurologic examination, several laboratory investigations have proven valuable in the assessment of neuropathy in general and painful neuropathy in particular. These include psychophysical, neuropathologic, and histopathologic investigations.

Psychophysical tests investigate the relationship between physical stimulus properties and corresponding perceptions of the stimulus. The sensory component of the standard neurologic examination is a series of psychophysical tests. The term quantitative sensory testing (QST) is often used to describe one of several psychophysical testing paradigms for quantitative determination of perception of thermal or mechanical stimuli. In addition to threshold testing, QST can be used to obtain an intensity rating in response to application of a stimulus with fixed suprathreshold predetermined properties. For example, QST can be used to establish either a thermal pain threshold or the perceived intensity of pain evoked by a thermal stimulus of fixed intensity. Like the neurologic examination, QST can be used to determine whether a subject’s sensory function is normal and, if not, the characteristics of those abnormalities. In addition, as a quantitative tool, QST can be used to monitor neuropathy and associated pain and as a tool in research.

There is growing interest in developing a standardized assessment protocol for neuropathic pain to include tests of thermal, mechanical, and even chemical sensory function, including presence and intensity of allodynia and hyperalgesia. It is the expectation that comprehensive assessments of neuropathic pain features such as these would allow clinicians to identify patterns of pain phenotypes that would reveal underlying mechanisms irrespective of the etiology of neuropathy and point to the unique treatment options of neuropathic pain for individual patient groups. This type of development would complement now-standard
neurologic examination which has proved critical for lesion localization and disease pattern recognition. Thermal hyperalgesia applying suprathreshold stimuli would be tested along with thermal sensory threshold testing, using commercially available devices. A comprehensive test of sensory thresholds, allostynia, and hyperalgesia has been designed and implemented by the German Neuropathic Pain study group. A simpler test which combines mapping of areas of allodynia or hyperalgesia with fixed stimulus intensity rating and multimodality neuropathic pain assessment has been proposed by the Neuropathic Pain Research Consortium (NPRC) in the United States. These efforts are still in their infancy and await further validation and large-scale implementation.

Neurophysiologic studies investigate the activity of electrically excitable tissues (nerve or muscle cells) either at rest, during normal activity, or in response to externally applied stimuli. The most commonly used neurophysiologic studies are nerve conduction studies and electromyography (NCS/EMG). NCS/EMG can provide objective evidence of dysfunction of large myelinated (Aβ) nerves, valuable evidence of whether the primary pathology is in the myelin or axon, and information about the distribution of disease.

One of the major limitations of NCS/EMG is that it provides no information about the functional status of small myelinated (Aδ) or unmyelinated (C) fibers. In the last two decades, the advent of immunohistochemical staining of skin biopsy tissue for evaluation of epidermal nerve fibers (ENFs) has allowed the identification of patients with normal nerve conduction studies but loss of cutaneous nerves. In most cases, there are corresponding signs of abnormal nociception and thermal perception, consisting of both sensory loss and spontaneous or stimulus-evoked neuropathic pain, although such patients likely lose large (Aβ) fibers over time as well. This syndrome is known as SFN, and the ability to diagnose it through skin biopsy has spurred tremendous interest. Because small myelinated (Aδ) fibers also innervate sweat glands, neurophysiologic quantitative assessment of the stimulated sweat gland output, by quantitative sudomotor axon reflex testing (QSART) or other methods, is also valuable to diagnose SFN. Currently, investigational approaches for the evaluation of small fiber function include
microneurography, \(^\text{22}\) laser-evoked potentials, and corneal confocal microscopy. \(^\text{23}\)

Pathologic examination of peripheral nerve trunks also plays an important role to establish the specific cause of the neuropathy, especially when vasculitis, amyloidosis, granulomatous, or neoplastic disorders are suspected. Nerve biopsy can also be used to support a diagnosis of CIDP or other chronic demyelinating neuropathies. \(^\text{24}\)

### Painful Neuropathies

There is a higher incidence of pain among some etiologic categories of neuropathy than others. In this section, we describe those common neuropathies that are often painful.

#### DISTAL SYMMETRIC POLYNEUROPATHIES

##### Metabolic Causes

**Diabetic Neuropathy**

The most readily recognized cause of distal symmetric polyneuropathy (DSP) in the developed world is diabetes. Diabetic neuropathy is often but not always painful. The prevalence of painful neuropathy symptoms in one community study of diabetics was 25% to 50%. \(^\text{25}\) All features of neuropathic pain, including mechanical allodynia, mechanical and thermal hyperalgesia, spontaneous shooting pains, and spontaneous burning, may occur. Like the sensory deficits of diabetic neuropathy, diabetic neuropathy pain presents in a length-dependent, symmetric pattern. Therefore, focal neuropathic pain in a diabetic should prompt consideration of an alternative etiology for the pain. Mononeuropathies in diabetes are discussed later under the heading “Painful Mononeuropathy Multiplex and Focal Neuropathic Syndromes.”

There is no established metabolic or genetic distinction between diabetics whose neuropathy is or is not associated with neuropathic pain, although it has been suggested that neuropathic pain often develops early in the course of nerve injury and recedes when neuropathy becomes more severe. Experimental models of diabetic neuropathy have provided evidence that pain in diabetic neuropathy is probably mediated by
pathophysiologic processes at peripheral or central nervous system (CNS) levels. Work in the streptozotocin model has demonstrated altered expression and kinetics of voltage-gated sodium; transient receptor potential cation channel, subfamily A, member I (TRPA-I); and T-type calcium channels at the axon terminals, or shaker-potassium channels in nodes of Ranvier, mediated by methylglyoxal or other metabolites. CNS mechanisms include altered descending inhibition of pain and aberrant neuroplasticity. It remains to be determined whether these mechanisms apply in people with diabetic neuropathy.

Investigation of the syndrome of SFN has revealed a disproportionate number of patients with impaired glucose tolerance (IGT), suggesting that the etiology of neuropathy in such cases is incipient diabetes and the mechanism is the same as that of diabetic neuropathy. Although appealing, this remains a hypothesis only. Many such patients also have the metabolic syndrome. Among disorders of lipids, hypertriglyceridemia in particular has been found to be prevalent in this syndrome. Conversely, there is some evidence that, among diabetics, the prevalence or severity of neuropathy is greater if other components of the metabolic syndrome are present. These observations suggest that microvascular disease exacerbates the nerve injury associated with hyperglycemia.

**Infectious Causes**

Both HIV infection and several of the commonly used highly active antiretroviral therapies (HAART) for HIV infection are associated with DSP. The two etiologies may coexist, and the neuropathies associated with them are clinically indistinguishable; therefore, initial management for DSP in a patient on HAART usually consists of a therapeutic trial of medication change or discontinuation. DSP is most closely associated with the use of dideoxynucleoside analogues stavudine (D4T), zalcitabine (ddC), and didanosine (ddI). The mechanism of this effect is believed to be the inhibition of mitochondrial DNA polymerization, leading to mitochondrial dysfunction and, in turn, reduced energy availability. DSP in HIV infection commonly presents with symptoms of small fiber involvement, with prominent pain and paresthesias. The mechanism of HIV directly on development of pain and neuropathy is unknown,
although there is some experimental evidence implicating inflammatory mechanisms triggered by infection of periaxonal Schwann cells.\textsuperscript{32}

Chronic hepatitis C virus (HCV) infection is a well-recognized cause of polyneuropathy. DSP, SFN, mononeuropathy multiplex, and cranial neuropathy can all be seen in this context. Polyneuropathy due to HCV infection is usually, but not always, associated with secondary cryoglobulinemia, and nerve biopsy often demonstrates features suggestive or diagnostic of vasculitis. Depending on the severity and time course of the condition, as well as the pathologic findings, treatment can be supportive or may include antiviral therapy, immunomodulating therapy, or both.\textsuperscript{35,36}

Lyme disease is a well-recognized cause of cranial neuropathy and polyradiculopathy. Less commonly, polyneuropathy and mononeuropathy multiplex have been described in the context of Lyme disease. Although direct infection is difficult to demonstrate, a diagnosis of peripheral nervous system Lyme disease can be inferred in the context of a subacute progressive neuropathy with clinical and serologic evidence of Lyme and clinical improvement with antibiotic therapy. Lyme radiculopathy, polyneuropathy, and mononeuropathy multiplex could all be associated with pain.\textsuperscript{37,38}

**Toxic Neuropathies**

Neurotoxic substances impair a number of neural processes such as protein synthesis, axonal transport, and myelin maintenance. Exposure to several industrial toxins is well known to lead to polyneuropathy. These usually cause motor symptoms and signs, although painful and dysesthetic symptoms may ensue in a minority of patients. Very few pathologic studies have been conducted in humans. N-hexane, a common ingredient in household glue, and methyl-n-butyl ketone, an industrial solvent, are known to cause focal swelling of axons to 2 to 3 times their normal diameter and can result in painful neuropathy.\textsuperscript{39,40}

Several pharmaceutical agents may cause painful polyneuropathy. Vincristine, taxanes, bortezomib, and the newer agents, ixabepilone and eribulin, all can cause painful polyneuropathy by interference with the function of microtubules.\textsuperscript{41} Recent evidence also implicates mitochondrial
dysfunction in chemotherapy-induced neuropathy, which will probably dictate treatment strategies for this type of painful polyneuropathy. Of particular interest are the recent descriptions of immune-mediated neuropathies related to the use of immune checkpoint inhibitors for metastatic cancers, including the cytotoxic T-lymphocyte antigen 4 inhibitor, ipilimumab, and the PD-1 inhibitors nivolumab and pembrolizumab. Treatment of those neuropathies requires not only discontinuation of the offending agent but also immunosuppression.

Many other drugs are known to cause polyneuropathies which are not always painful. Among these are isoniazid, gold, disulfiram, nitrofurantoin, amiodarone, and bezafibrate.

**Nutritional Neuropathies**

**Pyridoxine Deficiency from Isoniazid Use**

Isoniazid is an effective and inexpensive antituberculosis drug, but it is associated with distal neuropathy when administered in high doses. Patients with a genetic predisposition for slow metabolism of isoniazid are more susceptible to this adverse effect. Isoniazid interferes with essential metabolic functions of pyridoxine, leading to axonal damage. This axonopathy affects small and large fibers, causing motor deficits, sensory deficits, and pain. Pain is described as deep aching pain in calf muscles and burning paresthesias in upper and lower extremities. Oral pyridoxine in doses of 30 to 100 mg per day can prevent or reverse isoniazid neuropathy. Excessive doses should be avoided because pyridoxine itself can cause neuropathy if given in excess.

