These seemingly divergent factors that are proven, theorized, or hypothesized to be involved in the pathophysiology of CRPS can be synthesized.\textsuperscript{14} The peripheral factors such as nerve and tissue damage and inflammation (regional and neurogenic) cause an afferent barrage that begins the process of peripheral and central sensitization. Central effects such as changes in the dorsal horn, brainstem, limbic areas, and cortex acutely and chronically occur. An efferent response evolves as feedback from all these areas along the motor (corticospinal) and sympathetic (limbic-hypothalamic-brainstem) systems. This efferent outflow may then substantially impact the peripheral dynamic by affecting the nutritional and inflammatory stasis in the damaged region. All of these sites interconnect, for instance, by ephapses and short loops in the CNS (e.g., the sensory to sympathetic ganglion, dorsal to lateral horn, brainstem). Overlying all of this is variance in response on the basis of genetics (nature) and psychosocial factors (nurture). Thus, nested feedback and feed forward loops and cascades within the neuraxis develop. Importantly, these feedback and feed forward loops can be self-maintaining and can “spread” (come to involve more and more elements of the central nervous) (Fig. 25.1).
**FIGURE 25.1** Complex regional pain syndrome maintained and reinforced by nested, reverberating, feed forward (afferent) and feedback (efferent) loops. Overlaying this are the vectors of genetics (endogenous) and sociologic operant paradigms (exogenous). NE, norepinephrine. (Modified from Merskey H, Bogduk N. Classification of chronic pain: descriptions of chronic pain syndromes and definitions of pain terms. 2nd ed. Seattle: IASP Press; 1994. This table has been reproduced with permission of the International Association for the Study of Pain® [IASP]. The table may not be reproduced for any other purpose without permission.)

### Diagnosis

In the past, CRPS was diagnosed using a variety of nonstandardized and idiosyncratic diagnostic systems (e.g., Gibbons and Wilson,96 Bonica,163 Kozin et al.,164 Wilson et al.165), each of which was derived from the authors’ clinical experiences and none of which achieved wide acceptance. This lack of a common diagnostic criteria hindered clinical progress for decades.

**THE INTERNATIONAL ASSOCIATION FOR THE STUDY OF PAIN CRITERIA**

After much debate, the name for the syndrome was ultimately changed to complex regional pain syndrome (CRPS) at a consensus workshop in Orlando, Florida, in 1994,54,166 with the new name and diagnostic criteria codified by the IASP taskforce on taxonomy (see Table 25.1).5 This new
diagnostic entity was meant to be descriptive, general, and not to imply any pathophysiology (including any direct role for the SNS). According to these criteria, CRPS can be diagnosed regardless of whether the pain is SMP (SNS block responsive) or sympathetically independent pain (SIP). These IASP-endorsed criteria had the potential to lead to improved clinical communication and greater generalizability across research samples.\textsuperscript{54} However, realization of this potential has been somewhat limited by the fact that these rather vague criteria were derived solely by consensus. Also, since publication in 1994, utilization of the criteria has been sporadic (although increasing) in the literature,\textsuperscript{167} and certain groups had resisted the change (especially certain advocacy groups and payors). As a consequence, the full benefits of common criteria have not been completely realized.

Experience gained in developing diagnostic criteria in headache and psychiatric disorders indicates that consensus-based criteria can be significantly improved by systematic empirical validation\textsuperscript{168} and consensus-derived criteria that are not subsequently validated may lead to over- or underdiagnosis, thus reducing the ability to provide timely, optimal treatment. Results of validation studies to date suggest that the 1994 IASP criteria are adequately sensitive (i.e., rarely miss a case of actual CRPS); however, both internal and external validation research suggest potential problems with specificity (overdiagnosis).\textsuperscript{97,169,170} The 1994 IASP criteria implicitly assume that signs and symptoms of vasomotor, sudomotor, and edema-related changes provide redundant diagnostic information; that is, presence of any one of these is sufficient to meet criterion 3 (see Table 25.1). This combination of multiple distinct elements of the syndrome into the same diagnostic criterion and allowing patient-reported symptoms are likely elements contributing to overdiagnosis in the 1994 IASP scheme.\textsuperscript{97,171} An additional weakness of these criteria was the failure to include motor/trophic signs and symptoms, which could lead to important information being ignored that may help discriminate CRPS from other syndromes.

These conclusions are supported by the results of factor analysis (a statistical pattern recognition technique) that was conducted in a series of 123 CRPS patients. These results indicated that signs and symptoms of
CRPS clustered into four statistically distinct subgroups. The first of these subgroups was a set of signs and symptoms indicating abnormalities in pain processing (e.g., allodynia, hyperalgesia). Skin color and temperature changes characterized the second subgroup, indicative of vasomotor dysfunction. Edema and sudomotor dysfunction (e.g., sweating changes) combined to form a third unique subgroup. The finding that vasomotor signs and symptoms were statistically distinct from those reflecting sudomotor changes/edema is in contrast to the 1994 IASP criteria, which treats all three of these as diagnostically equivalent. A fourth and final subgroup was identified that included motor and trophic signs and symptoms. Numerous studies have described various signs of motor dysfunction (e.g., dystonia, tremor) as important characteristics of this disorder, and trophic changes have frequently been mentioned in historical clinical descriptions. The absence of both of these features from the 1994 IASP criteria is therefore notable, especially given factor analytic findings that this subgroup of signs and symptoms does not overlap significantly with other characteristics of CRPS currently used in diagnosis.

External validity, which addresses the ability of the diagnostic criteria to distinguish CRPS patients from those with other types of pain conditions, is also an important issue. In the absence of a definitive pathophysiology of CRPS and thus the absence of a definitive objective test to serve as a “gold standard,” providing evidence for the external validity of diagnostic criteria is challenging. However, the upper limit of external validity can be evaluated by using the original criteria themselves as a reference point. In this methodology, a CRPS patient group is identified using a strict application of the 1994 IASP/CRPS criteria with a comparison group of non-CRPS neuropathic pain patients defined by independent diagnostic information (e.g., diabetic neuropathy diagnosed by presence of chronic diabetes with ascending symmetrical pain and corroborated by electrodiagnostic studies). Existing criteria and modifications to these criteria can then be evaluated with regard to their ability to distinguish between these two groups based on patterns of signs and symptoms. This model was used to test the utility of the 1994 IASP/CRPS criteria for discriminating between 117 patients meeting 1994
IASP criteria and 43 neuropathic pain patients with established non-CRPS etiology. The 1994 IASP/CRPS criteria and decision rules (e.g., “evidence at some time” of edema or color changes or sweating changes satisfy criterion 3) did discriminate significantly between the CRPS and non-CRPS groups. However, closer examination of the results indicated that although diagnostic sensitivity (i.e., being able to detect the disorder when it is present) was quite high (.98), specificity (i.e., minimizing false-positive diagnoses) was poor (.36), and a positive diagnosis of CRPS was likely to be correct in as few as 40% of cases.97,170

For clinical purposes, sensitivity is extremely important. On the other hand, the issue of specificity is quite important for selection of research samples as well as for minimizing unnecessary, potentially invasive treatments. The clinical implication of high sensitivity at the expense of specificity is that CRPS may be overdiagnosed and, ultimately, overtreated. It also has the very significant downside of identifying pathophysiologically heterogeneous groups for research, contributing potentially to negative results in clinical trials.97

THE BUDAPEST CRITERIA

A meeting of international researchers and clinicians with expertise in CRPS (the “Budapest Group”) was held in Budapest, Hungary, in 2003 to make consensus recommendations on proposed revisions to the 1994 IASP diagnostic criteria. The criteria ultimately proposed by the Budapest group were consensus-based modifications of the criteria that were statistically derived from the validation studies, as in the earlier discussion.97,170 These modified criteria assessed CRPS characteristics within each of the four statistically derived factors described earlier. Given evidence that objective signs on examination and patient-reported symptoms both provide useful but nonidentical information, the modified criteria required the presence of signs and symptoms of CRPS for diagnosis.97,169,174 A test of these modified criteria regarding their ability to discriminate between the CRPS and non-CRPS neuropathic pain groups indicated that they could increase diagnostic accuracy.97,173 Results indicated that a decision rule requiring that two of four sign categories and three of four symptom categories be positive for a diagnosis to be made resulted in a sensitivity of .85 and a
specificity of .69. This decision rule represented a good compromise between identifying as many patients as possible in the clinical context while substantially reducing the high level of false-positive diagnoses associated with 1994 IASP criteria. This decision rule was therefore adopted in a set of proposed clinical diagnostic criteria endorsed by the Budapest group (summarized in Table 25.2). \cite{97,174}
**TABLE 25.2 Budapest Diagnostic Criteria for Complex Regional Pain Syndrome (Officially Adopted by IASP in 2012)**

**General Definition of the Syndrome**

Complex regional pain syndrome describes an array of painful conditions that are characterized by a continuing (spontaneous and/or evoked) regional pain that is seemingly disproportionate in time or degree to the usual course of any known trauma or other lesion. The pain is regional (not in a specific nerve territory or dermatome) but may spread and usually has a distal predominance of abnormal sensory, motor, sudomotor, vasomotor, and/or trophic findings. The syndrome shows variable progression over time.

To make a clinical diagnosis, the following criteria must be met:

1. Continuing pain, which is disproportionate to any inciting event
2. Must report at least one symptom in three of the four following categories:
   - **Sensory**: reports of hyperesthesia and/or allodynia
   - **Vasomotor**: reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry
   - **Sudomotor/edema**: reports of edema and/or sweating changes and/or sweating asymmetry
   - **Motor/trophic**: reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
3. Must display at least one sign at time of evaluation in two or more of the following categories:
   - **Sensory**: evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement)
   - **Vasomotor**: evidence of temperature asymmetry and/or skin color changes and/or asymmetry
   - **Sudomotor/edema**: evidence of edema and/or sweating changes and/or sweating asymmetry
   - **Motor/trophic**: evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
4. There is no other diagnosis that better explains the signs and symptoms.

*a For research purposes, diagnostic decision rule should be at least one symptom in all four symptom categories and at least one sign observed at evaluation in two or more sign categories. Modified from Harden RN, Bruehl S, Stanton-Hicks M, et al. Proposed new diagnostic criteria for complex regional pain syndrome. Pain Med 2007;8(4):326–331. Reproduced by permission of American Academy of Pain Medicine.

The proposed clinical diagnostic criteria described reflected an improvement over 1994 IASP criteria for clinical purposes but still suffered from less than optimal specificity for use in the research context. Tests of the aforementioned modified CRPS criteria indicated that modifying the decision rules to require that two of four sign categories...
and four of four symptom categories be positive for diagnosis to be made resulted in a sensitivity of .70 and a specificity of .94. Of all the permutations tested, this decision rule resulted in the greatest probability of accurate diagnosis for both CRPS and non-CRPS patients (approximately 80% and 90% accuracy, respectively). This high level of specificity was considered desirable in the research context by the Budapest consensus group and therefore was adopted as part of a set of proposed research diagnostic criteria. Current distinctions between CRPS type I and CRPS type II subtypes, reflecting respectively the absence and presence of evidence of PNI, were ultimately retained despite ongoing questions by the consensus group as to whether such distinctions have clinical utility. The Budapest criteria were adopted by the IASP in 2012 after they consistently demonstrated a better way to maintain sensitivity and specificity when diagnosing CRPS.

Thus, CRPS is a clinical diagnosis made with simple bedside testing techniques known by all physicians. Technical testing procedures are sometimes used to corroborate or objectively document clinical impressions (e.g., thermography, bone scans). Recently, there was a study that suggested osteoprotegerin, an inhibitor of osteoclastic function, may aid as a biomarker for diagnosis. To date, none of these have been formally validated.

**SEQUENTIAL STAGES AND SUBSETS OF COMPLEX REGIONAL PAIN SYNDROME**

Although not part of clinical diagnosis per se, it is lore among clinicians that CRPS entails three sequential stages that differ in patterns of signs and symptoms. This traditional staging model is summarized by Bonica. The early, acute stage of CRPS (stage I) was characterized by pain/sensory abnormalities (e.g., hyperalgesia, allodynia), vasomotor and sudomotor dysfunction, and prominent edema. Stage II (dystrophic stage) was proposed to occur 3 to 6 months after onset and to be characterized by more marked pain/sensory dysfunction, with continued evidence of vasomotor dysfunction and development of significant motor/trophic changes. Stage III (atrophic stage) was characterized by decreased pain/sensory disturbance, continued vasomotor disturbance, and markedly
increased motor/trophic changes. Although until recently, there had been only limited empirical tests of this hypothesized staging of CRPS, the concept has frequently been accepted as fact in the CRPS literature.\textsuperscript{163,177,178}

The limited available prospective research that followed patients who develop CRPS-like symptoms after surgery, fracture, or severe hand injury suggests that in many cases, the condition does not progress through increasingly problematic stages like those described earlier.\textsuperscript{12,71,179,180} Retrospective surveys completed by CRPS patients with an average pain duration of over 3 years similarly indicate that CRPS symptoms often tend to remain stable or improve rather than progressively deteriorate.\textsuperscript{169} More recently, the statistical technique of cluster analysis was used to test for evidence of sequential stages.\textsuperscript{181,182} In one study, three unique subgroups were identified, with patients in each subgroup displaying statistically similar patterns of symptoms but that there were no significant pain duration differences between the three subgroups, and in contrast to the traditional staging model, the group with the most motor/trophic signs and symptoms had a slightly shorter mean pain duration.\textsuperscript{181} The observation of pain duration having no statistical significance, or relevance, between subgroups was reported in a subsequent study that examined CRPS patients with an average prolonged disease duration of 5.8 years when using cluster analysis.\textsuperscript{182} Findings such as these suggest the possibility that the presumed sequential “stages” often reported by clinicians may reflect CRPS subtypes rather than an actual staging that follows a progressive, deteriorating course. There is some evidence that “temperature staging” may occur; early CRPS may tend to present with increased temperature (“hot CRPS”) and longer duration CRPS to present with decreased temperature (“cold CRPS”).\textsuperscript{101,183} A recent large prospective trial conducted by Bruehl et al.\textsuperscript{184} used two-step cluster analysis with results identifying “warm CRPS” and “cold CRPS” subtypes. Analysis of the “warm CRPS” patient cluster was characterized as warm, red, edematous, and sweaty extremity and the “cold CRPS” patient cluster was characterized as cold, blue, and less edematous extremity. The inflammatory characteristics of the “warm CRPS” cluster were diminished over time during the trial.\textsuperscript{184} This is consistent with other studies as
inflammatory and immune biomarkers have been observed to be increased in patients with an early diagnosis of CRPS and diminish over time. However, there would be greater power in future studies of CRPS temperature subtypes if they included inflammatory and immune biomarkers.

**PSYCHOLOGICAL FACTORS IN COMPLEX REGIONAL PAIN SYNDROME**

It is critical to properly deem CRPS (as all chronic pain conditions) a biopsychosocial disease; as such, it is crucial to clinical success that psychological and “sociologic” diagnoses be identified and targeted for intervention. Psychological factors could theoretically influence onset or maintenance of CRPS via adrenergic mechanisms believed to contribute to CRPS pathophysiology as described earlier. The impact of catecholamine release in the pathophysiologic mechanisms described earlier may be important to recognize given that psychological factors such as life stress and dysphoric emotional states (e.g., anxiety, anger, depression) can be associated with increased catecholaminergic activity (e.g., Charney et al., Light). For example, levels of plasma epinephrine were found to correlate significantly with depressive symptoms in a sample of 16 CRPS patients. Similarly, plasma norepinephrine levels were significantly higher in a sample of 15 CRPS patients than in age- and gender-matched healthy controls, and these elevations were associated significantly with higher scores on a measure of posttraumatic stress symptoms. It is plausible that stress and emotional distress could, through their impact on catecholamine release, interact with adrenergically mediated pathophysiologic mechanisms to contribute to onset or maintenance of CRPS. Interestingly, recent evidence suggests that elevated stress levels in CRPS patients may also be associated with altered immune response, which could potentially impact on CRPS as well.

Examination of the historical CRPS literature frequently reveals the implicit assumption that psychological dysfunction (usually emotional disorders) contributes to CRPS in at least some patients. This assumption probably colored physicians’ conceptualization of CRPS patients despite the absence until 10 years ago of a significant body of controlled studies.
examining this issue. In the existing research literature, most studies assessing the role of psychological factors in CRPS have been limited to case series descriptions or cross-sectional psychological comparisons between CRPS patients and non-CRPS chronic pain patients.\(^{191}\)

The ability to make conclusions about psychological factors contributing to onset of CRPS depends on prospective research designs in the CRPS literature. One prospective study indicated that higher levels of anxiety symptoms prior to total knee arthroplasty were associated with greater likelihood of displaying CRPS-like symptoms at 1 month postsurgery.\(^{12}\) These latter findings would be consistent with the psychophysiologic model proposed earlier. However, it is notable that neither anxiety nor depression predicted occurrence of CRPS-like symptoms at 6 months, so the long-term impact of psychological factors on development of chronic CRPS remains unclear. Even if the psychophysiologic model is accurate, this should not be taken to imply that the presence of psychological “risk factors” alone would be either necessary or sufficient to cause CRPS. For example, one prospective study indicated that among 88 consecutive patients assessed shortly after acute distal radius fracture, 14 had significantly elevated life stress but did not develop CRPS, and the 1 patient who did develop CRPS had no apparent psychological risk factors (i.e., no major life stressors, average emotional distress levels).\(^{192}\) Another prospective study reported anxious personality as a risk factor for developing CRPS at a 2- to 4-month follow-up.\(^{193}\) A large multicenter prospective trial of patients recruited from emergency rooms postfracture were evaluated and found that multiple psychological factors, including anxiety and depression, did not develop CRPS type I.\(^{194}\) There is some disparity in the literature about whether psychological factors contribute, or predict, the onset of CRPS, but the majority supports that they do not.\(^{195}\)

In the absence of other prospective studies, the question of whether psychological factors affect the development and maintenance of CRPS must be addressed solely on the basis of case reports and retrospective or cross-sectional research designs which do not allow causation to be inferred. Two uncontrolled retrospective case series reported a relationship between onset of CRPS and contemporaneous emotional loss or major life
stressors, although these can at best be considered anecdotal. The only controlled study regarding the role of life stress in CRPS onset found that 80% of patients in a CRPS sample recalled a stressful life event temporally concurrent with the initiating physical trauma, in contrast to only 20% of non-CRPS controls. Although this suggests that stressful life events occurring concurrently with a physical trauma may contribute to development of CRPS, this study’s findings still must be viewed with caution due to its retrospective design.

If psychological dysfunction is somehow uniquely involved in onset or maintenance of CRPS, one might expect an increased prevalence of psychiatric disorders or elevated levels of emotional distress in this population. Based on structured interviews, estimates for prevalence of Axis I psychiatric disorders (e.g., anxiety and depressive disorders) in CRPS patients indicate a prevalence ranging from 24% to as high as 65%. It should be noted that only Monti et al. included a non-CRPS chronic pain control group, and these authors reported that prevalence of Axis I disorders was not significantly higher in CRPS compared to non-CRPS pain patients. None of the aforementioned studies documented psychiatric status prior to CRPS onset and therefore cannot address the issue of causality. At present, there is no evidence that CRPS patients suffer from diagnosable psychiatric disorders at a higher rate than do other chronic pain patients.

Controlled studies have also addressed the issue of whether CRPS patients are more emotionally distressed than other types of chronic pain patients. Several cross-sectional studies have found that CRPS patients report being more emotionally distressed than non-CRPS pain patients in terms of greater depression and/or anxiety levels. These findings for depressed mood may be relevant when one considers that in a study using time series diary methodology, depression levels on a given day were a significant predictor of CRPS pain intensity on the following day.

More recently, results of a prospective study indicated that patients displaying signs and symptoms of CRPS 6 months following total knee replacement reported significantly higher levels of anxiety than did patients not displaying CRPS despite the fact that both groups were
continuing to experience at least some degree of pain. However, baseline anxiety and depression did not predict CRPS status at 6 months, suggesting that the observed elevations in psychological distress were a result of CRPS pain rather than a cause. Follow-up of this dataset in a subsequent study demonstrated increased CRPS symptom severity at 6 months and 12 months if there were greater depressive symptoms presurgically and at 1 month postsurgery. A recent prospective study evaluated a sample of patients diagnosed with CRPS according to the 1994 IASP to increase the sample size and found that patients with higher baselines of anxiety and pain-related fear had increased CRPS severity scores over 12 months. In light of these findings, one possible explanation for elevated distress often reported in CRPS patients relative to non-CRPS chronic pain patients might be that the unusual and sometimes dramatic symptomatology of CRPS (e.g., allodynia, hyperalgesia, vasomotor changes, significant edema, motor changes) is more distressing than experiencing more common forms of chronic pain. Moreover, the validity of these symptoms is often questioned by health care providers, potentially adding to patient distress.

Some studies suggest CRPS patients are more distressed than comparable non-CRPS chronic pain patients, yet other studies have reported no such differences. For example, work by Ciccone and colleagues provided only partial support for this hypothesis, finding that CRPS patients reported more somatic symptoms of depression than non-CRPS patients with local neuropathy yet displayed no emotional differences relative to low back pain patients. Other studies have found no evidence of elevated distress among CRPS patients compared to low back pain patients or headache patients. In the absence of additional well-controlled studies, it remains unclear whether the findings suggesting uniquely elevated distress in CRPS patients are an artifact of sample selection.

Two studies report that emotional distress, when present, may have a greater impact on pain intensity in CRPS than in other types of chronic pain. For example, correlations between pain intensity and both anxiety and anger expressiveness are significantly stronger in CRPS patients than in non-CRPS chronic pain patients. These results
suggest that even if CRPS patients are not uniquely distressed, the impact of that distress may be unique, possibly due to the hypothesized adrenergic interactions described earlier. These findings could have significant treatment implications, as psychological interventions that reduce distress may directly contribute to reductions in CRPS symptoms (e.g., pain, vasomotor changes).

Another important operant mechanism that may contribute to CRPS is the sometimes dramatic disuse that patients develop in an effort to avoid stimuli that may trigger pain. Even in healthy individuals, prolonged disuse leads to temperature/color changes and hyperalgesia similar to those observed in CRPS. Significant inverse correlations between CRPS pain intensity and ability to carry out activities of daily living suggest that pain avoidance is likely one of the common reasons for CRPS-related activity impairments. Learned disuse, reinforced by either avoidance of actual pain or reduced anxiety subsequent to avoiding anticipated pain exacerbations (kinesophobia), may prevent desensitization and eliminate the normal tactile and proprioceptive input from the extremity that may be necessary to restore normal central signal processing. Learned disuse may also inhibit the natural movement-related pumping action that helps prevent accumulation of catecholamines, tachykinins, and other nociceptive and inflammatory mediators in the affected extremity, which may impact negatively on CRPS signs and symptoms. A recent study utilized a rat tibia fracture model to demonstrate immobilization without fracture and immobilization with fracture had similar increases of inflammatory mediators and CRPS clinical features at 4-week follow-up. Pain-related learned disuse might therefore interact with other pathophysiologic mechanisms to help maintain and exacerbate both the pain-related and autonomic features of CRPS (see following discussion).

In summary, although the contribution of psychological factors to the development and maintenance of CRPS is largely speculative, it is theoretically consistent and highlights the importance of addressing psychological factors in the clinical management of CRPS.

Treatment
THE RATIONALE FOR FUNCTIONAL RESTORATION

CRPS can be a very challenging condition to successfully manage. It is biomedically heterogenous and should be treated as such. The patient presentation often changes over time, and the natural history is variable and poorly characterized. Evidence for efficacy of various treatment modalities is scarce and has developed slowly, due in large part to the vagaries of diagnosis. The only treatment methodology that can have a reasonable chance of successfully bridging the varied presentation and mechanisms of disease and the profound gaps in treatment evidence is a systematic and orderly interdisciplinary approach. Interdisciplinary treatment is defined as a dedicated, coherent, coordinated, specially trained group of relevant professionals that meet regularly to plan, coordinate care, and adapt to treatment eventualities. It is critical to identify and aggressively treat all spheres of the pain experience in CRPS; obsessing with the biomedical alone dooms the clinician and patient to failure, especially in CRPS in which pathophysiology is incompletely understood. Psychosocial targets that may impact pain and dysfunction are often readily and effectively treatable and should be embraced as important avenues of help.

Pain is a central component of CRPS diagnosis, and thus, appropriate analgesia must figure prominently in any treatment regimen. However, its subjective nature makes this symptom a “moving target” that can only be effectively addressed by addressing not only subjective pain but also learned pain behavior and dysfunction. Thus, it is critical to target both subjective and objective clinical benchmarks and outcomes. Ideally, the treatment of CRPS should rely on an intuitive, measurable, and stepwise functional restoration algorithm as the pivotal feature of treatment. This line of reasoning has been codified by two large international consensus-building conferences. The Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials has concluded that physical functioning is a “core domain” in the assessment of pain treatment efficacy, second only to pain assessment. Functional restoration emphasizes physical activity (“reanimation”), desensitization, and normalization of sympathetic tone in the affected limb and involves a steady progression from the most gentle, least invasive
interventions to the ideal of complete rehabilitation in all aspects of the patient’s life (Fig. 25.2). Although the benefits of functional restoration are intuitive (and are becoming dogma), the evidence as to which modalities are optimal, when to use what and for how long, is currently unavailable. In an early pivotal paper, Davidoff et al. conducted a prospective uncontrolled study in RSD that supported the functional restoration approach with three key findings: (1) Objective functional components and biometric data could be quantified longitudinally, (2) these components were reactive enough to display change over time (e.g., in response to a functional restoration-based interdisciplinary program), and (3) they were associated with improvements in subjective outcomes (e.g., decreased pain). This study supplied a primary rationale for a reliance on functional measures as the basis for assessing success in the treatment of CRPS. Various uncontrolled studies suggest that CRPS patients benefited from certain physiotherapeutic modalities, including stress loading and isometric techniques. Oerlemans et al. conducted a prospective controlled study of 135 CRPS patients with pain located in an upper extremity and reported that both physical therapy (PT) and occupational therapy proved valuable in managing pain, restoring mobility, and reducing impairment. Birklein et al. similarly found that pain reports were notably lower for patients undergoing PT.
Immobilization is recognized as a possible cause and/or perpetuating factor in the syndrome.⁵ Patients (and animals) with prolonged casting of a limb often have many signs and symptoms considered part of the CRPS syndrome: vasomotor and sudomotor asymmetry, trophic/dystrophic changes including osteopenia, and occasionally sensory disturbances.²²² Diminished active range of motion is common in early CRPS,²²³ and CRPS is associated with significantly reduced mobility and impaired ability to use the affected area normally.²²⁴ Thus, normalized movement is a key objective in treating central changes linked with the syndrome, loosely categorized under the rubric of “altered central processing” and salient to this argument, “neglect.”²²⁵ “Pain-related fear is more disabling
than pain itself,” and this fear appears to be a dynamic clinical factor in CRPS.\textsuperscript{226,227} The ability to impact this “kinesophobia” seen in most CRPS patients clinically provides a persuasive argument for functional restoration as fundamental. Meta-analyses have shown that an interdisciplinary approach like that used in comprehensive functional restoration programs for CRPS improves symptoms in patients with chronic pain.\textsuperscript{228,229}

A recent observational study examined 49 CRPS patients who completed an interdisciplinary program. McCormick et al.\textsuperscript{230} assessed and tracked a variety of metrics, finding improvement in physical functioning and perceived disability, chronic pain acceptance, and emotional distress. Furthermore, initial medication use was significantly reduced, and 14 of the 16 worker’s compensation patients were successfully released to work when discharged from the program. Patient report of pain was not significantly reduced. These results continue to demonstrate that the main utility of functional restoration programs is to improve a patient’s life in multiple domains despite the pain\textsuperscript{230} and to break the firm link between pain and disability.

**REHABILITATION-BASED TREATMENT MODALITIES**

Occupational therapists are the ideal therapeutic leaders in the functional restoration process, as they are trained in the biopsychosocial principles of disease and are primary in functional assessment and treatment.\textsuperscript{231} An occupational therapist begins with an assessment of the patient’s status and current function (e.g., range of motion, activities of daily living, edema). Occupational therapy treatment should aim to normalize sensation and posture, decrease muscle guarding, minimize edema, and increase normalized use.\textsuperscript{232,233} Specialized garments, bandaging, and manual edema mobilization techniques can help manage edema.\textsuperscript{234} Regular use of the affected limb during everyday tasks is promoted and strongly reinforced throughout the rehabilitation process. A stress-loading (“scrubbing” and “carrying”) program should be implemented as soon as possible.\textsuperscript{211,235} Later, treatments emphasizing active range of motion, coordination/dexterity, strengthening, and proprioceptive neuromuscular facilitation can be applied (see Fig. 25.2).\textsuperscript{236} In extreme CRPS cases,
functional splinting may be required to encourage improved circulation/nutrition to the affected area as well as to promote more normal tissue length/positioning during rehabilitation. Graded motor imagery (GMI) is a treatment modality that is employed by occupational therapists with CRPS patients in an effort to activate cortical networks to improve cortical abnormalities without limb movement before beginning mirror therapy.\textsuperscript{237} The latest Cochrane review on physiotherapy and CRPS concluded GMI and mirror therapy may improve pain and function with CRPS patients, but the quality of the supporting evidence is low.\textsuperscript{238} One study attempted to evaluate GMI in clinical practice using a “prospective audit” and failed to demonstrate significant efficacy.\textsuperscript{239} Large high-quality studies are needed to determine the efficacy of GMI for CRPS patients.

PT plays an equally critical role in functional restoration.\textsuperscript{240,241} PT emphasizes range of motion, flexibility, posture, and, later, weight bearing and strength through the use of gentle progressive exercise. PT must be executed within the bounds of the patients’ tolerance\textsuperscript{242} and never when the affected limb is insensate (such as immediately after a block\textsuperscript{243}). Inappropriately aggressive PT can trigger extreme pain, edema, distress, and fatigue and may in turn exacerbate the inflammation and sympathetic symptoms of CRPS. However, there have been recent studies that examine pain exposure physical therapy (PEPT). This treatment consists of a progressive-loading exercise program and management of pain-avoidance behavior without the use of specific CRPS medications or analgesics.\textsuperscript{244} One small randomized controlled trial (RCT) compared PEPT with “conventional” treatment of CRPS type I patients and found they had similar outcomes on multiple psychometrics, but PEPT had greater active range of motion compared to “conventional” treatment.\textsuperscript{245} Another small RCT similarly exposed CRPS type I patients to performing regular daily activities compared with “treatment as usual” and found the patients with exposure to daily activities had reduced self-reported disability in daily life when they had at least moderate levels of pain-related fear.\textsuperscript{246} The efficacy of this type of therapy has not been replicated.

Oerleman’s group\textsuperscript{220,221,247} has shown that PT (and to a lesser extent occupational therapy) improves pain scores and “active mobility” versus controls.\textsuperscript{220,221,247} In children with CRPS, a single-blind, randomized trial
of PT combined with cognitive-behavioral therapy demonstrated significant improvement on five measures of pain and function and in a prospective review of 103 children with CRPS, “intensive PT” (aerobic, hydrotherapy, and desensitization) supplemented by psychological counseling was effective. The therapy program should be primarily based on functional goals and achieved through active or active-assisted means or the use of low-tech devices (e.g., swiss balls, foam rolls). PT should encourage pacing and include rest breaks and relaxation techniques as well. Mat exercises provide strengthening of both the extremity and the postural muscles in a non–weight-bearing approach and may include movement therapies such as Feldenkrais or Pilates. Virtually all patients with advanced CRPS will present with myofascial pain syndrome of the supporting joint, and effective treatment of this is critical to optimize outcomes. Aquatic therapy can be quite valuable to CRPS patients because of its hydrostatic/compressive principles and its buoyancy effect. Massage, electrostimulation, ultrasound, and contrast baths are empirical modalities administered by PT (see Fig. 25.2).

The recreational therapist is often the first clinician to succeed in getting the CRPS patient to initiate increased movement. The incentive of returning to a favorite pastime is often the appropriate reinforcer to modify kinesophobia and bracing. Through the use of modifications, adaptive equipment, and creative problem solving (e.g., large handled gardening equipment, bowling with the nondominant hand), a patient can enhance self-efficacy and develop confidence through previously lost recreational activities (see Fig. 25.2).

Unfortunately, poor reimbursement for recreational therapy has prevented development and research with this promising modality.

The vocational rehabilitation (VR) counselor helps prepare appropriate CRPS patients for return to work; the “ultimate” functional restoration. Consultation with employer, supervisor, employee health nurse, and work site visits are potential interactions initiated by VR. The VR counselor uses information from medical, occupational, educational, financial, and labor markets interfaced with the client’s job description/analysis to attempt to reset negative operant paradigms and operationalize “the benefits of work.” The VR counselor should participate in the work capacity
evaluation, transferable skills analysis, job-specific reconditioning, work hardening, and functional capacities evaluation and be central in the development and documentation of modifications, restrictions, return-to-work assessments, and work release documents.\textsuperscript{241,250,251} VR counselor, occupational therapist, and responsible physician work closely together in these tasks, with an ideal goal of return to the original job with the original employer (see Fig. 25.2). The sociologic issues surrounding CRPS are pervasive but very poorly characterized. The best approach to managing these is to compassionately and firmly pursue the goals of optimal functional restoration while proactively providing tools for closure in the forensic and compensation arenas.

Because the symptoms of CRPS patients encompass all the biopsychosocial complexities of chronic pain, the best hope of helping patients is the adoption of a systematic, stable, empathetic, and, above all, interdisciplinary approach that addresses those symptoms.\textsuperscript{241} Pharmacotherapy, psychotherapy, and interventional techniques should be efficiently deployed for patients who either cannot begin or fail to progress using the interdisciplinary functional restoration approach outlined earlier. Most patients will require medication and psychotherapy from the beginning to be successful in the pivotal functional restoration algorithm (see Fig. 25.2).\textsuperscript{241,252} That functional restoration can and should be the central intervention, and outcome standard in CRPS is a theory that must be tested. Until then, the interdisciplinary approach for treating patients with CRPS clearly remains the most pragmatic, helpful, and cost-effective therapeutic approach available today.

**PHARMACOTHERAPY**

In the 130 years since Weir-Mitchell recommended laudanum (tincture of opium) and the use of a new invention, the hypodermic syringe, to perform cocaine nerve blocks,\textsuperscript{1} multiple pharmacotherapeutic interventions for CRPS have been described.\textsuperscript{76,214,252} Unfortunately, there are very few RCTs in CRPS.\textsuperscript{148,253} The best empirical approach must therefore employ the limited data available, extrapolate from better evidence that is available in related conditions (e.g., neuropathic pain),\textsuperscript{254} and pragmatically utilize sequential informed drug trials in each unique case based on putative
mechanisms, driven by close monitoring of outcome and risk (Fig. 25.3).

**FIGURE 25.3** Pharmacotherapy considerations. These very general guidelines are overruled by individual patient presentation. It is also important to note that certain drugs, such as bisphosphonates, may be associated with analgesia as well as the more primary action. (Modified with permission from Harden R. Complex Regional Pain Syndrome: Treatment Guidelines. Milford, CT: RSDSA Press; 2006.)

Pharmacotherapy in CRPS, as with most chronic pain syndromes, achieves the greatest benefit when used in conjunction with an interdisciplinary approach to treatment. In CRPS patients, the initial pain intensity is often sufficient that pharmacotherapy may be necessary to begin available nonpharmacologic treatments and “rational polypharmacy” is usually required to optimize analgesia. In treating CRPS, the clinician must construct a drug regimen that draws from two basic classes of medications: prophylactic drugs (for maintenance, drugs used on a scheduled basis) to obtain baseline analgesia and abortive drugs (rescue agents, “as needed” [PRN]) for breakthrough pain or symptom flares. Although analgesia for its own sake has obvious value, a unifocal palliative strategy without concurrent functional restoration is useless in CRPS.

A recent network meta-analysis evaluated multiple class drugs in the treatment of CRPS and rank ordered them according to efficacy. In this study, 16 RCTs were utilized and determined the most efficacious treatment of CRPS based on duration of symptoms and results of follow-
up at different time intervals. Bisphosphonates were the most effective drug class for the treatment of CRPS of short-term duration (i.e., less than 12 months of symptom duration) with continual relief after 2-month follow-up. Calcitonin had superior effects than bisphosphonates in more chronic stages of CRPS (i.e., 12 months or more) in the short term (i.e., less than 2 months). However, calcitonin was recommended to be limited to 6 weeks maximum due to a potential association with cancer incidence and limited efficacy after 2 months. It was also noted that, of all the medications evaluated, only bisphosphonates, N-methyl-D-aspartate (NMDA) analogs and vasodilators showed better long-term (i.e., 2 months or more) pain relief than placebo.

Nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, cyclooxygenase-2 (COX-2) inhibitors, and free radical scavengers are generally used to treat CRPS pain in the context of discernible inflammation. As described previously, there is evidence that inflammatory components are critical to the development or perpetuation of CRPS, especially early in the course.\textsuperscript{49,256} Anti-inflammatory medications can be used for both rescue and prophylaxis. NSAIDs have shown mixed results in several clinical trials of neuropathic pain, including one trial that showed that NSAIDs had no value in treating CRPS type I.\textsuperscript{257} Even though COX-2 selective inhibitors have not been properly assessed in CRPS, they have been used anecdotally.\textsuperscript{258}

Oral corticosteroids are the only anti-inflammatory drugs with strong evidence in CRPS,\textsuperscript{148,259} and there are three RCTs supporting their efficacy, at least in acute CRPS,\textsuperscript{260–262} as there are numerous obvious contraindications to chronic steroid use. “Free radical” oxygen species are known to have a role in inflammatory processes and may be involved in CRPS; thus, specific antioxidants in theory might have a role in CRPS treatment.\textsuperscript{40} One early RCT of the antioxidant vitamin C was found to reduce the incidence of RSD in patients with wrist fractures.\textsuperscript{263} This was followed up by multiple RCTs that examined the role of vitamin C in preventing CRPS.\textsuperscript{264–267} One large prospective, double-blind, randomized controlled multicenter study evaluated the dose response of vitamin C patients in three treatment groups (200, 500, and 1,500 mg daily for 50 days). The prevalence of CRPS after the trial was 2.4% in the vitamin C
groups and 10.1% in the placebo group. This was not replicated with a large double-blind RCT of 336 patients with an acute fracture of the distal radius that used 500 mg daily for 50 days in the treatment arm. In fact, there was an increased incidence of CRPS at 6 weeks compared to placebo, and no significant difference in the development of CRPS between groups for the remainder of the 1-year trial. Further high-quality studies are needed to examine the role of vitamin C as a treatment to prevent the incidence of CRPS. Neuroimmune modulators affecting inflammation such as thalidomide have showed some efficacy in case reports and open some label support. Lenalidomide, a derivative of thalidomide with a more favorable side effect profile, was studied in a randomized, double-blind, placebo-controlled study to evaluate its efficacy in CRPS patients. Although lenalidomide was well tolerated, the efficacy of the treatment arm was no better than placebo. This high-quality study provides an excellent framework for the design of future CRPS trials.

There is mostly anecdotal support for anticonvulsant drugs in CRPS. There are meta-analytic and systematic reviews compiling evidence for the efficacy of certain anticonvulsant compounds as prophylactic agents in other forms of neuropathic pain and the diverse mechanisms of action of some anticonvulsants theoretically should be useful in addressing some of the putative pathophysiologic mechanisms underlying CRPS. Gabapentin, pregabalin, and carbamazepine have strong evidence supporting their use in neuropathic pain conditions and anecdotal support in CRPS. One small RCT of gabapentin that was double-blinded and placebo-controlled demonstrated mild improvement in pain for the first half of the trial but was no better than placebo at the end of the trial. Interestingly, gabapentin was found to reduce the sensory deficits of the effected limb.

There are also several meta-analyses of the analgesic efficacy of antidepressant/anxiolytics (ADs) in neuropathic conditions, with some low-quality evidence supporting the use of ADs in CRPS. These drugs have obvious use in managing some of the comorbidities in CRPS, such as major depression and anxiety. Second-generation ADs have not been studied in CRPS, but the so-called
serotonin/norepinephrine reuptake blockers show some promise.

The use of opioids for general chronic pain management is still the subject of some controversy, but this class has anecdotal support for both abortive and prophylactic treatment in CRPS. Only one RCT has been conducted specifically in CRPS, with negative results. In general, neuropathic pain does not respond to opioids as well as nociceptive pain; consequently, neuropathic pain may require higher doses (with an increase in the risk of side effects). Moreover, some animal data suggest that long-term opioid use may actually evoke symptoms characteristic of CRPS, such as allostynia and hyperpathia. NMDA receptor antagonists (e.g., MK-801, ketamine, amantadine, and dextromethorphan), which theoretically should reduce central sensitization, have been considered for the treatment of neuropathic pain, but some of these have proven too toxic for regular clinical use in oral formulations. Ketamine has shown favorable results in case reports of patients with CRPS. There is some ongoing interest in high-dose anesthetic ketamine protocols, although there are no well-controlled studies supporting this approach. There are multiple small RCTs that have evaluated the efficacy of subanesthetic ketamine infusions. These treatment protocols demonstrated some utility, but larger well-designed RCTs are needed to better evaluate safety and efficacy. Amantadine has shown some benefit in neuropathic pain. Dextromethorphan may augment the effect of other medications, especially opioids.

Clonidine has been considered for the treatment of CRPS but most often by the epidural route. A case series showed that transdermal clonidine could reduce local CRPS-induced hyperalgesia and allodynia, but results of a systematic review failed to support the efficacy of this treatment approach. Nifedipine has demonstrated some benefit in uncontrolled trials, particularly for the management of vasoconstriction. Phenoxybenzamine and phentolamine have some low-quality evidence supporting their use in CRPS. Calcitonin is one of the best studied drugs in the treatment of CRPS. A meta-analysis of a limited number of controlled calcitonin studies supported the therapeutic value of intranasal doses of 100 to 300 U per day for the management of CRPS. However, one study reported no
improvement after administration of 200 IU twice daily for 4 weeks. A recent Cochrane review determined there is a lack of high-quality evidence for the effectiveness of calcitonin treating CRPS.

There are multiple small positive randomized studies of bisphosphonates for the treatment of CRPS. These trials demonstrate an improvement in pain and function. The impact of these drugs on the osteopenia (Sudeck’s atrophy) that is often prominent in chronic CRPS is unknown. Large, definitive trials of bisphosphonates are planned.

Topical medications may also be of some use in management of CRPS. There is limited research endorsing the use of local anesthetic creams in neuropathic pain, but RCTs have not been performed. A patch containing 5% lidocaine is U.S. Food and Drug Administration (FDA)-approved for the management of postherpetic neuralgia and is used anecdotally for CRPS. A study of high-dose topical capsaicin with pretreatment with regional anesthesia demonstrated partial efficacy. In one high-quality study, the topical free radical scavenger dimethyl sulfoxide (DMSO) (50% cream for 2 months) showed significant pain reduction when compared with placebo. Topical clonidine has been mentioned, as discussed earlier. Topical ketamine demonstrated a reduction in allodynia in a small RCT for patients with CRPS.

In most cases, no single drug will provide sufficient analgesia long term, nor will it completely prevent the need for abortive/rescue agents. This clinical reality usually requires multiple medications to adequately manage the pain (see Fig. 25.3). There are numerous other medications that have been anecdotally mentioned as treatments for CRPS (e.g., case reports), but there is insufficient evidence to justify their inclusion in this chapter.

**PSYCHOLOGICAL INTERVENTIONS**

As psychological and sociologic factors often contribute to CRPS pain and dysfunction, and given the relative effectiveness of psychotherapeutic interventions, it is clear psychological and behavioral treatments must play an important role in CRPS management. Such interventions are likely to be maximally effective if provided in the context of multidisciplinary care. Psychological interventions for CRPS, typically
based on cognitive-behavioral therapy principles, should target learned disuse, fear of pain, cognitive responses to CRPS (e.g., catastrophizing), life stress, and emotional distress that may contribute to maintenance or exacerbation of the disorder. Training in relaxation techniques (progressive muscle relaxation, breathing relaxation, autogenics, imagery) is of anecdotal use in giving patients some degree of control over their symptoms, particularly if complemented with biofeedback (especially thermal and myogenic). Moreover, as in all types of chronic pain, better pain coping skills may lead to improved functioning and quality of life and increased ability to self-manage pain. At minimum, such treatments are likely to enhance patients’ sense of control over the condition and thereby reduce fears that may be a barrier to achieving success in functional therapies. Interventions that target a family’s reinforcing responses to the patient’s pain may also be helpful in addressing problems with learned disuse and dysfunction. It should be noted that the aforementioned psychological interventions will only be successful to the extent that patients are willing to accept some responsibility for managing their condition, as opposed to an exclusive focus on achieving a medical “cure.” Facilitating this cognitive shift to a self-management approach is often the first step necessary to achieve successful outcomes in both functional and psychological therapies.

A number of studies have addressed efficacy of psychological interventions for CRPS, although nearly all of these reflect uncontrolled designs that permit only limited conclusions to be drawn. An additional caveat regarding these studies is that the criteria used to diagnose CRPS were often not adequately described and in all likelihood varied substantially across studies. This lack of consistent or specified diagnostic criteria limits the ability to generalize these results to patients diagnosed according to current IASP criteria.

Only one randomized trial specifically testing psychological interventions in CRPS patients has been published to date. In this pilot study, Fialka et al. randomized treatment for 18 CRPS patients to receive either home PT or home PT plus once-weekly autogenic relaxation training for 10 weeks. In this small trial, both groups showed similar improvements in pain, range of motion, and edema, although patients in
the PT plus autogenics group could demonstrate significantly greater improvements in limb temperature.\textsuperscript{337} The impact of this learned control over vasomotor tone and the probable improvement in self-efficacy are unknown.

Results of several published case studies and small case series in adult CRPS patients further support the potential utility of a variety of psychological techniques, including relaxation training, imagery, and thermal and muscular biofeedback. In all of these studies, 75\% to 100\% pain relief was reported despite the fact that these patients had chronic CRPS that had failed to improve with previous medical treatments.\textsuperscript{336,338–341} It should be noted that the complete resolution of symptoms described in some of these cases using only psychological interventions may be atypical. Although the uncontrolled designs used in these studies prevent definitive conclusions from being drawn regarding the efficacy of psychological techniques for CRPS, they clearly support the recommendation that such techniques should play an important role in effective interdisciplinary treatment. Key to this analysis is the very favorable risk–benefit ratio.\textsuperscript{214}

Other research has addressed psychotherapy in the context of multidisciplinary treatment, suggesting that integration of psychological methods with medical and PT may be helpful in managing CRPS.\textsuperscript{220,233,248,342} Two RCTs examining efficacy of PT for CRPS have included components of psychological treatment in the therapy package. Oerlemans et al.\textsuperscript{220,221} tested a PT protocol that included relaxation exercises and cognitive interventions (designed to increase perceived control over pain). This combined intervention was found to produce significantly greater improvements in pain, active range of motion, and impairment levels than were observed in the social work control group.\textsuperscript{221,342} In another RCT of PT, Lee et al.\textsuperscript{248} examined two different frequencies of PT treatment (once per week vs. three times per week) for child and adolescent CRPS patients, with both groups additionally receiving six sessions of cognitive-behavioral treatment. Although no attentional control group was available for comparison, both groups were found to improve significantly in terms of pain and function when compared to their pretreatment baselines.\textsuperscript{248} Although the multicomponent
interventions in both of these studies do not indicate the unique efficacy of psychological interventions, they do suggest that psychological treatment in combination with PT may prove effective in a rehabilitation-focused approach to management of CRPS.214

The efficacy of psychological interventions for CRPS would not be surprising, given the strong evidence of their utility in other types of chronic pain.343–350

**INTERVENTIONAL THERAPIES**

Multiple interventional therapies, including a variety of nerve blocks, infusions, stimulators, and implants, have been used over the years for management of CRPS.217,351 Because the SNS is traditionally implicated in the symptomatology and perhaps the pathogenesis of the syndrome, it is logical (but unfortunately not evidence-based) that sympathetic nerve blocks (SNBs) and surgical sympathectomies have played a prominent role in the treatment (and diagnosis) of CRPS.163,352 In fact, CRPS diagnosis at one time was determined primarily based on a positive response to a sympathetic block.96 However, at present, analgesia to SNBs merely indicates the presence of SMP. SMP is a subset of CRPS, whereas some CRPS patients display sympathetically independent pain.353 The presence of SMP provides a rationale for using SNBs to relieve pain and to provide a “therapeutic window” to allow initiation of, or continued participation in, functional restoration.

Ideally, the pain relief following SNB should outlast the somatic effect of the local anesthetic and may be very long-lasting in some cases.354,355 A systematic review of local anesthetic blocks included 19 retrospective reports, 5 prospective case series, 2 nonrandomized controlled studies, and 3 RCTS; unfortunately, due to the wide range of methodology in the studies, the results were inconclusive.356,357 In the absence of better evidence, if an SNB provides good analgesia in a specific patient, then a short series of empiric blocks in conjunction with active reactivation-focused therapy is advocated based on consensus recommendations.217,351

The brachial plexus is anatomically well suited for continuous regional anesthesia in upper extremity CRPS because of its well-defined perivascular compartment and the close proximity to nerves supplying the
Axillary blocks and catheters have their advocates. Epidural infusions of local anesthetics and sympatholytics (single or continuous infusions) are used empirically and have some research support. Intrathecal analgesia has less support with the exception of research using baclofen. The complications of these interventions must be weighed versus the putative benefits and include bleeding, infection, intravascular injection, intrathecal injection, epidural abscess, pneumothorax, and others.

Use of systemic infusions, especially of sympatholytics such as phentolamine, has been proposed for both treatment and diagnosis of CRPS. One early study showed positive results with guanethidine regional infusion. A later study suggested that neither placebo, phentolamine, nor phenylephrine infusions conferred any benefit. Phentolamine infusion is now seldom used therapeutically and principally used as a putative diagnostic tool to differentiate SIP from SMP. A small RCT reported reduced pain in refractory CRPS patients who received intravenous immunoglobulin treatment. Intrathecal drug delivery of baclofen demonstrated some benefit in a single-blind, placebo-run-in, dose escalation study of CRPS patients with dystonia. However, there was a high complication rate insinuating whether this invasive procedure is worth the risk.

Intravenous regional anesthesia (IVRA) is a procedure that allows infusion of medications directly into the affected region, usually using a variety of sympatholytic agents. IVRA with guanethidine, lidocaine, bretylium, clonidine, droperidol, ketanserin, or reserpine have been described. Although three IVRA studies with active controls have shown positive results, the majority of studies and results of meta-analysis suggest no significant benefits. Some authors advocate combination drug IVRA therapy, and the use of new agents with this technology may eventually establish the worth of this technique (e.g., anticytokine agents).

There is one prospective RCT comparing spinal cord stimulation (SCS) versus “conservative therapy” for upper extremity CRPS. This trial showed a significant reduction in pain and a positive global perceived effect at 6 months, without functional improvement. Marginal
improvement in these features, as well as in health-related quality of life, were maintained at 2 years. At 5-year follow-up, the trial reported no difference between the SCS group and PT alone group. It should be noted that the SCS technology used in this trial was low-frequency, and there has been a call for a new prospective trial to evaluate whether higher frequency or burst stimulation may provide better relief. A recent prospective case series suggested DRGs stimulation may be a more specific neuromodulation technique to target pain in CRPS patients. There are several case reports, predictably supportive of the procedure. There are a variety of other interventions that have been mentioned, such as peripheral nerve stimulation or cortical stimulation, but there is no compelling evidence supporting such interventions to date. Currently, neuromodulation through SCS is being promoted as a cost-effective treatment for CRPS that should be considered early rather than a last resort. Larger prospective trials are needed with the latest technology to determine the efficacy of this treatment modality for patients with CRPS.

DRG stimulation is a new evolving form of neuromodulation for the treatment of CRPS. In a recent prospective case series, eight CRPS subjects with lower extremity pain were implanted with a neurostimulation system placed near lumbar DRGs and reported some degree of pain relief. At 12 months, six of the eight subjects reported ≥50% pain relief in the foot. A prospective observational cohort study randomly compared traditional SCS with DRG stimulation as the preferred treatment of choice for CRPS patients with knee pain after a 16-day trial period. After the trial period, 10 out of the 12 patients preferred DRG stimulation for their preferred treatment. Recently, a large prospective multicenter RCT evaluated the safety and efficacy of DRG stimulation compared to traditional SCS for the treatment of CRPS of the lower limbs. In this trial, 152 subjects were initially randomized into a DRG stimulation group or an SCS (control) group. All subjects that received a trial stimulator (n = 139) and a fully implantable system (n = 114) were analyzed. The primary endpoint was ≥50% pain relief in the primary area of pain and freedom from stimulation-induced neurologic deficits. The percentage of subjects achieving the primary endpoint for DRG stimulation and SCS trial
populations were 81.2% versus 55.7% at 3 months and 74.2% versus 53% at 12 months, respectively. The percentage of subjects achieving the primary endpoint for DRG stimulation and SCS implant populations were 93.3% versus 72.2% at 3 months and 86% versus 70% at 12 months, respectively. These results demonstrate DRG stimulation to be potentially superior to SCS for the treatment of lower limb CRPS. DRG stimulation is a very promising treatment modality for CRPS, and larger trials are needed to further explore its efficacy including duration of benefit.

In the face of this lack of evidence for most interventions in CRPS, it is incumbent on the clinician to carefully consider and fully educate patients as to the risks and cost of any intervention entertained and not overplay anecdotal benefits. One recommended strategy is to use interventional treatments for CRPS only in patients who are having difficulty either starting or progressing in a functional restoration/interdisciplinary program, starting with less invasive blocks, then infusions, and finally, if necessary, progressing to the more experimental neurostimulation techniques.

As surgery is often mentioned as a cause of CRPS, it is somewhat illogical to consider surgery as an effective treatment. Nonetheless, surgical sympathectomy has a long anecdotal history in the treatment of RSD, and more recently, endoscopic and radiofrequency sympathectomy have been tried. There are no RCTs available, and the risks are significant. There is also no strong evidence, and specifically no RCTs, supporting the efficacy of neurolytic procedures, either chemical or radiofrequency.

OTHER THERAPEUTIC MODALITIES
Hyperbaric oxygen therapy has been assessed in one RCT and produced a significant decrease in pain and edema versus “normal air.” These results need replication, but cost–benefit considerations will also be important. Although acupuncture is mentioned in many treatment reviews, there is only one small RCT in CRPS, and this trial failed to show significance. The authors noted that a “definitive trial” was planned, but this has been pending since 1999. There is no evidence supporting the
use of chiropractic manipulation in CRPS. There are many, many other interventions that have been mentioned in the literature but without experimental support. Discussion of the myriad anecdotes extant is far beyond the scope of this effort. Obviously, there is a critical need for well-designed, well-executed, randomized, and, if possible, placebo-controlled trials in CRPS.

In summary, because the symptoms of CRPS patients encompass all the biopsychosocial complexities of chronic pain, the best hope of helping our patients is the adoption of a systematic, stable, empathetic, and, above all, interdisciplinary approach that addresses those symptoms. Drugs, psychotherapy, and interventions should be efficiently deployed for patients who either cannot begin or fail to progress using the interdisciplinary approach outlined here. Many patients will require medication and psychotherapy from the beginning to be successful in the pivotal functional restoration algorithm. Treatment guidelines that center on progressive functional restoration delivered by an interdisciplinary team are traditional; have substantial empiric and anecdotal support; and have been assessed and ultimately codified by three large, expert, consensus-building conferences. Although high-level evidence supporting the rationale for interdisciplinary treatment of CRPS is fairly sparse (as it is for any treatment of CRPS), much stronger evidence exists for the efficacy of the interdisciplinary approach in other pain conditions, such as chronic low back pain. That functional restoration can and should be the central intervention and outcome standard in CRPS is a theory that must be tested (see Fig. 25.2). Until then, the interdisciplinary approach for treating patients with CRPS remains the most pragmatic, helpful, and cost-effective therapeutic approach available today.149

Ambrose Pare, a French military surgeon, is credited with first describing phantom limb pain (PLP) in the 16th century. The concept of PLP was further popularized by Silas Weir Mitchell, a 19th century Civil War surgeon, who coined the term “phantom limb pain” in a publication of a long-term study on the fate of Civil War amputees. PLP may occur in up to 85% of amputees and tends to be seen in the first 3 weeks after amputation, although less commonly may develop 1 to 12 months following amputation. Most phantom sensations resolve without treatment after 2 to 3 years.

Phantom pain refers to pain perceived in a missing body part and may occur in up to 50% to 80% of all amputees. Pain may be related to certain positions or movements of the phantom and may be elicited or exacerbated by a range of physical factors (e.g., changes in weather or pressure on the residual limb) and psychological factors (e.g., emotional stress). It seems to be more intense in the distal portions of the phantom and can have several different qualities, such as stabbing, throbbing, burning, or cramping.

Residual limb pain (RLP)—previously referred to in the literature as stump pain—refers to a regional pain restricted to the distal residual limb. Unlike phantom pain, it occurs in the area of the body that actually exists. Patients may also experience feelings of tingling, itching, cramping, or involuntary movements in the residuum.

Commonly, the phantom is exactly the same size and shape as the missing limb immediately after the amputation. Over time, the phantom may gradually reduce in size and shorten into the residual limb (telescope) so that eventually only the foot, hand, or digits are left on the stump.
Hill\textsuperscript{12} proposed that telescoping occurs in one-third of amputees. The exteroceptive component describes the feelings within the phantom. Examples are “pins and needles,” “tingling,” “tickling,” “itching,” “numbness,” and “like it is asleep.”\textsuperscript{8,12–17} Superadded sensations are the sensation of an object such as a ring, wristwatch, or shoe still being present on the phantom\textsuperscript{18,19} or the return of a painful condition such as an ingrown toenail that existed some time before the amputation.\textsuperscript{10,20} Superadded sensations were identified by 5 of 68 amputees (7\%) in one study.\textsuperscript{11,21} Exteroceptive sensations included pins and needles (50\%) and itching (42.9\%).\textsuperscript{11} The high report of itching is interesting in terms of the mechanism of both PLP and itch. It has been found that similar areas of the brain, including the premotor areas, are involved in both sensations.\textsuperscript{22,23}

**Epidemiology**

In 1983, Sherman and Sherman\textsuperscript{24} published a survey of 590 war veteran amputees in which 85\% reported phantom pain. A study with 2,694 amputees showed that 51\% experienced PLP severe enough to hinder lifestyle on more than 6 days per month, 21\% reported daily pain over a 10- to 14-hour period, and 27\% for more than 15 hours per day.\textsuperscript{25} The incidence of PLP increases with more proximal amputation. RLP is reported in up to 50\% of amputees.\textsuperscript{14,26–31}

PLP is also a major contributor to overall morbidity in veterans and service members after major limb amputation. Of 298 veterans who served in the Vietnam war and 283 service members and veterans who served in Operation Iraqi Freedom/Operation Enduring Freedom (OIF/OEF), 72.2\% (Vietnam) and 76.0\% (OIF/OEF) reported PLP, and 48.3\% (Vietnam) and 62.9\% (OIF/OEF) reported RLP.\textsuperscript{32} Investigation of pain phenotypes in 124 active military service members after traumatic amputation injury found a significant association between neuropathic RLP and posttraumatic stress disorder (PTSD) and depression.\textsuperscript{32}

Predisposing factors for developing PLP have been more challenging to discern. Most prospective studies report that increased pain before amputation is associated with increased PLP after amputation. However,
other studies report no such association. Differences in these findings may be due, in part, to the fact that patients enrolled in prospective studies generally have a preexisting medical disease necessitating the amputation and often exclude patients who suffer traumatic amputation resulting in an overestimation of the association between preamputation pain and PLP.

A retrospective study by Dijkstra et al. of 536 amputees further characterized risk factors based on a logistic regression analysis, finding bilateral amputation and amputation of a lower limb to be the strongest risk factors for PLP. Anxiety as well as passive coping and catastrophizing personality traits were found in one study to be independent contributors to persistent postamputation pain. In addition, there may be a sympathetic component to PLP triggered by stress, anxiety, depression, and other emotional states.

PLP has been reported to occur as early as 1 week after amputation and as late as 40 years after amputation. However, most studies report that the onset of PLP occurs within the first week for 75% of patients, with onset occurring within the initial 24 hours after amputation for nearly 50% of patients. Phantom pain may diminish with time and eventually fade away. However, some prospective studies indicate that even 2 years after amputation, the incidence is not greatly diminished from that at onset.

Modulation of Phantom Pain
Phantom pain may be modulated by multiple factors, both internal as well as external. Exacerbations of pain may be produced by trivial, physical, or emotional stimuli. Anxiety, depression, urination, cough, defecation, sexual activity, cold environment, or changes in the weather may worsen PLP. It also has been reported that general, spinal, or regional anesthesia in amputees may cause appearance of phantom pain in otherwise pain-free subjects.

Pathophysiology of Phantom Pain
The mechanisms underlying phantom pain are complex and multifactorial. Although incompletely understood, the pathophysiology likely involves
peripheral, spinal, and supraspinal mechanisms as well as psychological factors.

After amputation, the distal end of axotomized afferent fibers initially undergoes retrograde degeneration with subsequent regenerative sprouting. These enlarged and disorganized endings of C fibers and demyelinated A fibers often form neuromas that show an increased rate of both spontaneous, ectopic activity, and abnormal, evoked activity in response to mechanical (e.g., pressure, Tinel sign) and chemical (e.g., norepinephrine) stimulation. The proliferation of heterotopic sodium channels (Nav1.3, Nav1.7, Nav1.8) may also lower the stimulation threshold and provoke ectopic discharge.

Clinically, peripheral causes of PLP is supported by the observation that RLP and phantom pain can be temporarily reduced in some (but not all) patients after injection of local anesthetics into stump neuromas. There have also been reports of alleviation of PLP after the removal of neuromas. In contrast, two independent studies found that repetitive touching of the residual limb results in increased PLP. Studies reporting the reduction of phantom pain with drugs blocking the sodium channels lend further support to this theory.

Ectopic discharges can also occur at the level of the dorsal root ganglion (DRG), independently of stump neuromas. This can result in amplification of peripheral signals and recruitment of neighboring neurons. Electrophysiology studies by Nyström and Hagbarth have shown that blocking stump neuromas eliminates the percussion-evoked Tinel sign and associated evoked activity, but does not block the ongoing spontaneous discharge recorded in the nerve. When compared to neuromas, the DRG has proved to be a more robust source of spontaneous firing than neuromas.

The sympathetic nervous system may play a role in potentiating phantom pain. Sympathetic nerve blocks can temporarily relieve phantom pain in some patients, whereas injection of norepinephrine can exacerbate pain. Catecholamines can promote firing of peripheral mechanoreceptors, which in turn may activate sensitized dorsal horn neurons. Increased sympathetic tone can also promote ephaptic neuronal transmission in the periphery. Sympathetic tone is inversely related to skin temperature at the
amputated stump. Investigators have also shown an inverse relationship between phantom pain and skin temperature, suggesting that sympathetic tone promotes pain sensation.

Peripheral nerve injury is also accompanied by reorganization of signal processing at the spinal cord level. Selective degeneration of unmyelinated C fibers results in functional denervation of lamina II neurons in the dorsal horn. A compensatory arborization of Aδ and Aβ fibers “sprouting” into lamina II can occur. This change in innervation is accompanied by phenotypic switching, whereby Aβ-fiber terminals release substance P, a nociceptive peptide. These changes may form the anatomic and neurochemical substrate for the clinical phenomenon of allodynia, where a non-noxious mechanical stimulus is perceived as painful.

Increased excitatory input at the dorsal horn following nerve injury can cause apoptosis of inhibitory interneurons expressing γ-aminobutyric acid and glycine. Activation of microglia after neural injury can result in release of brain-derived neurotrophic factor, which promotes phenotypic switching of inhibitory interneurons, and may lead to release of excitatory neurotransmitters (e.g., glutamate). Opioid receptors are also downregulated along with upregulation of cholecystokinin, which is an endogenous opioid receptor antagonist.

Nikolajsen and Jensen explained that the pharmacology of spinal sensitization involves increased activity in N-methyl-D-aspartate (NMDA) receptor complex, and many aspects of the central sensitization can be reduced by NMDA receptor antagonists. This was supported in human amputees where the evoked stump or phantom pain produced by repetitive stimulation of the stump by nonnoxious pinprick was reduced by the NMDA receptor antagonist, ketamine.

Waxman and Hains proposed that abnormal expression of Nav1.3 sodium channels in the second- and third-order neurons along nociceptive pathways after spinal cord injury may make these neurons hyperexcitable. These neurons may then function as pain amplifiers/generators and conceivably contribute to phantom phenomena.

Peripheral injury after amputation is also accompanied by remapping of supraspinal synaptic networks, including those in the primary somatosensory cortex. Some patients with PLP exhibit “topographical
remapping,” where stimulation of an unaffected site (e.g., face) will result in a sensation perceived in the phantom limb. Functional imaging studies have shown activation of areas in the primary somatosensory cortex and are both adjacent and distant from the area normally subserving the affected limb. Topographical remapping appears to correlate with persistence of phantom pain, with data showing that upper extremity amputees with phantom pain have expansion of the mouth area into the hand area in the sensory homunculus (primary somatosensory cortex). These findings have also been described in the primary motor cortex of amputees, with good correlation between reorganization and presence of phantom pain symptoms.

Melzack\textsuperscript{63} observed that a substantial number of children who are born without a limb feel a phantom of the missing part and suggested the existence of a neural network, or neuromatrix, that subserves body sensation and has a genetically determined substrate that is modified by sensory experience. Lotze et al.\textsuperscript{64} revealed that functional magnetic resonance imaging (fMRI) data from amputees without pain and healthy volunteers during a lip pursing task were similar. In amputees with PLP, however, the cortical representation of the mouth extends into the region of the hand and arm. Giummarra et al.\textsuperscript{65} proposed that phantom pain may reflect a maladaptive failure of the neuromatrix to maintain global bodily constructs. Cortical map reorganization may be facilitated via selective loss of C fibers, which occurs after amputations. C fibers appear to have an important role in the maintenance of cortical maps.

Psychological factors can also play a role in the pathogenesis of phantom pain. Although these factors may not play a causative role, they may certainly modulate the pain experience.

Longitudinal diary studies showed that there is a significant relation between stress and the onset and exacerbation of episodes of PLP, probably mediated by activity in the sympathetic nervous system and increases in muscle tension.\textsuperscript{66} Patients who received less support before the amputation tend to report more PLP.\textsuperscript{27}

Animal work on stimulation-induced plasticity suggests that extensive behaviorally relevant (but not passive) stimulation of a body part leads to an expansion of its representation zone.\textsuperscript{67} Intensive use of a myoelectric
prosthesis is positively correlated with reduced cortical reorganization and analgesic effects. These effects could not be achieved with standard medical treatment and general psychological counseling because it is felt that in order to achieve analgesia, input into the amputation zone of the cortex is needed in order to “undo” the reorganizational changes induced by amputation. Similar beneficial effects on phantom pain and cortical activation were reported for imagined movement of the phantom and may also occur to some degree with mirror treatment (where a mirror is used to trick the brain into perceiving movement of the phantom when the intact limb is moved).

**Prevention of Phantom Pain**

PLP cannot currently be completely prevented; however, perioperative epidural techniques, placement of peripheral nerve catheters, and other analgesic strategies utilized preoperatively, intraoperatively, and postoperatively may at least address postoperative pain control better than not employing any specific perioperative analgesic techniques. Madabhushi and colleagues reported on a patient with a history of PLP from a below-knee amputation who then came for an above-knee amputation in the same extremity. Before transection, the sciatic nerve was infiltrated with 0.25% bupivacaine 5 mL and clonidine 50 µg. After the nerve was severed, a 20-gauge epidural catheter was inserted into the nerve sheath and externalized laterally through a separate skin incision. Before closure, 0.25% bupivacaine 10 mL and clonidine 50 µg was injected and then 0.1% bupivacaine and clonidine 2 µg/mL was infused perineurally for the first 96 hours postoperatively. The mean postoperative pain score (from 0 to 10) for 96 hours was 1.2 ± 0.7. The patient required a total of 10 mg of oxycodone postoperatively. Over a 1-year follow-up period, the patient never reported stump or phantom pain.

**Treatment of Phantom Pain**

Treatment for phantom pain often requires a multimodal approach. Treatment options range from behavioral techniques and pharmacologic
treatments to invasive electrical brain and spinal cord stimulation (SCS) and surgical interventions. There remains a paucity of data from large randomized controlled trials to guide treatment options. As a general rule, initial treatments should be low-risk, low-cost, and noninvasive, with more expensive and invasive treatments reserved for patients who fail conservative care.

Pharmacologic Interventions

**ANTIDEPRESSANTS**

Antidepressants are commonly used for many painful conditions but especially for neuropathic pain. Although antidepressants are utilized for the treatment of postamputation pain, they have not been well studied for PAP. Wilder-Smith et al. studied 94 treatment-naive posttraumatic limb amputees with phantom pain (intensity: mean Visual Analog Scale [VAS] score [0 to 100], 40 [95% confidence interval, 38 to 41]) who were randomly assigned to receive individually titrated doses of tramadol, placebo (double-blind comparison), or amitriptyline (open comparison) for 1 month. Wilder-Smith and colleagues concluded that in treatment-naive patients, both amitriptyline and tramadol provided excellent and stable phantom limb and stump pain control with no major adverse events.

Alternatively, Robinson et al. studied 39 persons with amputation-related pain lasting more than 6 months in a 6-week randomized controlled trial of amitriptyline (titrated up to 125 mg per day) or an active placebo (benztropine mesylate). No significant differences were found between the treatment groups in outcome variables when controlled for initial pain scores, thus not supporting the use of amitriptyline in the treatment of postamputation pain.

Kuiken et al. studied four individuals with PLP for at least 3 months after amputation. All subjects received oral mirtazapine between 7.5 and 30 mg per day. An 11-point numeric rating scale (0 to 10) measured pain intensity and relief during monitored outpatient follow-up visits. Mirtazapine use improved the PLP experienced by these subjects by at least 50%, measured by an 11-point numerical rating scale (NRS-11). Subjects with PLP-related sleeping difficulties reported the greatest pain
relief concomitant with improved sleep quality.  

**ANTIEPILEPTIC DRUGS**

Carbamazepine, an anticonvulsant (and heterocyclic), has also been well documented for use in neuropathic pain syndromes and serves as a potent sodium channel blocker. Historically, it has also been the most commonly prescribed anticonvulsant for pain. Despite this, the results of its efficacy on PLP have been mixed. Patterson reported cases of phantom pain that were alleviated with the use of oral carbamazepine. However, only brief, shock-like pain was assessed. There are no studies that have shown its effectiveness in treating any of the other qualities of pain.

The effectiveness of gabapentin in postamputation PLP was studied in a randomized, double-blind, placebo-controlled, crossover study by Bone et al. They evaluated analgesic efficacy of gabapentin in PLP in patients attending a multidisciplinary pain clinic. The daily dose of gabapentin was titrated in increments of 300 mg to a maximum dose of 2,400 mg or the maximum tolerated dose. Nineteen eligible patients were randomized, of which 14 completed both arms of the study. Both placebo and gabapentin treatments resulted in reduced VAS scores compared with baseline. However, the pain intensity difference was significantly greater than placebo for gabapentin therapy at the end of the treatment. Bone et al. concluded that after 6 weeks, gabapentin monotherapy was better than placebo in relieving postamputation PLP.

In contrast, two other studies did not find an association between gabapentin therapy and relief of PLP. One study of 24 patients with chronic phantom limb and stump pain following amputation of various etiologies, found that the average phantom pain intensity differences on the NRS-11 (mean [standard deviation]) in the gabapentin phase did not differ significantly from placebo (0.94 [1.98] vs. 0.49 [2.20], t = 0.70). The second study by Nikolajsen et al. concluded that gabapentin administered in the first 30 postoperative days after amputation does not reduce the incidence or intensity of postamputation pain. Pregabalin may exhibit analgesic effects on postamputation pain states but has not yet been evaluated.

Four PLP subjects were treated during a larger prospective, double-
blind, randomized, placebo-controlled pilot study conducted to test the efficacy of topiramate in managing various neuropathic pain conditions associated with rehabilitation. Three of the four subjects who had experienced over 2 years of refractory PLP experienced significantly reduced pain after treatment with topiramate.

**OPIOIDS**

Mishra et al. reported a case of intractable PLP that did not respond to usual treatment, however, high dose of morphine made the patient totally pain-free.

Wilder-Smith et al. evaluated a recent study of 94 treatment-naive posttraumatic limb amputees with phantom pain who were randomly assigned to receive individually titrated doses of tramadol (mean dose 448 mg) or placebo (double-blind comparison) for 1 month. It was found that tramadol provided excellent and stable PLP and RLP control with no major adverse events. A separate review found a 50% to 90% reduction in pain at 12 to 26 months with methadone 10 to 20 mg per day.

Huse and colleagues studied the efficacy of oral long-acting morphine sulfate (MS) against placebo in a double-blind crossover design in 12 patients with PLP after unilateral leg or arm amputation. The dose of MS was titrated to at least 70 mg per day and at highest 300 mg per day. Pain, reorganization of somatosensory cortex, and pain thresholds were assessed pre- and posttreatment. A significant pain reduction was found during MS therapy but not during placebo. A clinically relevant response to MS (pain reduction of more than 50%) was evident in 42%, with a partial response (pain reduction of 25% to 50%) in 8% of the patients. Neuromagnetic imaging utilizing magnetoencephalographic recordings of three patients showed initial evidence for reduced cortical reorganization with MS treatment concurrent with the reduction in pain intensity. Huse et al. concluded that opioids show efficacy in the treatment of PLP and may also potentially influence cortical reorganization.

Intravenous lidocaine and morphine have also been evaluated for their therapeutic use in postamputation pain. Wu et al. conducted a randomized double-blind trial to compare the analgesic effects of intravenous morphine and lidocaine on postamputation stump and
phantom pains. A bolus of morphine, lidocaine, and an active placebo (diphenhydramine) were used over a span of 3 consecutive days. The results showed that 31 of 32 subjects enrolled completed the study. Eleven subjects had both stump and phantom pains; 11 and 9 subjects had stump and phantom pain alone, respectively. Compared with placebo, morphine reduced both RLP and phantom pains significantly. In contrast, lidocaine decreased RLP but not phantom pain. The authors concluded that the mechanisms of RLP and phantom pain are different.88

**NMDA RECEPTOR ANTAGONISTS**

To date, six studies have investigated the effectiveness of NMDA receptor antagonists in PLP: Maier et al., Schwenkreis et al., and Wiech et al. examined memantine versus placebo; Abraham et al. investigated dextromethorphan versus placebo; Nikolajsen et al. investigated ketamine versus placebo; and Eichenberger et al. examined ketamine versus calcitonin, combination ketamine and calcitonin, and placebo.89

Pain intensity was not significantly decreased with 30 mg per day of memantine for 3 to 4 weeks in traumatic amputees with chronic pain in three independent studies.89 Another randomized, double-blind, controlled trial of 19 patients with acute traumatic amputation of the upper extremity found that memantine (20 to 30 mg daily) reduced the number of requested ropivacaine bolus injections during the first week after amputation and significantly decreased PLP prevalence and intensity at 4 weeks and 6 months but not at 12-month follow-up.

A double-blind, placebo-controlled, crossover study of three cancer patients with PLP who received oral dextromethorphan (120 to 180 mg daily) during a 3-week study followed by an additional 1-month continued treatment regimen reduced PLP compared to placebo.90

Stannard and Porter91 described three cases in which PLP was successfully treated with ketamine hydrochloride. Nikolajsen et al.92 administered ketamine intravenously to a patient with established stump pain in a double-blind saline-controlled fashion. Following infusion, stump pain was alleviated for 31 hours.92 Ketamine reduced the allodynic area and wind-up–like pain and increased pressure pain thresholds.92 Treatment was started with ketamine 50 mg taken four times daily dissolved in
juice. No side effects or development of tolerance were observed during a 3-month treatment period.

Nikolajsen et al. administered ketamine (bolus at 0.1 mg/kg/5 min followed by an infusion of 7 µg/kg/min) intravenously to 11 patients with established stump pain and PLP in a double-blind saline-controlled study. All 11 patients responded with a decrease in the rating of RLP and PLP assessed by VAS and McGill Pain Questionnaire (MPQ). Ketamine increased pressure pain thresholds significantly. Wind-up–like pain (pain evoked by repeatedly tapping the dysesthetic skin area) was reduced significantly by ketamine. In contrast, no effect was seen on pain evoked by repeated thermal stimuli. Side effects were observed in nine patients.

Eichenberger et al. conducted a randomized, double-blind, crossover study in which 20 patients received four intravenous infusions of 200 IU calcitonin, ketamine 0.4 mg/kg (only 10 patients), 200 IU of calcitonin combined with ketamine 0.4 mg/kg, placebo, and 0.9% saline. Intensity of phantom pain (VAS) was recorded before, during, at the end, and the 48 hours after each infusion. Ketamine, but not calcitonin, reduced PLP. The combination was not superior to ketamine alone.

**CALCITONIN**

Although calcitonin may have analgesic effects for amputation pain postoperatively, it does not appear to be effective for chronic amputation pain conditions.

Two studies have examined the effectiveness of S-calcitonin infusion in treating PLP. Jaeger et al. compared calcitonin to saline placebo in a group of 21 patients with severe PLP developing within a week after amputation. Eichenberger et al. compared calcitonin to ketamine, combination ketamine and calcitonin, and placebo in 20 patients with chronic PLP. Neither study demonstrated significant improvement in pain scores compared to placebo, and both studies described adverse events including headache, vertigo, facial flushing, nausea, vomiting, sedation, dizziness, and increased phantom sensation.

**TRANSIENT RECEPTOR POTENTIAL CATION CHANNEL SUBFAMILY V MEMBER 1 (TRPV1)**
MODULATORS
Topical capsaicin has been utilized for the treatment of PLP. In a study performed in a double-blind fashion with 24 patients, the authors concluded that capsaicin may be used as an alternative treatment for PLP.97 A 12-week prospective, observational study in 21 patients with PAP (10 with PLP, 4 with RLP, 7 with PLP and RLP) treated with a single 8% capsaicin transcutaneous patch significantly reduced the average pain intensity. After the observational period, 80% of patients with PLP and 50% with both RLP and PLP expressed the wish to receive retreatment with capsaicin 8% patches.98 Future developments may produce higher strength capsaicin products, more potent capsaicin analogues, TRPV1 antagonists, and intravenous capsaicin formulations.

INTERVENTIONAL THERAPY
A wide range of neural blockade techniques have been utilized in the treatment of PLP, including trigger point injections, sympathetic blocks, stump injections, and peripheral nerve blocks as well as epidural and subarachnoid blocks.24 Despite this, studies have shown that only 14% of patients report a significant temporary change and 5% report a prolonged change with these blocks.24

The use of neural blockade in the treatment of PLP is largely based on anecdotal reports in the literature.99–101 Blankenbaker99 reported that sympathetic blocks are successful if amputees are treated soon after the onset of PLP. However, Halbert et al.,102 in a systematic review to evaluate evidence for the optimal management of acute and chronic phantom pain, were unable to find any trials that met criteria for inclusion. A crossover pilot study by Ilfeld et al.103 suggests that ropivacaine 0.5% delivered via continuous peripheral nerve catheter may offer therapeutic relief for intractable PLP.

The use of botulinum toxin A injections in PLP patients has also been utilized for RLP control. It is possible that muscle tension, perhaps resulting from cortical reorganization, may contribute to phantom pain as a trigger of spinal reflexes. Botulinum toxin may work by initiating muscle relaxation in the stump or by modulating the release of neurotransmitters that cause analgesia. In a small pilot trial, researchers injected 100 IU
botulinum toxin A in four muscle trigger points of a residual stump. It was found that the use of botulinum toxin A reduced phantom pain about 60% to 80%. These findings were supported by another pilot study with targeted injection of 500 IU botulin toxin A via electromyography into the residual stump.

Kern et al. administered a total dose of 2,500–5,000 IU of botulinum toxin type B to the residual stump of upper and lower extremity amputees. Two patients reported that the injection was very painful. All patients experienced a reduction in RLP, which lasted for many weeks. Other reports included a reduction in the frequency of pain attacks, cessation of “balloon feelings,” improvement in stump allodynia, and decreased occurrence of involuntary stump movements. In addition, quality of sleep at night significantly improved in one patient.

Furthermore, Kern and colleagues suggested that by diminishing muscle tone, pain, and hyperhidrosis, botulinum toxin may facilitate prosthesis use. Four postamputation patients (one with phantom pain, three with RLP) were each treated with 100 IU botulinum toxin A, divided between several trigger points in the distal stump musculature. In one female patient, in addition to pronounced reduction in phantom pain, the patient reported hyperhidrosis of the stump ceased completely, probably after diffusion of the drug into the dermal sweat glands, leading to longer and safer use of the prosthesis. Intentional intradermal injection for this purpose therefore could be potentially valuable. Another patient was able to use her prosthesis for the whole day again after botulinum toxin A treatment for substantial RLP, compared with only 4 hours a day before treatment. In two male patients, RLP while wearing the prosthesis subsided to a considerable extent, and one of the two reported an improvement in steadiness of gait. They suggested that stump treatment with botulinum toxin in rehabilitative medicine should be investigated in more detail.

In a larger, randomized, double-blind pilot study, 14 amputees with intractable RLP and/or PLP who had failed conventional treatment received either one botulinum toxin injection or an injection of lidocaine and methylprednisolone (Depo Medrol). The study found that both botulinum toxin and lidocaine/methylprednisolone (Depo Medrol)
injections resulted in immediate improvements of RLP and pain tolerance for the entire 6-month follow-up period. However, no immediate improvement of PLP and no change in posttreatment VAS-PLP were observed after botulinum toxin or lidocaine/methylprednisolone (Depo Medrol) injection.  

Dahl and Cohen treated six soldiers with RLP and phantom pain with a series of perineural etanercept injections. Five of the six patients reported significant improvements in RLP at rest and with activity, PLP, functional capacity, and psychological well-being 3 months after injections. The one soldier who failed therapy was the only patient who presented with pain greater than 1 year in duration. At the reduced doses administered, no adverse effects were observed. These results seem to warrant further large well-designed studies.

**NEUROMODULATION**

Transcutaneous electrical nerve stimulation (TENS) has been used with some success in the treatment of phantom pain. Katz and Melzack reported that 10 minutes after receiving low-frequency (4 Hz), high-intensity (10 to 30 V) auricular TENS, phantom pain patients demonstrated a modest yet statistically significant decrease in pain as measured by the MPQ. Investigators have reported good to excellent results in roughly 25% of patients treated with TENS. A case series involving two patients with PLP showed a significant improvement in perception of PLP and sensations that was maintained at 1-year follow-up using TENS applied to the contralateral limb. The study author acknowledges that a randomized controlled trial to confirm these outcomes is necessary. A systematic review of controlled clinical trials investigating the effectiveness of acupuncture/TENS for phantom limb syndrome found that there is some evidence for the use of acupuncture and TENS for the treatment of PLP/phantom limb sensation but insufficient high-quality evidence.

Repetitive transcranial magnetic stimulation (rTMS) focused at the motor cortex has demonstrated therapeutic benefit in treating PLP in multiple studies. The therapy is thought to target synaptic mechanisms linked to long-term potentiation and long-term depression.
phenomena. A study of 27 patients with unilateral amputation found reduced PLP pain scores in patients who received real rTMS compared to sham after five treatments and at 1 and 2 months after stimulation. A randomized, double-blind, placebo-controlled, parallel group study of 54 landmine victims found that active rTMS induced a significantly greater reduction in pain intensity 15 days after treatment compared with sham; however, this effect was not significant 30 days after treatment. Similarly, transcranial direct current stimulation has shown encouraging results in two independent small-scale, double-blind, sham-controlled studies.

SCS has also been used for PLP since the 1970s. Early studies in patients with PLP implanted with subdural and epidural electrodes found 45% to 100% had greater than 50% pain relief at initial follow-up. Seigfried and Zimmerman reported that 51% of patients with SCS had a 50% or more decrease in pain but without long-term follow-up. Viswanathan et al. found that 100% of patients had >80% pain relief and McAuley et al. found that 92% and 100% had >50% pain relief immediately and at long-term follow-up (median of 11 years), respectively. These studies propose that SCS for PLP may be an effective intervention for select patients who have not obtained adequate relief with other interventions.

Direct stimulation of the DRG is a relatively novel therapeutic treatment option that offers more targeted paresthesia stimulation. A pilot study of eight patients with PLP looked at percentage of pain relief and change in analgesic medication intake immediately after placement and at 5- to 24-month follow-up. The average immediate pain relief was 50%. Of the seven patients available for follow-up, three continued to have >50% pain relief. The use of radiofrequency stimulation prior to DRG implantation has been proposed as a method to improve accurate coverage of the phantom limb by targeting the DRG.

Peripheral nerve stimulation allows even more focused targeting of electrical stimulation. A few devices have been marketed specifically for PLP based on limited pilot data and case reports. Larger studies are needed to evaluate long-term efficacy of these devices.

Bittar and colleagues concluded that deep brain stimulation has been
utilized successfully for the treatment of PLP resulting in decreased pain scores, decreased opiate intake, and improved quality of life. Bittar et al.\textsuperscript{133} published a meta-analysis supporting this pain improvement as well, especially in the burning component—perhaps via a reorganization in the central nervous system.

Sol et al.\textsuperscript{134} used chronic motor cortex stimulation in three patients with intractable PLP after upper limb amputation. fMRI correlated to anatomical MRI permitted frameless image guidance for electrode placement. Pain control was obtained for all the patients initially, and the relief was stable in two of the three patients at 2-year follow-up. fMRI data may be useful in assisting the neurosurgeon in electrode placement for this indication.\textsuperscript{134}

**SURGICAL INTERVENTIONS**

PLP has generally been difficult to treat with surgical interventions. Part of the difficulty in addressing PLP and stump pain surgically lies in the postsurgical restriction or growth retardation of stump neuromas. Residual limb neuromas develop at the site of the severed end of peripheral nerves. Surgical management may involve implanting the end of severed nerves into a nearby/adjacent large muscle belly, which may alleviate stump pain somewhat, although it does not permanently cure patients.\textsuperscript{93}

Sakai et al.\textsuperscript{135} theorized that preventing neuroma formation might also significantly decrease the incidence of postamputation stump pain. Techniques to prevent neuroma formation include nerve transposition or ligation, embedding of the nerve end in bone or muscle, and capping of the nerve stump with a nerve graft, epineurium, or atelocollagen.\textsuperscript{135,136}

Sehirlioglu et al.\textsuperscript{137} retrospectively studied 75 patients who were treated for painful neuroma after lower limb amputation following landmine explosions between the years 2000 and 2006.\textsuperscript{137} The average time period from use of prosthesis to start of symptoms suggesting neuroma was 9.6 months. The average time period from start of pain symptoms to neuroma surgery was 7.8 months. All clinically proven neuromas were surgically resected.\textsuperscript{137} In the mean follow-up of 2.8 years, all patients were satisfied with the end results, and all were free of any pain symptoms.\textsuperscript{137} In a painful residual limb with clinical diagnostic findings of neuroma, if
conservative measures fail, surgery may be considered as a therapeutic option.\textsuperscript{137}

Aggressive surgical techniques, such as anterolateral cordotomy and dorsal root entry zone lesions, have been attempted in PLP but do not have large multicenter studies supporting their use at all and have significant morbidity and some mortality.

**BEHAVIORAL MEDICINE INTERVENTIONS**

Many psychological modalities have been investigated for managing symptoms of PLP, including biofeedback, relaxation techniques, mirror therapy, virtual reality training, and eye movement desensitization and reprocessing.\textsuperscript{138}

Biofeedback treatments resulting in vasodilatation or decreased muscle tension in the residual limb may help to reduce PLP and seem promising in patients in whom peripheral factors contribute to the pain.\textsuperscript{139} Harden et al.\textsuperscript{140} conducted a pilot study that examined the effectiveness of biofeedback in the treatment of nine individuals with PLP who received up to seven thermal/autogenic biofeedback sessions over the course of 4 to 6 weeks. Pain was assessed daily using the VAS, the sum of the sensory descriptors, and the sum of the affective descriptors of the McGill short form. Interrupted time series analytical models were created for each of the participants, allowing biofeedback sessions to be modeled as discrete interventions.\textsuperscript{140} Analyses of the VAS revealed that a 20% pain reduction was seen in five of the nine patients in the weeks after session 4 and that at least 30% pain reduction (range: 25% to 66%) was seen in six of the seven patients in the weeks following session 6.\textsuperscript{140}

Relaxation training has also been shown to provide significant benefit in many patients. One report noted that 12 of 14 patients with chronic PLP improved with muscular relaxation training.\textsuperscript{138} Hypnotic imagery has been used alone and with relaxation training; however, further studies need to be done before any conclusions regarding this therapy can be made.\textsuperscript{141}

Ramachandran and Rogers-Ramachandran\textsuperscript{16} described another behaviorally oriented approach: A mirror was placed in a box, and the patient inserted his or her intact arm and the residual limb. The patient was then asked to look at the mirror image of the intact arm, which is perceived
as an intact hand where the phantom used to be, and to make symmetrical movements with both hands, thus suggesting real movement from the lost arm to the brain. This procedure may reestablish control over the phantom limb and alleviate pain in some patients, although controlled data are lacking.

Graded motor imagery is a promising, nonpharmacologic means of treating PLP. A randomized controlled trial using graded motor imagery to treat complex regional pain syndrome type 1 and PLP showed number needed to treat of 3 at 6 months for a composite endpoint of 50% pain reduction and improvement in function.142 Patients in the placebo arm of this study received standard physical therapy and usual medical care. Graded motor imagery involves training patients to improve right/left discrimination and imagine pain-free movements of affected and normal limbs followed by practicing pain-free movements with the aid of a mirror box.142

Murray et al.143 reported three patients who experienced PLP (two with an upper limb amputation and one with a lower limb amputation) that took part in between two and five immersive virtual reality (IVR) sessions over a 3-week period. The movements of patients’ anatomical limbs were transposed into the movements of a virtual limb.143 All patients reported the transferal of sensations into the muscles and joints of the phantom limb, and all patients reported a decrease in phantom pain during at least one of the sessions.143 The authors suggested the need for further research studying IVR for PLP using controlled trials.

Schneider et al.144 evaluated eye movement desensitization and reprocessing (EMDR) treatment with extensive follow-up. Five patients with PLP ranging from 1 to 16 years who were on extensive medication regimens underwent 3 to 15 sessions of EMDR, which was used to treat the pain and the psychological ramifications.144 EMDR resulted in a significant decrease or elimination of phantom pain, reduction in depression and PTSD symptoms to subclinical levels, and significant reduction or elimination of medications related to the phantom pain and nociceptive pain at long-term follow-up.144 Further research is needed to explore the theoretical and treatment implications of this information-processing approach.144
MISCELLANEOUS TREATMENTS FOR RESIDUAL LIMB PAIN

Chronic RLP may occur as a result of skin pathology, vascular insufficiency, infection, bone spurs, or neuromas.\textsuperscript{12,39,40,136} Fitting of a prosthetic socket is a critical stage in the process of rehabilitation of a transtibial amputation (TTA) patient because a misfit may cause pressure ulcers or a deep tissue injury (DTI; necrosis of the muscle flap under intact skin) in the residual limb.\textsuperscript{145} To date, prosthetic fitting topically depends on the subjective skills of the prosthetist and is not supported by biomedical instrumentation that allows evaluation of the quality of fitting.\textsuperscript{145} Portnoy et al.\textsuperscript{145} concluded that real-time patient-specific finite element analysis of internal stresses in deep soft tissues of the residual limb in TTA patients is feasible. This method may be improving the fitting of prostheses in the clinical setting and protecting the residual limb from pressure ulcers and DTI.\textsuperscript{145}

The use of a myoelectric prosthesis might be one way to influence PLP. Intensive use of a myoelectric prosthesis was positively associated with both less PLP and less cortical reorganization.\textsuperscript{146} One study found that use of a forearm prosthesis with somatosensory feedback is effective in reducing PLP.\textsuperscript{147}

Topical clonidine patches (and other topical therapies) have been utilized on the residuum but have not been studied. For relatively superficial neuromas, lidocaine via iontophoresis (e.g., LidoSite patch [developed and manufactured by Vyteris, Inc, Fair Lawn, NJ]) theoretically may be useful.

Gruber et al.\textsuperscript{148} prospectively evaluated “neurosclerosis” of residual limb neuromas, present after amputation, on 82 patients by means of high-resolution sonographically guided injection with up to 0.8 mL of 80% phenol solution. During treatment, all patients had marked improvement in terms of reduction of pain measured with a VAS.\textsuperscript{148} Twelve (15\%) of the subjects were pain-free after one to three treatments, with 9 of the 12 achieving relief with the initial instillation.\textsuperscript{148} After 6 months, patients had an overall decrease in median VAS score from 10.0 ± 1.5 (standard deviation) (range, 2 to 10) to 3.0 ± 2.6 (range, 1 to 10) after one (25 patients), two (12 patients), and three treatment sessions (15 patients).
the 6-month follow-up evaluation, 20 (38%) of the 52 patients reported almost unnoticeable pain, and 33 (64%) reported pain equal to the minimum pain they had reached during phenol injection therapy. In 18 (35%) of the 52 patients, the incidence of painful periods had markedly decreased.\textsuperscript{148} The “neurosclerosis” procedure had a low complication rate (5% rate of minor complications, 1.3% rate of major complications).\textsuperscript{148}

Pulsed radiofrequency treatment of the DRG at the L4 and L5 nerve root level was utilized as a therapeutic option for two patients with peripherally mediated intractable stump pain. A decrease in pain intensity and improved toleration of the limb prosthesis was appreciated in both patients.\textsuperscript{136}

Anecdotes of other analgesic strategies such as acupuncture\textsuperscript{149} and electroconvulsive therapy\textsuperscript{117} for postamputation pain exist.

**Summary**

Phantom pain remains an incompletely understood, difficult to treat pain condition. It is present, at least in the early stages after amputation, in a majority of postamputation patients. It is a painful condition in which an obvious loss of sensory information coupled with a disruption of the nervous system leads to pain. Phantom pain also appears to be a painful condition in which the involvement of supraspinal mechanisms may be more intuitive than in the case of other painful conditions. Optimal treatment approaches involve the coordination of an interdisciplinary pain medicine team familiar with the therapy of postamputation pain syndromes. A combination of pharmacologic, physical medicine and rehabilitation, behavioral medicine, neuromodulation, and interventional treatments may be needed to achieve optimal outcomes. Further basic and clinical research is needed to better understand the pathophysiologic mechanisms, prevention strategies, and optimal treatment approaches for different patients and their varying phantom conditions.

The objective of this chapter is to provide an overview of the clinical presentation and management of herpes zoster and its most common complication in immunocompetent patients, postherpetic neuralgia (PHN). Herpes zoster is a viral infection caused by the reactivation of the varicella-zoster virus (VZV). The primary varicella infection occurs when the patient contracts chicken pox. Following the resolution of chicken pox, the virus then remains dormant in dorsal sensory ganglia and cranial nerve ganglia for years to decades. Individuals are asymptomatic while the virus is dormant, and reactivation of VZV results in a characteristic and usually painful vesicular dermatomal rash. Some patients with herpes zoster develop PHN, and this persisting neuropathic pain can last for years.

Herpes zoster afflicts millions of older adults worldwide each year and causes significant suffering and disability because of both the acute pain that occurs in association with the rash and the chronic pain that is present in those patients who develop PHN. VZV-induced neuronal destruction and inflammation causes pain that interferes with activities of daily living and reduces quality of life. Contemporary advances have improved our ability to both diminish the incidence of these conditions as well as manage the remaining cases more effectively. These include the development of herpes zoster vaccines, consensus that antiviral therapy and aggressive pain management can reduce the burden of this disease, the identification of efficacious treatments for PHN, and the recognition of PHN as a study model for neuropathic pain research. An interesting ongoing development is recognition of phenotype-based identification of subsets of patients that may help clinicians make individualized...
Clinical Picture and Natural History of Herpes Zoster

Herpes zoster is a neurodermatomal illness that does not cross the midline. Typically, a single dermatome is affected in immunocompetent patients, although in some cases, involvement of adjacent dermatomes can be seen due to normal variation of cutaneous innervation. In immunocompromised patients, there can be cutaneous dissemination and, rarely, visceral dissemination. The sequence of events described in the following sections is typically observed.

PRODROME

Herpes zoster may begin with fatigue, headache, or flu-like symptoms, including fever, neck stiffness, malaise, and nausea. This may be accompanied by unilateral dermatomal pain and abnormal sensations, including pruritus. The prodromal symptoms usually precede the appearance of a rash by 3 to 7 days, although longer periods have been reported. The prodrome probably occurs in association with the initiation of viral replication and the accompanying inflammatory response. This process results in ganglionitis as well as the destruction of neurons and supporting cells in the dorsal root ganglion (DRG) and accompanying dermatome. In cases where patients experience a prolonged course of prodromal symptoms, diagnostic investigations are frequently undertaken to identify other medical conditions that may cause pain in the affected anatomic distribution. Common examples include pursuing the diagnosis of glaucoma in cases of herpes zoster ophthalmicus; sciatica in cases of sacral dermatomal involvement; and angina, renal colic, or cholecystitis in cases of truncal involvement. Diffuse or regional adenopathy is seen in a minority of cases and has not been correlated with any residual or long-term complications.

RASH

The reactivated virus replicates in the sensory ganglion and travels antidromically via the cutaneous nerves to the nerve endings at the
dermoepidermal junction. Further replication in the skin results in tissue inflammation and necrosis which ultimately leads to the appearance of a rash in the same distribution as the prodrome. The rash is initially maculopapular and evolves into the classic appearance of grouped vesicle formations on an erythematous base. Regional lymphadenopathy may appear at this stage. Over the next 7 to 10 days, the lesions progress to a pustular rash. Open lesions will develop superficial crusting. Scabs are cleared within 2 to 3 weeks. Skin in the affected region may be left completely normal or may develop a patchwork of either hypo- or hyperpigmented scarring (Fig. 27.1).

![Order of Rash Progression](image)

**PAIN**

Pain often precedes or accompanies the herpes zoster rash.\(^7,8\) Pain may be accompanied by other sensations such as itching, paraesthesias (i.e., nonpainful abnormal sensations that are not unpleasant), and dysesthesias (i.e., nonpainful abnormal sensations that are unpleasant). The timing of the pain may be constant or intermittent, and the quality of the pain is variously described as burning, throbbing, stabbing, electric shock-like, or various combinations of these. It is frequently associated with increased
tactile sensitivity and allodynia (i.e., pain in response to a normally nonpainful stimulus). The pain may interfere with the patient’s sleep and other aspects of physical and emotional functioning. The acute pain associated with herpes zoster gradually resolves in most patients around the time that the rash resolves. Pain that persists beyond the acute phase of the rash is considered subacute herpetic neuralgia or PHN, depending on its duration. A distinction between these three phases of pain associated with herpes zoster has been identified and is useful in both clinical and research settings. Acute herpetic neuralgia has been defined as pain that occurs within 30 days of rash onset, subacute herpetic neuralgia as pain that persists beyond 30 days from rash onset but that resolves before the diagnosis of PHN can be made, and PHN as pain that persists for 120 days or more after rash onset (Fig. 27.2).

![Diagram](image)

**FIGURE 27.2** Natural history of herpes zoster and postherpetic neuralgia.

**DISTRIBUTION OF HERPES ZOSTER**
Thoracic dermatomes are the most commonly affected sites. These are followed, in order of incidence, by the ophthalmic division of the trigeminal nerve, other cranial nerves, and cervical, lumbar, and sacral dermatomes. The reason for this pattern is not understood, but it has been speculated that this may reflect the characteristic distribution of the chicken pox rash. The pattern of rash seen in herpes zoster follows the same centripetal distribution observed with the primary varicella infection. Patients can develop lesions in the adjoining dermatomes, and much less commonly, a diffuse cutaneous or even visceral dissemination can occur, most often in immunocompromised individuals.

### CLINICAL VARIANTS

#### Herpes Zoster Ophthalmicus

Herpes zoster ophthalmicus (HZO) occurs in approximately 10% to 20% of herpes zoster cases.\(^1\) The involvement of the ophthalmic branch of the fifth cranial nerve is five times as common compared with cases involving the maxillary or mandibular branches. The predilection for the ophthalmic branch may be due to more frequent trauma to that area with subsequent virus reactivation.\(^2\) It is easily recognized by the presence of vesicles and erythema of the ipsilateral forehead and upper eyelid. HZO requires particularly prompt treatment and careful follow-up monitoring because of the possibility of ocular involvement, which occurs in approximately one-half of patients with HZO (Fig. 27.3).

![Ophthalmic Zoster](image)

#### Herpes Zoster Oticus (Ramsay-Hunt Syndrome)

This presentation of herpes zoster is relatively rare, but this may reflect, at least in part, a failure to properly recognize and diagnose cases.
Classically, herpes zoster oticus begins with otalgia and the formation of herpetiform vesicles within the external ear canal. Associated findings that may be present include facial paralysis resulting from facial nerve (cranial nerve VII) involvement, auditory symptoms including unilateral deafness, and/or vestibular symptoms. This condition may also result from zoster of the 9th or 10th cranial nerves because the external ear has complex innervation by branches of several cranial nerves (V, VII, IX, and X) as well as vertebral nerves C2 and possibly C3.

**Zoster Sine Herpete**
Herpes zoster infections presenting with only dermatomal pain in the absence of rash have been described in the literature for many years.\(^{13,14}\) The actual prevalence of this condition is unknown. Positive serology in the acute or convalescent phase is the only definitive way to establish the diagnosis in such patients. Given that it would be rare to perform the required serologic studies early in the disease course in most clinical settings, this diagnosis is rarely confirmed.

**Diagnosis of Herpes Zoster**
The diagnosis of herpes zoster is usually established based on the clinical findings of a characteristic dermatomal rash (Fig. 27.4) and the presence of associated pain. The differential diagnosis frequently includes contact dermatitis. Herpes simplex virus (HSV) infection must also be considered, particularly if sacral dermatomes are involved. The main differentiating features of an HSV infection are that it tends to occur predominantly around the mouth or genitalia, is more prevalent in younger patients versus the predilection for herpes zoster to afflict more elderly patients, and HSV has a propensity for recurrent outbreaks which are relatively rare in herpes zoster. In cases of atypical presentations or when there is confusion as to whether VZV or HSV is the pathogen, diagnosis can be confirmed by laboratory testing.
LABORATORY TESTING

Viral Culture
Isolation of the virus in cell cultures can be done but takes 1 to 2 weeks to complete. The virus is also quite labile and may be difficult to recover from lesion swabs especially after the vesicular phase has resolved. This test has low sensitivity but high specificity. Treatment of presumed cases should not be delayed to await culture results given the prolonged turnaround time and low sensitivity (and thus high false-negative rate) of the test.

Direct Immunofluorescence Assay
Direct immunofluorescence assay is often preferable to viral culture due to its low cost and rapid turnaround time, which can be within 1.5 hours. Sensitivity is approximately 90% but decreases if the lesions are beyond the vesicular stage.

Viral DNA Testing
Viral DNA can be detected in the vesicle fluid and cutaneous tissue by polymerase chain reaction (PCR) technology. It has the advantage that it can be effective even on old and crusted lesions. It usually has a turnaround time of 1 day but can be completed in less than 5 hours with rapid real-time PCR. It is generally more expensive than other approaches and has exceptional sensitivity and specificity of near 100%.
**Biopsy**
A biopsy is not typically needed in clinical practice and should be reserved for difficult to diagnose cases. Histologic findings of ballooning degeneration and acantholysis of keratinocytes resulting in intraepidermal vesicles are common to all herpes infections. Multinucleated giant cells with accentuation of nuclear material at the periphery of the nuclei are present. Underlying leukocytoclastic vasculitis is often a prominent finding and helps differentiate zoster from other herpesvirus infections.

**Testing for Underlying Disorders**
If clinically indicated, testing for HIV or occult malignancy may be advisable, but this is typically not necessary and is not recommended on a routine basis.

**Epidemiology of Herpes Zoster**
The epidemiology of herpes zoster is primarily affected by a combination of the incidence of primary varicella infections as well as age and level of immunosuppression in the population. Herpes zoster is among the most common of neurologic illnesses, affecting about 1 million people in the United States annually. According to the Centers for Disease Control and Prevention (CDC), the lifetime incidence of herpes zoster in the United States is estimated to be 32%. A systematic review of global herpes zoster incidence rates found between 3 and 5 cases per 1,000 person-years in North America, Europe, and the Asia Pacific, with a precipitous increase beyond that noted with aging. At 60 years old, the incidence increases to 6 to 8/1,000 person-years and 8 to 12/1,000 person-years at 80 years of age. The findings were similar in a subsequent study of the incidence of herpes zoster in the United States. Accordingly, increasing age is the most potent risk factor for herpes zoster in both immunocompetent and immunocompromised individuals (Table 27.2). The decline in VZV-specific cell-mediated immunity is believed to drive the increase in herpes zoster observed in patients as they age. There is a notable increase in disease rates around 50 years of age, and the lifetime prevalence reaches approximately 50% in individuals.
living to be 85 years of age. There has also been a higher incidence in women, thought to be related to a combination of biologic factors (immunologic or hormonal) as well as differences in health seeking behaviors.

Immunocompromised individuals have a relatively high risk for developing herpes zoster. Patients with a history of HIV infection, solid organ and bone marrow or stem cell transplantation, immunosuppressive chemotherapy, or systemic lupus erythematosus are 2 to 10 times more likely to develop herpes zoster compared to immunocompetent individuals. Immunocompromised individuals also experience higher recurrence rates of zoster compared to those who are immunocompetent.

Other factors that appear to increase the risk for herpes zoster that are less well replicated include Caucasian versus African American racial group, presence of elevated psychological stress, physical trauma, and diabetes mellitus. Exposure to varicella antigen, either through contact with chicken pox or by vaccination, has a protective effect and reduces the incidence of herpes zoster.

The epidemiology of varicella and herpes zoster is likely to change as childhood vaccination against the primary infection alters the long established relationships between humans and this viral infection. The incidence of primary varicella infections has declined dramatically in the
United States since the implementation of routine childhood vaccination. It has been hypothesized that there will be an acceleration of incidence of herpes zoster beyond expectations in the future as the opportunities for subclinical immune boosting in aging adults, which result from exposure to VZV, will decline due to the decreased incidence of chicken pox. To date, there is little evidence to support this hypothesis, as multiple studies have demonstrated rates of herpes zoster increasing across all adult age groups before the implementation of the varicella vaccine in 1996, and that have continued since. Furthermore, the rates of herpes zoster are similar in areas with high levels of varicella vaccination and those without. One population-based study analyzed the incidence of herpes zoster over a 60-year period and noted an over fourfold increase was not likely related to introduction of the varicella vaccine. Furthermore, a decrease in the number of herpes zoster cases in children less than 10 years of age has been reported, presumably due to vaccination. It is possible that there has not been enough time since the implementation of the recommended childhood varicella vaccination for the acceleration in zoster incidence to be observed.

Eventually, as children immunized against VZV grow into adulthood, the number of adults infected with latent wild-type virus will decrease. Therefore, the incidence of herpes zoster is expected to decline as the live attenuated virus used in the varicella vaccine appears to be less likely to reactivate and cause herpes zoster.

Pathophysiology of Herpes Zoster and Mechanisms of Acute Pain

As noted earlier, herpes zoster most commonly manifests in the distribution of a single dorsal sensory or cranial nerve ganglion. Why the reactivation occurs in one ganglion when latent virus is present throughout the patient’s sensory ganglia is not clear. Declining cellular immunity is a major risk factor for reactivation of the virus, which is thought to occur when cell-mediated immunity falls below a critical level. This impression is supported by evidence that even individuals with adequate levels of serum antibodies to VZV antigen can, over time, exhibit T cells
with reduced ability to proliferate and defend against VZV infections.\textsuperscript{44}
Hence, cell-mediated immunity appears to play a crucial role in preventing reactivation of latent VZV (Fig. 27.5). Common causes of decreased cellular immunity include increasing age, various diseases, and immune-suppressing medical interventions, all of which are known risk factors for herpes zoster.

**FIGURE 27.5** Host factors in varicella-zoster virus (VZV) latency and reactivation. Varicella is the primary infection caused by VZV, and its resolution is associated with the induction of VZV-specific memory T cells (blue line). Memory immunity to VZV may be boosted periodically by exposure to varicella or silent reactivation from latency (red peaks). VZV-specific memory T cells decline with age. The decline below a threshold (black line below zoster threshold) correlates with an increased risk of zoster. The occurrence of zoster, in turn, is associated with an increase in VZV-specific T cells. The administration of zoster vaccine to older persons may prevent VZV-specific T cells from dropping below the threshold for zoster occurrence (dashed blue line). (Reprinted from Arvin A. Aging, immunity, and the varicella-zoster virus. *N Engl J Med* 2005;352[22]:2266–2267. Copyright © 2005 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

During reactivation of the virus, newly synthesized viral particles are transported in a retrograde and anterograde fashion to the central and distal axons of the involved spinal or cranial sensory ganglion. Viral replication causes inflammatory and neural tissue injury in the affected dermatome,\textsuperscript{5} which can ultimately result in infectious hemorrhagic necrosis and subsequent neuronal loss and scarring centered in the sensory ganglion of affected cranial and peripheral nerves.\textsuperscript{4,45} Microscopic examination of the zoster affected ganglion shows significant hypocellularity and collagen scarring. The corresponding peripheral nerves may exhibit a long-lasting reduction in myelinated axons and increased numbers of small unmyelinated axons. These structural changes contribute to the pain and other characteristic sensory findings along the corresponding sensory
dermatomes of the involved ganglion. Excessive electrical activity in the damaged peripheral nociceptors is the major cause of pain in the acute herpes zoster infection. Although VZV is a sensory-specific virus, involvement of anterior horn cells, autonomic neurons, and leptomeninges can be observed as a result of a bystander effect, with consequent muscle weakness, palsy, and/or pleocytosis of cerebral spinal fluid (CSF).

Complications Associated with Herpes Zoster

In general, the frequency and severity of complications are greater in older and immunocompromised individuals. The most common morbidity of herpes zoster in immunocompetent individuals is the development of PHN; this often severe pain can persist well beyond the resolution of herpes zoster. This complication is discussed in detail in the latter part of this chapter.