**Beriberi**

Beriberi is the most widely recognized nutritional neuropathy and is a disease of the peripheral nerves and heart caused by thiamine deficiency. If the heart is affected, it presents with heart failure (wet beriberi), but the majority of patients present with neuropathy alone (dry beriberi). Presenting symptoms are slowly progressive distal weakness, paresthesias, and pain. Rarely, beriberi develops acutely. There are multiple presentations of pain symptoms, including dull, constant ache, lancinating brief pain similar to tabes dorsalis, tightness, and burning. Unlike
idiopathic distal symmetric SFN, in beriberi, burning usually involves the hands as well as the feet shortly after onset. Physical examination reveals symmetric sensory loss across all modalities as well as positive phenomena such as allodynia, hyperalgesia, and hyperpathia as well as distal weakness and areflexia. Large fiber involvement is demonstrated by nerve conduction studies. Nutritional supplementation with thiamine is essential. With treatment, beriberi neuropathy improves slowly.

Pellagra Neuropathy
Pellagra is a nutritional disorder that when fully developed affects the skin, gastrointestinal, hematopoietic, and nervous systems. Nervous system manifestations include encephalopathy, myelopathy, and neuropathy. Neuropathy is infrequent but can be quite disabling.

Alcohol Neuropathy
It is well established that excessive and prolonged intake of alcohol is associated with a DSP which is often characterized by distal paresthesias, burning, and other features of neuropathic pain. The precise cause of alcohol polyneuropathy is unknown. For decades, the principal question has been whether alcohol polyneuropathy is due solely to deficiency of thiamine and, perhaps, other B vitamins or is due to a direct toxic effect of alcohol, its metabolites, or even other neurotoxins in alcoholic beverages. Support for a neurotoxic role of alcohol comes from an animal model of alcoholic neuropathy in which rats that are provided adequate nutritional supplementation along with alcohol develop polyneuropathy. Some interesting clinical observations support this as well. For example, alcohol polyneuropathy is prevalent among Danish alcoholics despite the fact that beer, which is the alcoholic beverage of choice in that country, is supplemented with B vitamins. In addition, an elegant series of studies of Japanese alcoholics has demonstrated that neuropathy is prevalent among alcoholics with normal serum thiamine levels and that sural nerve pathology differs between alcoholics with and without thiamine deficiency.

Neuromuscular Manifestations of Intestinal Malabsorption after Bariatric Surgery and Other Gastrointestinal Surgical Procedures
The growing use of bariatric surgery has led to resurgence in awareness of neurologic disorders associated with malabsorption, some of which can be associated with neuropathic pain. Wernicke’s encephalopathy, beriberi, and subacute combined degeneration due to vitamin B₁₂ or copper deficiency are among the neurologic disorders attributable to known deficiency states that have been described after bariatric surgery. In some cases, a presumed nutritional myeloneuropathy has been ascribed to multiple nutritional deficiencies or deficiency of an unknown nutrient in such patients. Neuropathic pain can occur in beriberi, and in subacute combined degeneration, the latter most likely as a result of an associated sensory neuropathy.

**Hereditary Neuropathies**

CMT is the most common hereditary neuropathy, with an estimated prevalence of 40 per 100,000. The clinical syndrome is a progressive symmetric length-dependent motor and sensory neuropathy. CMT differs from the length-dependent polyneuropathy seen in diabetes and most other metabolic, nutritional, and toxic disorders because, in CMT, weakness and atrophy are prominent early signs, and both upper and lower extremities are typically affected. Most forms of CMT are inherited in an autosomal dominant fashion, the exception being the X-linked form (CMTX). Neuropathic pain is uncommon in CMT, and when it occurs, it is usually not the most prominent symptom. Fatigue, neuromuscular discomfort, and aching pain from foot deformities and overuse syndromes do occur. Acute intermittent porphyria is an autosomal dominant disorder with neuropathy which may have pain as one of the presenting symptoms, but pain is always overshadowed by weakness.

**Fabry’s Disease**

Fabry’s disease is one of the few hereditary neuropathies in which neuropathic pain is the cardinal symptom. It is a multisystem disorder affecting peripheral nerves, kidneys, heart, and skin. It is inherited in X-linked recessive fashion, and its symptoms start in childhood or adolescence. The biochemical abnormality is a deficiency of α-galactosidase, a lysosomal enzyme. The estimated prevalence is about 2
per 100,000 males. The clinical features include red punctate skin lesions in the lower body and thighs, corneal opacifications, cardiac and renal failure, and polyneuropathy. Cardiac and renal failures are terminal events for these patients. The neuropathy of Fabry’s disease is characterized by continuous burning pain in the hands and feet, with spontaneous paroxysms of more severe pain. On examination, there are surprisingly modest sensory deficits, and muscle stretch reflexes are preserved. Nerve conduction studies are usually normal. In addition to pain, patients with Fabry’s disease have marked autonomic dysfunction manifesting with episodic diarrhea, vomiting, urinary retention, and diminished sweating. Gastrointestinal symptoms can be relieved with metoclopramide.49

Fabry’s disease may be unique in that it appears to exclusively affect small myelinated and unmyelinated axons, at least until such time as renal insufficiency occurs and causes a superimposed mixed polyneuropathy. This has been demonstrated pathologically by comparison of ENF density with sural nerve morphometry in the same patients. Enzyme replacement therapy has been shown to have multiple benefits, including an improvement in the Brief Pain Inventory.50,51 In a recent study of 120 patients, enzyme replacement improved proximal skin innervation only, and this effect was limited to men with preserved renal function. ENF densities and thermal thresholds remained otherwise unchanged.52 Clearly, more needs to be learned about the effect of enzyme replacement therapy on the neuropathy of Fabry’s disease.51,52

Hereditary Sodium Channelopathies

The SCN9A and SCN10A genes encode for the sodium channels Nav 1.7 and Nav 1.8, which are selectively expressed in sensory and autonomic neurons at the dorsal root ganglia. Dominant gain of function mutations in Nav 1.7 and 1.8 can lead to a number of effects including lower threshold for activation and slowed deactivation. As a result, the channel is kept open longer once activated, and normally, subthreshold stimuli can result in depolarization.53 The ultimate result is hyperexcitability and degeneration of small nerve fibers, mediated by increased sodium load and reversal of sodium–calcium exchange. The prototypical disorders described in association with SCN9A mutations are inherited.
erythromelalgia and paroxysmal extreme pain disorder (PEPD).\textsuperscript{54,55} Inherited erythromelalgia is characterized by episodic burning pain and red discoloration of hands and feet, with onset usually in the first two decades of life. The attacks can be triggered by mild warming stimuli, including exercise, and can often be ameliorated by cooling the affected limbs. PEPD is characterized by attacks of pain involving the rectum, eyes, and jaw, often associated with flushing and other autonomic disturbances. Recently, SCN9A, and more rarely SCN10A, variants were found in approximately one-third of patients labeled as having idiopathic SFN.\textsuperscript{56,57} The penetrance of those variants is not fully understood, and for that reason, they may be considered major risk factors, as opposed to penetrant causative mutations for SFN. This important discovery has led to the targeted development of small molecules that inhibit Nav1.7 or Nav1.8 channels, many of which are currently in clinical trials for various conditions associated with neuropathic pain.\textsuperscript{58}

Amyloid Neuropathy
Neuropathy is a common, early, and often prominent manifestation of amyloidosis. Neuropathy can occur in both familial and acquired amyloidosis. There are several distinct clinical groups of familial (transthyretin [TTR]) amyloidosis, but all of them have an autosomal dominant inheritance pattern. The prevalence varies greatly among ethnic groups. The initial symptoms are numbness, paresthesias, and pain in the feet and lower legs. Autonomic involvement is also common, manifesting with abnormal pupillary reflexes, miosis, anhidrosis, orthostatic hypotension, diarrhea alternating with constipation, and impotence. Cranial nerve involvement manifests late in the disease. About half of the patients have neuropathic symptoms at onset, whereas half present with cardiac, hematologic, or renal dysfunction.

Patients with familial amyloid polyneuropathy can benefit from liver transplantation\textsuperscript{59} or newly developed small molecules that function as TTR tetramer kinetic stabilizers, including tafamidis,\textsuperscript{60} which is approved in Europe. Experimental stabilization of TTR tetramer with diflunisal, and the antisense oligonucleotide patisiran, appear promising.\textsuperscript{61}
OTHER WIDESPREAD BUT NONLENGTH-DEPENDENT NEUROPATHIES

Neuropathy with Paraproteinemia

Monoclonal gammopathy, defined as the presence of a single clone of immunoglobulin (Ig) identified via serum protein electrophoresis or immunofixation, is common in the elderly. Although sometimes due to myeloma or lymphoma, monoclonal gammopathy can present in the absence of a malignant lymphoproliferative disorder and, in such cases, is referred to as monoclonal gammopathy of undetermined significance (MGUS). There is an increased prevalence of neuropathy among individuals with MGUS and an increased prevalence of MGUS among individuals with otherwise unexplained neuropathy. Despite this, with the exception of a few well-characterized specific antibody-mediated syndromes, such as the syndromes associated with IgM antibodies to the sulfated glucuronyl paragloboside epitope of myelin-associated glycoprotein (MAG-SGPG) and disialosyl antibodies, there is no compelling evidence of a causal relationship between MGUS and neuropathy. Nonetheless, the association is sufficiently common that it is prudent to obtain a serum protein immunofixation as part of the evaluation of idiopathic neuropathy and to consider that MGUS in a patient with neuropathy may represent more than a chance association.

Several clinical phenotypes, both axonal and demyelinating, have been described in neuropathy with MGUS. CIDP, a chronic acquired demyelinating neuropathy that usually responds to immune manipulation, is occasionally associated with MGUS. Distal acquired demyelinating syndrome (DADS) is an indolent syndrome of sensory ataxia, often with distal weakness, with electrophysiologic evidence of distal predominant demyelination. DADS is usually associated with an IgM monoclonal gammopathy which, in about two-thirds of cases, is directed against MAG-SGPG. Allodynia was recently reported as presenting manifestation of DADS, with good response to intravenous Ig (IVIg).

Axonal pathology is also common in MGUS neuropathy, particularly among patients with IgG and IgA monoclonal proteins. Axonal MGUS neuropathy is usually an indolent condition with prominent negative and positive sensory symptoms.
Neuropathy can be associated with lymphoproliferative malignancies as well. Perhaps most notably, polyneuropathy is part of the POEMS syndrome, an acronym which refers to polyneuropathy, organomegaly, endocrinopathy, M-spike, and skin changes. POEMS syndrome most often occurs in the setting of osteosclerotic myeloma, multiple myeloma, or angiofollicular lymph node hyperplasia (Castleman’s syndrome). The polyneuropathy in POEMS syndrome, unlike most polyneuropathies associated with MGUS, is usually progressive and disabling but does often respond to appropriate treatment of the associated lymphoproliferative syndrome. Electrophysiologic studies usually reveal a primary demyelinating pattern.\textsuperscript{66}

Neuropathic pain can occur with all paraproteinemic polyneuropathies. Although negative sensory symptoms usually predominate in acquired demyelinating neuropathies, pain and paresthesias can occur and are occasionally severe. Although speculative, it is possible that this reflects dysfunction or ectopic discharge of small myelinated nociceptors, loss of collateral inhibition of afferent input from small myelinated and unmyelinated axons, or sensitization due to the expression of inflammatory cytokines in nerve.