OPHTHALMIC COMPLICATIONS

The incidence of complications associated with HZO has been reported to be 2% to 6% of cases. A variety of complications have been described, including retinitis, keratitis, iritis, scleritis, secondary glaucoma, and ptosis. These are obviously serious problems that can result in temporary or permanent deterioration in visual acuity or complete blindness. For these reasons, patients with ophthalmic zoster should be evaluated by an ophthalmologist as promptly as possible following diagnosis.

MOTOR NEUROPATHY

Motor nerve involvement is present in 5% to 15% of patients presenting with herpes zoster. Paresis in extraocular nerves, facial nerves, and a variety of other motor nerves has been described. Diaphragmatic paresis is not an uncommon occurrence with the involvement of the phrenic nerve, and intercostal nerve involvement may lead to paresis of intercostal muscles (Fig. 27.6). Involvement of cervical motor nerve roots may present as shoulder and arm weakness, and lower extremity weakness can occur when lumbosacral nerve roots are affected. In some cases, significant motor weakness may be the presenting symptom, and this can
delay accurate diagnosis. In general, paresis improves with time and physical rehabilitation; however, the likelihood and completeness of muscle function recovery appears to decrease with older age and greater initial severity of the paralysis.

![Figure 27.6](image1.jpg)

**FIGURE 27.6** T8 motor neuropathy in an otherwise healthy 59-year-old man who presented with vesicles in the T8 distribution 4 weeks before this photo was taken. The patient was treated with an antiviral agent for 7 days and with analgesics as needed. As the rash resolved, this bulge became apparent; it is consistent with motor damage by varicella zoster virus to the muscles of the abdomen. (Reproduced from Dworkin RH, Johnson RW, Breuer J, et al. Recommendations for the management of herpes zoster. Clin Infect Dis 2007;44[1]:S1–26. Reproduced by permission of Infectious Diseases Society of America)

**RARE NEUROLOGIC COMPLICATIONS**

VZV is a common cause of aseptic meningitis with a sharp pleocytosis and elevated proteins evident on CSF studies. Most patients with VZV meningitis experience a complete resolution of the symptoms in 1 to 2 weeks, although meningeal involvement can result in long-term sequelae from subsequent scarring of the involved neural structures. Myelitis and encephalitis are other rare central manifestations of reactivated VZV. VZV encephalitis can present as an acute delirium accompanied by few focal neurologic signs. Factors that elevate the risk of central nervous system (CNS) involvement include the presence of altered immune function (e.g., HIV), cranial nerve or ophthalmic involvement, two or more prior zoster episodes, and evidence of cutaneous dissemination. Although more common in immunocompromised patients, CNS involvement has also been reported in immunocompetent individuals and in both children and adults. Herpes zoster may be a risk factor for Guillain-Barré syndrome developing within the 2 months following the rash.
**VISCERAL COMPLICATIONS**
Visceral involvement in herpes zoster is rare but may result in organ dysfunction as a consequence of scar formation around the involved structures. In such cases, the associated signs and symptoms would be related to the specific structures mechanically affected by scarring.

**DECREASED QUALITY OF LIFE**
The acute pain associated with herpes zoster can cause significant suffering and is often accompanied by interference in the patient’s ability to carry out normal activities of daily living. In addition, acute pain is associated with the greater use of analgesic medications and their attendant side effects, most notably sedation and constipation.\(^{53-58}\) The resultant impact of herpes zoster and related complications on health-related quality of life is at least as great as what has been found with other chronic diseases such as diabetes or congestive heart failure.\(^57\)

**Treatment of Herpes Zoster**
All patients should have a thorough medical evaluation with added attention to factors related to the individual’s immunocompetence. Patient education, reassurance, and supportive therapy are essential to allay fears and promote compliance with pharmacologic therapy. The primary goals of pharmacologic therapy are to reduce the severity and duration of pain, promote healing of skin lesions, prevent PHN, and decrease ongoing viral replication and shedding, thereby reducing the risk of transmission. Limiting viral replication has been shown to reduce the incidence and severity of acute pain associated with herpes zoster. The primary pharmacologic approaches include the use of antiviral therapy in conjunction with analgesic agents. Steroids have also been used, but their role is more controversial. The potential roles of neural blockade, neuroaugmentation strategies, and complementary and alternative medicine are also controversial.

**PATIENT EDUCATION**
It is important to educate patients and their family members about their
disease. Patients and caretakers can be reassured that herpes zoster does not cause any illness in seropositive individuals who have contact with the patient. Herpes zoster does, however, pose a risk of viral transmission to individuals who do not have preexisting immunity to VZV. Given this, it is important for patients with herpes zoster to avoid contact with individuals who are known to be seronegative for VZV or have known or suspected immune system impairment, especially if it is unclear whether they have a history of chicken pox. Patients should be counseled regarding maintaining appropriate nutrition and optimal levels of social and physical activities. In addition, patients should be told to keep the rash area clean and to avoid application of ointments or adhesive dressings because these can cause skin irritation and secondary infections. Patients should inform their physician if fever, confusion, or other significant constitutional symptoms develop and should return for further evaluation if rash healing appears delayed.

ANTIVIRAL THERAPY
Antiviral therapy has been shown to be efficacious in suppressing viral replication and also has beneficial effects on both acute and chronic pain (Table 27.3).\textsuperscript{59–64} Antiviral medication is recommended for all herpes zoster patients who are older than 50 years, have moderate to severe pain, have a moderate to severe rash, have ophthalmic involvement, or are immunocompromised.\textsuperscript{68} In current clinical practice, most physicians prescribe antiviral therapy to all patients with herpes zoster because of the very favorable risk–benefit ratio of these medications. Antiviral treatment should be started as soon as possible; this should ideally be within 72 hours of the onset of rash, the inclusion criterion for initiating treatment in the clinical trials of antiviral agents in herpes zoster patients. The early initiation of antiviral therapy is intuitively logical and an important treatment objective. However, viral replication may continue beyond the third day after rash onset, suggesting that even delayed antiviral therapy may provide some benefit. Unfortunately, there are no well-designed clinical trials examining the efficacy of initiating antiviral therapy beyond 72 hours of rash onset. Two uncontrolled trials examined the effectiveness of antiviral treatment initiated at a later time, and the results suggested that
such treatment may have beneficial effects. In clinical practice, the diagnosis of herpes zoster is often not made within 72 hours of the onset of symptoms; nevertheless, it is important to identify patients who could still benefit from antiviral medication even when it is initiated relatively late in the disease course. One example of patients who warrant such later initiation of treatment is those with ophthalmic zoster. The duration of viral shedding from the ocular surface is highly variable and may continue for a longer period of time. Immunocompromised patients, those with disseminated zoster, patients with neurologic complications, and possibly those with new lesions still forming should also be started on antiviral medication irrespective of whether they are beyond 72 hours of rash onset.

There are two main classes of antiviral medication, and these are differentiated by their reliance on viral phosphorylation to be activated. The first class of drugs is nucleoside analogues that require phosphorylation by viral thymidine kinase and includes acyclovir, brivudin, famciclovir, and valacyclovir (Table 27.4). These drugs are phosphorylated to a triphosphate form that impairs viral replication by inhibiting viral DNA polymerase. Acyclovir, famciclovir, and valacyclovir are all available in the United States and are approved by the U.S. Food and Drug Administration (FDA) for the treatment of herpes zoster. These medications are excreted renally, and dosages should therefore be adjusted in patients with renal insufficiency. Special dosing regimens are also needed in patients on dialysis. Although the dose necessary to treat HZV is higher than that for HSV, these medications have established safety and are generally well-tolerated. Acyclovir must be taken five times daily for 7 days, whereas famciclovir and valacyclovir are taken three times daily for 7 days. Thus, patient compliance with famciclovir and valacyclovir is
likely to be considerably greater than with acyclovir, and this may translate to somewhat greater efficacy. Famciclovir and valacyclovir may also be somewhat better than acyclovir in reducing the incidence of prolonged pain.66,67,71 Although brivudin is currently not available in the United States, it has been approved for the treatment of herpes zoster in several other countries; it is dosed once daily for 7 days.

NOTE: All antivirals are renally excreted; hence, dosage needs to be adjusted in patients with renal insufficiency, including patients on dialysis. Nausea and headache are common side effects.

The second class of antiviral medications is not dependent on viral phosphorylation. These agents noncompetitively inhibit viral DNA polymerase, and include vidarabine, foscarnet, and cidofovir. Foscarnet is useful in patients with known resistance to acyclovir due to lack of viral thymidine kinase, which can be seen in patients with AIDS or prolonged exposure to acyclovir (as in transplant patients). Hence, this agent plays an important role in treating infections in individuals with known resistance to acyclovir.

**ANALGESIC TREATMENT**

Antiviral therapy does not completely abolish the acute pain associated with herpes zoster, nor does it necessarily prevent PHN,\(^27\) and supplemental analgesic medications are required in most patients. Effective analgesia improves patient comfort and may also reduce the risk of PHN beyond what is achieved by antiviral therapy alone.\(^72,73\) These considerations argue for aggressive management of the acute pain associated with herpes zoster. A multimodal analgesic strategy should be used to balance efficacy, safety, and tolerability of the medication regimen. Unfortunately, well-designed studies to delineate which combinations of therapies are optimal have rarely been conducted. In lieu of focused studies, clinicians must use the available data, extrapolate available information, and individualize therapy based on patient-specific factors. The World Health Organization analgesic ladder can be applied as one useful analgesic strategy with well-proven efficacy and ease of application. Patients with mild pain can be started on acetaminophen alone or in combination with a mild opioid analgesic such as tramadol. Nonsteroidal anti-inflammatory drugs (NSAIDs) can also be used provided
there are no contraindications to their use. Patients with moderate pain can be started on short-acting opioid medications and, if tolerated, can be converted to a timed-release preparation if clinically warranted. Opioids have not been well-studied in patients with herpes zoster, but one small clinical trial did show that controlled-release oxycodone was superior to placebo in relieving acute pain within the first 2 to 3 weeks of rash onset, although the small sample size precluded an evaluation of the effect of this treatment on the development of PHN.\textsuperscript{74}

If acute pain in herpes zoster patients is not adequately controlled with the mentioned analgesics, other medications that have demonstrated efficacy in the treatment of chronic neuropathic pain can also be used in combination with antiviral therapy.\textsuperscript{68} Gabapentin, pregabalin, and tricyclic antidepressants such as nortriptyline and desipramine can be considered in patients when conventional analgesic medications are not adequate in managing acute pain. Studies are limited, but a single-dose trial of 900 mg of gabapentin versus placebo did demonstrate a reduction in acute pain over 6 hours in patients with herpes zoster.\textsuperscript{75} Both gabapentin and pregabalin would seem like reasonable alternatives because they not only have efficacy in the treatment of PHN but have also demonstrated efficacy in reducing pain and analgesic requirements in some acute pain conditions.\textsuperscript{76,77}

Although tricyclic antidepressants have not been well-studied in patients with herpes zoster, they have proven efficacy in chronic neuropathic pain and are additional rational choices for treating acute pain associated with herpes zoster. Dual reuptake inhibitors (selective serotonin and norepinephrine reuptake inhibitors) can be considered in lieu of tricyclic antidepressants given their more favorable side effect profiles. Both duloxetine and venlafaxine have demonstrated efficacy in painful diabetic peripheral neuropathy\textsuperscript{78,79} and could thus be considered a potential therapy for the treatment of acute pain in patients with herpes zoster.

A pragmatic approach is to start with a short-acting opioid in combination with acetaminophen or an NSAID. Gabapentin or pregabalin can then be added if conventional analgesics are not entirely effective. Many clinicians would use one of these medications rather than a tricyclic antidepressant because of their generally safer side effect profile. The
analgesic regimen should be tailored based on the individual patient’s needs and tolerances (Table 27.5). Frequent follow-up and reassessment are vital to assess efficacy and tolerability while titrating analgesic therapy.

**CORTICOSTEROIDS**

The use of corticosteroids in the treatment of herpes zoster has been controversial.\(^{80,81}\) One placebo-controlled trial demonstrated a benefit in terms of significantly accelerated return of uninterrupted sleep, cessation of analgesic therapy, and return to normal activity in patients treated with the combination of a corticosteroid and acyclovir as compared to those treated with acyclovir alone.\(^{81}\) The patients in this trial were 60 years of age on average and possessed no contraindications to corticosteroid treatment. Based on these results, the addition of oral corticosteroids can be considered in healthy older adults with moderate-to-severe pain unrelieved by antiviral therapy and analgesics, provided there are no contraindications to steroid use.

Oral steroids are empirically used in VZV-induced facial nerve palsy or...
other cases of cranial neuritis, although there is limited evidence supporting the effectiveness of such treatment. It must be emphasized that corticosteroids should not be used alone in herpes zoster and must be initiated in combination with antiviral therapy.

**Lidocaine Patch**

A 5% lidocaine patch is traditionally used for PHN pain and approved by the FDA for the same indication. A randomized placebo-controlled study showed that lidocaine patches reduced pain associated with herpes zoster\(^{82}\), based on this information and the excellent side effect profile of lidocaine patches, their use can be considered. The patch should only be applied to intact skin after the initial rash has completely healed.

**NEURAL BLOCKADE**

Although no conclusive and strong recommendations can be made for the use of any invasive interventions due to lack of consistent data, if pain is not controlled with medical management, referral to a pain specialist should be considered for possible interventions. These may include neuraxial injections of local anesthetics and steroids, neuraxial local anesthetic infusion, paravertebral blocks, or sympathetic blocks. All these interventions have been used for years in clinical practice, but few controlled studies have been conducted to systematically examine their effects on herpes zoster acute pain or the development of PHN. As per NeuPSIG recommendations, moderate quality of available evidence provided the basis for a weak recommendation for the use of epidural or paravertebral blocks with local anesthetic and steroids injections for herpes zoster pain.\(^{83}\) These guidelines were based on three RCTs.\(^{84–86}\) One of the RCTs\(^{84}\) found significant reduction in acute pain following a single epidural injection of steroid and local anesthetic within the first month after rash onset as compared to standard therapy alone. The incidence of developing PHN, however, was not reduced in this study. A more recent systematic review and meta-analysis also showed a favorable outcome with the use of interventional procedures for the management of acute herpes zoster related pain; in addition, these authors also addressed the role of interventions in reducing the incidence of PHN.\(^{87,88}\) The findings
suggest that nerve blocks do shorten the duration of acute pain in herpes zoster and repeat or continuous epidural blocks and paravertebral blocks reduce the likelihood of PHN. Single stellate ganglion blocks fail to decrease the incidence, but multiple blocks may have a beneficial effect in this regard. The exact mechanism by which sympathetic or somatic blocks could prevent PHN or lessen its severity is poorly understood. The sympathetic nervous system is important in mediating pain in some neuropathic pain conditions. It has been hypothesized that in the acute phase of herpes zoster, inflammation induces intense stimulation of the sympathetic nervous system leading to reduced intraneural blood flow with resultant neuronal hypoxia and endoneural edema. Other putative mechanisms of sympathetic nervous system involvement include the formation of ephaptic connections between the sensory system and the sympathetic system as well as the upregulation of adrenoreceptors. These phenomena could result in inappropriate activation of primary nociceptive fibers in response to sympathetic nervous system activation. Blockade of sympathetic nerves with local anesthetics may reverse these effects. It is also hypothesized that these interventions may favorably affect the progression of herpes zoster acute pain to PHN because the effective treatment of acute pain may prevent the development of PHN or at least decrease the severity of subsequent PHN.

In conclusion, we do not make a strong recommendation for routine use of interventions for acute herpes zoster pain. Interventions can be considered if the pain is not well controlled, or if pharmacotherapy results in intolerable side effects. The use of local interventions should be carefully considered, and the type of intervention should be guided by the patient’s condition and the provider’s expertise.

COMPLEMENTARY AND ALTERNATIVE MEDICINE
Complementary and alternative medicine modalities are becoming increasingly popular in patients with acute as well as chronic pain conditions and herpes zoster, and related pain syndromes are no exception. Integrative (complementary) therapies include meditation, hypnosis, relaxation therapy, imagery, music therapy, magnet therapy, dietary and herbal supplements, and acupuncture. There are no reliable data available
that will help make strong and specific recommendations in the treatment of zoster-related pain with these approaches.

Acupuncture has been examined in small studies for the treatment of herpes zoster pain. One of the mechanisms of action is thought to be associated with endorphin release at both the spinal and supraspinal levels. In a small randomized study, subjects were randomized to receive weekly acupuncture treatment versus standard therapy including pregabalin, local anesthetic injections for all patients and opioids for patients who had intractable pain. Patients in the acupuncture arm were only allowed acetaminophen as a rescue analgesic. No significant differences were observed between the groups in terms of mean pain reduction, incidence of PHN or total pain burden, concluding that acupuncture could have similar efficacy as conventional analgesic therapies. Although this study alone does not provide high-quality evidence to support the routine use of acupuncture, it does provide some evidence as to the potential role of acupuncture in the treatment of acute herpes pain.

SPINAL CORD STIMULATION

Spinal cord stimulation (SCS) has been tried in a case series of four patients with active herpes zoster and reported to be effective. It is difficult to extrapolate these results to routine clinical practice as the majority of patients with herpes zoster have resolution of their symptoms as part of the natural history of the disease; hence, authors do not recommend this modality of treatment for acute zoster.

Prevention of Herpes Zoster

CHILDHOOD VACCINATION

The propensity to develop herpes zoster and PHN can ultimately be traced back to an individual’s primary varicella infection. Thus, one obvious prevention strategy would include the prevention of the primary VZV infection through the use of varicella vaccination in childhood. Two types of vaccines are approved by the FDA for vaccination in children from 12 months to 12 years of age; both are based on the Oka virus. The first agent is a single-antigen vaccine, and the more recent vaccine is a combination
product and protects against multiple childhood infections (i.e., measles, mumps, rubella, and varicella). The current recommendations for routine immunization of immunocompetent children are two doses of varicella vaccine (either single antigen or combined product) with the first dose at 12 to 15 months, followed by a second dose at 4 to 6 years of age. The live attenuated Oka vaccine virus establishes latency in sensory ganglia, like wild-type VZV, but it appears to cause herpes zoster much less frequently. Hence, childhood varicella vaccination should eventually result in an overall decrease in the incidence of herpes zoster and PHN.

### VARICELLA-ZOSTER IMMUNOGLOBULIN
Temporary passive immunization may be required in specific circumstances. The CDC currently recommends administration of purified varicella-zoster immune globulin preparation, VariZIG (Cangene Corp, Winnipeg, Canada), to prevent or modify clinical illness in immunocompromised or pregnant seronegative persons and a select group of infants with recent exposure to patients with chicken pox or zoster. VariZIG should be administered as soon as possible, ideally within 96 hours of exposure to provide maximum benefit, but it may be used within 10 days. Treatment with VariZIG should be followed by vaccination in eligible patients 5 months after administration.

### HERPES ZOSTER VACCINATION FOR ADULTS
Herpes zoster is caused by reactivation of VZV from a single sensory ganglion. The precise mechanism of reactivation is not known but thought to be due to waning VZV specific cell-mediated immunity. Therefore, adult vaccination can confer the immunologic boost to prevent herpes zoster and the associated pain, suffering, and decreased quality of life.

In 2006, a live attenuated Oka virus–based varicella vaccine was approved by the FDA for adults 60 years of age or older. The approval was based on the results of the Shingles Prevention Study—a large, multicenter, randomized, placebo-controlled trial—that established efficacy and safety of a single-dose herpes zoster vaccination. The results of the trial indicated that the herpes zoster vaccine reduces the likelihood of developing herpes zoster in immunocompetent individuals 60
years of age or older. Important results of this study included a decrease in the incidence of herpes zoster by 51.3%, a reduction in the overall burden of illness (BOI) by 61.1%, and a decrease in the incidence of PHN by 66.5%. Subsequently, in order to investigate the durability of benefit from vaccination, the Short-Term Persistence Substudy (STPS) was performed by the same group of investigators. The study was designed to evaluate efficacy up to 7 years postvaccination. The major findings included a drop in efficacy in herpes zoster BOI by 11%, 6.4% for PHN incidence, and 11.7% for herpes zoster incidence. The results regarding incidence for BOI and incidence of herpes zoster were significant through 5 years postvaccination leading the authors to conclude the persistence of efficacy at 5 years but the benefit beyond that time point was unclear. To address this question, the same group performed the Long-Term Persistence Substudy (LTPS) evaluating patients 7 to 11 years postvaccination. All participants in the prior two studies had been vaccinated, leaving no controls to use for comparison. Therefore, the authors used regression models to estimate incidences of herpes zoster and PHN, finding that efficacy of the vaccine continued to decline. Only for herpes zoster BOI was efficacy retained at 10 years, efficacy for incidence of herpes zoster persisted through year 8. The findings from the LTPS have been supported by an analysis of over 175,000 vaccinated individuals from an integrated health care organization, which found the effectiveness of the vaccine drops from 68.7% in the first year to 4.2% in the 8-year postvaccination. In order to address the issue of waning efficacy the logical next step would be evaluation of a “booster” dose of vaccine. In fact, that work has been initiated and demonstrated enhanced VZV-specific cell-mediated immunity in individuals >70 years of age who received a second dose of varicella zoster vaccine. The findings are promising and support further investigation of the use of booster doses to prevent herpes zoster.

Recently, a novel glycoprotein-based herpes zoster subunit vaccine has been developed, potentially for adults older than 50 years and immunocompromised hosts. It has been evaluated in two phase 3, large, international, multicenter, randomized, placebo-control trials. The first demonstrated an overall vaccine efficacy against herpes zoster of 97.9 %
Clinical Picture of Postherpetic Neuralgia

PHN is the most common complication of herpes zoster in the immunocompetent patient. This condition can result in significant patient suffering and causes a large economic burden to society. Our ability to diagnose and treat PHN has benefited from consensus among researchers as to its definitions and guidelines for treatment of chronic neuropathic pain conditions. Currently, the term PHN is used to describe dermatomal pain that persists for more than 90 to 120 days after the onset of the herpes zoster rash. Pain persisting for more than 180 days after the rash onset is less likely to resolve and hence can be considered “well-established PHN” to reflect its recalcitrant nature. Following the same pattern as herpes zoster, PHN is most commonly found in the thoracic, cervical, and trigeminal dermatomes.

A variety of signs and symptoms are characteristic of patients with PHN, although none are pathognomonic. These include various types of stimulus-independent pain, for example, intermittent sharp, shooting, or electric shock-like pain and continuous burning or throbbing pain. Stimulus-evoked pain is also very common in patients with PHN and includes tactile allodynia, one of the most debilitating symptoms associated with this condition. Tactile allodynia can be so severe that patients with truncal PHN may not be able to tolerate the sensation of clothing against their skin and those with craniofacial PHN may not be able to wear hats, glasses, or tolerate even breezes or air conditioning on the affected site. Estimates of allodynia in PHN patients have ranged from 48.6% to over 90%, with differences likely due to varied quantitative sensory testing (QST) protocols and patient heterogeneity.
Hyperalgesia, which is an abnormally increased perception of pain in response to a painful stimulus, can occur with application of painful thermal or mechanical stimuli. These types of stimulus-independent and stimulus-evoked pain are caused by nerve damage (i.e., neuropathic pain), but musculoskeletal pain can also occur in patients with PHN as a result of excessive guarding of the affected area. Myofascial trigger points, atrophy, and reduced joint range of motion may be seen in severe cases where pain has resulted in excessive guarding.

Additional sensory abnormalities are also common in PHN. Involved areas may be hypoesthetic, which can occur even in regions that exhibit tactile allodynia. The areas of altered tactile sensitivity may become larger than the sites originally affected by the zoster rash. Alterations in temperature sensation have also been demonstrated. Furthermore, various paresthesias and dysesthesias (abnormal or unpleasant but not painful sensations) can occur. Chronic pruritus can persist or develop following herpes zoster and is particularly problematic for some individuals; it may be present with or without comorbid pain.

Areas of hyperpigmentation, hypopigmentation, or scarring may be present in the affected dermatomes following rash healing, and affected areas may also exhibit a persistent reddish or brownish hue. These cosmetic changes do not occur in all patients, and the skin in the affected dermatome is normal in appearance in many patients with PHN.

Although less well-studied and generally less disabling than pain, altered motor function occurs in herpes zoster and can persist after rash healing. Facial paralysis may be evident in the form of ptosis or loss of the nasolabial fold in cases of facial nerve involvement. In cases of thoracic involvement, a truncal bulge resulting from intercostal muscle weakness may be present (see Fig. 27.6).

**DIAGNOSIS AND ASSESSMENT OF POSTHERPETIC NEURALGIA**

PHN is diagnosed primarily based on clinical findings. A history of herpes zoster rash, followed by persistent pain in the same distribution, usually establishes the diagnosis. The presence of known risk factors (see the following text) on history and sensory abnormalities on physical exam
such as allodynia or hyperalgesia also support the diagnosis. Occasionally, patients report having a quiescent period between the resolution of the initial herpes zoster–associated pain and the onset of the pain associated with PHN. In a study of 156 patients with PHN, Watson et al.\textsuperscript{104} noted that 25% of patients with a poor outcome said that they could recall a time after the rash when they had little or no pain. This pain-free hiatus has been observed to last for a period of weeks to as much as 12 months. The recurrence of dermatomal pain is not associated with a recurrent episode of herpes zoster but may coincide with changes in the patient’s emotional or physical status. As mentioned in the earlier discussion, a clear history of rash may not be present in all patients (i.e., zoster sine herpete). In these cases, a definitive diagnosis of VZV-related pain would require serial serologic assessments that are unlikely to be obtained in most clinical settings.

In addition to assessing the location, intensity, and characteristics of the pain, it is important to evaluate the overall impact that the pain has had on the patient. PHN can cause significant deleterious impacts on physical, emotional, and social functioning and therefore can have a widespread adverse effect on health-related quality of life.\textsuperscript{105–108} In addition, PHN can lead to excess health care costs, albeit not as costly as painful diabetic peripheral neuropathy.\textsuperscript{109,110} PHN can result in fatigue, insomnia, anxiety, depression, and suicidal ideation, and careful screening for the presence of any psychiatric comorbidities or any escalation of preexisting psychiatric symptoms should be performed.

**Laboratory Diagnosis**

Diagnostic tests have limited application in the clinical management of PHN patients. A variety of studies may be used but are predominately limited to clinical research settings. These include QST, skin biopsy, and nerve conduction studies. QST has been used to identify different phenotypic subtypes of PHN patients with distinct constellations of signs and symptoms, which are thought to reflect different pathophysiologic mechanisms. This is an especially interesting area of future research, and the hope is that such phenotypic subtypes will ultimately be used to guide mechanism-based treatment.\textsuperscript{1,2}
Epidemiology and Natural History of Postherpetic Neuralgia

High-quality systematic studies of the epidemiology of specific chronic pain conditions are limited, including PHN. The large variation in definitions utilized, study design, and study population makes accurate estimates of incidence and prevalence of PHN difficult to obtain. Estimates of the prevalence of PHN have ranged from 500,000 to 1 million in the United States\textsuperscript{111,112} but should decrease as herpes zoster vaccination becomes more widespread. One systematic review analyzed data from 49 studies and found the risk of developing PHN after herpes zoster varied from 5% to more than 30% worldwide.\textsuperscript{18} Subsequent data from population-based studies\textsuperscript{113–115} and large clinical trials\textsuperscript{95,99} had similar findings; however, the precise figures differ greatly depending on whether patients in the community or in clinical trials were studied.

PHN is a chronic pain syndrome that can last for years. There is a relative paucity of data on its natural history due to the lack of population-based studies of zoster-related pain. Multiple studies consistently indicate that the majority of patients experience resolution of pain over weeks to months following rash onset.\textsuperscript{62,104,105,107,116,117} The presence of persistent pain at 6 months after initial PHN diagnosis has been estimated to be 48% and 20% at 1 year.\textsuperscript{10,118–120} There are few prospective studies that have followed and characterized patients for more than 6 months following the diagnosis of PHN. Hence, the exact number of patients who enjoy a complete resolution of PHN is unknown.

RISK FACTORS FOR POSTHERPETIC NEURALGIA
The most well-established risk factors for PHN in patients with herpes zoster include older age, presence of a painful prodrome, greater severity of acute pain, greater rash severity, and ophthalmic involvement.\textsuperscript{105,121,122} Increasing age is a particularly potent risk factor for the development of PHN. The risk for PHN increases by 1.22 to 3.11 for every 10 year increase in age.\textsuperscript{123} Approximately 20% of patients older than 50 years of age continue to have pain at 6 months after the onset of rash despite starting antiviral agents in a timely fashion.\textsuperscript{62,67,121,124}
duration of pain, patients 50 years of age or older were shown to have a 14.7-fold higher prevalence (95% confidence interval [CI], 6.8 to 32.0) of pain 30 days after rash onset compared with patients younger than 50 years.\textsuperscript{125} Elderly patients also seem to be predisposed to developing particularly refractory cases of PHN that do not respond to currently available treatments.\textsuperscript{104} Other risk factors for PHN are listed in Table 27.6.

**Pathophysiology of Postherpetic Neuralgia**

Viral replication is thought to result in a combination of neural and inflammatory damage, leading to sensitization of the peripheral and central sensory neural elements. There is evidence that various risk factors identified for the development of PHN make independent contributions to the likelihood of developing this chronic pain condition,\textsuperscript{105,126} and these risk factors may reflect distinct underlying pathophysiologic mechanisms. For instance, elderly patients who are at high risk for PHN are more likely to have a subclinical polyneuropathy, which may reduce the amount of viral damage needed to cause PHN.\textsuperscript{127,128} Other examples of the possible relationships between risk factors for PHN and underlying mechanisms include the presence of a prodrome, reflecting earlier and more extensive viral damage in the affected sensory ganglion\textsuperscript{129}; greater rash severity, reflecting greater damage to and loss of epidermal nerve fibers\textsuperscript{130–132}; and severe acute pain, reflecting the initiation of processes that ultimately
result in central and peripheral sensitization.\textsuperscript{133,134} These relatively independent processes may combine to cause more severe cases of PHN.

More severe zoster infections are accompanied by greater neural damage, and it has been proposed that this neural damage contributes prominently to the development of PHN.\textsuperscript{133,135} However, knowledge of the pathophysiologic mechanisms of PHN remains limited. It is mainly derived from autopsy and skin biopsy neuroanatomic studies and research on patterns of sensory dysfunction and pharmacologic response. A variety of pathophysiologic mechanisms have been described and are hypothesized to be causally related to the qualitatively different types of pain associated with PHN. Different mechanisms may coexist in an individual patient, and there may be pathophysiologically distinct subgroups of patients.\textsuperscript{136–138}

Modern anatomic understanding is based on data limited by the small number of patients studied to date. Watson and colleagues\textsuperscript{129} compared autopsy tissue from patients with and without PHN following herpes zoster. They found that patients with PHN showed marked atrophy of the spinal cord dorsal horn on the ipsilateral versus contralateral side, a difference that was not present in the patients with a history of zoster but not PHN. Punch skin biopsy permits quantitative measurement of epidermal sensory nerve endings. Such studies have shown that PHN patients have reduced innervation density in the affected dermatome compared to the contralateral side (Fig. 27.7). In one murine study of PHN, the severity of dermal denervation correlated to the development of allodynia and hyperalgesia beyond the margins of the initial herpes zoster rash.\textsuperscript{139} Notably, in both the postmortem and skin biopsy studies, pathologic features were only identified in PHN patients and were not found in patients with a history of zoster who did not go on to develop PHN.
Sensory testing can be used to investigate the function of small afferent fibers including nociceptors. This type of testing helps create a detailed sensory profile of the affected area. Rowbotham and Fields have conducted a landmark series of studies of sensory dysfunction and pharmacologic response in an attempt to address the pathophysiology of PHN. The results of this research, along with that of others, have emphasized the role of central processes in interpreting sensory dysfunction and its relationship to pain in patients with PHN and have suggested that at least two different pathophysiologic mechanisms contribute to the development of PHN and other peripheral neuropathic pain conditions—sensitization and deafferentation.

Both peripheral and central sensitization appear to contribute to PHN. Peripheral sensitization occurs predominately in small unmyelinated C-fiber nociceptors. Clinically, there can be minimal sensory loss in areas of marked allodynia. However, thermal sensory thresholds can be decreased (heat hyperalgesia) by up to 2° to 4° C in allodynic regions.
Heat hyperalgesia is a well-known consequence of peripheral nociceptor sensitization. These observations all suggest that sensitization of C nociceptors can be responsible for the spontaneous burning pain and heat hyperalgesia seen in some patients. In many PHN patients, the area of mechanical or tactile allodynia is much larger than the area originally affected during herpes zoster and the painful area may continue to change with time. Allodynia in a subset of PHN patients may be caused by ectopic discharges from damaged C nociceptors maintaining a state of central sensitization. The major excitatory neurotransmitter involved in spinal cord pain processing is glutamate, and binding at the N-methyl-D-aspartic acid (NMDA) receptor has been thought to play a key role in central sensitization. The importance of persistent sensitization has been supported by the work of Petersen and Rowbotham, who found patients with PHN were more likely to have a positive response to capsaicin application with expansion of allodynic area when compared to those with no pain at 6 months after having herpes zoster.

Dynamic and tactile allodynia may also result from sprouting of Aβ fibers into the superficial layers of the dorsal horn in response to partial loss of C-fiber input. This sprouting may lead to connections between these fibers, which normally do not transmit pain, and the ascending pain pathways that were formerly responsive to C-fiber input. This process would explain why nonpainful stimuli such as light touch or pressure can become painful in patient with PHN.

Deafferentation may also be playing a significant role in the maintenance of PHN. In a subset of patients, there is a loss of both large and small diameter sensory afferent fibers. This loss of peripheral input can result in the development of spontaneous discharge in deafferented central neurons. This may produce constant pain in the area of sensory loss. Interestingly, these patients may still suffer from severe mechanical allodynia. Assuming that the DRG and central connections are lost in such patients, the pain may be due to intrinsic CNS changes. However, there have been some studies that question the role of deafferentation in PHN due to the findings of persistent sensory abnormalities in patients with PHN and those without pain after HZ.

The mentioned data suggest that there may be subsets of patients within
the PHN population who have different underlying mechanisms responsible for the generation and maintenance of their chronic pain. These different mechanisms may account for the varied presentations of pain in patients with PHN. Unfortunately, these observations have yet to provide the foundation for a mechanism-based approach for selecting specific pharmacologic treatment options in clinical practice. This, of course, would be an extremely desirable goal to improve the therapeutic effects of existing treatments.

### Treatment of Postherpetic Neuralgia

Tricyclic antidepressants, various anticonvulsants, opioid analgesics, and topical lidocaine are efficacious in the management of PHN (Table 27.7). There is a limited role of invasive interventions and alternative modalities, but these are utilized for patients who are refractory to conservative modalities. The choice of which therapy is used is often individualized based on the patient’s comorbidities, concomitant medication use, and associated symptoms. Recent studies have evaluated the relative efficacy of these treatments.\(^ {146,147} \) Additionally, consensus recommendation and guidelines for the pharmacotherapeutic treatment of neuropathic pain, including PHN, have been published and serve as useful guides in selecting between the growing list of treatment options.\(^ {148–151} \) Despite the publication of treatment recommendations, many patients in the community with PHN do not receive evidence-based pharmacotherapy.\(^ {152} \) In clinical practice, certain anticonvulsants, topical lidocaine, and tramadol are often used as first-line medications, followed by serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants, opioids, and high-dose capsaicin patch. Capsaicin patch as a second-line therapy is used in part because of better tolerance in elderly patients. Needless to say, all patients should have a thorough assessment, and treatment should be tailored to address their individual needs.

ANTICONVULSANTS: GABAPENTIN AND PREGABALIN

Although a number of anticonvulsants have been used for many years for the treatment of PHN and other neuropathic pain conditions, the greatest evidence of efficacy exists for gabapentin and pregabalin. Both are well-tolerated and much less toxic than the first-generation anticonvulsants.
previously used to treat neuropathic pain. There is good evidence to support the use of gabapentin in PHN. In two large clinical trials, its use was associated with a statistically significant reduction in daily pain ratings as well as improvements in sleep, mood, fatigue, and depression as well as other quality of life indicators like improved function and work at daily dosages of 1,800 to 3,600 mg. A meta-analysis of these trials indicated the number needed to treat (NNT) for gabapentin in the treatment of PHN is approximately 4.4 (95% CI, 3.3 to 6.1). The precise mechanism of its analgesic action is not known, but evidence derived from rodent models suggests that gabapentin acts at the α₂δ subunit of voltage-dependent calcium channels to decrease calcium influx. This effect inhibits the release of the excitatory neurotransmitters, including glutamate. As noted in the earlier discussion, glutamate, via its effect at the NMDA receptor, is the primary neurotransmitter responsible for maintaining central sensitization.

Gabapentin is rapidly absorbed after oral administration. However, its absorption is mediated by a transport mechanism present only in the proximal part of small intestine that becomes saturated at higher doses. This phenomenon reduces the bioavailability of gabapentin as the dose is increased. For example, the bioavailability of gabapentin at a dose of 300 mg is about 60%, but the bioavailability falls to 40% with a 600-mg dose. Additionally, its half-life is 5 to 7 hours, necessitating three or four doses in a day. Peak serum concentrations are achieved approximately 3 hours after oral administration. Gabapentin does not exhibit significant protein binding, is eliminated unchanged via the kidneys, and is not metabolized by the liver.