\section*{Autoimmune Demyelinating Neuropathies}

\subsection*{Guillain-Barré Syndrome}

GBS is an inflammatory polyneuropathy with an estimated 100,000 people developing it annually, worldwide.\textsuperscript{67} The syndrome is characterized by rapidly progressive, widespread, and often severe weakness of the limbs and cranial musculature with areflexia. Approximately 20\% to 30\% of patients require ventilatory support. Weakness reaches a nadir within 4 weeks, with substantial spontaneous recovery in the majority of patients. Nonetheless, despite a generally good prognosis for recovery of strength, many patients are left with considerable fatigue, and some with distal weakness and paresthesias.

Electrophysiologic investigations demonstrate features of demyelination, including focal motor conduction block, in most patients with GBS. This is concordant with pathologic investigations which demonstrate lymphocytic infiltration and macrophage-mediated...
Thus, until recently, the descriptive term acute inflammatory demyelinating polyradiculoneuropathy (AIDP) was considered synonymous with GBS. Occasional patients with evidence of axon loss were felt to have suffered secondary axonal injury in a fulminating demyelinating disease. In 1995, a seminal description of Chinese patients with an epidemic form of GBS without electrophysiologic or pathologic features of demyelination led to the elucidation of GBS subtypes, now referred to as acute motor axonal neuropathy (AMAN) and acute motor axonal sensory motor neuropathy (AMSAN), which appear to reflect immunologically mediated disruption of paranodal sodium channels, leading to reversible conduction failure without myelin disruption. Whether they are AIDP, AMAN, or AMSAN, all forms of GBS often develop several weeks following a systemic infection, suggesting molecular mimicry as a triggering event, but AMAN in particular is strongly associated with preceding gastrointestinal infection with Campylobacter jejuni and the subsequent development of serum IgG antibodies directed against ganglioside GM1, which are probably pathogenic. Pain has been reported to be one of the presenting symptoms in more than three quarters of patients with GBS, and in many, it precedes weakness. Pain is present throughout the course of GBS, and in half of those patients, it is rated as severe. Pain intensity upon admission does not correlate with neurologic disability. The major pain syndromes observed in GBS are back and leg pain, dysesthetic extremity pain, and myalgic extremity pain.

About two-thirds of patients experience back and leg pain at sometime during the course of GBS. This pain is usually described as a deep, aching, or throbbing pain in the low back frequently radiating to the buttocks, thighs, and occasionally to the calves. This pain may reflect root inflammation or endoneurial edema. Dysesthetic extremity pain, described as burning, tingling, or shock-like, involves the legs more frequently than the arms, and is also common in GBS. This type of pain is present in a minority of patients upon admission, although about half experience dysesthetic pain sometime during the course of the illness. It may persist indefinitely in 5% to 10%. It is postulated that neuropathic pain of this type is due to ectopic impulse formation at sites of demyelination and
axonal degeneration or regeneration.\textsuperscript{73} Myalgic extremity pain, described as aching or cramping pain, often with joint stiffness, is less frequent than radicular low back pain. This pain is most notable during the passive and active assisted exercises associated with physical therapy.\textsuperscript{72}

A recent review of pain symptoms in GBS demonstrated that backache, interscapular pain, and myalgias are most common early in the course of the disease and generally resolve during the recovery phase, whereas dysesthesias and paresthesias are more likely to persist, sometimes for months or longer.\textsuperscript{72} This is compatible with the theorized etiologies noted previously.

Pain Management in Guillain-Barré Syndrome
In a prospective study, 75\% of patients required oral or parenteral opioids to provide adequate pain relief.\textsuperscript{71} Epidural morphine has been used as an alternative to systemic opioids in ventilated patients with primarily low back and leg pain.\textsuperscript{74} In nonventilated patients in the acute stage of illness, opioid analgesics must be titrated carefully because of increased risk of respiratory depression. During the recovery phase, when muscle and joint pain is routinely precipitated by passive and active exercises, immediate-release codeine or morphine can be given an hour or two prior to treatment to facilitate compliance with physical therapy. Most patients do not require opioid analgesics beyond the first 8 weeks of illness.

A wide variety of medications used to manage neuropathic pain in other settings can be used in GBS, although caution should be taken with medications that can exacerbate hypotension or precipitate cardiac arrhythmias because of the autonomic instability which is common in GBS.

There are no controlled studies on the efficacy of any treatment of pain associated with GBS.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy
CIDP is a chronic peripheral nervous system disorder that can have progressive, relapsing-remitting, and monophasic courses. The prevalence of CIDP has been estimated at 0.8 to 1.9 per 100,000. In contrast to GBS, association with preceding viral illnesses is uncommon. Some autoimmune and infectious disorders, such as MGUS, lupus, and HIV infection, have
been associated with CIDP, but most cases are unrelated to systemic illness. The presenting symptoms are numbness and/or weakness with hyporeflexia progressing over at least 8 weeks’ time. Pain may or may not occur, but when it does, it can have any of the features of neuropathic pain. Therapy is aimed at treating the underlying disease process with immunotherapy, usually steroids or IVIg.\textsuperscript{75,76} Pain management should follow the basic principles of neuropathic pain pharmacologic therapy.

\textbf{PAINFUL MONONEUROPATHY MULTIPLEX AND FOCAL NEUROPATHIC SYNDROMES}

The conditions discussed next are commonly associated with substantial pain. About 50\% of vasculitic neuropathies are painful, and when present, the pain is usually severe, requiring treatment with multiple medications including narcotic analgesics. In addition to characteristic features of neuropathic pain, a deep, aching, boring pain is often present in peripheral nerve vasculitis. This has been attributed to infarction of vasa nervorum. Immunohistologic studies have demonstrated a correlation between neuropathic pain and the presence of cytokines in nerve biopsy specimens, and it is a common observation that the pain of vasculitic neuropathy is alleviated promptly by steroid therapy.

Like vasculitic neuropathy, the pain of NA and diabetic amyotrophy also often has a deep, aching quality and, if treated promptly, can improve with immunomodulating therapy.

\textbf{Vasculitic Neuropathy}

Vasculitis is an autoimmune disorder characterized by inflammation and necrosis of blood vessel walls. The principal primary systemic vasculitides affecting peripheral nerve include polyarteritis nodosa, Churg-Strauss syndrome, and Wegener’s granulomatosis. Peripheral nerve vasculitis also occurs as a complication of systemic inflammatory and infectious disorders, including lupus, rheumatoid arthritis, Sjögren’s syndrome (SS), progressive systemic sclerosis, chronic hepatitis C infection, and HIV infection. Peripheral nerve vasculitis can also occur in isolation. Although immunomodulation is almost always indicated, important differences exist in therapy and prognosis between the types of vasculitis, making accurate
classification important. Thus, a comprehensive general medical evaluation and serologic studies relevant to the aforementioned disorders are indicated if vasculitis is suspected. The diagnosis can only be confirmed by tissue biopsy; in cases of peripheral nerve involvement, the sural, superficial peroneal, and superficial radial nerves are most commonly studied. Ideally, a biopsy should be taken from a nerve that is affected, based on clinical and electrophysiologic criteria, but not one that has undergone severe and long-standing injury. The diagnostic histologic finding is transmural lymphocytic infiltration and fibrinoid degeneration of the medium-sized arteries in the epineurium and axonal degeneration that is nonuniform both within and between nerve fascicles.

Most patients with neuropathy due to vasculitis experience sensory loss and weakness in a multifocal pattern, although in long-standing vasculitis, the deficits can become confluent and mimic a symmetric process. In about 20% of cases of peripheral nerve vasculitis, the presentation is of a DSP at onset. When present, as it is in about 50% of cases, pain has characteristics of acute neuropathic pain as well as a continuous deep, aching pain.

The primary treatment goal in vasculitic neuropathy is control of the underlying disease process. This usually requires prompt and aggressive immunotherapy with corticosteroids and, in some circumstances, other immunomodulatory agents such as cyclophosphamide. The pain associated with necrotizing vasculitis is different in character and pathogenesis than the neuropathic pain associated with nonvasculitic neuropathy. A combination of opioids and other medications indicated specifically for neuropathic pain is usually required in this setting.

**Neuralgic Amyotrophy**

NA usually manifests as sudden, severe, deep aching pain in the shoulder girdle and proximal upper limb, followed within days to weeks by marked atrophy and weakness and relatively modest sensory loss. Weakness can be isolated to the distribution of one or two nerve trunks only and can include nerves, such as the phrenic nerve, which involve the upper body but not the upper limb per se. Commonly affected nerves include the long thoracic, suprascapular, phrenic, musculocutaneous, and anterior...
interosseous. NA can occur at any age and is more common in men than women. It is also known as idiopathic brachial neuritis and as Parsonage-Turner syndrome. The etiology of this syndrome is not established, although the following clinical observations suggest that it may be disimmune. First, NA often follows a viral infection, as is the case in GBS. Second, NA often begins with severe focal pain followed by atrophy and weakness, as is often the case in vasculitic neuropathy. Third, NA is a mononeuropathy multiplex, which is the most common pattern seen in peripheral nerve vasculitis. Careful clinical and electrodiagnostic examination often reveals differential fascicular involvement within a nerve trunk. The natural history of NA is of very gradual improvement over the course of 1 to 2 years, as axonal regeneration occurs. Empiric immunotherapy is occasionally used. It is our impression that steroid therapy accelerates recovery and pain relief, but this has not been evaluated systematically. 78, 79

Pain in NA is usually described as deep, aching, and severe. It is made worse with movements of the affected limb, and as a result, patients often avoid movement at the shoulder joint, resulting at times in a secondary adhesive capsulitis (frozen shoulder). Deep aching pain generally improves over a matter of weeks but can persist and can be followed by painful paresthesias and dysesthesias. Residual weakness and pain can occur. A hereditary form, known as hereditary neuralgic amyotrophy (HNA), has been identified and may represent a substantial proportion of cases. 80 HNA is inherited in an autosomal dominant fashion and has been linked to a mutation in the SEPT9 gene, which is responsible for the formation of a possible cytoskeletal protein. 81

**Diabetic Amyotrophy**

Like NA, diabetic amyotrophy is a well-recognized syndrome characterized by sudden, severe pain, usually in the proximal segment of the limb, followed shortly thereafter by striking atrophy and weakness. Unlike NA, diabetic amyotrophy usually affects the lower limb, although similar presentations involving the upper limb have been described. Also unlike NA, and as indicated by the name, diabetic amyotrophy occurs almost exclusively in diabetics, although an identical syndrome has been
described in patients with IGT. This syndrome is also known as the Bruns-Garland syndrome and as diabetic lumbosacral radiculoplexus neuropathy, which describes the postulated localization of the pathology. Biopsy of proximal cutaneous nerves has demonstrated features of microvasculitis. In keeping with this, there is extensive anecdotal evidence of prompt resolution of pain, and possible acceleration of recovery, after immune manipulation with steroids or IVIg.

Other Diabetic Mononeuropathies
All health care providers should also be familiar with diabetic mononeuropathies because of their clinical management implications as well as the striking pain associated with these conditions. In addition to inducing a predisposition to entrapment neuropathies, diabetes is associated with several acute, painful mononeuropathies or focal neuropathic syndromes affecting cranial nerves (third, fourth, sixth, seventh), roots (thoracic radiculopathy), and root/plexus (diabetic amyotrophy). In addition, a multifocal polyneuropathy (“diabetic mononeuropathy multiplex”) can occur in the setting of diabetes. There is published evidence, supported by biopsy material, that several of these diabetic mononeuropathy syndromes are vasculitic. Recognizing clear risks associated with both treatments in this population, there is also anecdotal evidence that immunotherapy with steroids or Ig infusions may accelerate pain relief and possibly recovery of function in diabetic focal neuropathies.

SENSORY NEURONOPATHIES
The following conditions are believed to reflect pathology in the cell bodies of sensory neurons. PHN follows reactivation of a viral infection, whereas the others are believed to represent primary disimmune processes. In all cases, neuropathic pain is often the principal symptom. The high prevalence of neuropathic pain in sensory neuronopathies may be attributable to the presence of an inflammatory process in relative proximity to the dorsal horn of the spinal cord.

Postherpetic Neuralgia
PHN is one of the most common and disabling neuropathic pain states. Epidemiologic surveys estimated the incidence of herpes zoster at 4.1 per 1,000 person-years, with PHN developing in 18% of cases.\textsuperscript{85} Herpes zoster is due to a reactivation of varicella-zoster virus (VZV), which remains sequestered and clinically dormant in cells of sensory ganglia after an initial infection but becomes reactivated in the context of age-related or disease-related reduction in cell-mediated immunity to the virus. There is some evidence of persistent active infection in patients with PHN. PHN is presumed to be due to sensitization of nociceptors and central sensitization after herpes zoster. PHN is more likely to occur in patients with pain associated with acute zoster and patients with zoster affecting multiple dermatomes. There is a positive correlation between age at the time of developing herpes zoster and the likelihood of developing PHN.\textsuperscript{86,87} Several studies have demonstrated that antiviral treatment of herpes zoster substantially reduces the risk of developing PHN and the duration of PHN if it develops.\textsuperscript{88–90} PHN is described in greater detail in Chapter 27.

\textbf{Sjögren’s Syndrome}

SS is a systemic autoimmune disorder. The cardinal features are sicca syndrome, supported by objective evidence of diminished tear production, salivary gland inflammation, and serologic evidence of antibodies highly correlated with this disorder.\textsuperscript{91} SS is commonly associated with disease of both the peripheral system and CNS. The range of neurologic disorders that have been associated with SS is remarkably broad, including multiple sclerosis-like cerebral disorders, myelopathy, polyradiculoneuropathy, sensory neuronopathy, vasculitic mononeuropathy multiplex, and myositis.\textsuperscript{92} The peripheral nervous system disorders for which the association with SS is clearest are sensory neuronopathy and vasculitic neuropathy. In patients with SS, sensory neuronopathy can present with sensory ataxia, neuropathic pain, or both, presumably reflecting the relative involvement of large and small sensory neurons. Sensory neuronopathy from SS is usually an indolent, progressive condition.\textsuperscript{92–94} Evidence of response to immunotherapy is anecdotal. Disimmune sensory neuronopathy can occur as an idiopathic phenomenon as well.

As with other systemic autoimmune conditions, necrotizing peripheral
nerve vasculitis from SS is a rapidly progressive, disabling, and commonly painful condition which nonetheless does respond to immunotherapy.

**Paraneoplastic Sensory Neuronopathy**
Paraneoplastic sensory neuronopathy is one of several paraneoplastic syndromes associated with the presence of anti-Hu antibodies which is encompassed under the rubric of paraneoplastic encephalomyelitis. The predominant clinical syndrome is a sensory ataxia rather than neuropathic pain. Paraneoplastic sensory neuronopathy may respond to treatment of the tumor and, occasionally, immunomodulating therapy, but the prognosis is nonetheless poor.95

**Toxic Neuronopathy**
Cisplatin is an antineoplastic agent known to cause sensory loss and neuropathic pain. The pathophysiology is felt to be disruption of mitochondrial DNA synthesis resulting in a sensory neuronopathy.96

**Treatment of Painful Neuropathies**

**GENERAL PRINCIPLES OF THERAPY**
Treatment of neuropathy and neuropathic pain is complementary. Treatment of neuropathy is targeted at the underlying disease process. Such therapy should be administered as soon as possible to control or even reverse the process responsible for neuropathy and neuropathic pain. Nevertheless, in the authors’ experience, patients commonly report persistent neuropathic pain even after stabilization or reversal of neuropathy. This is particularly true in vasculitic neuropathy, where progressive weakness and sensory loss can be aborted with steroid therapy, but pain often persists even years after resolution of necrotizing vasculitis. Assuming that inflammation and injury in peripheral nerve terminals has stabilized or receded in these cases, this observation might be attributable to central sensitization.

**ANALGESIA THERAPY: GUIDELINES FOR PHARMACOTHERAPY**
Treatment of neuropathic pain should begin as soon as possible and in tandem with treatment of neuropathy. Postulated mechanisms of neuropathic pain and neuropathic pain pharmacotherapy are addressed in other chapters. Here, we address treatment of painful neuropathy in particular.

Diabetic neuropathy is the most prevalent painful neuropathy in developed countries and has therefore been most widely studied as a target for treatment of neuropathic pain from neuropathy. It follows, therefore, that most clinical trial data regarding efficacy of analgesic treatments in painful neuropathy were obtained in patients with diabetic neuropathy pain. There is little formal evidence that these data apply to neuropathic pain from other etiologies.

Primary outcome measures of most large clinical trials are overall change in pain severity and improvement in quality of life indicators. There is a growing recognition that clinical trial design in neuropathic pain should also include systematic evaluation of individual neuropathic pain symptoms and signs. Thus, there is potential utility in the systematic evaluation of the effect of treatments on specific neuropathic pain symptoms, such as paresthesias, dysesthesias, and burning; neuropathic pain descriptors, such as sharp, dull, stabbing, or exhausting; and neuropathic pain signs, such as dynamic mechanical allodynia, punctate hyperalgesia, thermal allodynia, and thermal hyperalgesia. It is not clear at present whether it is better to ask the question “Which treatment is best for neuropathic pain from this disease?” or, rather, “Which treatment is best for this neuropathic pain symptom/sign complex?” Implied in the latter is the hypothesis that pain symptoms and signs inform us about the principal mechanisms of pain in a given individual, which in turn may match the mechanism of action of a particular treatment.

For now, however, evidence-based treatment of neuropathic pain from neuropathy is based largely on evidence of reduction in overall pain severity in diabetic neuropathy and few other conditions, and practitioners are obliged to extrapolate from these data. Most large clinical trials in this arena are industry-supported pivotal trials of the agent in question against placebo. There is very little evidence comparing treatments against each other. One way to try to make such a comparison is by comparing the
number needed to treat (NNT), defined as the average number of individuals that must be treated with a medication to obtain a defined degree of pain relief in one subject. NNT takes into consideration treatment failures for any reason, both lack of efficacy and lack of tolerability. Although NNT is usually based on 50% improvement, it has been shown that 30% improvement in pain severity or a reduction in pain severity by at least 2 points on a 0-to-10 Likert scale is clinically meaningful. The medication classes with the best evidence for efficacy in the management of neuropathic pain are tricyclic agents (TCAs), α₂δ ligands, serotonin and norepinephrine reuptake inhibitors (SNRIs), and opioids. Tramadol and tapentadol, which are believed to both inhibit serotonin and norepinephrine reuptake and act as μ-opioid agonists, have demonstrated efficacy as well.

**Tricyclic Agents**

TCAs are believed to derive their analgesic effect from serotonin and norepinephrine reuptake inhibition as well as sodium channel blockade. The benefit is independent of an antidepressant effect. Most undesirable effects from this class derive from its anticholinergic properties. TCAs have been demonstrated to be beneficial in relieving neuropathic pain from diabetic neuropathy in several small series. A recent Cochrane review found an overall class NNT of 3.6 for moderate pain relief among 17 studies of TCAs for neuropathic pain. TCAs should be used with caution in patients at risk for cardiac arrhythmias because they can prolong the QTc interval. The most common side effects of the tricyclics are due to their anticholinergic activity and include constipation, dry mouth, blurred vision, cognitive changes, tachycardia, and urinary hesitancy. Sedation and weight gain may occur from antihistaminergic activity. α-Adrenergic receptor blockade may result in orthostatic hypotension. All of these potential side effects can be minimized by slow titration. Nortriptyline and desipramine are better tolerated than their parent drugs, amitriptyline and imipramine. Contraindications to the tricyclics include closed-angle glaucoma, benign prostatic hypertrophy, and acute myocardial infarction.

Treatment with a tricyclic should be initiated with a dose of 10 or 25 mg...
a few hours before bedtime to minimize daytime sedation. The lower 10-mg dose should be prescribed for the elderly, frail, or side effect–prone patient. The dose is titrated by one tablet, 10 or 25 mg, every 7 days if the patient has poor pain relief and does not complain of intolerable side effects. The majority of patients will report significant pain relief or intolerable side effects within the dose range of 30 to 150 mg. The mean dose of amitriptyline that often results in pain reduction is 75 to 150 mg per day. Onset of the analgesic effect occurs within 1 to 2 weeks and peaks around 4 to 6 weeks. \textsuperscript{104,105} Improvement in sleep, mood, and anxiety can augment the benefit of pain control.