The optimal dosing schedule for gabapentin has not been well characterized. One review suggested that dosing should be initiated at 300 mg on the first day, followed by 300 mg twice daily on the second day, and then increased to 300 mg three times daily on the third day. At that point, the titration should be slowed down with a goal of reaching 600 mg three times daily over the ensuing 2 weeks. Daily dosages of up to 3,600 mg have been studied and shown efficacious. The daily dosage should be divided into three or four doses per day as this drug has a relatively short half-life. In elderly patients, dosages should be reduced and titration
should be executed more slowly. In frail patients, it is typical to start with 100 mg per day, increasing by 100 mg every 3 to 4 days. Once patients are tolerating a daily dose of 600 mg, the titration rate may be increased by 300 mg per day every 3 to 4 days to a target of 1,800 to 2,400 mg per day. The titration schedule may need to be modified if efficacy is achieved at lower dosages or unmanageable side effects are encountered. As gabapentin is excreted renally, dosages need to be adjusted in patients with renal insufficiency. Patients on dialysis should be started on a single dose of 100 mg given 1 hour after dialysis treatment on alternate days. This dose then can be titrated up slowly and cautiously. Of note, gabapentin is also available as an oral solution in 250 mg/5 mL preparation.

Side effects associated with gabapentin include somnolence, dizziness, peripheral edema, and gait or balance problems. In general, the side effects are short lived, but they can require monitoring and occasionally dosage adjustment.

Newer formulations of gabapentin have attempted to circumvent the issue of variable bioavailability of gabapentin. These include gastroretentive formulation of gabapentin (G-GR) and gabapentin enacarbil (GEn). The G-GR preparation is designed in a way that leads to a slow and steady release of gabapentin, resulting in a more efficient absorption, improved bioavailability, and possibly reduced side effects of somnolence and dizziness compared to regular gabapentin. Patients can titrate up an effective dose more quickly than regular gabapentin. An 11-week randomized, double-blind, placebo-controlled phase 3 clinical trial showed significant reduction in pain intensity and sleep interference in patients with PHN. It is administered as a once-daily dosing of 1,200 to 1,800 mg with an evening meal. The dose should be adjusted in patients with renal impairment and is contraindicated in patients on hemodialysis. Once-daily dosing could be a tremendous help in terms of patient compliance.

GEn is a prodrug of gabapentin that is actively transported and provides sustained, dose-proportional exposure to gabapentin. It is absorbed by a high-capacity transport system throughout the gut in comparison with the low-capacity transporter system in the upper intestine for regular gabapentin, hence, is said to provide a dose-proportional and extended
exposure to gabapentin. It can be dosed in twice-daily dosing. Three different doses have been studied: 1,200, 1,800 and 3,600 mg total daily dose (divided into two dosages). All three daily dosages were efficacious in reducing pain intensity in patients with PHN, but the 1,200-mg dose demonstrated the most favorable balance between efficacy and adverse effects.\textsuperscript{159}

G-GR or GEn are not as popular in clinical practice as the regular gabapentin despite significant advantages over the latter. The possible reasons could be provider familiarity and lower costs of standard generic gabapentin. Pregabalin appears to have a similar mechanism of action as gabapentin, and several large randomized clinical trials have demonstrated its efficacy in the treatment of PHN and other neuropathic pain conditions. Three double-blind trials comprising 776 patients with PHN showed that pregabalin resulted in superior pain relief and improved pain-related sleep interference compared to placebo. Dosages in these studies ranged between 150 and 600 mg per day,\textsuperscript{160} and both fixed as well as flexible dosing schedules have been efficacious in clinical trials.\textsuperscript{161,162} Pregabalin can be given in two divided doses each day. Frequently reported side effects are the same as with gabapentin: somnolence, dizziness, peripheral edema, and balance problems.

Pregabalin has also been demonstrated to possess an anxiolytic effect in patients with generalized anxiety disorder.\textsuperscript{163,164} As patients with chronic pain often have comorbid anxiety disorders, it is possible that this anxiolytic effect may provide additional benefit in PHN patients. The analgesic efficacy and side effect profiles of gabapentin and pregabalin appear to be comparable. Pregabalin has greater convenience than gabapentin because of its twice-daily dosing and simpler titration, however, and an effective analgesic dosage can be reached more rapidly with pregabalin. Pregabalin CR is an extended release preparation in once-daily dosing. In a recent study, it was found to be more effective in decreasing weekly mean pain scores when compared with placebo as early as week 1 and the effect was maintained until the final end point.\textsuperscript{165} Primary efficacy outcome was time to loss of therapeutic response (LTR) (<30% decrease in weekly mean pain score from single-blind baseline or discontinuation due to adverse event or lack of efficacy). Time to LTR was
significantly longer with pregabalin CR than with placebo. Pregabalin CR was significant in improving several secondary measures such as patient global impression of change as well as other quality-of-life measures.

ANTIDEPRESSANT MEDICATIONS

Tricyclic Antidepressants

Tricyclic antidepressant medications have a number of proposed mechanisms that might explain their efficacy in the treatment of PHN. These include inhibition of the reuptake of norepinephrine and serotonin and sodium channel blockade.\[166–168\] There have been several clinical trials and meta-analyses of these agents demonstrating efficacy in the treatment of pain associated with PHN, with pooled data showing NNTs of 2.1 to 2.6.\[76,169,170\]

Amitriptyline has been the most widely studied antidepressant for PHN. Available evidence and clinical experience suggest that nortriptyline and desipramine\[171\] are equally effective\[76\] but are better tolerated than relatively more side effect prone amitriptyline. Thus, these secondary amine tricyclics are generally preferred, especially in elderly and frail patients. Both amitriptyline and nortriptyline are often helpful in patients with insomnia because of their sedating properties. Desipramine has significantly less sedation than these two medications and is thus preferred in patients who may be intolerant to the sedative effects of this class of medication.

Both significant side effects and toxicities must be considered when using tricyclic antidepressants. Major side effects include tachyarrhythmias, prolongation of QT intervals with the potential for the precipitation of life-threatening arrhythmias, and the worsening of acute angle glaucoma. It would be prudent to review a baseline electrocardiogram (ECG) before starting these medications in elderly patients or those who possess other risk factors for increased cardiac toxicity.\[172,173\] Minor side effects include dryness of mouth, dizziness, weight gain, sedation, constipation, urinary retention, and orthostatic hypotension. These medications should be started at a low dose, typically 25 mg at night, and titrated slowly to a target dose of 75 to 100 mg per day in a single evening dose. In elderly or frail individuals, these agents can be
started using a 10-mg evening dose. Concomitant use with selective serotonin reuptake inhibitor antidepressants should be monitored carefully as there is a risk of developing toxic tricyclic serum levels and serotonin syndrome with such combinations.

**Selective Serotonin and Norepinephrine Reuptake Inhibitors (Dual Reuptake Inhibitors)**

Two antidepressant medications, duloxetine and venlafaxine, are selective serotonin and norepinephrine reuptake inhibitors that have shown efficacy in patients with painful diabetic and other peripheral neuropathies but have not been studied in PHN. Milnacipran is another SNRI that is approved by FDA to treat pain due to fibromyalgia but has not been well studied or often used clinically for neuropathic pain. Duloxetine is approved by the FDA for the treatment of painful diabetic peripheral neuropathy and fibromyalgia as well as chronic musculoskeletal pain. Clinically, this medication seems to be better tolerated compared with tricyclic antidepressants and hence is being used in clinical practice for PHN. Randomized, double-blind, placebo-controlled clinical trials have found that duloxetine at 60-mg daily dose was superior to placebo in reducing pain scores and improving multiple quality of life measures in patients with diabetic neuropathy pain.\(^{79,174}\) Two randomized clinical trials have shown that venlafaxine at higher dosages is also efficacious in painful diabetic and other peripheral neuropathies, but its value in treating patients with PHN is unknown.\(^{149}\)

**OPIOID ANALGESICS**

Historically, the role of opioid analgesics in the treatment of chronic nonmalignant pain, and particularly neuropathic pain, has been controversial. Recent evidence, however, has shown that this class of drugs is efficacious in neuropathic pain conditions, including PHN. They are now recommended as second- or third-line analgesics by several respected sources.\(^{148–150,175}\) These sources reserve them as second- and third-line agents based on concerns regarding their side effects, the potential for the development of tolerance, and concerns regarding misuse and abuse. The analgesic efficacy of oral oxycodone was evaluated in a
double-blind, crossover trial in which treatment resulted in significant reductions in alldynia, steady pain, and spontaneous paroxysmal pain.\textsuperscript{176} Oxycodone treatment also resulted in superior scores for global effectiveness, disability reduction, and patient preference compared to placebo. A quantitative review of pooled results for opioid therapy yielded an NNT of 2.67 (2.07 to 3.77).\textsuperscript{76} It is noteworthy, however, that more frequent side effects were associated with the opioid therapy as compared to both tricyclics\textsuperscript{176,177} and gabapentin\textsuperscript{178} in head-to-head comparisons. Prescribers should carefully review the CDC guidelines for prescribing opioids for chronic pain prior to making a decision about initiating opioid therapy.\textsuperscript{179} If opioids are prescribed, the patients should be carefully counseled regarding common side effects such as nausea, sedation, urinary retention, pruritus, and constipation. Monitoring for immune suppression and hypogonadism is needed if opioid use is required chronically. Other adverse effects associated with chronic opioid use include tolerance, physical dependence, and possibly opioid-induced hyperalgesia, which also require appropriate patient counseling and monitoring. Lastly, opioids cannot be prescribed without some risk of developing misuse, abuse, or addiction, but this appears to be relatively rare in elderly patients with no prior history of addictive disorders.

Clinical recommendations based on the CDC guidelines\textsuperscript{179} for the use of opioid analgesics in the treatment of PHN include the following: (1) clear and realistic treatment goals and expectations of reducing pain and improvement in function; (2) use of the lowest effective dose, initiating therapy with short-acting opioids, for example, 2.5 to 5 mg oxycodone or 5 to 10 mg morphine every 4 to 6 hours as needed with <50 morphine milligram equivalents (MME) per day; (3) if a patient needs more than 90 MME per day, a rigorous assessment of risks and benefits should be done and documented clearly; (4) once a patient demonstrates tolerability to the initial opioid therapy, conversion can be made to a long-acting opioid preparation (controlled release oxycodone or morphine), transdermal fentanyl patch, or methadone, this should only be done by providers who are familiar with using these opioid medications; (5) proactive effort should be made to anticipate and manage common side effects of nausea and constipation (with antiemetics and laxatives); and (6) regular
assessment for efficacy and tolerability should be made. If the treatment is not effective, these medications should be tapered gradually to prevent the development of withdrawal symptoms.

**TRAMADOL**

Tramadol, a synthetic 4-phenyl piperidine analogue of codeine, is an analgesic medication with a unique mechanism of action. It has a µ-agonist effect like opioids, but in addition, it inhibits the reuptake of serotonin and norepinephrine like the antidepressants that are efficacious in neuropathic pain. Tramadol can be dosed 50 to 100 mg every 4 hours on an as-needed basis. The daily dose should not exceed 400 mg. Lower doses should be used in the elderly and in patients with impaired renal function. It has been shown to possess efficacy in the treatment of PHN in one randomized controlled trial in which a sustained-release preparation was compared to placebo. Superior pain relief and improved quality of life was seen with tramadol, and the NNT was 4.8 (CI 95%, 3.5 to 6.0). However, these results have yet to be replicated, and overall, evidence for use of tramadol in neuropathic pain at best is low quality. The most contemporary guidelines in the management of neuropathic pain recommend use of tramadol as a second-line drug.

Adverse effects include nausea, vomiting, dizziness, constipation, urinary retention, somnolence, and headache. Concomitant use with medications that are inhibitors of CYP2D6, such as antidepressant medications, can lead to serotonin syndrome. Abuse of tramadol was thought to be rare but has recently been observed in increasing numbers. In July 2014, tramadol was placed into schedule IV of the US Controlled Substances Act, a designation that indicates that tramadol has some potential for abuse. Furthermore, tramadol is associated with an increased risk of precipitating seizures in patients who have a history of seizures or who are also receiving drugs that can reduce the seizure threshold. These considerations usually result in clinicians avoiding tramadol in patients receiving CYP2D6 inhibitors or those patients at increased risk for seizures.

**TAPENTADOL**
Tapentadol is a centrally acting synthetic analgesic. Although its exact mechanism is unknown, analgesic efficacy is thought to be due to µ-opioid agonist activity and the inhibition of norepinephrine reuptake. It has structural similarities to tramadol but its µ-opioid agonist activity is stronger than tramadol. The usual adult dose is 50 to 100 mg every 4 to 6 hours, with a maximum daily dose is 600 mg per day. It is thought to have a lower incidence of gastrointestinal (GI)-related adverse events compared with equivalent doses of oxycodone. It is available in multiple strengths including 25-, 50-, 75-, and 100-mg tablets. It is also available as an extended-release product. Outpatient coverage by insurance carriers is variable due to the high cost of the drug. Dose adjustment is required in patients with renal and hepatic impairment. Side effects are similar to opioids but to a less severe degree. It may have drug interactions with antidepressant medications and use is contraindicated in patients with concomitant monoamine oxidase inhibitor use.

In our clinical experience, this medication is fairly well tolerated, especially when compared to strong opioids, and seems to be equally effective. However, due to the paucity of existing data for PHN, no conclusive recommendation can be made.

**TOPICAL THERAPIES**

An inherent advantage of topical therapies is that they are associated with few systemic effects due to minimal systemic absorption of the medication. The concept of establishing phenotypic subtypes to ultimately guide mechanism-based treatment is very attractive and may lead to development of novel topical therapies. For example, one trial of a topical sodium channel inhibitor (TV-45070) showed a preferential response to treatment in a subset of patients. The postulated hypothesis was partially based on the thought that enhanced pain perception is mediated through an increased activity of the Nav1.7 sodium channel in patients with an R1150W polymorphism. Therefore, individuals with this genotype may render them more susceptible to pharmacologic intervention by specific sodium channel inhibitors such as TV-45070 compared with their wild-type counterparts. For now, high-dose capsaicin patch and 5% lidocaine patch are the only topical medications approved by the FDA for
Lidocaine patches are the most commonly used topical modality for PHN in clinical practice because of ease of application and favorable side effect profile. High-dose capsaicin patch can be applied only by trained providers in an office setting. Over-the-counter capsaicin cream and other compounded mixtures are used less commonly.

**Topical Lidocaine**
Five percent lidocaine patches result in a local analgesic effect. Clinical trials have shown greater efficacy with the use of lidocaine patches as compared to vehicle-controlled patches in PHN patients presenting with allodynia. There was no significant difference in the side effects between patients receiving lidocaine versus the control patches. The NNT is 4.4. It is interesting to note that patients may respond well to topical lidocaine even if the skin at the targeted site appears to be completely devoid of nociceptors. Lidocaine patches possess both excellent safety and tolerability profiles, making them an attractive treatment option for many older adults with PHN. Efficacy can be ascertained within 2 to 3 weeks of initiation of treatment; hence, there is no need for a prolonged trial period. The side effects are minimal because of the minimal systemic absorption of the lidocaine. Lidocaine patches are not approved for use in herpes zoster and should not be used in patients with active zoster lesions.

Clinical recommendations for use of lidocaine patches in the treatment of PHN include the following: (1) the patches can be cut to fit the affected area (unlike fentanyl patches); (2) three patches can be applied with no additional risk of systemic side effects; (3) the recommendations are to keep the patches on for 12 hours and off for 12 hours, but the patches can be left on for 18 hours at a time to improve effectiveness; (4) patches should be applied only on intact skin and directly over the area of maximum pain; and (5) lidocaine gel has also been shown to be efficacious in patients with PHN and allodynia, and its use can therefore be considered if lidocaine patches are not available, affordable, or their application is problematic.

**Topical Capsaicin**
Capsaicin is an extract of hot chili peppers and an agonist for the vanilloid
receptor (TRPV1), which is present on afferent nociceptor terminals. There are no systemic effects with a local application. In 2009, a high-concentration capsaicin patch (8%) was approved by the FDA for use in pain associated with PHN. Application is conducted in an office setting under medical supervision. To avoid discomfort, the affected area is prepared with topical local anesthetic cream for 45 to 60 minutes prior to application of patch. Depending on the area involved, up to four patches can be applied concurrently. Patients may also need additional analgesic before and after treatment. The transdermal patch releases capsaicin into the skin that act on the vanilloid receptor subtype 1 (TRPV1) receptors on nociceptor terminals. An initial phase of excitation is followed by dysfunction of these nociceptive fibers resulting in durable pain relief. Large clinical trials have evaluated its single application following a local anesthetic application. The results of these studies indicate that this approach can produce prolonged relief of pain in some PHN patients.\textsuperscript{189} A recent review led to a conclusion that although more study participants with the high-dose capsaicin patch experienced significantly better pain relief and other quality of life measures than controls, still quality of evidence was moderate or low with an NNT as 7 to 8.8.\textsuperscript{190} The patch is commonly used in clinical practice as a second- or third-line treatment.

Low-concentration capsaicin cream is also available over the counter in two concentrations, 0.025% and 0.075%. Pooled data from two placebo-controlled studies demonstrated superior pain relief following three to four times per day application of 0.075% capsaicin to the painful areas compared to an inert topical agent. The NNT was 3.3.\textsuperscript{191,192} Blinding in these studies was problematic given that capsaicin produces a distinct burning sensation on initial application. In clinical practice, it is difficult to use, especially in patients who are experiencing significant allodynia, and many patients discontinue treatment too quickly for any beneficial effect to occur. Ironically, these are the very patients who would be expected to be most likely to benefit from this therapy. Low-concentration capsaicin is rarely used as a first-line agent in patients with PHN. Patients should be warned about the unpleasant burning sensation it causes with initial application and to avoid contact with their eyes.
Other Topical Treatments

Topical anti-inflammatory preparations have been studied in a few randomized, placebo-controlled trials. There was significant heterogeneity in these studies, and definitive recommendations cannot be drawn from this literature. There have also been a few reports of other topical agents, including topical clonidine, cannabinoid, tricyclic antidepressants, gabapentin, ketamine, and vincristine as well as descriptions of novel delivery mechanisms, such as iontophoresis. The evidence for all these therapies is weak, and they are generally not used in clinical practice.

COMBINATION THERAPY

Although the use of combination therapy is common in clinical practice, few clinical trials have provided an evidence base for this approach. One study has demonstrated that the combination of gabapentin and morphine was superior to either of these medications used alone in relieving pain in patients with either painful diabetic neuropathy or PHN. Another trial evaluated a nortriptyline–morphine combination compared with each monotherapy alone in neuropathic pain patients including patients with PHN. The results suggest superior analgesia compared to monotherapy with either agent. According to a systematic review of available evidence for combination pharmacotherapy for neuropathic pain in adults, there are multiple, good-quality studies that demonstrate superior efficacy of two drug combinations; however, the low number of studies for any specific combination and other study factors prohibit any definitive recommendations to be made. The goal of combination therapy is to arrive at a balanced, multimodal approach that improves the efficacy and tolerability of treatment while minimizing side effects of the individual medications. Disadvantages of combination therapy include an increased risk of side effects as the number of medications is increased. It may also be difficult to determine which medication is responsible for side effects. Ideally, medications that can cause similar side effects (e.g., sedation) should not be started simultaneously. There should be a judicious interval of time (e.g., at least a week or more) before a new medication is introduced to the regimen.
N-METHYL-d-ASPARTIC ACID ANTAGONISTS
The NMDA receptor is thought to play an important role in central sensitization and maintenance of chronic neuropathic pain states including PHN. Ketamine, an NMDA antagonist, is the most commonly utilized agent among this group that also includes dextromethorphan and memantine. Common side effects for this class of medications include hypertension, tachyarrhythmias, hallucinations, and other CNS side effects. In a small double-blind crossover comparison between ketamine (0.15 mg/kg), morphine (0.075 mg/kg), and saline for the treatment of PHN, intravenous (IV) ketamine effectively reduced pain and allodynia and decreased wind-up pain. Interestingly, wind-up pain was actually aggravated by morphine.\textsuperscript{196} Dextromethorphan and memantine have been studied but did not show any benefit in decreasing pain due to PHN. Recommendations for use of this class of drugs are inconclusive as per the recent guidelines for the treatment of neuropathic pain.\textsuperscript{150} In clinical practice, ketamine can be used as outpatient infusion therapy or as a component of the topical compounded creams or compounded oral preparations in patients with intractable symptoms.

OTHER PHARMACOLOGIC THERAPIES
A variety of other agents have been evaluated in the treatment of PHN and other neuropathic pain conditions. Several anticonvulsant and antidepressant medications besides those discussed earlier have shown evidence of efficacy in other neuropathic pain conditions in single clinical trials but lack convincing evidence of efficacy.\textsuperscript{149,150} Cannabinoids have been studied in neuropathic pain, but there is little data to support their use in PHN. Similarly, the sodium channel blocker mexiletine has not demonstrated benefit in PHN, although there is some evidence of efficacy in painful diabetic peripheral neuropathy. However, this agent is usually avoided given its high toxicity profile. The use of all these medications can be considered in select circumstances, such as in cases where more conventional treatments have failed.

INVASIVE TREATMENTS FOR POSTHERPETIC NEURALGIA
A considerable percentage of PHN patients will not respond to currently available pharmacologic treatments. In these cases, a referral to a pain management center should be considered as early as possible. Invasive treatments may be considered for patients with refractory pain. A variety of interventional strategies have been described and examined as treatment options for PHN.

Unfortunately, the studies conducted to date have either been relatively poorly controlled or have not been replicated by independent investigators. Given the lack of objective evidence available to compare the efficacy of the various interventions available, the choice of specific therapy has been dependent on the treating physician’s clinical experience. The lack of evidence demonstrating the efficacy of interventional treatments points more toward the lack of adequate research as opposed to the conclusion that these interventions are inherently ineffective. As per the recent guidelines for role of interventional techniques in neuropathic pain, authors concluded that due to the paucity of high-quality clinical trials, no strong recommendations can be made, but based on the available data, authors made a strong recommendations against use of sympathetic blocks for PHN pain. Despite lack of strong evidence-based recommendation, a number of invasive interventions are used in clinical practice for patients with intractable symptoms.

**Botulinum Toxin**

Botulinum toxin has been traditionally used in the treatment of painful dystonias, headaches, and other spastic disorders. Multiple case reports and small studies have suggested that it may be efficacious in certain neuropathic pain conditions including PHN. There is a significant debate about its mechanism of action. Recent opinions on the mechanism responsible for antinociceptive effects of the toxin suggest that it inhibits the release of peripheral nociceptive neurotransmitters and inflammatory mediators responsible for pain generation and transmission from sensory nerves via TRPV1 receptors. There are three well-designed studies showing a beneficial effect of botulinum toxin A injections in patients with PHN. Injection of botulinum toxin is considered a third-line therapy in the management of PHN pain. Recommended dose range from 50 to
200 units injected over multiple sites of the affected area in small aliquots.

**Dorsal Root Ganglion Blocks**

A number of procedures targeting the DRG may be utilized to treat patients suffering with PHN including steroid injections and pulsed radiofrequency ablation (RFA). Currently, an intervention that is infrequently used is the injection of steroid into the involved DRG. This approach is performed in a nearly identical manner as that used for performing a transforaminal epidural steroid injection. If an inflammatory process at the level of the DRG is considered to play a role in the pathophysiology of PHN, then this treatment would seem rational. There is, however, no convincing evidence to support the routine use of this treatment.

In terms of ablative procedures, lesioning of DRG using pulsed radiofrequency (PRF) has been studied in an open, nonrandomized study, and it was found that PRF lesioning of the DRG resulted in significant pain relief compared with the conventional treatments in patients with intractable PHN.\textsuperscript{201} There has been another small, retrospective review published that reported good relief in all patients with zoster-related pain, but better pain relief was reported if procedure was performed within 90 days versus after 90 days of the rash onset.\textsuperscript{202} As with other invasive interventions, there is no convincing, high-quality evidence available at this time to make a recommendation for the use of these procedures in routine clinical practice.

**Peripheral Nerve Blocks**

As PHN most commonly affects the thoracic dermatome, intercostal nerves are an attractive and relatively safer therapeutic target for interventions. Chemical neurolysis with 10% phenol in select patients has been used in clinical practice. A safer alternative would be pulsed RFA as it may lead to decreased incidence of deafferentation pain as well as other side effects associated with chemical neurolysis. In a randomized, double-blind clinical trial, PRF treatment of the intercostal nerves at a level above and below the level of the PHN was done weekly for 3 weeks and was found to result in improved pain, reduced dose of analgesic medication,
and improvement in health-related quality of life domains compared to the sham group. In addition, an older study found that intercostal nerve blocks provided long-lasting relief in PHN patients. The quality of the evidence for intercostal nerve blocks or PRF treatment is limited, much as it is for the other neural blockade techniques described in the following text.

**Neuroaugmentive Techniques**

There has been an increasing role for neuromodulatory strategies in the management of chronic neuropathic pain conditions. Some encouraging data have been reported regarding the effects of SCS in patients suffering from PHN. In a case series of 28 patients (4 patients had herpes zoster and 24 patients had PHN), the effect of SCS was studied prospectively. Long-term relief was obtained in 82% of the patients with PHN. Patients served as their own controls by intermittently switching their spinal cord stimulator off and then monitoring themselves for the reappearance of pain. This is an interesting case series, but confirmation of the benefit of SCS in PHN patients will require further studies with the inclusion of a formal control group. There have been case series supporting the use of temporary SCS for the treatment of subacute PHN in those who failed to respond to medication or other intervention techniques. Also, SCS may be a viable option for those who cannot tolerate analgesics due to comorbidities such as chronic kidney disease. Use of deep brain stimulation (DBS) has been studied in a series of 11 patients with PHN. Four out of 11 patients were considered responders. Given the extent of resources, expertise needed and low quality of the available evidence, use of these therapies should be reserved for use only in patients with intractable symptoms.

An exciting development in this field could be the targeted DRG stimulation for the management of intractable PHN pain. A specially designed SCS system that has flexible small-diameter leads has been developed, allowing electrodes to be placed via standard percutaneous placement under fluoroscopic guidance in the vicinity of involved DRG. Potential benefits of DRG neuromodulation relative to traditional SCS include better pain-paraesthesia concordance and decreased side effects.
like paraesthesias with changing body positions compared to the conventional SCS. The new device has been studied in patients with chronic neuropathic pain, and 1 year outcomes demonstrate similar efficacy as tradition SCS with the added benefit of more targeted and precise coverage.\textsuperscript{209} It is too early to draw any strong conclusions about its efficacy in PHN patients, but it is an exciting new development in the field of neuromodulation.

**Sympathetic Nerve Blocks**

Sympathetic nerve blocks have been used for the treatment of both the acute pain of herpes zoster and the chronic pain associated with PHN. Unfortunately, there is little high-quality evidence supporting the use of this treatment in patients with PHN. Retrospective data indicate that these blocks may provide temporary pain relief. These studies reported that 41\% to 50\% of patients with PHN noted short-term relief following the injection, but the effectiveness waned over time based on long-term follow-up.\textsuperscript{210} Of note, the most recent guidelines make a strong recommendation against the use of sympathetic blocks in the management of PHN pain.\textsuperscript{83} Based on these guidelines and our clinical experience, we no longer use sympathetic blocks for treatment of PHN.

**Neuraxial Blocks**

Similar to the literature regarding sympathetic blockade, there are inadequate data to convincingly demonstrate that neuraxial therapy is both safe and effective for the routine treatment of PHN. One study has yielded encouraging results with the use of subarachnoid methylprednisolone,\textsuperscript{211} but concerns regarding the failure to replicate these results and the association between this therapy and the development of adhesive arachnoiditis have precluded its routine use.

In clinical practice, epidural injections of both local anesthetic and steroids are used in patients with pain that has been refractory to conservative treatment. The authors will occasionally use continuous thoracic epidural analgesia with a home infusion pump for a period of 1 to 2 weeks in patients with intractable PHN pain for symptom palliation. We have observed this approach to be helpful for severe cases, but objective
evidence for this therapy is lacking. It does require home nursing care and significant coordination of care by the treating physician. In general, it is reserved for the most severe cases.

**PSYCHOLOGICAL INTERVENTIONS**

PHN has been demonstrated to adversely affect overall quality of life by impairing physical and emotional functioning. Studies have shown that the degree of catastrophizing predicts the level of pain in elderly patients with PHN,\(^{212}\) and this has been shown to be independent of depressive symptoms. There also has been work that shows an association between anxiety and depression and severity of pain in PHN.\(^{120,213}\) Although the effects of cognitive-behavioral therapy and other psychosocial treatments have not been specifically studied in patients with PHN, it would seem logical and prudent to utilize these treatments on an individualized patient basis. There are ample data to support the use of these therapies in other chronic pain conditions, and it is reasonable to extrapolate this evidence of efficacy to the treatment of patients with PHN.

**ELECTROANALGESIA**

**Transcutaneous Electrical Nerve Stimulation**

There have been conflicting responses reported to transcutaneous electrical nerve stimulation (TENS) therapy in patients with PHN. There are a few small case series\(^{214,215}\) that showed beneficial effects with use of this treatment, but other similar reports failed to demonstrate any benefit. However, when used in combination with pregabalin, it was found to be more beneficial than pregabalin + TENS placebo in a blinded randomized placebo-controlled trial.\(^{216}\) TENS is still clinically offered to many patients on a trial basis given its safety profile. Those patients who have a favorable response to the trial therapy can procure a TENS device for more long-term use.

**Scrambler Therapy**

Scrambler therapy is a relatively novel and noninvasive technique that utilizes electrocutaneous stimulation to relieve pain. In theory, it works through replacing painful afferent input associated with chronic pain with
nonpainful information.\textsuperscript{217} The nonpainful information is generated by 10 electrodes working through five channels which act as artificial neurons. The output from the artificial neurons is highly variable and difficult for the existing pain pathways to interpret, hence the name, scrambler. It is believed to accomplish this through activation of cutaneous nerves resulting in the synthetic nonpainful information enhancing neuroplasticity, retraining the brain to feel no pain in previously painful areas, although the exact mechanism is still unclear. The therapy has shown significant benefit in small trials of patients with chemotherapy-induced peripheral neuropathy and other neuropathic pain conditions. However, the data on PHN are less robust but nonetheless promising.\textsuperscript{217–219} The authors have also had positive results treating a limited number of PHN patients. In order to better gain an understanding of the therapy and its potential benefit, further study with larger clinical trials is warranted.

**Surgical Approaches**

Multiple surgical approaches are described in the literature for the treatment of PHN. In general, these are quite drastic procedures with no proven long-term benefit. Surgical treatments are largely avoided given the limited literature to support their use, their potential for serious sequelae (including pain exceeding presurgical levels)\textsuperscript{220} and the expanding list of safer and more efficacious options.

**Prevention of Postherpetic Neuralgia**

The prevention of PHN is obviously closely tied to the prevention of herpes zoster. Thus, the salutary effects of vaccines in preventing herpes zoster described earlier in this chapter apply to the prevention of PHN as well. The beneficial effects of antiviral medication in decreasing the severity but not necessarily occurrence of PHN have also been reviewed in the earlier discussion. These approaches are the mainstays in our arsenal to prevent PHN. There are only scant data to suggest any other therapies are genuinely helpful in preventing PHN.

A small, placebo-controlled, randomized trial evaluated the effect of 25
mg daily of amitriptyline initiated within 48 hours of rash onset in herpes zoster patients older than 60 years of age. Treatment with amitriptyline was associated with a 50% decrease in pain prevalence 6 months after rash onset. These results should be confirmed in a trial that controls for the presence of antiviral therapy. Although treatment with amitriptyline may have a beneficial effect in reducing the incidence of PHN, its use should be weighed carefully against potential side effects in elderly or otherwise frail patients.

Use of other medications that are efficacious in PHN, such as gabapentin and pregabalin, may decrease the severity of acute pain in herpes zoster and possibly reduce the incidence of PHN beyond what can be achieved by antiviral therapy alone. There are promising data in animal experiments to support this hypothesis, and results of a single-dose trial of gabapentin versus placebo demonstrated a reduction in acute pain in patients with herpes zoster.75

Two double-blind, randomized, controlled trials of corticosteroids given for a 21-day duration in herpes zoster did not show any effect on the incidence or duration of PHN.80,81 The findings from these studies have been corroborated by a more contemporary Cochrane review which found moderate quality evidence that oral corticosteroids do not prevent PHN 6 months after herpes zoster.222 Therefore, the currently available data do not support the routine use of corticosteroids as a strategy to prevent PHN.

The use of sympathetic blocks has been used for acute pain in herpes zoster, and uncontrolled studies have claimed a reduction in the development of PHN.223,224 Other studies, however, failed to replicate this effect.225 There may be some benefit in reducing PHN occurrence by applying local anesthetic and corticosteroids via the epidural route and paravertebral route (in addition to antiviral treatment and analgesics) during acute zoster, either in a series of injections (every 48 hours for 1 week) or as a single injection.226

However, these findings have yet to be replicated. Because the pain of herpes zoster and PHN improves over time as part of their natural history, a control group is critically important in any study of the effects of these and other treatments intended to reduce the incidence and duration of pain. Thus, currently available uncontrolled studies are inadequate to
definitively support the routine use of blocks as a strategy for preventing PHN. In clinical practice, injections are still used for pain management in patients who are refractory to conservative therapy. This is empirically recommended by some authors with the rationale that better pain control in the acute phase of herpes zoster is an important clinical objective in its own right and may also favorably affect the likelihood of developing PHN.

Conclusions

Herpes zoster and its most common complication, PHN, affect millions of people annually. Their epidemiology is expected to change in complex and potentially unpredictable ways as a result of the implementation of varicella and zoster vaccination programs. Nevertheless, it is difficult to imagine a complete disappearance of these challenging conditions in the near future. Hence, there is a need to develop improved strategies for the treatment of both herpes zoster and PHN. Ongoing research into the underlying mechanisms of these conditions will shape the direction of future treatments. For instance, a better understanding of the biologic factors that contribute to the transition from acute to chronic pain may guide us toward therapies that will facilitate a more rapid and complete recovery of infected neurons. Genomic research also has the potential to guide us to new therapies. Identification of patient subtypes by phenotyping may result in finding new mechanism-based treatment options in addition to identification of patients who have a better chance of responding to conventional therapies than others. For now, clinicians should treat herpes zoster with antiviral therapy and analgesic medications. Corticosteroids should not be routinely prescribed but can be considered in special circumstances, such as patients with ophthalmic involvement, associated motor deficits, or severe acute pain. Supplemental therapy with tricyclic antidepressants, gabapentin or pregabalin, and neural blockade can be considered in refractory cases where more conservative therapy has failed, although the evidence base for these treatments is weak. The treatment of PHN is likely to be an ongoing challenge, at least into the near future. At the present time, there is good evidence to support the use of some pharmacologic therapies,
including tricyclic antidepressants, gabapentin and pregabalin, topical lidocaine patches, and high-dose capsaicin patches as well as opioid analgesics. The potential merits of each of these agents needs to be carefully balanced against each patient’s ability to tolerate their side effects. This is a particularly salient consideration given that many patients with PHN are older or otherwise frail. Invasive modalities such as SCS may play an important role in the future, especially in patients with intractable pain. Further controlled clinical trials will be needed before this treatment approach can be recommended for widespread use. Finally, the role of patient and family education and psychological support cannot be overemphasized given that the currently available treatments will not be effective for all patients.

Our major treatment recommendations may be summarized as follows:

1. Primary varicella vaccine in children is recommended to prevent chicken pox, and this is also expected to ultimately decrease the incidence of herpes zoster and PHN as vaccinated children become adults and replace those with wild-type virus in the population.

2. Herpes zoster vaccination is recommended for older immunocompetent adults >60 years of age to decrease the incidence of herpes zoster and PHN and to reduce the overall BOI. The utility of a second “booster” dose of the live attenuated herpes zoster vaccine is currently being debated.

3. In the future, new vaccine preparations with greater and potentially more durable efficacy and increased availability to immunocompromised individuals will likely become available.

4. Patients with herpes zoster should be treated with antiviral therapy as rapidly as possible to hasten the rate of healing, minimize neural damage, decrease the pain caused by the acute infection, and decrease the incidence and duration of PHN.

5. Acetaminophen, NSAIDs, tricyclic antidepressants, dual reuptake inhibitor antidepressants, gabapentin and pregabalin, and opioid analgesics can be used in patients with herpes zoster to treat acute pain, although it is important to recognize that few studies have investigated the efficacy of such treatments.

6. Topical treatments such as lidocaine patch and high-dose capsaicin
patch may be considered as first-line treatments in frail elderly patients because of a better safety and tolerability profile compared to systemic therapies.

7. Gabapentin, pregabalin, tricyclic antidepressants, selective SNRIs, topical lidocaine patches, high-dose capsaicin patch, tramadol, and strong opioid analgesics can be used for the treatment of PHN given their well-established efficacy in this and other chronic neuropathic pain conditions.