\textbf{α\textsubscript{2}δ Ligands}

Mechanical allodynia in neuropathic pain is believed to be mediated in part by increased expression of N-type calcium channels in the central terminals of primary afferent neurons, resulting in pathologically enhanced neurotransmission in the dorsal horn. Gabapentin and pregabalin are chemically related compounds that have been shown to have a modulatory effect via binding to the α\textsubscript{2}δ subunit of the calcium channel. Several studies have demonstrated that gabapentin alleviates diabetic neuropathy pain at doses ranging from 900 to 3,600 mg per day, with a combined NNT for 50% pain relief of 2.9. Two small series comparing gabapentin with amitriptyline demonstrated improvement in pain ratings with both drugs, and no statistically significant difference in benefit between them. \textsuperscript{106,107} It should be noted, however, that serious adverse events can occur with amitriptyline and are virtually unknown with gabapentin. Gabapentin can cause weight gain, reversible cognitive symptoms, and peripheral edema.

Gabapentin bioavailability is limited because absorption from the gastrointestinal tract is dependent on a single saturable active transport mechanism. Pregabalin shares gabapentin’s presumed mechanism of action but demonstrates more linear kinetics than gabapentin. Presumably for this reason, pregabalin is absorbed more quickly and demonstrates more linear kinetics than gabapentin. Pregabalin has been shown to be effective in relieving the pain of diabetic neuropathy, with NNTs for 50% pain relief of 3.4 and 3.3 for the 300 mg per day and 600 mg per day.
Like gabapentin, pregabalin can cause cognitive side effects which are usually mild to moderate in severity as well as weight gain and peripheral edema.

Serotonin and Norepinephrine Reuptake Inhibitors
Serotonin and norepinephrine reuptake inhibition is believed to alleviate neuropathic pain by facilitating descending inhibition of afferent pain signaling. This descending inhibition is mediated by neurons of the rostroventral medulla. It is believed that both neurotransmitters are important in this pathway, which may explain the observation that selective serotonin reuptake inhibitors (SSRIs) alone are of little benefit in alleviating pain from neuropathy. Duloxetine, an SNRI with relative balance between serotonergic and noradrenergic effects, has demonstrated efficacy in relieving pain from diabetic neuropathy, with an NNT for 50% pain relief of 4.3 at a dose of 60 mg per day and 3.8 at a dose of 120 mg per day. Venlafaxine, an SNRI with balanced pharmacology at high doses, has also been shown to be beneficial, with an NNT of 4.5 for 50% pain relief in the 150- to 225-mg dose range. SNRIs can cause nausea, hyperhidrosis, and sexual side effects in some patients. Although they do not have substantial anticholinergic properties, they can cause some symptoms of dry mouth and dizziness, possibly on a noradrenergic basis; however, these effects are probably less frequent or severe than with tricyclic medications. Combining SNRIs with other serotonergic agents, including other antidepressants, triptans, and tramadol, should be done with caution because of the risk of serotonin syndrome. SNRIs are also known to inhibit the metabolism of other antidepressants, thus substantially increasing blood levels of such drugs when they are used in combination. For these reasons, it is usually best to avoid the use of SNRIs with other antidepressants and to consider using one SNRI or TCA alone to treat both pain and depression if treatment of both conditions is indicated.

Opioids
Opioids strongly inhibit central nociceptive neurons mainly through interaction with µ-opioid receptors, producing neuronal membrane
hyperpolarization. Although controlled-release oxycodone has been shown to reduce pain from diabetic neuropathy in two small randomized controlled trials, with an NNT for moderate pain relief of 2.6,\textsuperscript{112,113} complications of chronic opioid use, including dependence, tolerance, and hyperalgesia, have led to substantial morbidity and mortality among users of opioids for noncancer pain in the last two decades. Systematic review of evidence does not support or refute long-term use of opioids for treatment of neuropathic pain.\textsuperscript{114} However, a recently published large population study showed that patients using opioids for polyneuropathy pain had lower self-reported functional outcome scores compared to users of nonopioid medications.\textsuperscript{115} These facts have led to a substantial reduction in opioid prescriptions for neuropathic pain in recent years, along with increased monitoring of prescriptions and stricter mandates for training of prescribing providers by federal agencies. Particular caution is required in patients with pulmonary disease. Prophylactic treatment of common side effects such as nausea or constipation can improve patient compliance.

**Tramadol and Tapentadol**

Tramadol and tapentadol are both inhibitors of serotonin and norepinephrine reuptake and μ-opioid agonists. Both have been shown to effectively alleviate pain in diabetic neuropathy.\textsuperscript{116–118} They are available in immediate- and extended-release formulations.

**Other Pharmacologic Agents**

Several other agents approved for the treatment of epilepsy have demonstrated limited evidence of efficacy in the management of pain from neuropathy. These include oxcarbazepine, which has demonstrated benefit in one randomized controlled study in diabetic neuropathy pain, lamotrigine, and topiramate, both agents which have demonstrated conflicting results in randomized controlled trials for pain from diabetic neuropathy.\textsuperscript{119–123} Despite limited evidence of efficacy, these have all been used on occasion as second- or third-line agents for patients who have not responded to or tolerated other treatments. Carbamazepine, which is approved for pain from trigeminal neuralgia, has been found to be effective in two double-blind, placebo-controlled studies for control of
pain in diabetic neuropathy\textsuperscript{124,125} Prior to the availability of many of the aforementioned agents for neuropathic pain management, phenytoin was shown to be effective in controlled trials of pain from diabetic polyneuropathy\textsuperscript{126} and pain in Fabry’s disease.\textsuperscript{127} Phenytoin is no longer commonly used to treat pain due to neuropathy.

Bupropion, a unique agent which inhibits norepinephrine and dopamine uptake, has shown benefit in one study involving pain from a variety of neuropathy etiologies.\textsuperscript{128}

Acetyl-L-carnitine (ALC) is believed to have several potentially neuroprotective properties that have led to extensive study of this agent as a treatment for diabetic, HIV, and chemotherapy-induced neuropathy.\textsuperscript{129–131} It also has analgesic properties. ALC has been administered at doses between 1 and 3 g per day. α-Lipoic acid, a potent antioxidant, has also been studied as a potential treatment of both diabetic neuropathy and diabetic neuropathy pain. The recently completed SYDNEY 2 trial showed that daily oral therapy at a dose of 600 mg per day, the lowest dose yet studied, reduced the neuropathy total symptom score by 50% or greater with an NNT of 2.8.\textsuperscript{132,133}

**Cannabinoids**

In the last decade, the use of cannabis and selective cannabinoids (synthetic cannabinoids containing only tetrahydrocannabinol [THC] and cannabis-based medicinal extracts containing a combination of THC and cannabidiol [CBD]) has gained popularity for the treatment of neuropathic pain. Cannabinoid receptors, CB1 and CB2, are linked to pain modulation, whereby activity at these receptors causes inhibitory effects on pain responses.\textsuperscript{134,135} Furthermore, endocannabinoids have been shown to interact with other receptor systems including γ-aminobutyric acid (GABA), serotonergic, adrenergic, and opioid receptors, many of which are involved in the analgesic mechanisms of neuropathic pain drugs. A recent elegant meta-analysis of 11 randomized controlled trials including a total 1,219 patients, showed that patients who received selective cannabinoids reported a significant, but clinically small, reduction in mean numerical rating scale pain scores compared with placebo groups (−0.65 points; $P = .002$). Use of selective cannabinoids was also associated with
improvements in quality of life and sleep with no major adverse effects. Major limitations of the studies included variability in quality of reporting, etiology of neuropathic pain, and type and dose of selective cannabinoids. Larger randomized controlled trials, with better control of the aforementioned variables, as well as regulatory changes, would be needed before cannabinoids can become standard of care for the management of painful neuropathies.

Topical Agents
Capsaicin stimulates the release of substance P from small-caliber primary afferent neurons and is believed to alleviate neuropathic pain with regular use by exhausting stores of substance P. Capsaicin also causes prompt epidermal denervation so reliably that capsaicin denervation has become an important human model of neuropathy. Although capsaicin can alleviate neuropathic pain with sustained use, it also causes considerable burning discomfort which limits its use. A high-potency capsaicin patch is presently undergoing clinical trials and demonstrated efficacy and safety for treatment of pain in DPN.

Topical lidocaine, a local anesthetic which acts via sodium channel blockade, has been approved for the treatment of PHN. It is used on occasion to treat cutaneous pain from other neuropathic conditions as well. Systemically administered lidocaine, mexiletine, and tocainide have also been demonstrated to have analgesic effects for control of diabetic neuropathic pain and in PHN. Systemically administered local anesthetics block ectopic discharges due to experimental peripheral nerve injury and in axotomized dorsal root ganglion cells of the peripheral nerves, probably by blocking sodium channels. In addition, there is evidence that lidocaine and similar local anesthetics have actions on G protein-coupled receptors that can result in long-lasting modulation of pain via effects both on sensitization and on the immune response to nerve injury.

Principles of Pharmacotherapy for Pain from Neuropathy
Polypharmacy is common in the treatment of pain from neuropathy for several reasons. First, neuropathy pain can be treated with several classes
of agents, with different postulated mechanisms of action. Second, on a more practical level, there is (fortuitously) relative compatibility among these medication classes. And finally, despite evidence that these treatments are generally efficacious, it is uncommon to achieve complete or even adequate pain relief with a single agent, although it is common to encounter significant adverse effects. Therefore, one usually begins with slow upward titration of one of the first-line drugs (SNRIs, $\alpha_2\delta$ ligands, or tricyclics), followed by the addition of another first-line agent (but generally not an SNRI with a tricyclic) if pain relief is inadequate at the highest tolerated dose of the first drug. Because these are generally chronic conditions, there is no need to titrate faster than tolerability will permit. Opioids or tramadol is often used as third-line agents or as rescue drugs and are particularly helpful for patients who can predict an increase in pain after a physically active day. Topical and nonpharmacologic treatments are particularly valuable as add-on therapy for patients who do not tolerate medication well. Cognitive-behavioral therapy, discussed in Chapter 84, can be very helpful because it is often the distress associated with pain, sometimes more than the pain itself, that causes pain-related disability.

**Unresolved Questions**

There are a number of unresolved questions in the evaluation and management of painful neuropathies. First, the pathophysiologic mechanisms responsible for the wide variety of painful neuropathy symptoms remain inadequately understood. Second, it is not known whether treatment of neuropathic pain influences the natural history of neuropathy or even whether successful treatment with an analgesic medication alters the natural history of pain. There is also insufficient evidence to guide duration of therapy. For example, do patients who report significant pain relief with a certain medication need to be treated with that particular medication at that dose indefinitely? Most pivotal clinical trials in this field run for about 12 weeks’ duration, which is woefully inadequate in the context of conditions that usually persist for years.

Much of our understanding of mechanisms, such as ectopic and ephaptic transmission, neurogenic inflammation, descending modulation, and
Peripheral and central sensitization, comes from animal models that do not mimic human neuropathies. A better understanding of mechanism in humans will likely require systematic investigation of pain in people with neuropathy. Just as the diagnosis and management of conditions causing neurologic deficit rely on an ever more sophisticated clinical/laboratory/radiographic correlation, so too the management of pain from neuropathy must advance with the help of evidence gleaned in a systematic fashion from neuropathic pain questionnaires; neuropathic pain examinations; and relevant imaging, pathologic, and laboratory tools.

Complex regional pain syndrome (CRPS) is the current taxonomy for the syndrome previously known by various names, including reflex sympathetic dystrophy (RSD), causalgia, Sudeck’s atrophy, shoulder–hand syndrome, neuro-algodystrophy, and reflex neurovascular dystrophy, etc. It was originally recognized as a distinct pain syndrome seen among Union veterans of the War Between the States following traumatic nerve injury (“causalgia”).

It is an extremely heterogeneous disease with inflammatory, autoimmune, sympathetic, and neuropathic features that change over time. It is usually a chronic disease that involves a full measure of biopsychosocial features, and it can be significantly disabling.

Epidemiology

Epidemiologic data regarding CRPS in the general population are limited, although three large-scale studies are available. Sandroni et al. reported an incidence of 5.46 new cases of CRPS type I per 100,000 annually (see Table 25.1 for distinction between type I and type II). A larger study reported an incidence as high as 26.2 new cases per 100,000 annually. Based on this reported incidence, over 50,000 new cases of CRPS type I could be anticipated annually in the United States alone. However, both of these studies used the 1994 International Association for the Study of Pain (IASP) diagnostic criteria. These results may be inflated as the new 2012 IASP criteria, being more objective, have been demonstrated to reduce diagnostic rates by about 50% when compared to the old 1994 IASP criteria. Most recently, a retrospective analysis from a Nationwide Inpatient Sample Database during 2007 to 2011 demonstrated 22,533 patients with a discharge diagnosis of CRPS type I sampled from 33,406,123 patients. Based on these data, the general prevalence of CRPS

1177
type I in an inpatient environment could be 67.4 cases per 100,000 patients. However, these numbers are limited to an inpatient environment and should not be generalized to patients or healthy individuals in an outpatient setting. Further, there was no relevant data indicating what criteria were used to make the diagnosis leaving validity of the diagnostic coding uncertain. For physicians making pain diagnoses, the incidence of CRPS in relevant at-risk populations (e.g., postfracture) may be more clinically relevant. Three recent large-scale prospective studies examine the incidence of CRPS postfracture. Beerthuizen et al. reported an incidence of 7.0% from 596 patients after acute fracture of the wrist or ankle and receiving conventional treatment. The highest rate of incidence occurred at about 3 months after the fracture. Moseley et al. reported an incidence of 3.8% within 4 months of a wrist fracture in 1,549 patients. Bullen et al. reported an incidence of 0.3% within 3 months of ankle fracture or postoperative treatment of ankle fracture in 300 patients. Several smaller prospective studies suggest that acute CRPS type I may develop in up to 11% to 18% of patients following fracture or total knee arthroplasty, although most cases resolve relatively quickly with conservative care.
1. The presence of an initiating noxious event or a cause of immobilization
2. Continuing pain, allodynia, or hyperalgesia with which the pain is disproportionate to any inciting event
3. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain
4. This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

Type I: without obvious nerve damage (aka “reflex sympathetic dystrophy”)
Type II: with obvious nerve damage (aka “causalgia”)

Based on available epidemiologic data, fractures and sprains may be the most common events triggering CRPS. CRPS appears to be more common in the upper extremities, is more common in females, and is most likely to occur in the 50 to 70 years age range.\(^2\),\(^3\)

Pathophysiology

CRPS remains one of the most enigmatic and difficult to treat of all pain conditions. Although good clinical characterizations started to appear in the literature in the late 1800s,\(^1\) a definitive pathophysiology remains to be determined, and it may be that there are a collection of distinct pathophysiologies, early or late, that are currently grouped under the rubric of CRPS. This lack of a precise, singular mechanism partially explains the relative lack of clinical progress to date.\(^14\) There is a great deal of discussion now of identification of clinically relevant subsets, both pathophysiologically and diagnostically. In the following section, animal and human models that have relevance to understanding CRPS are first described and then several pathophysiologic mechanisms that may contribute are reviewed.

ANIMAL MODELS

There are several animal models that may shed light on the mechanisms of CRPS, albeit indirectly. However, as always, one must be cautious...
extrapolating from animal models to human syndromes. The most useful animal model, best paralleling CRPS type II (causalgia) in which major nerve injury is a key feature, is the chronic constriction injury model in rat that was first described by Bennett and Xie. This model produces some behavioral features (e.g., guarding, disuse, vasomotor disturbance) that mimic some of the features of human CRPS (e.g., allodynia, hyperpathia, spontaneous pain) as well as some of the sympathetic abnormalities. This model has been utilized in the preclinical screening of pharmacologic interventions for CRPS. Another model that may be useful is the spinal nerve injury model, although there is some controversy as to whether this model actually produces “sympathetically maintained pain” (SMP) and how similar the resulting pain syndrome is to human CRPS. A third model, involving partial ligation of the sciatic nerve, may also have some relevance to human CRPS type II. All three models likely generate ectopic activity at the site of injury and/or the dorsal root ganglion (DRG) which may (or may not) be responsive to sympathetic outflow and which may cause/maintain central sensitization. These models also result in various other phenomena putatively related to CRPS, such as sprouting of fibers in lamina II of the dorsal horn. All of the aforementioned models appear most relevant to understanding CRPS type II, although two less widely used models may be relevant to understanding CRPS type I (no major nerve injury evident). Models using tetanic electrical stimulation and an ischemic reperfusion injury appear to produce a syndrome that mimics some of the features of CRPS type I in the absence of signs of major nerve injury. These animal models may help somewhat in understanding mechanisms of CRPS, but their ultimate value may be in screening pharmaceutical interventions.

HUMAN MODELS
Intracutaneous injection of capsaicin induces burning pain and cutaneous mechanical hypersensitivity (allodynia) and as such may represent a useful model to study certain features of CRPS. The capsaicin model demonstrates the impact of intense nociceptive stimulation of normal skin with the rapid development of areas of primary and secondary hyperalgesia, alldynia, wheal, and flare peripheral sensitization. This
model results in hyperalgesia to suprathreshold heat within the capsaicin-induced secondary hyperalgesic skin despite the absence of changes in heat pain threshold. Another interesting human model of CRPS-like pain is the controlled heat injury model, which also leads to a zone of secondary hyperalgesia to suprathreshold heat. These models and other lines of evidence corroborate a primary role of central sensitization in CRPS; however, the overlapping regions of flare/vasodilatation and hyperalgesia may also suggest peripheral sensitization. Peripheral sensitization likely has a significant role in clinical CRPS. Polymodal C receptors may mediate the temperature allodynia, polymodal A receptors the pinprick hyperalgesia, and Aβ receptors the mechanical allodynia in these models. Whole-body cooling (to induce sympathetic activation) and sympathetic block have shown no effects on features of either the capsaicin or heat injury models, although phentolamine (an adrenergic antagonist) reduces the area of allodynia in the capsaicin model. Given these mixed findings, the value of these models in understanding interactions between sympathetic nervous system (SNS) activity and pain in CRPS remains uncertain. Although some features of these models are concordant with signs and symptoms of CRPS, the usefulness of these normal nociception models in unraveling disease specific mechanisms in CRPS is limited to date. As with animal models, a primary use of these human models may be in the testing of certain interventions for CRPS.

INFLAMMATION
Clinical evidence indicates that some features of acute/early CRPS often attributed exclusively to sympathetic hypofunction (i.e., vasodilatation, swelling, and edema) could perhaps be better explained by an exaggerated localized inflammatory process. Sudeck was the first to propose this, along with a “patchy inflammatory osteoporosis,” and Goris revitalized this idea. Consistent with inflammatory mechanisms, one experimental study demonstrated that 82% of “acute” CRPS patients exhibited a progressive accumulation of immunoglobulin in the affected extremity relative to the unaffected extremity compared to only 17% of “chronic” CRPS patients (in this study, Oyen et al. defined chronic as 5 months or more since onset). Analyses of joint fluid and synovial biopsies in CRPS
patients have shown an increase in protein concentration, synovial hypervascularity, and neutrophil infiltration.\textsuperscript{42–44} Free radicals, suspected to play a prominent role in inflammation and ischemic damage, recreate acute CRPS symptomatology in a rat model (vasomotor abnormalities, edema, and pain behavior), and this is the partial rationale for some investigators recommending free radical scavengers in acute CRPS patients.\textsuperscript{45} Eisenberg et al.\textsuperscript{46} demonstrated an increase in antioxidant levels in saliva and serum for 31 CRPS type I patients compared to 21, and they suggest these lab markers could be utilized as a potential screening tool for CRPS. From these lines of evidence, it is logical to conclude that an inflammatory component is likely in CRPS type I, particularly in the early phase.\textsuperscript{45,47} A shift toward a pro-inflammatory cytokine profile in patients with CRPS suggests a potential pathogenic role for these compounds in the generation of pain and other symptoms.\textsuperscript{48} In plasma, no alterations in inflammatory mediators were observed in CRPS patients. However, in “blister fluid” obtained in the region of CRPS pain, significantly higher levels of interleukin (IL)-6 and tumor necrosis factor-α (TNF-α) were observed in the involved extremity relative to the uninvolved extremity.\textsuperscript{49} Wesseldijk et al.\textsuperscript{50} demonstrated the differences in levels of TNF-α and IL-6 of 12 CRPS type I patients are significantly decreased in blister fluid 6 years, compared to levels taken at 6 and 30 months, after their initial event. In addition, significantly elevated CSF levels of pro-inflammatory cytokines (IL-1β, IL-6) have been shown in CRPS patients compared to healthy controls and those with other types of pain.\textsuperscript{48} Results to date do not support genetic factors as determinants of the cytokine profile that may contribute to CRPS.\textsuperscript{51} Mast cells might also be involved in inflammatory reactions observed in CRPS type I and probably play a role in the production of proinflammatory cytokines such as TNF-α.\textsuperscript{49}

Some evidence suggests that “neurogenic inflammation” is facilitated in CRPS patients. Transcutaneous electrical stimulation caused increased axon reflex vasodilatation and provoked protein extravasation only in CRPS patients, whereas it resulted in decreased axon reflex vasodilatation in healthy controls.\textsuperscript{52} Animal studies demonstrate that the SNS can influence the intensity of an inflammatory process.\textsuperscript{53–56} In human pain models, sympatholytic procedures can reduce pain, inflammation, and
edema.\textsuperscript{57,58}