8. Early referral to a pain specialist should be considered in case of intractable symptoms.

Central neuropathic pain or central pain is defined as “pain caused by a lesion or disease of the central somatosensory nervous system.”\(^1\) Central pain is well described in stroke, multiple sclerosis (MS), and spinal cord injury (SCI), with the latter involving both traumatic and disease-related injuries. Other conditions associated with central pain include brain trauma, brain tumors, and possibly pain in epilepsy and Parkinson’s disease. Central pain often becomes chronic and may be disabling with a negative impact on quality of life, mood, sleep, and functioning. Treatment of central pain remains challenging. This chapter describes the diagnosis, clinical characteristics, assessment, mechanisms, and treatment of central pain.

**Diagnosis**

A grading system for defining the level of certainty as to how likely a given pain condition is neuropathic in nature was first published in 2008\(^2\) and updated in 2016.\(^3\) It follows the classical clinical diagnostic methods used in neurology, in that history, clinical examination, and diagnostic test consecutively add to the level of diagnostic certainty.\(^3\) The grading system adapted for central pain is illustrated in Figure 28.1.
Central pain is suspected when the history suggests that the pain is related to a central nervous system (CNS) disorder and not to other causes such as spasms, fractures, inflammation, etc. Different pain questionnaires have been developed as screening tools using clusters of descriptors to identify the presence of neuropathic pain. These include the Neuropathic Pain Questionnaire (NPQ), the Leeds Assessment of Neuropathic Symptoms and Signs (LANSS), the Douleur Neuropathique en 4 Questions (DN4) questionnaire, the painDETECT questionnaire, the ID-Pain questionnaire, and the Spinal Cord Injury Pain Instrument (SCIPI) developed for patients with SCI. These screening tools may be useful in epidemiologic research, but they cannot be used alone for identifying central pain in the individual patient.

The first level of the grading system is possible central pain (see Fig. 28.1). Two criteria need to be fulfilled for possible neuropathic pain: (1) There should be a history of a relevant CNS disorder and pain development at or after the onset of the CNS disorder. Following stroke, SCI, and other acute onset CNS disorders, the pain typically develops within months after the onset, but the onset of central pain may be delayed.
up to about 1 year after the incident.\textsuperscript{11–13} (2) The pain distribution should be neuroanatomically plausible, which means that the pain should be distributed within the area of the body that is affected by the CNS disorder—either the complete affected area or a smaller or larger proportion.

The next level is probable central pain (see Fig. 28.1). This involves a clinical sensory examination and confirmation of sensory abnormalities in the same neuroanatomical location. Demonstration of sensory loss to one or more sensory modalities such as touch, pinprick, cold, and warmth compatible with the CNS lesion is essential. Positive sensory signs (e.g., dynamic or cold allodynia) should also be compatible with the CNS lesion. Sensory abnormalities are often present on clinical examination, but a more thorough examination using quantitative sensory testing may be necessary.\textsuperscript{3,14}

The final level is definite central pain (see Fig. 28.1). This requires a diagnostic test that confirms the CNS lesion. This often includes a computed tomography (CT) or magnetic resonance imaging (MRI) scan of the brain in patients with stroke, MS, SCI, or other CNS lesion. Heat- or laser-evoked potentials can also be used to demonstrate a lesion or disease of the spinothalamic tract (STT) pathways, and trigeminal reflex recordings may be useful in the diagnosis of secondary trigeminal neuralgia in MS. Reaching the level of definite central pain using these positive criteria in the grading system means that a CNS lesion can explain the pain but does not determine the cause of the pain.\textsuperscript{3} This poses particular problems in CNS lesions where sensory abnormalities are common regardless of the presence of pain. Therefore, the exclusion of other causes of pain is critical when diagnosing central pain.

The exclusion of other types of pain is challenging given the lack of specific identifiers for distinguishing neuropathic pain from other pain types. Also, many patients experience more than one type of pain, and sometimes, different pain types occur in the same body location making diagnosis even more difficult.\textsuperscript{15–17} A number of differential diagnoses should be considered when diagnosing central pain, including musculoskeletal pain, which is very common following CNS lesions due to overuse, myofascial shoulder pain, stress fractures, spasticity, dystonia, etc., visceral pain, and peripheral neuropathic pain.\textsuperscript{16,18–22}
Clinical Characteristics

Central pain is characterized by spontaneous and/or evoked pain in an area with partial or complete sensory loss to one or more modalities. Decreased sensation to thermal or painful stimuli is present in most patients with central pain, whereas decreased sensation to other modalities is less common.\textsuperscript{23–26} The location of pain and sensory abnormalities is within an area compatible with the CNS lesion (Fig. 28.2). Spontaneous pain may be ongoing, intermittent, or paroxysmal. Studies in different central pain conditions show that pain descriptors such as hot/burning, shooting, pricking, pins and needles, cold, sharp, squeezing, and aching are common.\textsuperscript{9–11,21,25,27–35} Evoked pain may be present as allodynia, which is pain due to a stimulus that does not normally provoke pain, and hyperalgesia, which is increased pain from a stimulus that normally provokes pain.\textsuperscript{36,37} There may also be aftersensations, which is pain continuing after the stimulation has ceased. Cold allodynia and touch-evoked allodynia are particularly common in central pain.\textsuperscript{24,27,31,32,34,38} Hyperpathia is an abnormal—often explosive—painful reaction to a stimulus in an area with increased sensory threshold when the stimulus exceeds the threshold. Due to aftersensations, the distinction between spontaneous and evoked pain may be difficult. Spontaneous pain may also be generated by central sensitization mechanisms by which decreased thresholds and temporal summation cause ongoing pain from stimuli common in daily life (e.g., movement, breathing, ambient temperature).\textsuperscript{39} Nonpainful abnormal sensations are also common.\textsuperscript{11,31,35,40} These include paresthesia, which are evoked or spontaneous abnormal sensations that are not unpleasant, and dysesthesia, which are unpleasant abnormal sensations.\textsuperscript{36} Such sensations are described in terms of tingling, numb, cold, pressing, or warm.
FIGURE 28.2  A: Distribution of sensory abnormalities (blue) and central pain (red) in a patient with central poststroke pain. A 64-year-old woman with a stroke affecting the left side of the body. Magnetic resonance imaging showed an infarct in the right internal capsule extending into part of the thalamus. A few months after the stroke, she complains of a burning, pricking pain in the left lower arm and left leg and touch-evoked allodynia in the hand and arm. The sensory examination showed abnormal sensation, particular to warmth and cold in the left side of the body and touch- and cold-evoked pain in the hand and lower arm.  

B: Distribution of sensory abnormalities (blue) and central pain (red) in a patient with central pain in spinal cord injury. A 55-year-old man with a spinal cord injury (SCI) after a motorbike accident. He has a complete SCI, a neurologic level Th5. Within the first months of his injury, he gradually developed two types of neuropathic pain. One pain was felt at the level of injury. It was described at an intermittent paroxysmal pain and pain
Clinical Assessment

In the assessment of central pain, it is relevant to evaluate the intensity, impact, treatment, quality, and temporal aspects of pain as well as physical and emotional functioning and quality of life (Table 28.1). The pain intensity of average and worst pain may be evaluated using a numerical rating scale, a visual analog scale (VAS), or a verbal rating scale. Different scales have been developed to assess the multidimensional aspects of pain. One such scale is the Multidimensional Pain Inventory (MPI), which assesses pain and the impact of pain on physical and emotional functioning. It has been adapted for use in SCI (MPI-SCI). Other scales may be used to assess mood, sleep, resilience, pain catastrophizing, disability, and satisfaction with life.

The quality of spontaneous and evoked pain may be assessed using open-ended questions or by providing the patients with a list of typical pain descriptors, for example, by using specific neuropathic pain scales such as the Neuropathic Pain Symptom Inventory (NPSI), the NPQ, and the painDETECT questionnaire.

A sensory examination is important to identify sensory loss and gain by assessing decreased or increased sensation in the affected area compared with an area not affected by the CNS lesion. Simple bedside tests include assessment of static and dynamic touch using a brush or cotton ball; assessment of pinprick sensation using a stick, pin, or monofilament; assessment of vibration sense with a 128-Hz tuning fork; and assessment of cold and warm sensation using thermo rollers or cold and warm metal or glass objects (see Table 28.1). Allodynia and hyperalgesia can be quantified by using a numeric rating scale for evoked pain intensity. Mapping of sensory abnormalities and pain is a crucial part of the diagnosis of central pain to ensure that the distribution is compatible with a CNS lesion (see Fig. 28.2). Detailed quantitative sensory testing can supplement bedside sensory examination, but it is time-consuming and
mainly used for research purposes.

Laboratory tests can be used to confirm the diagnosis of a CNS lesion and specific abnormalities of the pain pathways, including the use of CT and MRI scans. Trigeminal reflexes are used in the diagnosis of trigeminal pain, and contact heat- and laser-evoked potentials are useful for assessing the function of the spinothalamic tract.  

**Specific Central Pain Conditions**

**CENTRAL POSTSTROKE PAIN**

Central poststroke pain (CPSP) is pain arising after a cerebrovascular lesion including ischemic and hemorrhagic lesions of the brainstem, thalamus, operculum-insula, and cerebral cortex.  

Central pain occurs in 3% to 8% of stroke patients and is particularly common in patients with infarctions in the lateral medullary infarctions, where the prevalence may be as high as 25%, and in the thalamus, where the prevalence is reported to be around 17% to 18%.  

CPSP is experienced contralateral to the side of the stroke. It may affect small areas such as the hand or the whole hemibody, which is common in thalamic infarctions. In patients with lateral medullary infarctions, the pain distribution may be crossed, involving one side of the body.
contralateral to the lesion and the other side of the face ipsilateral to the
lesion, and periorbital pain is commonly described.\textsuperscript{12,53}

**CENTRAL PAIN IN MULTIPLE SCLEROSIS**

MS is a gradually progressing demyelinating disease with multiple sites of
demyelination in the CNS. MS is an autoimmune disorder triggered by
environmental factors in patients with a genetic predisposition. The
inflammatory attacks give rise to plaques in the white matter of the brain
and spinal cord and as the disease advances, the myelin loss is followed by
damage to the axons and neurons with associated grey matter loss.\textsuperscript{54,55}
Central pain is present in about 25\% of patients with MS.\textsuperscript{56}

The distribution of central pain is compatible with spinal or brain
lesions of the somatosensory nervous system.\textsuperscript{57,58} It may be described as
burning, tingling, pricking, and squeezing pain, sometimes associated with
evoked pain.\textsuperscript{34,56} In addition to this central pain type that is similar to
central pain in other conditions, patients with MS may experience two
specific types of central pain conditions, namely, secondary trigeminal
neuralgia and Lhermitte’s phenomenon.\textsuperscript{56,59–62} In patients with trigeminal
neuralgia, the MRI scan should document a lesion in the ipsilateral side of
the pons along the cause of trigeminal afferents or the recordings of
trigeminal reflexes and trigeminal-evoked responses should show
increased latency.\textsuperscript{62} The pain is similar to classical trigeminal neuralgia
with brief, severe, paroxysmal pain attacks restricted to one or more
division of the trigeminal nerve. It is often unilateral but may be bilateral.
The attacks may arise spontaneously or be triggered by movement or
mechanical stimuli.\textsuperscript{61,62} Lhermitte’s phenomenon is an electric shock-like
sensation that is transient and short lasting. It is typically provoked by
neck movement and is felt spreading down in the back.\textsuperscript{59,61} It is more
common in younger patients and in patients with a progressive or
progressive-relapsing cause and is assumed to be caused by ectopic
discharges due to demyelination in the dorsal column.\textsuperscript{60,61,63}

**CENTRAL PAIN IN SPINAL CORD INJURY**

SCI is a term that includes both traumatic and nontraumatic causes. The
most common traumatic causes are traffic accidents and falls, and
nontraumatic causes include syringomyelia, tumors, ischemia, hemorrhage, arteriovenous malformations, transverse myelitis, and infections. Chronic pain is one of the most disabling consequences of an SCI—present in 70% to 80% of patients. Neuropathic pain is present in about 50% of patients. The onset of central pain may be immediately after the SCI or it may be delayed up to 1 year. A delayed onset and facial pain should alert the physician to the possibility of development of syringomyelia. Neuropathic pain following SCI is divided into pain felt at and below the level of lesion. At-level pain is located within the dermatome of the neurologic level of injury and three dermatomes below the neurologic level. This type of neuropathic pain may be caused by the SCI or a lesion of the nerve roots, and it is often not possible to determine whether it is a peripheral neuropathic pain caused by root lesion or a central pain caused by spinal cord lesion. Below-level pain is pain felt more than three dermatomes below the neurologic level and is a central pain caused by the spinal cord lesion. In patients with syringomyelia, the pain distribution is often segmental. Different types of pain seen following SCI, including central pain, can be found in Chapter 40, and the readers are referred to that chapter for further details on SCI pain.

OTHER CENTRAL PAIN CONDITIONS

The diagnosis of central pain in brain trauma is often difficult and only few studies exist. The central pain is similar to that of other central pain patients. The onset may be delayed for several months and often becomes persistent. The pain distribution is often unilateral, corresponding to the side with most severe sensory abnormalities and related to decreased thermal sensitivity. Ongoing pain described as pricking, cold, pressing, wretched, and burning is common, and some patients described touch- and cold-evoked allodynia. There are very few reports in the literature on central pain in brain tumors, but it has been described in tumors affecting the thalamus and the parietal cortex. Central pain following surgery such as dorsal root entry zone lesions, thalamic destructions, and mesencephalic and medullary tractotomies are only infrequently reported because these procedures are rarely done today.
Pain is a common problem in Parkinson’s disease. The pain is often located in the lower back and lower extremities, and musculoskeletal pain is the most common type.\textsuperscript{78,79} It is also suggested that some pain conditions in Parkinson’s disease are related to the CNS disease and has been termed central pain.\textsuperscript{78–80} This type of pain is rare and is a poorly localized diffuse pain that is often associated with “off condition,” autonomic symptoms, visceral pain, and improvement with levodopa administration.\textsuperscript{78,79,81} This type of pain, however, does not entirely fulfill the criteria for central pain. Even though altered thermal and pain thresholds have been found in Parkinson’s disease, suggesting altered responsiveness to painful stimuli,\textsuperscript{81,82} lower laser N2/P2 amplitudes are also found in pain-free patients,\textsuperscript{83} and one study found that the pain thresholds were not different in patients with and without pain.\textsuperscript{84} However, there is increasing evidence that the basal ganglia and the dopaminergic system play an important role in the gating of nociceptive information and pain modulation,\textsuperscript{85,86} and it is possible that some pain types in Parkinson’s disease are related to altered sensory processing of nociceptive inputs.\textsuperscript{80} Epileptic seizures may rarely be reported as pain.\textsuperscript{87,88} One case report describes a patient with a dysplasia in the posterior insula.\textsuperscript{89} Spontaneous high-frequency activity and spiking from this area propagated to other areas including the parietal operculum and the midcingulate gyrus. During the attack, the patients reported hemibody pain that started in the left hand and foot.\textsuperscript{89}

Preclinical Models

Different models of SCI, stroke, brain trauma, and MS are used in preclinical pain research.\textsuperscript{90–96} SCI models include hemisection, contusion, ischemic, electrolytic, and excitotoxic models.\textsuperscript{97–100} The models mimic human CNS lesions reasonably well, but the assessment of pain and its translation into human central pain remains a challenge.\textsuperscript{101}

One of the most obvious challenges for all preclinical models of pain is the difficulty in assessing the correlate of ongoing pain. Except for a very few studies that have used conditioned place preference paradigms\textsuperscript{102} or overgrooming,\textsuperscript{103} most preclinical studies of central pain exclusively use
evoked responses to mechanical, cold, or warm stimuli. This may be valid because evoked pain is common and predicts the development of central pain, but evoked pain-related responses do not always correlate with ongoing pain, and ongoing central pain may exist without evoked pain. A particular challenge in assessing pain-like behavior in models of CNS injury is the frequent coexistence of spasticity making the use of simple withdrawal reflexes unreliable as a pain-like behavioral outcome. Because withdrawal reflexes are spinally mediated, persist after complete spinal transection, and may be increased as part of the spastic syndrome, methods that depend on brainstem or cortical processing (e.g., operant escape or place escape/avoidance paradigms) are needed.

**Mechanisms**

Experimental animal models and studies in humans have provided insights into the pathophysiology of central pain, which involves plasticity in various areas and pathways of the CNS. Sensitization of the CNS plays a major role in central pain and involves neuronal hyperexcitability resulting in an increased response to synaptic inputs, decreased threshold, expansion of receptive fields, and access of low-threshold Aβ mechanoreceptors to pain pathways. The clinical consequences are allodynia, hyperalgesia, and aftersensations. Central sensitization may also include spontaneous discharges. Spontaneous discharges in damaged pain pathways or deafferented rostral neurons may be responsible for spontaneous ongoing or intermittent pain. Seemingly, spontaneous pain may also be a result of decreased thresholds in nociceptor excitation and temporal summation of stimulus-evoked pain occurring at physiologic levels from stimuli caused by daily activity such as breathing, movement, and ambient temperature. Recent studies have found that sensory hypersensitivity (mechanical and cold allodynia, hyperalgesia, and temporal summation of pain) precedes and predicts later development of central pain (CPSP and below-level SCI pain), supporting a role of neuronal hyperexcitability also for ongoing pain.

The functional changes underlying central sensitization involve a range
of anatomical, neurochemical, excitotoxic, and inflammatory mechanisms. Changes in ion channels (sodium, calcium, potassium, acid-sensing) and phosphorylation of glutamate receptors may occur at various levels of the CNS, and altered opioid receptor binding has also been demonstrated in patients with central pain. Changes in the functions of microglia and astrocytes and release of inflammatory mediators also contribute to chronic pain following CNS injury.

Lesions of the STT and STT–thalamocortical pathways play an important but not well-understood role in the mechanisms of central pain. Impairment of pain and temperature sensation and STT injury are hallmarks of central pain, but abnormal STT function is not a sufficient condition as STT lesions are also frequent in pain-free subjects. Approximately 50% of patients with a lesion of the STT after SCI or operculo-insular strokes develop central pain, and the question is why STT lesions cause pain in some but not all individuals. Although central pain can occur in patients with complete lesions of the STT, it is suggested that central pain is caused by sensitization of partially preserved residual STT neurons in some patients. This is consistent with studies showing that microsimulation in the ventral caudal (Vc) sensory nucleus of the thalamus, which receives dense STT terminations, evokes pain in patients with central pain. It is likely that the role of lesioned versus preserved ascending pathways in central pain depends on the pain phenotype. Patients with evoked pain are more likely to have preserved large- and small-fiber function than patients with spontaneous pain only, as shown in studies using quantitative sensory testing, somatosensory, and laser-evoked potentials and functional MRI (fMRI).

The thalamus is implicated in central pain of spinal, brainstem, and brain origin. In addition to the Vc nucleus of thalamus, the medial and intralaminar nuclei, which receive STT input that further project to the
anterior cingulate cortex (ACC), have also been implicated in central pain. CPSP is particularly common in lesions of the ventral posterior and Vc thalamic nuclei, but the thalamus is also implicated in central pain following other CNS lesions.

Various disinhibition hypotheses have been proposed—but also questioned—for central pain. These include an imbalance between the relative preservation of the dorsal column compared to the STT pathways and an imbalance between spinothalamic and spinoreticulothalamic pathways following spinal cord and brainstem lesions. In 1911, Head and Holmes suggested that the pain in CPSP was due to a disinhibition of the medial thalamus caused by a lesion of the lateral thalamus. Later, Craig and colleagues suggested the thermosensory disinhibition theory. This theory suggests that cold allodynia and burning pain occur in areas of cold sensitivity loss because lesions of a lateral cool-signaling STT pathway from lamina 1 of the dorsal horn through the lateral thalamus to the insula disinhibit a medial STT pain-signaling pathway. Loss of descending inhibitory pathways and deficient ability to conditioned pain modulation have been shown to be involved in central pain in SCI, and injury to the periaqueductal gray (PAG), which plays an important role in descending pain modulation, was related to the degree of central pain in mild traumatic brain injury.

Changes in spinal cord excitability are important for central pain following SCI. Spinal transection and dorsal root-entry zone (DREZ) lesions may relieve below-level pain in some patients, supporting a crucial role of changes in the rostral part of the spinal cord lesion for central SCI pain. Also, sensory hypersensitivity and imbalance of pinprick and light touch sensation were more common at the level of injury in SCI patients with below-level pain, supporting the role of this region for central pain in SCI. But several remote changes in the CNS—beside the thalamic changes mentioned earlier—may also play a role for SCI pain. Central pain in SCI has been associated with changes in spontaneous electroencephalogram (EEG), and in addition, imagining movement results in increased desynchronization in the θ, α, and β bands in pain versus pain-free patients. Furthermore, reorganization of the primary somatosensory cortex has been linked to the intensity of neuropathic pain following
SCI,\textsuperscript{164} although results are conflicting,\textsuperscript{165} and a recent systematic review suggested that there is only limited evidence for a relationship between pain due to deafferentation and cortical reorganization.\textsuperscript{166} In addition, changes have been seen in anterior cingulate and prefrontal cortices following SCI.\textsuperscript{167–171} Overall, more information is needed to understand the interaction of these different CNS regions in the generation, amplification, or modification of central pain.

### Treatment of Central Pain

Treating central pain remains a great challenge, and a broad approach is essential. Patients with central pain may be elderly, and they may have concurrent medical problems and impairments such as paralysis, spasticity, gastrointestinal and autonomic dysfunctions, intellectual impairment, as well as depression, fatigue, sleep disturbances, or psychosocial problems. In addition, they may be treated with multiple drugs with unwanted CNS-related side effects. The diagnosis of central pain and the presumptive underlying mechanisms is the first important step and requires a thorough assessment. The treatment of central pain is often symptomatic, but in some cases, the underlying cause of neuropathic pain can be treated, for example, with the use of corticosteroids for the treatment of spinal cord compression. It is also important to be aware of factors that may exacerbate central pain (e.g., stress, depression, and urinary tract infections).\textsuperscript{22} Realistic expectations for the treatment outcome should be discussed with the patient, explaining that often only partial pain relief from central pain can be expected. The approach is to start the treatment with complementary and pharmacologic therapies, and in refractory cases, consider interventional therapies such as neuromodulation.\textsuperscript{116}

Treatment of neuropathic pain is often a “trial-and-error” process. In contrast to the disease-based classification of neuropathic pain, it is suggested that a mechanism-based classification will improve the treatment of the individual patient.\textsuperscript{172} Because we do not have reliable tools to assess which pain mechanisms are important in which pain patients, a phenotype-based classification has been advocated. This approach suggests that the presence of specific clusters of pain descriptors
or sensory profiles may reflect specific underlying pain mechanisms, and thus efficacy to specific drugs.\textsuperscript{33,173,174} There is, however, still limited evidence for this approach, and in future clinical trials, it is important to obtain a well-characterized description of the patient’s pain, including pain location, pain descriptors, sensory signs, and psychosocial factors, to gain more knowledge on phenotype-based pain classifications and treatments.

**PHARMACOLOGIC TREATMENT**

The drugs used for neuropathic pain have limited response rates, and typically, responders experience only partial pain reduction at tolerable doses. Because there is no evidence for a disease-based pharmacologic treatment of neuropathic pain, general treatment guidelines for neuropathic pain are also recommended for central pain—with the exception of topical treatments.\textsuperscript{175} Overall, randomized, double-blind, placebo-controlled studies in central pain support the general treatment recommendations for neuropathic pain (Table 28.2).\textsuperscript{175} A summary of pharmacologic treatments that are relevant for central pain is presented in the following discussion, and the reader is referred to Chapter 81 for a more detailed description of neuropathic pain pharmacotherapy. In the following, the NeuPSIG treatment recommendations will be used.\textsuperscript{175} NeuPSIG is the Neuropathic Pain Special Interest group of the International Association for the Study of Pain (IASP). The NeuPSIG treatment recommendations are based on a systematic literature search of published and unpublished studies, a meta-analysis, and an evaluation of the quality of evidence and strength of recommendation using the Grading of Recommendations Assessment, Development, and Evaluation (GRADE).\textsuperscript{175} Numbers needed to treat (NNTs) are used to describe effect sizes. The NNT is the number of patients needed to treat with a certain drug to obtain one patient with a defined degree of pain reduction (usually 50%) and is calculated as the reciprocal of the absolute risk reduction. As for neuropathic pain in general, there is a relatively large placebo response in clinical trials of central pain—sometimes making it difficult to show superiority of different treatments.\textsuperscript{185}

First-line Pharmacologic Treatments

First-line pharmacologic treatments in central pain include tricyclic antidepressants (TCAs), serotonin-noradrenaline reuptake inhibitors (SNRIs), pregabalin, and gabapentin (Fig. 28.3).

---

**Study includes nonneuropathic pain conditions.**

Ami, amitriptyline; BTX-A, botulinum toxin type A; Can, cannabinoid; Car, carbamazepine; CPSP, central poststroke pain; Dul, duloxetine; Gab, gabapentin; Lam, lamotrigine; Lev, levetiracetam; Mex, mexiletine; MS, multiple sclerosis; PEA, palmitoylethanolamide; pla, placebo; Pre, pregabalin; SCI, spinal cord injury; Tra, tramadol; Val, valproate.

---

### First-line Pharmacologic Treatments

| SCI | Finnerup et al. 2009 | 36 | Levetiracetam 3,000 mg | Lev = pla |
| CPSP | Jungehulsing et al. 2012 | 42 | Levetiracetam 3,000 mg | Lev = pla |
| CPSP | Falah et al. 2012 | 30 | Levetiracetam 3,000 mg | Lev = pla |
| **Opioids** | Norrbrink and Lundeberg 2009 | 36 | Tramadol 400 mg | Tra > pla |
| **Cannabinoids** | Svendsen et al. 2004 | 24 | Dronabinol 10 mg | Can > pla |
| MS | Rog et al. 2005 | 66 | Sativex spray | Can > pla |
| MS | Langford et al. 2013 | 339 | Sativex spray | Can = pla |
| SCI | Clinicaltrials.gov (NCT01606202) | 111 | Sativex spray | Can = pla |
| **Other** | Chiou-Tan et al. 1996 | 11 | Mexiletine 450 mg | Mex = pla |
| SCI | Han et al. 2016 | 40 | Botulinum toxin type A | BTX-A > pla |
| SCI | Andresen et al. 2016 | 73 | Palmitoylethanolamide 600 mg | PEA = pla |
FIGURE 28.3 Treatment algorithm for the pharmacologic treatment of central pain.

TCAs and SNRIs inhibit the presynaptic reuptake of serotonin and noradrenaline, and in addition, TCAs act on voltage-gated sodium channels and opioid and N-methyl-D-aspartate (NMDA) receptors.\textsuperscript{186,187} The site of action is through descending aminergic pathways at spinal or supraspinal sites, but a peripheral site of action via sympathetic fiber sprouting in the dorsal root ganglia may also be involved.\textsuperscript{186,187} The analgesic action of noradrenaline is likely to be mediated through both α2A and β2 adrenoceptors.\textsuperscript{187}

The combined NNT for TCAs in neuropathic pain was 3.6 (95% CI, 3.0 to 4.4) with a moderate quality of evidence, and the combined NNT for SNRIs was 6.4 (5.2 to 8.4) with a high quality of evidence.\textsuperscript{175} NNTs are not directly comparable due to differences in study design. The effect of antidepressants is independent of the antidepressant effect,\textsuperscript{176} although in a study in SCI patients, the effect on pain was more pronounced in those with considerable depressive symptomatology.\textsuperscript{178} Amitriptyline is the TCA most often studied in neuropathic pain, but there is no clinical evidence to suggest superior efficacy of one TCA, and imipramine and the TCAs with secondary amine structure (nortriptyline and desipramine) are often better tolerated.\textsuperscript{188} The first study in central pain compared the effect of amitriptyline 75 mg per day with that of carbamazepine 800 mg per day and placebo in 15 patients with CPSP (see Table 28.2).\textsuperscript{176} Amitriptyline,
but not carbamazepine, significantly relieved central pain, and the effect size was highest if the total plasma concentrations of amitriptyline and its metabolite nortriptyline exceeded 300 nmol/L. Later studies also found an effect of amitriptyline in SCI- and MS-related pain,\textsuperscript{178,179} whereas one study failed to show an effect of amitriptyline in SCI pain, but this study did not exclusively include neuropathic pain.\textsuperscript{177} In one small study, duloxetine relieved CPSP and SCI pain, but the difference was not statistically significant.\textsuperscript{180}

Side effects to TCAs include drowsiness, fatigue, weight gain, and effects related to anticholinergic actions such as dry mouth, constipation, urinary retention, and orthostatic hypotension. TCAs should not be used in patients with heart failure, and precautions should be taken in patients with cardiac conduction disturbances, seizures, and glaucoma. Tertiary amine TCAs (amitriptyline, imipramine, and clomipramine) and high TCA doses are not recommended in patients above 65 years of age due to the increased risk of falls or sudden cardiac death.\textsuperscript{189,190} TCAs should be used with caution in combinations with other serotonergic agents due to the risk of serotonin syndrome. TCAs should be titrated slowly, starting at 10 to 25 mg daily and titrated up to 75 to 100 mg per day. TCAs are metabolized by the hepatic cytochrome P450 system, and genetic polymorphisms at CYP2D6 cause variability in pharmacokinetics. Titration is normally guided by the clinical response, but serum drug concentration measurements may improve the outcome.\textsuperscript{186} SNRIs and selective serotonin reuptake inhibitors may cause nausea, abdominal pain, sedation, dizziness, sweating, and sexual dysfunction. They may also cause blood pressure elevation. Duloxetine is given at doses of 60 mg daily and should be avoided in patients with moderate liver disease and renal impairment with creatinine clearance below 30 mL per minute. Venlafaxine treatment should be titrated slowly up to 150 mg per day, with reduced dosage in patients with renal and liver impairment. For both drugs, drug–drug interactions concern serotonergic agents and drugs affecting coagulation.

Gabapentin and pregabalin are ligands of the \(\alpha_2\delta\) subunit of voltage-gated calcium channels, and the analgesic effects is thought to be mediated through an attenuation of calcium channels influx into cells and a reduced release of neurotransmitters, although other actions such as an effect on
Glia cells and expression of proinflammatory cytokines may also be involved. The expression of the $\alpha_2\delta$ calcium channel subunit can be increased in some neuropathic pain conditions, but the effect of gabapentin and pregabalin does not require increased $\alpha_2\delta$ subunits. Gabapentin and pregabalin act at peripheral, spinal, and supraspinal levels.

The combined NNT for gabapentin in neuropathic pain was 6.3 (95% CI, 5.0 to 8.3), and the NNT for pregabalin was 7.7 (95% CI, 6.5 to 9.4) with a high quality of evidence. Six studies have examined the effect of gabapentin or pregabalin in central pain, of which four were positive on the primary outcome (see Table 28.2). The two largest studies in SCI pain found an effect of pregabalin as add-on therapy on pain, pain-related sleep interference, and anxiety with a combined NNT of 7.0 (4.5 to 16.5). Pregabalin showed an effect on anxiety scores on the Hospital Anxiety and Depression Scale (HADS) in one study and on depression scores in another study, although patients did not have clinically relevant levels of anxiety and depression. Pregabalin tended to be more effective in those with a high HADS score.

Side effects include somnolence, dizziness, peripheral edema, and weight gain. The frequency of somnolence may be higher in patients with central pain, possibly due to a high frequency of concomitant medication for pain and spasticity. Gabapentin is initiated at 100 to 300 mg per day and increased up to 1,800 to 3,600 mg daily in three divided doses, and pregabalin is increased from 75 mg twice daily to 300 to 600 mg per day. Doses should be decreased in patients with renal insufficiency.

**Second- and Third-Line Pharmacologic Treatments**

Tramadol is a weak agonist of $\mu$-opioid receptors and a SNRI. The combined NNT for tramadol in neuropathic pain was 4.7 (95% CI, 3.6 to 6.7) with a moderate quality of evidence, and tramadol is recommended as a second-line drug. Tramadol is particularly useful in the treatment of episodic exacerbations of pain. The combined NNT for strong opioids, including morphine and oxycodone, in neuropathic pain was 4.3 (95% CI, 3.4 to 5.8) with a moderate quality of evidence. Due to potential safety concerns with risk of abuse, cognitive impairment, and endocrine and
immunologic changes, the final strength of recommendation was weak, and opioids were recommended as third-line drugs.

Other Drugs, Combination Therapy, and Intrathecal Drug Administration

The recommendations for other antiepileptics for neuropathic pain are inconclusive due to conflicting and overall negative results. However, some patients do seem to respond to sodium channel blockers, and there was an effect of lamotrigine in one study of CPSP, and post hoc analyses suggested effect of lamotrigine in SCI subjects with incomplete lesions and evoked pain. In addition, a recent study in peripheral neuropathic pain found that oxcarbazepine was effective in patients with preserved nociceptors and evoked pain but not in those without this pain phenotype. Therefore, sodium channel blockers may be indicated in some patients, although further studies are needed to confirm the specific predictors for effects. For neuropathic pain in general, there was an overall weak recommendation against the use of cannabinoids. Also in central pain, the results are conflicting (see Table 28.2), and more studies on the long-term efficacy and safety are needed to establish whether there is a role for the use of cannabinoids in central pain.

When treatment with a single drug is only partly effective, combination with another drug of a complementary mechanism of action may be tried. Side effects should be carefully monitored, and normally sequential add-on therapy is recommended.

In refractory cases, spinal drug administration may be considered. There is, however, little evidence from randomized controlled trials. One study examined clonidine, morphine, and their combination in SCI pain. Each drug alone did not provide significant pain relief, but the combination of clonidine and morphine provided effect on central pain. The effect size correlated with the concentration of morphine in the cervical cerebrospinal fluid, and it was suggested that if there is a pathology restricting the flow of cerebrospinal fluid, the drugs need to be administered above the level of injury. Ziconotide—a drug that is given intrathecally—is recommended for moderate to severe chronic pain and can be combined with intrathecal morphine or baclofen, but there is limited experience with central pain,
and the treatment is often associated with severe side effects.\textsuperscript{204} Short-term side effects to spinal drug administration include nausea, sedation, hypotension, and respiratory depression. Lidocaine, ketamine, and opioids given intravenously have also been shown to relieve central pain, but these treatments have a limited role in chronic pain treatment.\textsuperscript{205–209}

**PSYCHOLOGICAL AND PHYSIOTHERAPY TREATMENT**

The treatment of central pain often requires a multidisciplinary approach. A large proportion of patients use nonpharmacologic treatments, and patients with SCI reported that massage and heat were the nonpharmacologic treatments to result in the best pain alleviation.\textsuperscript{210} Concomitant psychological distress, anxiety, and depression should be treated. Cognitive-behavioral therapy and other psychological interventions may be useful.\textsuperscript{211} A Cochrane review evaluated the effects of psychological treatments on pain, disability, mood, and health care used in patients with neuropathic pain and found that there was insufficient evidence of psychological interventions with only two eligible studies.\textsuperscript{212} Smaller studies have found some effect of hypnosis on the impact of MS-related pain,\textsuperscript{213,214} personalized positive psychology exercises in different central pain conditions,\textsuperscript{215} and multidimensional pain management programs comprising educational, cognitive, and behavioral intervention in SCI pain.\textsuperscript{216,217} Another systematic review with less strict criteria concluded that virtual reality interventions and hypnosis are effective for pain related to MS and SCI.\textsuperscript{218}

Physical therapy may be useful in alleviating musculoskeletal pain, spasticity, and other complications to a CNS disorder. Visual illusion, where patients see a movie of a lower body walking aligned with a mirror image of their own upper body, has been shown to decrease pain in SCI in small trials.\textsuperscript{219,220} Other studies have found increased pain following movement imagery in patients with complete SCI,\textsuperscript{168} and neurofeedback aimed at self-regulating abnormal brain activity during imaged movement has been suggested to be effective in central pain in SCI.\textsuperscript{221} More information is needed on the methodology, long-term efficacy, and predictors of response of various techniques related to visual illusion and
neurofeedback.

**NEUROSURGICAL MANAGEMENT**

The neurosurgical management of central pain can be utilized when noninvasive treatment options fail. A multitude of techniques have been employed with myriad anatomical targets in the peripheral nervous system and CNS with varying degrees of efficacy. Lack of consistent evidence secondary to the variability in techniques across centers as well as small sample sizes has led to difficulty in drawing definitive conclusions. Currently, evidence for the majority of neurosurgical treatment options lies within case reports or small case series that consistently find improvement in variable degree in a subset of patients. Central pain syndromes are notoriously recalcitrant to medical treatment, and consideration should be given to offering neurosurgical intervention depending on the type of pain, severity, and influence on quality of life in each individual case.

**Targeted Drug Delivery**

Targeted drug delivery into the subarachnoid space for the treatment of refractory central pain has been attempted through various techniques including most commonly via a catheter inserted into the intrathecal space in the spinal column or less commonly directly into the brain via an intraventricular catheter. The catheters are subsequently connected to a subcutaneously implanted drug delivery pump allowing the controlled infusion of a variety of medications. Infused drugs of choice have included GABAergic agonists like baclofen or midazolam, sometimes in combination with an adrenergic agent such as clonidine.\textsuperscript{222,223} One randomized, double-blind study in 15 patients undergoing intrathecal drug delivery for the treatment of neuropathic pain after SCI found that the combination of morphine and clonidine produced significantly greater pain control than placebo or either medication given alone.\textsuperscript{203} Much of the literature about pain reduction via subarachnoid infusion of medication in central pain states comes from patients with SCI and MS undergoing intrathecal therapy for the treatment of spasticity and suggests that there is direct additional suppression of neuropathic pain distinct from the suppression of spasm-related pain,\textsuperscript{224} although no controlled studies have

1366
been published and there is general consensus that the effects are limited.

**Neuroablation**

Since the introduction of stereotactic surgery in the late 1940s, targeted neuroablative techniques have been utilized to intervene in central pain pathways in the most refractory patients suffering from pain syndromes. Some of the more successfully targeted regions include the sensory thalamus in patients undergoing stereotactic or radiosurgical thalamotomy and the spinothalamic and quintothalamic pathways in stereotactic mesencephalotomy\(^\text{225}\) most commonly used for the treatment of CPSP. New techniques have largely replaced these ablative procedures with the capacity for reversible and titratable modulation of deep brain-stimulating electrodes. These are now most often used in the treatment of pain except in certain circumstances where ablative techniques are preferred, most notably in the palliative treatment of cancer-related pain. Technologic advancements in our ability to create lesions in the brain through incisionless techniques, including new technology such as MR-guided high-intensity focused ultrasound, as well as improvements in the use of focused radiation may forecast a resurgence in interest in the revival of these ablative techniques.

**Neuromodulation**

**Motor Cortex Stimulation**

Perhaps the most robust evidence in the neurosurgical treatment of central pain lies in epidural cortical stimulation (ECS), most commonly of the motor cortex. This treatment modality was first reported in 1991 by Tsukobawa et al.\(^\text{226}\) after investigating the cortical patterns associated with burst hyperactivity of thalamic neurons in an animal model of STT deafferentation. They found that stimulation of the motor cortex provided complete, long-term inhibition of this burst hyperreactivity and applied this model to a case series of patients with thalamic pain syndrome by inserting epidural electrode over the motor cortex, ultimately achieving “excellent or good” pain control in all cases. Indications for motor cortex stimulation (MCS) have expanded over the last decade to include refractory SCI pain, phantom limb pain, and neuropathic facial pain among
This procedure is performed via a small craniotomy or burr hole contralateral to the region of pain. The sensory and motor cortices are typically mapped intraoperatively using electrophysiology to identify the central sulcus. Typically, one or two 4-contact strip electrodes are then placed in the targeted region in either a longitudinal orientation over the motor cortex or perpendicular to the central sulcus in the epidural space. The electrodes are then sutured down, and extension wires are typically externalized for a 3- to 7-day trial during which pulse width, frequency, and amplitude are optimized. There is a considerable amount of variation in stimulation parameters, and typically, the stimulus intensity is increased to test the motor threshold and decreased subsequently as a percentage of this amplitude. Patients typically do not experience paresthesias or other stimulation-induced sensory phenomena. If patients are felt to achieve sufficient (typically 40% or more) pain relief, stage 2 of the trial involves removing the trial extension wires and tunneling the lead to an infraclavicular implantable pulse generator (IPG), most often placed in the infraclavicular space. MCS has risks that are typical of most cranial procedures, including infection and the possibility of hemorrhage, as well as seizures and hardware problems; however, these complications are rare, and the procedure is considered overall to be safe.

Although the mechanisms that underlie the effects of MCS have not been clearly identified, studies suggest that activity in the first- and second-order somatosensory pathways is affected, and various patterns of cerebral blood flow changes have been noted in thalamus and other regions of the brain in successful cases. In a critical review of the literature, greater than 40% improvement in pain scores were reported in 54% of 117 patients with central pain. Good results have also been reported in isolated cases of patients with pain secondary to MS and pain after posttraumatic brain injury; however, CPSP has been the most comprehensively studied central pain indication. In a review of its efficacy, Nguyen et al. reported that MCS showed a greater than 40% pain reduction on the VAS in 60% of patients with CPSP. Although these and other trials have demonstrated the efficacy of MCS in the treatment of various types of neuropathic pain, they include a limited number of
patients and often patients with various etiologies of pain are analyzed concurrently. These findings thus need to be confirmed by larger, randomized controlled multicenter trials and include more methodical selection of patient cohorts.  

Deep Brain Stimulation
Deep brain stimulation has been used for the treatment of pain since the 1950s and became widely employed by the 1970s for the treatment of neuropathic pain of various origins. Enthusiasm for using this treatment modality for chronic, refractory pain was dampened when two industry supported open-label studies failed to reach their clinical endpoints for success. Critics of these trials contend that they were neither randomized nor case-controlled, had variability in patient selection, inconsistencies in neurosurgical technique, and lack of rigorous evaluation of individual pain etiologies which have been shown to have dramatically variable responses to invasive treatment. Utilizing improvements in hardware, imaging modalities, and with attention to patient selection, specialized centers across the country continue to use deep brain stimulation effectively for the treatment of various types of pain syndromes on an “off label” basis.

Currently, there is no consensus for best anatomical target in the treatment of pain, and many regions of the brain have been trialed over past several decades. The most commonly utilized targets the sensory-discriminative sphere of pain circuitry and includes the PAG area/periventricular gray area (PVG) and the Vc (ventral posterior lateral) nucleus of the sensory thalamus. More recently, efficacy has been found in regions targeting the affective components of pain including ACC and the anterior limb of the internal capsule (ALIC). The surgical approach is similar in nature and risk to the technique widely used for implanting deep brain-stimulating leads for the treatment of movement disorders including Parkinson’s disease and essential tremor. Risks are rare but potentially serious and include most commonly infection, hemorrhage, and hardware complications.

A variety of case reports and case series have demonstrated efficacy in the treatment of various central pain pathologies including MS, pain
from malignancy, pain after SCI as well as CPSP. In this cohort, 15 patients were treated with deep brain stimulation for CPSP with stimulators placed in the PVG, Vc, or both. VAS scores revealed a mean improvement of 48.8% with a wide variability between patients and was found to be an effective treatment overall in 70% of patients.

In 2016, the European Academy of Neurology (EAN) published guidelines on the role of neurostimulation in the treatment of neuropathic pain and concluded that studies for deep brain stimulation were heterogeneous and imprecise and despite some clear demonstration of efficacy were inconsistent in their findings. This lead the committee to an “inconclusive” recommendation as to the efficacy of this treatment modality. Although deep brain stimulation has proven to be a potentially effective tool for those patients with severe, refractory central pain who have failed all other less invasive treatment modalities, prospective, randomized controlled trials are needed to further delineate effective targets, reliable stimulation parameters, and to refine patient selection criteria.

Spinal Cord Stimulation
Spinal cord stimulation (SCS) therapy is used most often to treat peripheral neuropathic pain, pain from failed back surgery syndrome, or complex regional pain syndrome and is not commonly employed in the treatment of central pain, with some claiming that it plays no role in the treatment of brain central pain. Few case reports support its use in CPSP, citing modest long-term improvement. Reports of SCS in the use of pain from SCI similarly vary in their efficacy and are generally lacking. In one seminal series from 1972 of 30 patients undergoing SCS, 5 were implanted for pain from traumatic SCI including spinal fractures, gunshot wounds to the spine, and cord contusions, none of whom had an “excellent” response to treatment. Since then, further reports have corroborated a generally poor response in these patients when compared to traditional indications like failed back surgery syndrome and pain from
peripheral neuropathy, potentially owing in part to primary damage of the
circuitry being stimulated. In the treatment of central cord pain, however,
some continue to contend that given its less invasive nature, SCS should
be attempted in those patients with at least partially preserved
somatosensory pathways but note that the effects may be transient.222,223

Psychophysiology is a field of study that seeks to relate subjective awareness and behavior to physiologic events.\textsuperscript{1–3} As a field of scientific inquiry, it concerns itself with central mechanisms of perception, cognition, and behavior, including learning, the emotions, and the relationship of brain activity to consciousness. As a clinical area, psychophysiology has classically addressed somatoform disorders, stress (most recently posttraumatic stress disorders), and affective disorders in general. As a domain, psychophysiology is an important resource for the pain field for two primary reasons. On one hand, it offers a framework for understanding how stress contributes to pain, including the persistence of chronic pain. On the other hand, it uncovers links between cognitive processes (attention, expectancy, meaning, belief) and pain as well as pain relief through psychological intervention.

Most physicians and pain researchers think of pain as an unpleasant sensation that originates in traumatized or inflamed tissues; however, pain is more than sensory information about the condition of the body. Affect is an intrinsic dimension of pain. Any reasonable and unbiased observer studying mammals, particularly humans, would have to conclude that pain’s affective features rather than its sensory properties govern behavioral responses to injury. People who experience pain do not quietly report the fact; they express negative emotions.

Is the affective dimension of pain as important as its sensory aspect? The linguist, Elaine Scarry,\textsuperscript{4} described pain’s qualities as comprising extreme aversiveness, an ability to annihilate complex thoughts and other feelings, an ability to destroy language, and a strong resistance to objectification. Her perspective resonates with the lessons of everyday life:
Although pain has sensory features and lends itself to sensory description, it is above all else a powerful negative feeling state. One cannot evaluate and address the suffering of a person in pain without an appreciation of its emotional nature.

The International Association for the Study of Pain (IASP) acknowledged the central role of emotion in its keystone definition: “Pain [is] an unpleasant sensory and emotional [emphasis added] experience associated with actual or potential tissue damage, or described in terms of such damage.” This definition clearly emphasizes the role of affect as an intrinsic component of pain. Emotion is not a consequence of pain sensation that occurs after a noxious sensory message arrives at sensory cortices. Rather, it is an integral part of the pain experience.

Psychophysiology has revealed that emotion and cognition are interdependent. Strong emotions can alter thought processes, perceptions, beliefs, attitudes, and expectancies. Conversely, thoughts can generate negative or positive emotional states, and the physiologic changes associated with such states can interact with tissue injury or inflammation and alter both the sensory and affective aspects of pain. Because pain states rarely exist in isolation, it is important to consider the psychophysiologic context of a pain problem. The cognitive, emotional, and physiologic state of the patient presenting with pain is potentially very important for both assessment and intervention. We propose here that the best framework for characterizing this state is stress theory.

The purposes of this chapter are to describe the psychophysiologic mechanisms supporting the subjective experience of pain and to explore the importance of said mechanisms for the assessment and care of patients with pain. The psychophysiology of pain requires an incursion into mind–body issues, consideration of the nature of emotion and its interdependence with cognition, and the overarching influence of stress. In this chapter, we show that (1) pain (awareness of tissue trauma) has intrinsic affective properties, including negative emotional arousal; (2) the brain creates bodily states of arousal (negative emotions) in response to threat to biologic and psychological integrity; and (3) the affective dimension of pain is intrinsically linked to the related processes of defense and stress, and the physiologic mechanisms of these processes shapes the
affective dimension of pain.

**Historical Perspective: Mind–Body Issues**

Through most of the 20th century, our understanding of the relationship between mental processes and the body stemmed directly from Cartesian notions of mind–body dualism. For Descartes, a 17th century philosopher and mathematician, human beings are dualistic: The mind and body are separate entities. Descartes described the life processes of the body as though they were clockwork mechanisms. The actions of the mind were, in his thinking, the workings of the soul.

Descartes believed that the awareness of pain, like awareness of other bodily sensations, must take place in a specific location where the mind observes the body. Dennett\(^6\) termed this hypothetical seat of the mind the Cartesian theater. In this theater, the mind observes and interprets the array of multimodality signals that the body produces. The body is a passive environment; the mind is the nonphysical activity of the soul.

Today, most people will agree that such a theater of the mind cannot exist. Scientifically, the activity of the brain and the mind are inseparable; yet, Cartesian dualism is endemic in Western thought and culture. Classical approaches to psychophysiology stemmed from Cartesian thinking, as did psychophysics. Early work on psychosomatic disorders focused on mind–body relationships. Today, much of the popular movement favoring integrative medicine emphasizes the “mind–body connection,” keeping one’s self healthy through health-promoting cognitive approaches to better regulate immune responses. It is hard to avoid Cartesian thinking when the very fabric of our language carries it along as we reason and speak.

Cartesian assumptions are a subtle but powerful barrier for someone seeking to understand the affective dimension of pain. Relegating emotions to the realm of the mind and their physiologic consequences for the body is classical Descartes. It prevents us from appreciating the intricate interdependence of subjective feelings and physiology, and it detracts from our ability to comprehend how the efferent properties of autonomic nervous function can contribute causally to the realization of an
emotional state. This chapter emphasizes the interdependence of mental processes and physiology. What we call the mind is consciousness, and consciousness is an emergent property of the activity of the brain. In a feedback-dependent manner, the brain regulates the physiologic arousal of the body, and emotion is a part of this process.

**Emotions: Definition and Mechanisms**

**WHAT ARE EMOTIONS?**
The first step in understanding the nociceptive experience as an affective response is by appreciating the origins and purposes of emotion. Many physicians regard emotions as epiphenomenal feeling states associated with mental activity, subjective in character, and largely irrelevant to the state of a patient’s physical health. In fact, emotions are primarily physiologic and only secondarily subjective. Because they can strongly affect cardiovascular function, visceral motility, genitourinary function, and immune competence, patient emotions can have an important role in health overall and especially in pain management. Simple negative emotional arousal can exacerbate certain pain states such as sympathetically maintained pain, angina, headache, neuropathic pain, and fibromyalgia. It contributes significantly to musculoskeletal pain, pelvic pain, and other pain problems in some patients.

Emotions are complex states of physiologic arousal and awareness that impute positive or negative hedonic qualities to a stimulus (event) in the internal or external environment. The objective aspect of emotion is autonomically and hormonally mediated physiologic arousal. The subjective aspects of emotion, feelings, are phenomena of consciousness. Emotion represents in consciousness the biologic importance or meaning of an event to the perceiver.

Emotion as a whole has two defining features: valence and arousal. Valence refers to the hedonic quality associated with an emotion—the positive or negative feeling attached to perception. Arousal refers to the degree of heightened activity in the central nervous system and autonomic nervous system (ANS) associated with perception.

Although emotions as a whole can be either positive or negative in
valence, pain research addresses only negative emotion. Viewed as an emotion, pain represents a threat to the biologic, psychological, or social integrity of the person. In this respect, the emotional aspect of pain is a protective response that normally contributes to adaptation and survival. If uncontrolled or poorly managed in patients with severe or prolonged pain, it produces suffering.

**EMOTION IN A SOCIOBIOLOGIC PERSPECTIVE**

Psychologists have many frameworks for studying emotion. Nature has equipped us with the capability of negative emotion for a purpose; bad feelings are not simply accidents of human consciousness. They are protective mechanisms that normally serve us well, but like uncontrolled pain, sustained and uncontrolled negative emotions can become pathologic states that can produce both maladaptive behavior and physiologic pathology.

By exploring the emotional dimension of pain from the sociobiologic perspective, the reader may gain some insight about how to prevent or control the negative affective aspect of pain, which fosters suffering. Unfortunately, implementing this perspective requires that we change conventional language habits that involve describing pain as a transient sensory event.

Pain is a compelling and emotionally negative state of the individual that has as its primary defining feature awareness of, and adaptive adjustment to, tissue trauma or disease.

**ADAPTIVE FUNCTIONS OF EMOTION**

Emotions, including the emotional dimension of pain, characterize mammals exclusively, and they foster mammalian adaptation by making possible complex behaviors and adaptations. Importantly, they play a strong role in consciousness, producing and summarizing information that is important for selection among alternative behaviors. According to MacLean, emotions “impart subjective information that is instrumental in guiding behavior required for self-preservation and preservation of the species. The subjective awareness that is an affect consists of a sense of bodily pervasiveness or by feelings localized to certain parts of the body [emphasis added].” Because negative emotions, such as fear, evolved to
facilitate adaptation and survival, emotion plays an important defensive role. The ability to experience threat when encountering injurious events protects against life-threatening injury.

The strength of emotional arousal associated with an injury indicates and expresses the magnitude of perceived threat to the biologic integrity of the person. Within the contents of consciousness, threat is a strong negative feeling state and not a pure informational appraisal. In humans, threatening events, such as injury that are not immediately present, can exist as emotionally colored somatosensory images.

Phenomenal awareness consists largely of the production of images. Visual images are familiar to everyone: We can readily imagine seeing things. We can also produce auditory images by imaging a familiar tune, a bird song, or the sound of a friend’s voice. Similarly, we can generate somatosensory images. We can, for example, imagine the feeling of a full bladder, the sensation of a particular shoe on a foot, or a familiar muscle tension or ache. Cognition operates largely on images and plays a strong role in the experience of symptoms.

Patients can react emotionally to the mental image of a painful event before it happens (e.g., venipuncture), or for that matter, they can respond emotionally to the sight of another person’s injury. The emotional intensity of such a feeling marks the adaptive significance of the event that produced the experience for the perceiver. In general, the threat of a minor injury normally provokes less feeling than one that incurs a risk of death. The emotional magnitude of a pain is the internal representation of the threat associated with the event that produced the pain.

EMOTIONS AND BEHAVIOR
Negative emotions compel action, such as fight or flight, along with expression through vocalization, posture, variations in facial musculature patterns, and alterations of activity. This represents communication and often elicits social support, thus contributing to survival. Darwin,\(^8\) observing animals, noted that emotions enable communication through vocalization, startle, posture, facial expression, and specific behaviors. He held that emotions must be inborn rather than learned tendencies. Darwin\(^8\) pursued this issue by comparing the facial and other emotional expressions
of children born blind with those of other children, reasoning that blind children would express emotion differently if emotion is primarily a learned behavior. As others have since confirmed,\(^9\) Darwin\(^8\) learned that the basic blueprints for human emotional expression are innate.

Contemporary investigators who study emotions and human or animal social behavior emphasize that communication is a fundamental adaptive function of emotional expression.\(^10\),\(^11\) Social mammals, including humans, depend on one another or their social group as resources for adaptation and survival. The emotional expression of pain in the presence of supportive persons is socially powerful; it draws on a fundamental sociobiologic imperative: communicating threat and summoning assistance.

**THE CENTRAL NEUROANATOMY OF EMOTION: LIMBIC STRUCTURES**

The limbic brain represents an anatomical common denominator across mammalian species,\(^7\) and emotion is a common feature of mammals. Consequently, investigators can learn much about human emotion by studying mammalian laboratory animals. Humans and animals differ in that the limbic brain is more developed in humans, the frontal lobes are unique to our species, and the interdependence of cognition and emotion is greatest in humans.

Early investigators focused on the role of olfaction in limbic function, and this led them to link the limbic brain to emotion. Emotion may have evolutionary roots in olfactory perception. MacLean\(^12\) introduced the somewhat controversial term “limbic system” and characterized its functions. He identified three main subdivisions of the limbic brain: amygdala, septum, and thalamocingulate\(^7\) that represent sources of afferents to parts of the limbic cortex. He also postulated that the limbic brain responds to two basic types of input: interoceptive and exteroceptive. These refer to sensory information from internal and external environments, respectively. Figure 29.1 summarizes and extends this concept. Noxious signaling can arise from an injurious event in the external environment or from a pathologic condition in the internal environment.
FIGURE 29.1 Three subdivisions of the limbic brain and their relationship to limbic cortices.

MacLean proposed a three-part grouping of limbic structures and functions: amygdalar, septal, and thalamocingulate subdivisions. These divisions receive information, including noxious signaling, from the external environment (exteroceptors) and the internal environment (interoceptors). Cortical areas related to limbic function include the prefrontal and frontal cortices (related to executive function and sense of self), the cingulate cortices (the anterior cingulate cortex is related to attentional states), the parahippocampal and entorhinal cortices, which are important in memory, and the insular cortex (emotional–motivational integration).

Over the last decade, numerous studies have employed functional brain imaging to investigate how the human brain responds to painful laboratory stimulation as well as how it behaves in chronic pain conditions. These studies reveal unequivocally that limbic structures involved in emotion and cognition are active during pain. In addition, related studies show that cognitive processes such as threat appraisal and perceived control are related to pain modulation. Early brain imaging studies have shown that the following brain structures are consistently active during states of pain: thalamus, primary and secondary somatosensory cortices, insular cortex, anterior cingulate, and the prefrontal cortices (PFC) as well as deactivation of the posterior cingulate cortex and medial prefrontal cortex, which compose of the default mode network involved in self-referential processing. Thalamus and the somatosensory cortices played a prominent role in early neurophysiologic models of pain and processing of ascending nociceptive information. Insular cortex may play a role in the somatosensory representation of the body, and it appears to integrate multimodal sensory information. PFC control the executive functions of the brain and the sense of self. They are involved in threat appraisal, meaning, and the integration of information from the internal and external environment.
PERIPHERAL NEUROANATOMY OF EMOTION: THE AUTONOMIC NERVOUS SYSTEM

The ANS plays a major role in regulating the constancy of the internal environment, and it does so in a feedback regulated fashion under the direction of the hypothalamus, the solitary nucleus (nucleus tractus solitarius) and ventral lateral medulla, the amygdala, and other brain structures.\textsuperscript{18,19} In general, it regulates activities that are not normally under voluntary control. The hypothalamus is the principal integrator of autonomic activity. Stimulation of the hypothalamus elicits highly integrated patterns of response that involve the limbic system and other structures.\textsuperscript{20}

Many researchers hold that the ANS has three divisions: the sympathetic, the parasympathetic, and the enteric.\textsuperscript{21,22} Others subsume the enteric under the other two divisions. Broadly, the sympathetic nervous system makes possible the arousal needed for fight and flight reactions, whereas the parasympathetic system governs basal heart rate, metabolism, and respiration. The enteric nervous system innervates the viscera via a complex network of interconnected plexuses.

The sympathetic and parasympathetic systems are largely mutual physiologic antagonists—if one system inhibits a function, the other typically augments it. There are, however, important exceptions to this rule that demonstrate complementary or integratory relationships. The mechanism most heavily involved in the affective response to tissue trauma is the sympathetic nervous system.

During emergency or injury to the body, the hypothalamus uses the sympathetic nervous system to increase cardiac output, respiration rate, and blood glucose. It also regulates body temperature, causes piloerection, alters muscle tone, provides compensatory responses to hemorrhage, and dilates pupils. These responses are part of a coordinated, well-orchestrated response pattern called the defense response.\textsuperscript{23–25} It resembles the better known orienting response in some respects, but it can only occur following a strong stimulus that is noxious or frankly painful. It sets the stage for escape or confrontation, thus serving to protect the organism from danger. In an awake cat, both electrical stimulation of the hypothalamus and infusion of norepinephrine into the hypothalamus elicit a rage reaction.
with hissing, snarling, and attack posture with claw exposure, and a pattern of sympathetic nervous system arousal accompanies this.\textsuperscript{26–28} Circulating epinephrine and norepinephrine produced by the adrenal medulla during activation of the sympathoadrenomedullary (SAM) axis accentuate the defense response, fear responses, and aversive emotional arousal in general.

**Autonomic Arousal and Subjective Experience**

Because the defense response and related changes are involuntary in nature, we generally perceive them as something that the environment does to us. We typically describe such physiologic changes not as the bodily responses that they are but rather as feelings. We might describe a threatening and physiologically arousing event by saying that “It scared me” or that “It made me really mad.”

Phenomenologically, feelings seem to happen to us; we do not “do” them in the sense that we think thoughts or choose actions. Emotions are who we are in a given circumstance rather than choices we make, and we commonly interpret events and circumstances in terms of the emotions that they elicit. ANS arousal, therefore, plays a major role in the complex psychological experience of injury and is a part of that experience.

Early views of the ANS followed the lead of Cannon\textsuperscript{23} and held that emergency responses and all forms of intense aversive arousal are undifferentiated, diffuse patterns of sympathetic activation. Although this is broadly true, research has shown that definable patterns characterize emotional arousal and that these are related to the emotion involved, the motor activity required, and perhaps the context.\textsuperscript{18,19} An investigator attempting to understand how humans experience emotions must remember that the brain not only recognizes patterns of arousal but also creates them.

**The Role of Feedback**

One of the primary mechanisms in the creation and management of emotion is feedback. Feedback means that information about the output of a system passes back to the input and thereby dynamically controls the level of the output. System self-regulation and self-organization depend on
feedback, as does self-direction. Feedback loops can be negative or positive. Negative feedback permits stability, whereas positive feedback allows the organism to mount emergency responses. The regulatory processes of homeostasis and allostasis are negative feedback dependent. Negative feedback ensures system stability and maintains homeostasis. Feedback is positive when a variable changes and the system responds by changing that variable even more in the same direction, generating escalation and rapid acceleration. This process abandons stability for instability. From an adaptation point of view, positive feedback loop capability is essential for meeting acute threat with defensive arousal. Each mode of operation has adaptive value as a short-range response in certain types of injurious events.

In general, defensive reactions involve a pattern of rapid arousal created through positive feedback that prepares the body and brain for emergency response, followed by a negative feedback-controlled transition to recovery and return to normalcy. Because smaller physiologic systems are nested within larger physiologic systems, higher order systems typically limit positive feedback processes in smaller systems. In some cases, top–down regulation of positive feedback fails, for example, in a panic attack. In other cases, the event that triggered the emotion terminates, and the positive feedback process then stops. Sustained periods of positive feedback have the potential for destructive consequences.

Feedback is the basis of neuroendocrine regulation, as we describe it in the following discussion. Neuroendocrine feedback depends on blood-borne messengers that are typically hormones or peptides. The ANS uses feedback for afferent and efferent functions. The afferent mechanisms signal changes in the viscera and other organs, whereas efferent activity conveys commands to those organs. Consequently, the ANS can maintain feedback loops related to viscera, muscle, blood flow, and other responses. The visceral feedback system exemplifies this process.

The feedback concept is central to the field of psychophysiology: Awareness of physiologic changes elicited by a stimulus is a primary mechanism of emotion. The patient presenting with panic attack, phobia, or anxiety in a mental health setting is reporting a subjective state based on patterns of physiologic signals and not an existential crisis that exists
somewhere in the domain of the mind, somehow apart from the body. Similarly, the patient in a medical context expressing emotional distress during a painful procedure, or during uncontrolled postoperative pain, is experiencing the sensory features of that pain against the background of a cacophony of sympathetic arousal and neuroendocrine stress response.

**Relationship of Central and Peripheral Mechanisms**

Figure 29.2 illustrates that noxious signaling undergoes parallel processing at the cognitive, affective, and sensory levels. An event representing a threat to biologic integrity elicits strong patterns of sympathetic and neuroendocrine response. These, in turn, contribute to the awareness of the perceiver. Sensory processing provides information about the environment, but this information exists in awareness against a background of emotional arousal, either positive or negative, and that arousal may vary from mild to extreme.

**FIGURE 29.2** Parallel sensory, affective, and cognitive processing of noxious signaling arising from nociceptive or neuropathic sources. Parallel activation of sensory transmission and noradrenergic/limbic pathways leads to processing in somatosensory, limbic, and prefrontal/frontal cortical areas. In addition, noxious signaling triggers activity in the sympathoadrenomedullary (SAM) and the hypothalamo–pituitary–adrenocortical (HPA) axes. DNB, dorsal noradrenergic bundle; LC, locus coeruleus; PAG, periaqueductal gray.
The transition from acute to chronic pain may involve complex changes in these pathways. The hypothalamo–pituitary–adrenocortical (HPA) and SAM axes are vulnerable to dysregulation with prolonged exposure to a stressor or series of stressors. This can include prolonged noxious signaling, as might occur with degenerative disease, or unrelenting noxious neuropathic signaling. Dysregulation in these systems may cause sensitization or impair normal inhibitory modulation. Moreover, neural networks associated with threat, dysphoria, or other negative emotions such as the frontal-amygdalar system may strengthen and become self-sustaining so that they can persist even in the absence of noxious signaling. Duric and McCarson\textsuperscript{30} demonstrated that prolonged noxious signaling can produce stress-like damaging effects on the hippocampus, which is involved in the pathogenesis of depressive symptoms.

**NOXIOUS SIGNALING AND CENTRAL LIMBIC PROCESSING**

Central sensory and affective pain processes share common sensory mechanisms in the periphery. As other chapters in this book describe, A\textsubscript{δ} and C fibers serve as tissue trauma transducers (nociceptors) for both, the chemical products of inflammation sensitize these nociceptors, and peripheral neuropathic mechanisms such as ectopic firing excite both processes. In some cases, neuropathic mechanisms may substitute for transduction as we classically define it, producing afferent signal volleys that appear, to the central nervous system, like signals originating in nociceptors. Differentiation of sensory and affective processing begins at the dorsal horn of the spinal cord. Sensory transmission follows spinothalamic pathways and transmission destined for affective processing takes place in spinoreticular pathways.

Noxious centripetal transmission engages multiple pathways: spinoreticular, spinomesencephalic, spinolimbic, spinocervical, and spinothalamic tracts,\textsuperscript{31,32} as Figure 29.3 indicates. The spinoreticular tract contains somatosensory and viscerosensory afferent pathways that arrive at different levels of the brain stem. Spinoreticular axons possess receptive fields that resemble those of spinothalamic tract neurons projecting to medial thalamus, and, like their spinothalamic counterparts, they transmit
tissue injury information.\textsuperscript{33,34} Most spinoreticular neurons carry noxious signals, and many of them respond preferentially to noxious activity.\textsuperscript{35,36} The spinomesencephalic tract comprises several projections that terminate in multiple midbrain nuclei, including the periaqueductal gray (PAG), the red nucleus, nucleus cuneiformis, and the Edinger-Westphal nucleus.\textsuperscript{32} Spinolimbic tracts include the spinohypothalamic tract, which reaches both lateral and medial hypothalamus\textsuperscript{37,38} and the spinoamygdalar tract that extends to the central nucleus of the amygdala.\textsuperscript{39} The spinocervical tract, like the spinothalamic tract, conveys signals to the thalamus. All of these tracts transmit tissue trauma signals rostrally.

\textbf{FIGURE 29.3} Multiple pathways of corticopetal noxious signal transmission. A, spinoreticular; B, spinohypothalamic; C, spinomesencephalic; D, spinothalamic.

\textbf{Central Neurotransmitter Systems}

Central processing of noxious signals to produce affect undoubtedly involves multiple neurotransmitter systems. Four extrathalamic afferent pathways project to neocortex: the dorsal noradrenergic bundle (DNB) originating in the locus coeruleus (LC), the serotonergic fibers that arise in the dorsal and median raphe nuclei, the dopaminergic pathways of the ventral tegmental tract that arise from substantia nigra, and the acetylcholinergic (ACh) neurons that arise principally from the nucleus basalis of the substantia innominata.\textsuperscript{40} Of these, the noradrenergic and serotonergic pathways link most closely to negative emotional states.\textsuperscript{41–43}
The set of structures receiving projections from this complex and extensive network corresponds to classic definition of the limbic brain.\textsuperscript{7,43–45}

Although other processes governed predominantly by other neurotransmitters almost certainly play important roles in the complex experience of emotion during pain, we emphasize the role of central noradrenergic processing here. This limited perspective offers the advantage of simplicity, and the literature on the role of central noradrenergic pathways in anxiety, panic, stress, and posttraumatic stress disorder provides a strong basis.\textsuperscript{41,46} This processing involves two central noradrenergic pathways: the dorsal and ventral noradrenergic bundles (VNBs) (Fig. 29.4).

\textbf{FIGURE 29.4} Central noradrenergic transmission. This parasagittal view identifies cell bodies of neurons that produce norepinephrine as black circles. The major projections of these cell bodies are the dorsal noradrenergic bundle (DNB) and the ventral noradrenergic bundle (VNB). The solid blue lines are DNB projections, whereas the broken blue lines are VNB. The projection from the locus coeruleus (LC) to the cerebellum appears as a dotted line. Hypothalamus is orange. Noxious signaling from spinoreticular pathways excites the primarily noradrenergic LC, activating the DNB, which extends throughout the limbic brain and to neocortex. CBL, cerebellum; HB, habenula; INF, infundibulum; LRN, lateral reticular nucleus; ME, median eminence; NSC, nucleus subcoeruleus; NTS, nucleus tractus solitaries; PAG, periaqueductal gray; PVN, paraventricular nucleus of the hypothalamus.

**LOCUS COERULEUS AND THE DORSAL NORADRENERGIC BUNDLE**

Substantial evidence supports the hypothesis that noradrenergic brain
pathways are major mechanisms of anxiety and stress. The majority of noradrenergic neurons originate in the LC. This pontine nucleus resides bilaterally near the wall of the fourth ventricle. The locus has three major projections: ascending, descending, and cerebellar. The ascending projection, the DNB, is the most extensive and important pathway for our purposes. Projecting from the LC throughout limbic brain and to all of neocortex, the DNB accounts for about 70% of all brain norepinephrine. The LC gives rise to most central noradrenergic fibers in spinal cord, hypothalamus, thalamus, and hippocampus, and in addition, it projects to limbic cortex and neocortex. Consequently, the LC exerts a powerful influence on higher level brain activity.

The noradrenergic stress response hypothesis holds that any stimulus that threatens the biologic, psychological, or psychosocial integrity of the individual increases the firing rate of the LC, and this in turn results in increased release and turnover of norepinephrine in the brain areas involved in noradrenergic innervation. Studies show that the LC reacts to signaling from sensory stimuli that potentially threaten the biologic integrity of the individual or signal damage to that integrity. Spinal cord lamina I cells terminate in the LC. The major sources of LC afferent input are the paragigantocellularis and prepositus hypoglossi nuclei in the medulla, but destruction of these nuclei does not block LC response to somatosensory stimuli. Other sources of afferent input to the locus include the lateral hypothalamus, the amygdala, and the solitary nucleus. Whether noxious signaling stimulates the LC directly or indirectly is still uncertain.

It is quite clear that noxious signaling inevitably and reliably increases activity in neurons of the LC, and LC excitation appears to be a consistent response to noxious signaling. Notably, this does not require cognitively mediated attentional control because it occurs in anesthetized animals. Foote et al. reported that slow, tonic spontaneous activity at the locus in rats changed under anesthesia in response to noxious stimulation. Experimentally induced phasic LC activation produces alarm and apparent fear in primates, and lesions of the LC eliminate normal heart rate increases to threatening stimuli. In a resting animal, LC neurons discharge in a slow, phasic manner.
The LC reacts consistently, but not exclusively, to noxious signaling. LC firing rates increase following nonnoxious but threatening events, such as strong cardiovascular stimulation,\textsuperscript{53,60} and certain visceral events, such as distention of the bladder, stomach, colon, or rectum.\textsuperscript{48,61} Highly novel and sudden stimuli that could represent potential threat, such as loud clicks or light flashes, can also excite the LC in experimental animals.\textsuperscript{59} Thus, the LC responds to biologically threatening or potentially threatening events, of which tissue injury is a significant subset. Amaral and Sinnamon\textsuperscript{62} described the LC as a central analog of the sympathetic ganglia. Viewed in this way, it is an extension of the autonomic protective mechanism described earlier.

Invasive studies confirm the linkage between LC activity and threat. Direct activation of the DNB and associated limbic structures in laboratory animals produces sympathetic nervous system response and elicits emotional behaviors such as defensive threat, fright, enhanced startle, freezing, and vocalization.\textsuperscript{63} This indicates that enhanced activity in these pathways corresponds to negative emotional arousal and behaviors appropriate to perceived threat. LC firing rates increase two- to threefold during the defense response elicited in a cat that has perceived a dog.\textsuperscript{26} Moreover, infusion of norepinephrine into the hypothalamus of an awake cat elicits a defensive rage reaction that includes activation of the LC noradrenergic system. In general, the mammalian defense response involves increased regional turnover and release of norepinephrine in the brain regions that the LC innervates. The LC response to threat, therefore, may be a component of the partly “prewired” patterns associated with the defense response.

Increased alertness is a key element in early stages of the defense response. Normally, activity in the LC increases alertness. Tonically enhanced LC and DNB discharge corresponds to hypervigilance and emotionality.\textsuperscript{41,55,64} The DNB is the mechanism for vigilance and defensive orientation to affectively relevant and novel stimuli. It also regulates attentional processes and facilitates motor responses.\textsuperscript{40,43,48,65} In this sense, the LC influences the stream of consciousness on an ongoing basis and readies the individual to respond quickly and effectively to threat when it occurs.
LC and DNB support biologic survival by making possible global vigilance for threatening and harmful stimuli. Siegel and Rogawski\textsuperscript{66} hypothesized a link between the LC noradrenergic system and vigilance, focusing on rapid eye movement (REM) sleep. They noted that LC noradrenergic neurons maintain continuous activity in both normal waking state and non-REM sleep, but during REM sleep, these neurons virtually cease discharge activity. Moreover, an increase in REM sleep ensues after either lesion of the DNB or following administration of clonidine, an $\alpha_2$ adrenoceptor agonist. Because LC inactivation during REM sleep permits rebuilding of noradrenergic stores, REM sleep may be necessary preparation for sustained periods of high alertness during subsequent waking. Siegel and Rogawski\textsuperscript{66} contended that “a principal function of NE in the CNS is to facilitate the excitability of target neurons to specific high priority signals.” Conversely, reduced LC activity periods (REM sleep) allow time for a suppression of sympathetic tone.