**IMMUNOLOGIC FACTORS**

There has been a recent emphasis on immunologic factors being associated with the pathophysiology of CRPS.\textsuperscript{59–61} A possible autoimmune etiology of CRPS in some cases has also been proposed, and autoantibodies against nervous system structures have been described in some patients.\textsuperscript{62} Kohr et al.\textsuperscript{63} demonstrated autoantibodies from the serum of CRPS patients binding to autonomic neurons including sympathetic and myenteric plexus neurons compared to controls. They subsequently reported CRPS autoantibody binding against β2-adrenergic receptors and muscarinic-2 receptors.\textsuperscript{64} Dubuis et al.\textsuperscript{65} conducted a study reporting binding of long-standing (at least 6 months) CRPS patient autoantibody binding to α-1A receptors compared to controls. Interestingly, they noted that CRPS patients who had pain relief from an earlier trial of immunoglobulin treatment all had the binding CRPS autoantibody.\textsuperscript{65}

Autoantibodies from CRPS serum incubated with endothelial cells, smooth muscle cells, and osteoblasts have been demonstrated to produce changes that could explain the clinical signs of CRPS.\textsuperscript{66} Têkus et al.\textsuperscript{67} conducted a study where they injected mice with immunoglobulin G (IgG) from CRPS patients prior to making a hind limb muscle incision and reported the mice developing CRPS clinical signs including mechanical hyperalgesia and edema compared to mice injected with IgG from healthy subjects of saline. Reilly et al.\textsuperscript{68} demonstrated CRPS IgG binding to DRGs when they are incubated with inflammatory mediators representing an “inflammatory soup.” However, this did not occur without preincubation from inflammatory mediators.\textsuperscript{68}

Other immunologic factors besides immunoglobulins have been demonstrated to possibly contribute to CRPS clinical signs. Li et al.\textsuperscript{69} conducted a study that demonstrated the depletion of CD20+ B cells from anti-CD20 antibodies reduces the amount of CRPS changes seen in mice in a fracture/cast CRPS model compared to controls. Further, pro-inflammatory monocytes CD14+ and CD16+ have been found to be elevated in CRPS patients compared to controls along with a decreased IL-10, an anti-inflammatory cytokine IL typically low in CRPS patients.\textsuperscript{70}
Afferent Dysfunction

CRPS is characterized by “disproportionate” spontaneous and evoked pain (e.g., hyperalgesia, thermal and mechanical allodynia). Whether these sensory symptoms are due to peripheral and/or central sensitization is the subject of considerable debate and investigation. Sensory impairment occurs in more than 70% of CRPS patients. Although traditionally these sensory changes were thought to occur in a distal, regional distribution along with characteristic autonomic disturbances, some data suggest that the afferent disturbances may be hemilateral or quadrantic. Study observations corroborate that CRPS may be associated with more generalized sensory impairments. The types of remote sensory abnormalities described include not only the allodynia and hyperalgesia typical of CRPS but also hypoesthesia and other dysesthesias. Psychophysical technologies such as temperature quantitative sensory testing reveal that ipsilateral “hypoalgesia” is common, and contralateral hypoesthesia may occur in some cases. Patients found to have generalized sensory impairment were also found to have ipsilateral weakness. Another study showed that patients with generalized sensory impairment had ipsilateral hemibody increases in thresholds for touch, thermal sensation, and heat pain, whereas those with sensory deficits limited to the distal affected limb showed touch threshold elevations only in the affected limb. In this trial, 46% of patients showed abnormalities in nerve conduction testing, and 24% abnormalities in somatosensory evoked potentials, although these abnormalities did not correspond to the extent of sensory impairments observed on quantitative sensory testing. These studies and others suggest that the sensory impairments in CRPS often extend beyond the area affected by pain, and up to 50% of subjects show hypoesthesia and hypoalgesia in a quadrantic or hemibody distribution ipsilateral to the pain. These effects are more likely to occur with greater CRPS chronicity, suggesting centralization of the pathology over time.

Skin biopsies have revealed decreased C-fiber and Aδ-fiber axonal densities in the affected limb of CRPS type I patients compared to the unaffected side. It is not known whether such changes are primary to the disease or a consequence of nutritional changes and ischemia caused by
chronic vasoconstriction and inflammation. These changes could help account for some of the sensory alterations described earlier that may occur in CRPS type I (as well as CRPS type II).

A recent study examined patterns of sensory signs for upper limb CRPS type I, CRPS type II, and peripheral nerve injury (PNI) patients. Recruitment included 416 patients from the German Research Network on Neuropathic Pain. Quantitative sensory testing demonstrated several overlapping somatosensory abnormalities between CRPS and PNI patients. This suggests quantitative sensory testing cannot, alone, differentiate between CRPS and PNI patients. In all syndromes, most patients (66% to 69%) were determined to have a combination of sensory loss and hyperalgesia/allodynia. Increased pressure pain in CRPS patients was the only obvious differentiating sign between CRPS and PNI sensory abnormalities. Loss of mechanical detection was greater in CRPS type II than CRPS type I and was considered to be the greatest differentiator between these two syndromes in this study.

CENTRAL DYSFUNCTION

There is considerable evidence supporting centralization of the pathology in chronic CRPS. Further support comes from evidence suggesting presence of sympathetic and motor dysfunction in the region of pain (see discussion in the following section). An acute “nociceptive barrage” from an inciting trauma, or due to peripheral sensitization and/or neurogenic inflammation, can cause rapid changes in the central nervous system (brain and spinal cord), a process commonly referred to as central sensitization. As a corollary, it has been hypothesized that normalization of afferent activity will reset and/or dampen this sensitization (e.g., increased “functional” input on large fiber tracts may modulate or normalize activity of small fiber tracts or “shut the pain gate”).

Evidence for supraspinal central mechanisms in CRPS also derives from studies using neuroimaging techniques that permit exploration of changes in information processing in the brains of CRPS patients. Studies using magnetoencephalography (MEG), quantitative electroencephalography (EEG), functional magnetic resonance imaging (fMRI), and positron emission tomography (PET) techniques all indicate that alterations of
afferent input lead to cortical and thalamic plasticity and reorganization of sensory representations in patients with CRPS type I. Increased brain responsiveness among CRPS patients in some imaging studies also supports the presence of central sensitization. Some studies suggest a reduced size of the motor cortex devoted to the affected limb in unilateral CRPS type I patients compared to the unaffected side, and the relevance of such brain changes to clinical symptoms is supported by the fact that degree of this “shrinkage” correlates with the degree of hyperalgesia to pinprick. fMRI studies indicate different patterns of cortical activation to pinprick in the CRPS-affected side (S1, S2, insula, frontal, anterior cingulate cortex) compared to the unaffected side (S1, S2, insula only). Moreover, prospective research using MEG indicates that stimulation of early, unilateral CRPS type I subjects leads initially only to contralateral activation, whereas after 3 years of CRPS, the same stimulation leads to bilateral activation. Such results suggest one possible brain mechanism by which reported contralateral “spreading” of CRPS symptoms may occur. A meta-analysis that included six studies investigated S1 representation in upper extremity CRPS. They determined, from these limited data, that S1 representation is smaller in the CRPS-affected upper limb compared to the unaffected limb. A follow-up study comparing 17 patients with upper extremity CRPS and 16 healthy controls determined that the S1 representation was the same size in the affected limb of CRPS subjects and controls. Further, they found S1 representation in the unaffected limb of CRPS patients was larger than controls. This is consistent with the previous meta-analysis and provides interesting insight on the possible neuroplasticity changes that occur in CRPS pathology. Further studies are needed to explore these findings.

Imaging studies suggest that CRPS-related brain changes like those described earlier may reverse after successful treatment; thus, a reduction or resolution of CRPS pain may correlate with “resetting” of the cortical reorganization associated with the disorder.

SYMPATHETIC DYSFUNCTION
Although autonomic dysfunction has long been implicated as a key mechanism involved with CRPS pathology, the actual role of the SNS is
incompletely characterized. A seminal role of the SNS in CRPS is pivotal in most diagnostic criteria, emphasizing signs and symptoms of autonomic disturbance (e.g., vasomotor, sudomotor, and fluid regulation changes). The crucial role of the SNS in at least some cases of CRPS is also suggested by the fact that sympatholytic blocks cause substantial pain relief in a subset of patients (those with SMP; e.g., Wasner et al., and see following discussion). Because of the frequent beneficial response empirically seen to sympathetic blocks in chronic, cold, blue, sweaty CRPS, logically, sympathetic hyperactivity was originally thought to be a primary pathophysiologic mechanism. However, an analysis of the current available data provides evidence that sympathetic vasoconstrictor activity is inhibited rather than enhanced, at least in early CRPS. The clinical presentation of CRPS appears to take two distinct forms, which may be sequential. Acutely, vasodilatation and sudomotor dysfunction (hot, red, occasionally dry) is characteristically observed; in contrast, patients with chronic CRPS often exhibit signs of vasoconstriction and hyperhidrosis (cold, blue, sweaty). This apparent temporal progression of vasomotor dysfunction from hypoactive to hyperactive is in accord with the sequential changes in rat paw temperature observed in the chronic constriction injury animal model of CRPS. In a series of human studies examining thermoregulation and sympathetic reflexes in response to whole-body warming or cooling using a thermal suit, Wasner and colleagues have corroborated the temporal progression from acute, relative sympathetic hypofunction, through an intermediate stage, to a chronic state of relative hyperfunction. Whole-body cooling, a very effective stimulus to tonically activate cutaneous vasoconstrictor pathways, induced a much lower level of vasoconstriction in the affected side as compared with the healthy side in acute CRPS patients. Wasner et al. also reported a significant negative correlation (P < .001) between the duration of the disease and the maximal temperature difference between the affected and unaffected sides achieved during this thermoregulatory testing. The “cold” symptom pattern often seen in chronic CRPS is most likely related to adrenergic receptor supersensitivity, perhaps resulting from early sympathetic hypofunction due to local sympathetic nerve damage, decreased central drive, or both.
This hypothesis is supported by studies examining plasma catecholamines in CRPS and studies using PET scanning techniques.\textsuperscript{105–107} These mechanisms do not exclude processes at the capillary and venular site of the vascular bed that may involve the sympathetic and unmyelinated afferent neurons\textsuperscript{108} that could contribute to neurogenic inflammation and edema.\textsuperscript{58}

Results of thermoregulatory sweat tests and quantitative sudomotor axon tests often reveal increased sudomotor activity in acute CRPS; however, only results of the former are increased in chronic CRPS.\textsuperscript{98,109} Although these sudomotor changes are not entirely in line with the pattern of reported vasomotor changes in CRPS, they do support a central sympathetic dysregulation in this acute period that is in accord with known thermoregulatory mechanisms.\textsuperscript{98,109} The dysfunctional effectors of the SNS that are most prominent in CRPS (vasomotor and sudomotor) are thermoregulatory and thought to be primarily under hypothalamic control.\textsuperscript{95,110} It is important to note that these sympathetic signs and symptoms are highly variable between patients and even within patients over time.\textsuperscript{111,112}

During the 1980s and early 1990s, many clinicians and researchers considered the presence of SMP to be a central feature of CRPS. SMP was corroborated by reports of significant analgesia when the efferent sympathetic nerve supply to the affected area was blocked.\textsuperscript{113–115} The concept of SMP remains potentially useful clinically, as it suggests an intervention that may provide a relatively pain-free window of opportunity so that responsive patients might begin a functional restoration course. Physiologically, it is well established that nociceptive afferents are not influenced by sympathetic fibers under normal conditions,\textsuperscript{116,117} and the specific role of the SNS in perpetuating pain in pathologic states such as CRPS is not clear.\textsuperscript{118} However, evidence from several studies suggests potential direct interactions between SNS activity and CRPS pain. Drummond\textsuperscript{119} introduced a small dose of norepinephrine into capsaicin-treated skin by iontophoresis and showed markedly increased thermal hyperalgesia. Moreover, injection of adrenergic agonists into the symptomatic limb of CRPS patients often provokes or enhances pain, even if the limb has been sympathectomized.\textsuperscript{114,120,121} These findings are
consistent with the clinical observation that CRPS pain often increases in cold weather or in response to psychological stress, when catecholamine secretion would be expected to increase. Experimentally evoking the startle response also causes increased pain intensity in CRPS type I patients, presumably via sympathetic activation, and these pain changes are paralleled by significantly greater vasoconstriction on the affected side versus the unaffected side. Many of the motor abnormalities of CRPS have also been reported to improve with sympatholytic blocks, implying that some of these motor symptoms may also be sympathetically maintained. Despite the hyperalgesic impact of increased SNS activity on CRPS pain in experimental studies, and the common clinical assumption that SNS hyperactivity contributes directly to CRPS pain, unilateral fracture patients who later developed CRPS showed impaired SNS shortly after injury (recorded with laser Doppler fluxmetry). In addition, presence of impaired SNS function shortly after fracture prospectively predicted which later developed acute CRPS type I. In a small trial, 33.5% of CRPS patients exhibited asymmetric vasomotor responses compared to a homologous symmetric pattern of response in all healthy controls when both groups view ambiguous visual stimuli, which is meant to ilicit an autonomic response. Further, 61% of the CRPS patients had intense pain within seconds of viewing ambiguous visual stimuli.

A theoretical synthesis of this SNS data: There is acute damage to small efferent sympathetic fibers with the original trauma (such as a fracture or crush injury) resulting in relative sympathetic hypofunction (hot, red, dry). Soon thereafter, cholinergic receptor upregulation occurs in the target tissues (vessels, sweat glands), and importantly, adrenergic receptors may become activated/sensitized on afferent pain fibers as well. Ultimately, there may be regeneration of transformed sympathetic fibers into this pathologically altered region (or restitution/upregulation of central sympathetic drive), giving the clinical appearance of sympathetic hyperfunction (cold, blue, sweaty) and providing direct stimulation of noradrenergically sensitized nociceptors.

**TROPHIC, DYSTROPHIC, AND NUTRITIONAL**
ABNORMALITIES
Trophic/dystrophic changes to skin (thin and glossy, or thickened), nails (thickened, striated), and hair growth (increased or decreased) are ubiquitous in reports of chronic CRPS symptomatology but are of unknown etiology. These changes may simply be due to relative hypoxia with chronic vasoconstriction,\(^77,126,127\) and a similar process could also lead to the observed nerve dropout\(^76\) and osteopenia\(^39\) reported in CRPS. There is evidence of cellular hypoxia or impaired oxygen utilization in the CRPS affected side compared to the unaffected side based on magnetic resonance spectroscopy.\(^128\) Skin capillary hemoglobin oxygenation (HbO\(_2\)) has also been shown to be decreased on the affected side in CRPS patients as determined by microlight guide spectrophotometry.\(^127\) Skin, but not venous lactate, was also reported to be increased on the affected side as measured by dermal microdialysis, suggesting decreased oxygenation.\(^126\) The decreased range of motion often seen in CRPS could be due in part to trophic changes of joints, tendons, or ligaments. It is also possible that many of these changes could be caused by inflammation as originally suggested by Sudeck\(^39\) or by hormonal changes.\(^129\) Small-fiber dropout may be a nutritional/relative hypoxia type of “trophic” change or may be an essential etiologic factor in some cases.\(^76,130–132\)

Since Sudeck\(^133\) first described osteopenia in 1901, this bone loss has been shown to be a prominent feature of most chronic CRPS patients.\(^134\) Whether this is due to disuse or is an elemental change in the osteoclast/osteoblast relationship is unclear, and elements of both may be present in most subjects. Certainly, the correction of these aberrations (e.g., bisphosphonates, graded exercise) may provide treatment targets.

MOTOR AND MOVEMENT DISORDERS
Although older diagnostic criteria do not mention motor or movement disorders,\(^5\) the new empirically derived criteria and clinical experience feature motor system abnormalities prominently.\(^97,135\) Most CRPS patients show weakness, spasm, tremor, bradykinesia, and/or range of motion abnormalities at some time in the disease,\(^123\) whereas a minority (~10%) may show more dramatic aberrations such as dystonia.\(^136\) Weakness of skeletal muscles of the affected distal extremity is common, being either
true weakness (motor dysfunction) or weakness due to pain/kinesophobia. \(^{136}\) Tremor may occur in as many as 70% of patients with upper extremity CRPS, with most represented by an apparent increase in physiologic tremor.\(^{123,135}\) This tremor may decrease with sympathetic block or sympathectomy, suggesting that some motor features of CRPS may be sympathetically maintained.\(^ {123}\) Muscle spindles have extensive adrenergic innervation\(^ {137}\) and may become sensitized similar to the vasomotor system. Inflammatory mediators, especially cytokines, may also sensitize muscle spindles.\(^ {138}\) Bradykinesia is a common abnormality in CRPS and is likely a central abnormality at a spinal and/or cortical level.\(^ {123,135}\) Cerebral motor processing abnormalities have been shown in CRPS with kinematic and grip force analysis.\(^ {139}\) Increased reactivity of the motor cortex has been shown by MEG\(^ {88}\) and transcranial magnetic stimulation (TMS) studies.\(^ {140}\) In sum, numerous findings suggest clinically important motor abnormalities in CRPS that may be of central origin. A systematic review and meta-analysis attempted to examine the literature to determine the extent the motor cortex may be altered in CRPS.\(^ {141}\) There were 18 studies included in the systematic review that included 14 unique data sets using TMS, fMRI, MEG, and PET modalities with 8 studies included in the meta-analysis. The study determined there was limited evidence of bilateral M1 disinhibition in CRPS of the upper limb and better designed studies were needed to reexamine other claims about motor cortex involvement in CRPS. There is some evidence that there may be an incongruity between sensory input and motor output, and this hypothesis has been used as the rationale for a treatment that involves “normalizing” the sensory input with mirror therapy.\(^ {142}\) An apparent motor neglect syndrome could also contribute to significant motor dysfunction in some patients, further suggesting a central etiology of the motor dysfunction of CRPS.\(^ {143}\) CRPS-related motor dysfunction may worsen problems with disuse (see following discussion). An area of interest in motor dysfunction is the basal ganglia, as this is an area of somatosensory and motor processing physiologically positioned to explain motor aberrations in CRPS.\(^ {144}\) Chronic nociceptive input to the basal ganglia may lead to abnormal programming of motor tasks in CRPS patients.
IMMOBILIZATION AND DISUSE

Patients with prolonged casting/immobilization of a limb present with many signs and symptoms considered characteristic of CRPS (e.g., sensory disturbances, vasomotor and sudomotor asymmetry, atrophic and dystrophic changes including osteopenia\textsuperscript{145}). In rats casting of hind paw for 4 weeks led to warmer limbs, edema, enhanced cellular extravasation, allodynia, and periarticular osteopenia that reversed after removing the casts, and rats casted after tibial fracture showed vasomotor and nociceptive abnormalities that persisted for several months longer than casting alone.\textsuperscript{146} A follow-up study from Guo et al.\textsuperscript{147} demonstrated glucocorticoid treatment had no effect on periarticular osteopenia. The potential contribution of disuse to CRPS symptomatology provides a primary rationale for functional restoration as treatment.\textsuperscript{148,149}

Genetics

One of the unsolved questions in human pain is why only a minority of patients develop chronic pain after identical inciting events (e.g., nerve lesions).\textsuperscript{150,151} In contrast, in animal models of nerve lesion, almost all animals develop neuropathic pain behavior (e.g., Bennet and Xie,\textsuperscript{15} Kim and Chung,\textsuperscript{16} Selzer et al.,\textsuperscript{18} Blenk et al.,\textsuperscript{152} Decosterd and Woolf\textsuperscript{153}). In CRPS specifically, it is interesting to consider why some individuals who have frequent, sometimes severe injuries considered etiologic never develop CRPS (e.g., soccer players, American football players); yet in others, trivial injuries may lead to full-blown CRPS (e.g., intravenous starts, minor sprains).\textsuperscript{150} As always, there may be environmental considerations that predispose, but genetic factors will likely ultimately prove to be important. The human leucocyte antigen (HLA) molecules encoded by genes of the major histocompatibility complex (MHC) may contribute to several neurologic disorders including CRPS.\textsuperscript{154} A study evaluated 150 phenotypically homogenous CRPS patients with fixed dystonia and found a significant association with HLA alleles HLA-B62 and HLA-DQ8.\textsuperscript{155} The same research group conducted a follow-up study to evaluate whether a phenotypically homogenous CRPS group without dystonia has the same associations, and they found HLA-DQ8 to be the only significantly associated allele.\textsuperscript{156} However, these results were not
replicated by another group that interrogated about 83% of common single-nucleotide polymorphisms in the human genome, finding they were not associated with CRPS phenotype in their cohort.\textsuperscript{157} An early report described three families with two or more members in each affected by CRPS, suggesting the possibility that CRPS risk was heritable.\textsuperscript{158} In small studies, the HLA loci A3, B7, DQ1(06), DR2(15), and DR13 are specifically implicated.\textsuperscript{159–161} One Japanese study suggests an association between CRPS and the (non-MHC axis) angiotensin-converting enzyme gene and notes elevated angiotensin II in CRPS patients.\textsuperscript{162} At present, data regarding possible genetic contributions to CRPS are rather limited but are sufficient to justify further exploration of this very plausible contribution to pathophysiology.

**A Convergent Pathophysiologic Theory**