Both adaptation and sensitization can alter the LC response to threat. Abercrombie and Jacobs\textsuperscript{67,68} demonstrated a noradrenergically mediated increase in heart rate in cats exposed to white noise. Elevated heart rate decreased with repeated exposure as did LC activation and circulating levels of norepinephrine. Libet and Gleason\textsuperscript{69} found that stimulation via permanently implanted LC electrodes did not elicit indefinite anxiety. This indicates that the brain either adapts to locus excitation or engages a compensatory response to excessive LC activation under some circumstances. In addition, central noradrenergic responsiveness changes as a function of learning. In the cat, pairing a stimulus with a noxious air puff results in increased LC firing with subsequent presentations of the stimulus, but previous pairing of that stimulus with a food reward produces no alteration in LC firing rates with repeated presentation.\textsuperscript{59} These studies show that, despite its apparently “prewired” behavioral subroutines, the noradrenergic brain shows substantial neuroplasticity. The emotional response of animals and people to a painful stimulus can adapt, and it can change as a function of experience.

From a different perspective, Bremner et al.\textsuperscript{41} postulated that chronic stress can affect regional norepinephrine turnover and thus contribute to the response sensitization evident in panic disorder and posttraumatic
stress disorder. Chronic exposure to a stressor (including perseverating noxious signaling) could create a situation in which noradrenergic synthesis cannot keep up with demand, thus depleting brain norepinephrine levels. Animals exposed to inescapable shock demonstrate greater LC responsiveness to an excitatory stimulus than animals who have experienced escapable shock. In addition, such animals display “learned helplessness” behaviors—they cease trying to adapt to, or cope with, the source of shock. From an evolutionary perspective, this is a failure of the defense response as adaptation; it represents surrender to suffering. Extrapolating this and related observations to patients, Bremner and colleagues suggested that persons who have once encountered overwhelming stress and suffered exhaustion of central noradrenergic resources may respond excessively to similar stressors that they encounter at a later time.

THE VENTRAL NORADRENERGIC BUNDLE AND THE HYPOTHALAMO-PITUITARY-ADRENOCORTICAL AXIS

The VNB originates in the LC and enters the medial forebrain bundle. Neurons in the medullary reticular formation project to the hypothalamus via the VNB. Sawchenko and Swanson identified two VNB-linked noradrenergic and adrenergic pathways to paraventricular hypothalamus in the rat: the A1 region of the ventral medulla (lateral reticular nucleus [LRN]) and the A2 region of the dorsal vagal complex (the nucleus tractus solitarius, or solitary nucleus) which receives visceral afferents. These medullary neuronal complexes supply 90% of catecholaminergic innervation to the paraventricular hypothalamus via the VNB. Regions A5 and A7 contribute in a comparatively minor way to the VNB.

The noradrenergic axons in the VNB respond to noxious stimulation as does the hypothalamus itself. Moreover, noxious-signaling neurons at all segmental levels of the spinal cord project to medial and lateral hypothalamus and several telencephalic regions. These projections link tissue injury and the hypothalamic response, as do hormonal messengers in some circumstances.

The hypothalamic paraventricular nucleus (PVN) coordinates the HPA
axis. Neurons of the PVN receive afferent information from several reticular areas including ventrolateral medulla, dorsal raphe nucleus, nucleus raphe magnus, LC, dorsomedial nucleus, and the nucleus tractus solitarius. Still other afferents project to the PVN from the hippocampus, septum amygdala. Nearly all hypothalamic and preoptic nuclei send projections to the PVN. This suggests that limbic connections mediate endocrine responses during stress. Feldman et al. note that limbic stimulation always increases adrenocortical activity in rats.

In responding to potentially or frankly injurious stimuli, the PVN initiates a complex series of events regulated by negative feedback mechanisms, as Figure 29.5 indicates. These processes ready the organism for extraordinary behaviors that will maximize its chances to cope with the threat at hand, but they must limit overshooting and return to recover when the stressor has passed. Although laboratory studies often involve highly controlled and specific noxious stimulation, real-life tissue trauma usually involves a spectrum of afferent activity, and the pattern of activity may be a greater determinant of the stress response than the specific receptor system involved. Traumatic injury, for example, might involve complex signaling from the site of injury, including inflammatory mediators, baroreceptor signals from blood volume changes, and hypercapnia. Tissue trauma normally initiates much more than noxious signaling.
FIGURE 29.5 Response of the hypothalamo–pituitary–adrenocortical (HPA) axis to noxious signaling. The feedback modulated response involves six steps. In step 1, noxious signaling excites the ventral noradrenergic bundle (VNB), including several medullary and pontine nuclei (designated A1, A2, A5, and A7). When such signals reach hypothalamus, they stimulate the paraventricular nucleus (PVN); this is step 2. The PVN produces corticotropin-releasing hormone (CRH). CRH-producing neurons extend from the PVN to the median eminence (ME) where they release CRH into the portal circulation (step 3). At this point, the response becomes neurohumoral rather than neuronal. The anterior pituitary responds to CRH by releasing adrenocorticotropin (ACTH) into the systemic circulation (step 4). ACTH causes the adrenocortex to release corticosteroids into systemic circulation (step 5). In addition to their extensive metabolic effects, the corticosteroids bind to receptors at the PVN (step 6), thus closing the negative feedback loop. PAG, periaqueductal gray.

Diminished noxious signal transmission during stress or injury helps people and animals to cope with threat without the distraction of pain. The medullary mechanisms involved in this are complex and include the response of the solitary nucleus to baroreceptor stimulation. Laboratory studies with rodents indicate that animals placed in restraint or subjected to cold water develop analgesia. Lesioning the PVN attenuates such stress-induced analgesia. Some investigators emphasize that neuroendocrine arousal mechanisms are not limited to emergency situations, even though most research emphasizes that such situations elicit them. In complex social contexts, submission, dominance, and other transactions can elicit neuroendocrine and autonomic responses, modified perhaps by learning.
and memory. This suggests that neuroendocrine processes accompany all sorts of emotion-eliciting situations.

The hypothalamic PVN supports stress-related autonomic arousal through neural as well as hormonal pathways. It sends direct projections to the sympathetic intermediolateral cell column in the thoracolumbar spinal cord and the parasympathetic vagal complex, both sources of preganglionic autonomic outflow.\textsuperscript{88} In addition, it signals release of epinephrine and norepinephrine from the adrenal medulla. Adrenocorticotrophic hormone (ACTH) release, although not instantaneous, is quite rapid: It occurs within about 15 seconds.\textsuperscript{89} These considerations implicate the HPA axis in the neuroendocrinologic and autonomic manifestations of emotion associated with tissue trauma.

In addition to controlling neuroendocrine and ANS reactivity, the HPA axis coordinates emotional arousal with behavior.\textsuperscript{90} As noted earlier, stimulation of the hypothalamus in animals can elicit well-organized action patterns, including defensive threat behaviors and autonomic arousal.\textsuperscript{91} The existence of demonstrable behavioral subroutines in animals suggests that the hypothalamus plays a key role in matching behavioral reactions and bodily adjustments to challenging circumstances or biologically relevant stimuli. Moreover, stress hormones at high levels may affect central emotional arousal, lowering startle thresholds and influencing cognition.\textsuperscript{89} Saphier\textsuperscript{92} observed that cortisol altered the firing rate of neurons in limbic forebrain. Clearly, stress regulation is a complex, feedback dependent, and coordinated process. The hypothalamus appears to coordinate behavioral readiness with physiologic capability, awareness, and cognitive function.

**PRIMARY AND SECONDARY FEATURES OF THE AFFECTIVE DIMENSION OF PAIN**

The physiology of emotion suggests that the affective dimension of pain involves a two-stage mechanism. The primary mechanism generates an immediate experience akin to hypervigilance or fear. In nature, this rapid response to injury serves to disrupt ongoing attentional and behavioral patterns. At the same time, efferent messages from the hypothalamus, amygdala, and other limbic structures excite the ANS, and this in turn
alters bodily states. Cardiac function, muscle tension, altered visceral function, respiration rate, and trembling all occur, and awareness of these reactions creates a strong negative subjective experience. This body state awareness is the second mechanism of the affective dimension of pain.

Damasio contended that visceral and other event-related, autonomically mediated body state changes constitute “somatic markers.” That is, they serve as messengers, delivering affective evaluations of perceptual experiences that either confirm or deny the potential threat inherent in an event. A somatic marker is essentially a somatic image. Perceptually, the brain operates on images that are symbolic representations of external and internal objects or events. Just as it is more efficient for a listener to work with words in language as opposed to phonemes, cognition is more efficient when it uses images rather than simple sensations. The somatic marker images associated with tissue trauma are often complex patterns of physiologic arousal. They serve as symbolic representations of threat to the biologic (and sometimes the psychological or social) integrity of the person. Like other images, they can enter into complex patterns of association. Because the secondary stage of the affective response involves images and symbols, it represents cognition as well as emotion.

**SUMMARY OF THE CONSTRUCTION AND MODULATION OF PAIN**

Pain is a complex and subjective conscious experience constructed and modulated by a constellation of sensory, cognitive, and affective factors including mood, psychological disposition, meaning-related cognitions (e.g., suffering), learning, desires, and pre-pain cognitive states (e.g., expectations, anxiety) to provide a continually changing experience. Feedback connections between low-level afferent and higher order neural processes foster the cultivation of a distributed, multidimensional network associated with the subjective experience of pain. Nociceptive sensory events are first registered by peripheral primary afferents (first pain = Aδ; second pain = C fibers) at the site of injury/tissue damage that then relay said nociceptive information to the dorsal horn of the spinal cord. From the spinal cord, nociceptive information ascends contralateral to the site of
pain to the brain largely through the spinothalamic pathway. Nociceptive input is subsequently processed through feedback connections between lower level sensory regions including the parabrachial nucleus, PAG matter, thalamus, and primary and secondary somatosensory cortices. Ascending nociceptive information is then transmitted to the posterior and anterior insular cortices where it is “fine-tuned” to foster the subsequent evaluation of pain. The contextual meaning of pain is then facilitated through activation of higher order brain regions including the dorsal anterior cingulate cortex (dACC) and anterior cingulate cortex (ACC) and PFC. Yet, the subjective experience of pain is highly influenced by the context in which it occurs. That is, previous experiences, expectations, mood, conditioning, desires, sensitization/habituation, and other cognitive factors can dramatically amplify and/or attenuate pain.

Nonpharmacologic-based pain manipulations attenuate the subjective experience of pain through a common final pathway including overlapping endogenously driven and neural systems. Although the cognitive modulation of pain is mediated through a host of endogenous modulatory systems including cannabinoid, serotonergic, dopaminergic, cholecystokinin, adrenergic, and other neurochemical systems (i.e., vasopressin), the endogenous opioidergic system is the most understood (and studied) pain modulatory system. Endogenous opioidergic mechanisms have been repeatedly demonstrated to mediate analgesia produced by placebo, conditioned pain modulation, acupuncture, hypnosis, and attentional control. Pain relief produced by said cognitive techniques is associated with significant reductions in pain-related brain activation (i.e., primary and secondary somatosensory cortices, posterior insula, parietal operculum) and activation in higher order brain regions such as the ACC, PFC, and insula. Importantly, the PFC, insula, and ACC contain high concentrations of opioid receptors and are associated with producing analgesia through descending inhibitory systems. The ACC and PFC project to the PAG matter, a structure that can be directly activated by opioids. The PAG projects to the rostral ventral medulla that in turn projects to the spinal dorsal horn and can inhibit nociceptive
processing through multiple neurotransmitter systems.\textsuperscript{139}

**Emotion and Cognition**

Negative emotions and somatic markers are much more than reactions to undesirable events; in nature, they help an organism determine which things benefit and which things threaten survival, and they compel behavior consistent with such evaluations. Moreover, emotional expression communicates this judgment to others and thus sets up group approach or avoidance behaviors. MacLean\textsuperscript{7} described emotion as a process that imparts subjective information. In these respects, our feelings approximate crude intelligence. How we feel about something is often as important, or more important, than what we know about it. If emotion is a proto-intelligence, then evolutionarily newer structures, namely, the later stages of cortical development, should have demonstrable links with limbic structures and functions.

Such interconnections exist. Parts of the frontal lobe (the dorsal trend) appear to have developed from rudimentary hippocampal formation, whereas other parts (the paleocortical trend) originated in olfactory cortex. Although these two areas interconnect anatomically, the former analyzes sensory information, whereas the latter contributes emotional tone to that sensory information.\textsuperscript{68,69,140} Pribram,\textsuperscript{141} noting that limbic function involves frontal and temporal cortex, offered a bottom–up concept for how cognition relates to feelings; that is, emotion determines cognition. However, the multimodal neocortical association areas project corticofugally to limbic structures,\textsuperscript{142} which suggests that cognitions may drive emotions.

The debate on whether emotion or cognition is primary may never resolve. For immediate purposes, it seems best to conclude that knowing and feeling are closely interrelated. Still, these processes are not identical. We can know something about our feelings, and we can have emotional responses to what we know. The brain is a complex, dynamic organ, constantly constructing its internal model of reality from sensory input and memory storage. Feeling and thinking are major processes in this construction.
The Sense of Self

COGNITIVE PERSPECTIVE
Pain informs the brain of injury to bodily integrity, and its emotional aspect reflects the importance of that injury to the individual. An injury does not just cause objective harm, it harms “me.” That is, it harms what I consider myself. Similarly, a social affront harms what I consider myself, and I might metaphorically describe the incident as something that “hurt” me. What constitutes the self? What would happen if an injured person had an altered or poorly developed sense of self? Clinical observations of schizophrenic patients and other psychiatric patients indicate that they sometimes mutilate themselves horribly and apparently with little or no pain. This suggests that the sense of self may be an intrinsic part of the complex experience of pain because it is the focal point around which perceptions form and from which cognitions arise.

MULTIPLE PERSPECTIVES ON THE SELF
The self is a hierarchical construct that has different meanings at different levels of the neuraxis. Multiple levels of the self exist, and each level becomes a precondition for the existence of higher levels. At least two biologic definitions merit inclusion in the construct. At the level of the human genome, the self is the unique genetic code that makes each of us an individual. It sets the basic rules of life by defining sex, size and features, and basic abilities.

At a higher biologic level, the self is what the immune system recognizes as “me” versus “not me.” The immunologic self is an enigma because “me” and my genetic code are not identical. Our bodies host elaborate microbial ecosystems, and disturbing or damaging these systems (e.g., via antibiotic use) compromises health. Various microorganisms in our digestive tracts, oropharyngeal passages, and on our skin qualify as self to our immune systems; we live comfortably with them in a symbiotic relationship. Our microbial floras are clearly us, even though they do not carry our genetic code. For the immune system, there is neither single chemical marker that defines individuality nor is the self-limited to certain biologic structures. Thus, even at this basic level, the boundaries of the self
are fuzzy.

At a neurologic level, the self exists as a central representation of the body. Melzack termed this the body neuromatrix.\textsuperscript{144–146} The brain maintains a detailed map of the body at several levels of the neuraxis. Study of phantom limb patients and patients born without limbs reveals that the brain has an elaborate internal representation of the body. If a person loses a leg, the brain maintains its representation of the leg, and the person experiences a phantom limb. Even patients born without limbs have an internal sense or representation of the absent body parts. Thus, humans and almost certainly higher order animals carry within them a phenomenal representation of a body self.

These biologic selves exist below the level of consciousness. They are very much a part of every person, but they normally play little or no part in what we think of as “me.” Humans and animals do not differ with regard to self at this level.

Multiple psychological dimensions of the self also exist. At the most fundamental level, there is the self-as-agent, which engages in biologic adaptation and survival. From an evolutionary perspective, it is the agent that struggles to survive. The self-as-agent sets goals, chooses among alternatives, and engages in behaviors. Animals and humans share self-as-agent, and this self is, in part, social. That is, it exists not alone but in relation to others of its kind. Animals, including humans, engage in social dominance and submission. In this respect, each organism defines its relationship to others, often via struggle or conflict. The defined relationship often determines the extent of one’s opportunity to reproduce or one’s access to the resources necessary for survival. The self-as-agent is primitive and does not require cognition. It is something that the individual does, not something that the individual experiences as a phenomenal reality. In other words, this is a self of behavior. It does not entail subjective awareness.

At a higher, and perhaps uniquely human, level, the psychological self is also a point of view (self-as-perspective). It is the center of experiential gravity about which the brain organizes present circumstances, past history, future goals, and expectations. This is an inevitable outcome of the higher order self-organizing processes of the brain. This aspect of the self
stems from recognition of one’s physical being as an entity in the environment, and it becomes a frame of reference for all that happens to the person.

On still another level, the self represents the individual’s complex sense of identity, to which we have referred earlier as “me,” vide supra. This self-as-identity resembles the self-as-agent in some respects, but it is an age-dependent, autobiographically based narrative and interpretation, modified by the immediate circumstances and surroundings. Unlike the self-as-agent, the self-as-identity is the product of a developmental process, and it changes over time.

Finally, every human has a sociologic self. That is, we have an identity defined by our relationships to social groups and to society and culture as a whole. Gender roles, social class, education level, age roles, and our culture constrain who we are. To some degree, we are the roles that we play in our families, vocational settings, recreational pursuits, and elsewhere.

**Stress, Sickness, and Pain**

**BASIC DEFINITIONS: STRESS, HOMEOSTASIS, AND ALLOSTASIS**

Human life entails repeated adverse physical and psychosocial events, and these challenges require an adaptive response. The brain mounts a coordinated, adaptive reaction characterized by physiologic arousal. This response is often associated psychologically with the experience of threat or other negative affect. The term for this arousal reaction is the stress response, and any event that triggers such a response is a stressor. Some stressors are singular events, such as traffic accidents or surgery. Other stressors are constellations of vexing problems that never end. Examples include dysfunctional family relationships and vocational problems. Stress and negative emotion feed one another, and the processes involved affect pain.

We have discussed the defense response earlier. It resembles the stress response and shares common mechanisms. The defense response and stress have historically different origins in science but seem to be different
perspectives on a common adaptive mechanism. In order to integrate relevant information in these two fields, we consider the stress response to be a subset of the more general defense response. This position has the shortcoming of potentially obscuring an important distinction. Classically, the defense response pertained to threats appearing in the external environment and not the internal environment. However, the concept applies equally well to threatening internal events. The pain of a kidney stone, angina, or a migraine headache is threatening and can function as a stressor and elicit the physiologic changes common to the defense response and the stress response.

In everyday life, stress is the resource-intensive process of mounting adaptive coping responses to challenges that occur in the external or internal environment. A stressor may be a physical or social event, an invading microorganism, or, in the case of a chronic pain, patient pain itself. Selye first described this response as a syndrome produced by “diverse nocuous agents.” He eventually characterized the stress response as having three stages: alarm reaction, resistance, and, if the stressor does not relent, exhaustion. The normal stress responses of daily living consist of the alarm reaction, resistance, and recovery. Stressors have as their primary features intensity, duration, and frequency. The impact of a stressor is the magnitude of the response it elicits. This impact involves cognitive mediation (thought processes) because it is a function of both the predictability and the controllability of the stressor.

A stressor can threaten homeostasis, which strictly means a limited set of systems concerned with maintaining the essentials of the internal milieu. Homeostasis represents the control of internal processes truly necessary for life, such as thermoregulation, blood gases, acid–base balance, fluid levels, metabolite levels, and blood pressure. Generic threats to homeostasis include environmental extremes, extreme exercise, depletion of essential resources, abnormal feedback processes, aging, and disease. Of course, various defensive processes must exist to protect homeostasis.

The term for the general adaptive process that protects against threats to homeostasis is allostasis. Allostatic processes dynamically adapt multiple internal systems to changes in the environment and coordinate their
responses. Allostasis exists when changes in the external or internal environment trigger physiologic coping mechanisms such as autonomic arousal. These mechanisms ensure that the processes sustaining homeostasis stay within normal range. Allostasis is the essence of the stress response because it mobilizes internal resources to meet the challenge that a stressor represents. When a stressor, such as neuropathic signaling, persists for a long period of time, or when repeated stressors occur in rapid succession, allostasis may burn resources faster than the body can replenish them. The cost to the body of allostatic adjustment, whether in response to extreme acute challenges or to lesser challenges over an extended period of time, is called allostatic load.

**PHYSIOLOGIC MECHANISMS OF STRESS**

The major mechanisms of the stress response are the HPA axis based in the hypothalamic PVN and the SAM axis, which includes the LC noradrenergic system (see Fig. 29.1). The peripheral effectors of these mechanisms are the ANS, the SAM circulating hormones, principally the catecholamines epinephrine and norepinephrine together with the sympathetic cotransmitter neuropeptide Y (NPY), all of which originate in the chromaffin cells of the adrenal medulla. Circulating catecholamines increase blood pressure and heart rate, dilate pupils, and increase skin conductance, thereby initiating arousal for the fight or flight response. The stress response involves hypothalamically induced release of peptides derived from pro-opiomelanocortin (POMC) at the anterior pituitary. The POMC-related family of anterior pituitary hormones includes ACTH, β-lipotropin, β-melanocyte–stimulating hormone, and β-endorphin.

The hypothalamic PVN initiates the HPA stress response and controls it through negative feedback mechanisms. Corticotropin-releasing hormone (CRH) produced at the PVN initiates the stress response. CRH initializes and coordinates the stress response at many levels, including the LC. It is the key excitatory central neurotransmitter and regulator in the endocrine response to injury.

The PVN triggers another aspect of the stress response in the SAM axis by recruiting catecholaminergic cells in the rostral ventrolateral medulla. This structure is a cardiovascular regulatory area involved, along with the
solitary nucleus, in the control of blood pressure. The rostral ventrolateral medulla activates the solitary nucleus and, together with it, provides tonic excitatory drive to sympathetic vasoconstrictor nerves that maintain resting blood pressure levels. A normal stress response involves a complex pattern of autonomic arousal that includes increased blood pressure followed by a period of recovery when blood pressure and other aspects of arousal return to normal.

**Neural Substrates**

Viewing stress as a mechanism of defense brings additional neural substrates into focus. Chief among them are the medial hypothalamus, amygdala, and dorsal PAG. These structures respond reliably but not exclusively to noxious signaling; interact with one another; and actively integrate cognitive, sensory, and emotional processes. Some pain researchers have begun to address the issue of integration. Tracey et al.\textsuperscript{117} for example, employed functional brain imaging to study subjects attending to or distracting themselves from painful stimuli cued with colored lights. Distraction and pain reduction occurred in conjunction with activation of the PAG, linking cortical control and the PAG and the role of endogenous opioids to attenuate pain.

Frontal-amygdalar circuits are a well-studied aspect of the defense response.\textsuperscript{154–156} Cognitive variables such as interpretation, attention, and anticipation can influence amygdalar response through the frontal-amygdalar circuit. The amygdala, in turn, can influence the HPA axis.\textsuperscript{157–159} Frontal influences also affect patterns of activity at the LC, which is a part of the SAM axis.

An important implication of viewing stress within the defense response framework is that endogenous cognitive activity (thoughts) generated during anticipation or memory reconstruction can activate complex neural circuits that mobilize the stress response in the absence of tissue trauma. In other words, mental activity may have direct and deleterious physiologic consequences. Patients with chronic pain can stress themselves through negative thought processes, termed catastrophizing, and in so doing exacerbate and perpetuate their pain.\textsuperscript{160}

The central nucleus of the amygdala projects to the PAG, which
coordinates defensive behaviors.\textsuperscript{161} In general, the amygdala is proving to be a key mechanism of conditioned fear.\textsuperscript{162,163} It communicates with the hypothalamus via neural circuitry\textsuperscript{164,165} as well as the frontal cortices.

A second, and underestimated, aspect of the defense response depends predominantly on the immune system. The brain controls the immune system via the actions of the sympathetic nervous system and the hypothalamic secretion of releasing factors into the bloodstream. These messenger substances activate the anterior pituitary via the HPA axis.\textsuperscript{166} The pituitary body releases peptides related to POMC, such as ACTH and β-endorphin, and these in turn trigger the release of glucocorticoids. Because the cells and organs of the immune system express receptors for these hormones, they can respond to humoral messenger molecules of central origin. In this way, the brain enlists the immune system in the defense response.

**Immune Mechanisms**

Just as the nervous system is the primary agent for detecting and defending against threat arising in the external environment, the immune system is the primary agent of defense for the internal environment. Kohl\textsuperscript{167} described the immune system as “a network of complex danger sensors and transmitters.” This interactive network of lymphoid organs, cells, humoral factors, and cytokines works interdependently with the nervous and endocrine systems to protect homeostasis.

Physical trauma produces specific tissue breakdown, triggering release of nitric oxide (NO), bradykinin, histamine, and peptides, some of which are immunostimulatory. The neuropeptides substance P (SP) and neurokinin A (NKA) activate T cells and cause them to increase production of the proinflammatory cytokine interferon (IFN)-γ.\textsuperscript{168} In addition, another proinflammatory cytokine, interleukin (IL)1-β, stimulates the release of SP from primary afferent neurons.\textsuperscript{169} Thus, the neurogenic inflammatory response contributes to the immune defense response and at the same time is in part a product of that response.\textsuperscript{170}

The immune system detects an injury event in at least three ways: (1) through bloodborne immune messengers originating at the site of injury, (2) through nociceptor-induced sympathetic activation and subsequent
stimulation of immune tissues, and (3) through SAM endocrine signaling. Immune messaging begins with the acute phase reaction in the injured tissues.\(^\text{171}\) Local macrophages, neutrophils, and granulocytes produce and release into intracellular space and circulation the proinflammatory cytokines IL-1, IL-6, IL-8, and tumor necrosis factor (TNF)-α. This alerts and activates other immune tissues and cells that have a complex systemic impact.

The acute phase reaction to tissue trauma is the immune counterpart to noxious signaling in the nervous system in that it encompasses transduction, transmission, and effector responses. This is a feedback-dependent process. Sympathetic outflow following tissue injury can directly modulate many aspects of immune activity and provide feedback. This can occur because all lymphoid organs have sympathetic nervous system innervation\(^\text{172}\) and because many immune cells express adrenoceptors.\(^\text{173–175}\)

In addition to the familiar acute phase reaction, the immune system manifests several complex response patterns to tissue injury. In a primitive world, microbial invasion normally accompanies any breach of the skin, and when the microorganisms reach the bloodstream, sepsis occurs. Resultant inflammation therefore assists the immune system in defense. Redness, pain, heat, and swelling are its cardinal signs. The inflammatory process creates a barrier against the invading microorganisms and activates a variety of cells, including macrophages and lymphocytes that find and destroy invaders. It also sensitizes the injured tissue and thereby minimizes the risk of further injury. Inflammation reduces function and increases pain by sensitizing nociceptors. Tracey\(^\text{176}\) described the “inflammatory reflex” as an ACh-mediated process by which the nervous system recognizes the presence of, and exerts influence on, peripheral inflammation. Through vagal and glossopharyngeal bidirectional processes, the nervous system modulates circulating cytokine levels.\(^\text{177}\) Put another way, the nervous system can sense the activities of the immune system.

**The Sickness Response**
The immune system can mount a system-wide defense response characterized by fatigue, fever, and sickness with associated pain.\(^\text{178–183}\)
This is the “sickness response,” and although it is cytokine mediated, it depends on the central nervous system. Macrophages and other cells release proinflammatory cytokines including IL1-β, IL-6, IL-8, IL-12, IFN-γ, and TNF-α in response to tissue trauma. These substances act on the vagus nerve, the glossopharyngeal nerve, the hypothalamus, and elsewhere to trigger a cascade of unpleasant, activity-limiting symptoms.\textsuperscript{180,184}

Subjectively, the sickness response is a vivid and dysphoric experience characterized by fever, malaise, fatigue, difficulty concentrating, excessive sleep, decreased appetite and libido, stimulation of the HPA axis, and hyperalgesia. The sickness-related hyperalgesia may reflect the contributions of spinal cord microglia and astrocytes.\textsuperscript{182} Functionally, this state is adaptive; it minimizes risk by limiting normal behavior and social interactions and forces recuperation. Curiously, this response does not always resolve with physical healing.

**The Sickness Response and Depression**

Mounting evidence supports the hypothesis that the sickness response and depression are related immune response patterns. This hypothesis derives from evidence that proinflammatory cytokines are agents of depression. The specific mechanisms are still at issue,\textsuperscript{185} but proinflammatory cytokines instigate the behavioral, neuroendocrine, and neurochemical features of depressive disorders.\textsuperscript{186–189} The therapeutic use of proinflammatory cytokines INF-α and IL-2 for cancer treatment produces depression,\textsuperscript{190,191} and their administration generates hyperactivity and dysregulation in the HPA axis. These are common features of severe depression. The sickness response and depression overlap in that many of the behavioral manifestations of sickness are also manifestations of a depressive disorder. Whether sickness and depression constitute separate states of the system is still uncertain. It is becoming clear, however, that the immune defense responses associated with tissue damage contribute to bodily awareness and the complex, multidimensional experience of pain.

**SUMMARY OF THE PHYSIOLOGIC MECHANISMS OF STRESS**
This review of mechanisms reveals that the emotional aspects of pain are the product of the defensive and stress responses that tissue trauma, a related stressor, or a constellation of stressors evokes. These responses comprise two forms of allostasis. At the neuroendocrine level, the defense response is an adaptive reaction characterized by sympathetic arousal, hypervigilance, and a sense of threat. However, a coordinated immune system adaptive defense response also occurs at the immune level. Mediated by proinflammatory cytokines, it produces a sense of sickness and curtails normal activity. The sickness response produces fatigue, general malaise, fever, and hyperalgesia typically experienced as musculoskeletal pain. Depression is apparently related to the sickness response in that both are the product of proinflammatory cytokines. Thus, the defensive responses generate negative emotions in the general domains of anxiety/threat, depression, and fatigue and sickness.

**STRESS AND CHRONIC PAIN**

Stress and related defensive responses can promote chronic pain and related disability in at least three ways.

- First, noxious somatic or neuropathic signaling or a central mechanism generating the perception of pain can function as stressors, thereby triggering a defense response and stress. As the mechanism discussion indicates, this can lead to negative emotional states, depressed mood, general sickness, and fatigue. If this is prolonged, patients typically undergo physical deconditioning that makes the pain worse.
- Second, psychosocial stressors such as dysfunctional family relationships or poor vocational adjustment can trigger the stress response and lead to all of the consequences noted earlier.
- Third, comorbid disorders and associated interventions are stressors and can contribute to pain by producing negative affective states, the sickness response, and, ultimately, physical deconditioning. Immunologic diseases, cancer, diabetes, neurologic disorders, and other disease states can increase patient vulnerability to chronic pain through these mechanisms.

The three mechanisms are not mutually exclusive; they can exist in any
combination. The normal course of a stress response or defense response is immediate arousal with subsequent slow recovery to normalcy. When stressors confront a patient as a chain of events, the recovery process to the first mechanism may not finish before the second sets off another arousal pattern. A chain of stressors can dysregulate one or another feedback dependent aspect of the stress response system, such as the HPA axis. Hypercortisolemia, for example, characterizes almost half of severely depressed patients. Stress-induced chronobiologic dysregulation is perhaps more common. Patients with chronic pain often complain of disturbed sleep patterns.

**Future Directions**

Psychophysiology is a rapidly expanding domain of inquiry. We have been able to cover only a small fraction of the field in this review. Other relevant areas include sleep and sleep disorders, chronobiology, physiologic mechanisms of learning and memory, somatic representation, and psychoneuroimmunology. Painful conditions influence these various domains and in turn change in response to changes within these domains. Furthermore, functional brain imaging has opened new opportunities for pursuing the relationship of brain activity to physical and psychological manipulations and also subjective experience. Building an interdisciplinary scientific evidence base in the domain of psychophysiology should be a priority in pain research because this field bridges psychological states and physiologic health.

Multisymptom syndromes such as fibromyalgia syndrome, irritable bowel syndrome, and temporomandibular disorder pose major challenges in pain medicine and other medical areas. It is clear that these problems are related to stress, but the causal mechanisms of such disorders and their resistance to treatment remain ill defined. These disorders are mind–body problems that refuse to yield to either purely physiologic or purely psychological intervention. Psychophysiology is the only approach formally organized to pursue such mechanisms from an integrated body–mind perspective. Future research on the nature of multisymptom disorders and the development of management strategies or curative interventions
can benefit from a psychophysiologic approach.

Finally, psychophysiology as a field offers unique tools and methods for research that can address the mechanisms and benefits of interdisciplinary pain management. It is no surprise to experienced pain clinicians that psychological interventions and events have physiologic consequences, and conversely, physiologic events and interventions have psychological consequences. Psychophysiology as a field is well positioned to characterize such phenomena and also to optimize interdisciplinary intervention through the coordinated examination of subjective and objective outcomes.

One of the major contributions of the behavioral sciences to the area of medicine has been the application of learning principles to the development of effective illness management techniques. This has been especially true in the area of pain management. Before discussing these learning-based management techniques, an overview of the three major principles of learning will be provided.

Overview of the Three Major Principles of Learning

**CLASSICAL CONDITIONING**

Classical conditioning is one of the most basic forms of learning in which a learned association or connection develops between two stimuli or objects. As noted by Baum et al., the eminent Russian physiologist Ivan Pavlov (1849–1936) was the first to describe the process of classical conditioning with his work on the conditioned reflex. Reflexes are specific, automatic, unlearned reactions elicited by a specific stimulus. For example, if you have ever touched a surface that you did not know was hot (such as a hot stove), you showed a reflexive behavior—the immediate withdrawal of your hand from the stove. Similarly, if a piece of dust suddenly enters your eye, your eye will automatically blink and begin to secrete tears. These unconditioned reflexes are automatic and have a great deal of survival value for the organism. Pavlov demonstrated that such unconditioned reflexes could be conditioned, or learned. While studying dogs in order to understand more fully the digestive process, he began to notice that many of the dogs secreted saliva (an unconditioned reflex to the sight or smell of food) before food was delivered to them. He observed that this phenomenon occurred whenever the dogs either heard the...
approaching footsteps of the laboratory assistant who fed them or had a preliminary glimpse of the food. In order to investigate this phenomenon more systematically, Pavlov developed a procedure for producing a conditioned reflex. This procedure came to be called classical conditioning. It is one of the most basic forms of learning.

Pavlov conducted a series of well-known studies on the process of classical conditioning using dogs as experimental subjects (Fig. 30.1). In these studies, Pavlov studied situations in which a neutral stimulus or event (such as a bell) was presented to a dog just prior to the presentation of food (an unconditioned stimulus that normally elicits an automatic unconditioned reflex of salivation). After a number of such presentations, the bell (now a conditioned stimulus) would elicit a conditioned or learned salivation response when presented by itself in the absence of food. The conditioned reflex of salivation occurred to the bell alone. This represents the process of classical conditioning, and it is based on the learned association or connection between two stimuli, such that the bell is associated with food, that have occurred together at approximately the same point in time. An association is learned between a weak stimulus (such as the bell) and a strong stimulus (such as the sight of food) so that the weak stimulus comes to elicit the response originally controlled only by the stronger one (i.e., salivation).

FIGURE 30.1 Pavlov’s procedure of classical conditioning. CR, conditioned reflex; CS, conditioned stimulus; UCR, unconditioned reflex; UCS, unconditioned stimulus.
Pavlov also subsequently demonstrated what would happen if the neutral stimulus, such as a bell, was presented just prior to the presentation of an aversive stimulus such as an electric shock or a pinprick. Normally, such aversive stimuli presented alone will produce a variety of negative responses such as whining/whimpering and fear-type reactions such as urination. When the bell preceded such an aversive stimulus, eventually, the formerly neutral bell stimulus would automatically produce the negative emotional responses.

In another variety of this design, Pavlov then evaluated what would happen if, instead of preceding food with the sound of the bell, it was preceded by the aversive stimulus such as electric shock. What Pavlov found in this situation was that, after this conditioning, the dogs subsequently failed to demonstrate any negative emotional responses to the aversive stimulus. Instead, these dogs began perceiving these painful stimuli as signals that food was on the way. The electric shock now actually elicited salivation and approach behaviors.

**OPERANT CONDITIONING**

Operant conditioning (also referred to as instrumental conditioning) is a different form of learning that was originally formulated by Edward Thorndike (1874–1949) and then more comprehensively developed by B. F. Skinner (1904–1990). Unlike classical conditioning, operant conditioning develops new behaviors that bring about positive consequences or remove negative events. In classical conditioning, a new stimulus (such as a bell) is conditioned to elicit the same responses that had previously occurred to the unconditioned stimulus, whereas in operant conditioning, a new response is learned. For example, new behaviors that produce food, social approval, or other positive consequences, or that reduce damaging or aversive events, illustrate operant behavior. The behavior “operates” on the environment to bring about changes in it. Thus, animal training, such as that involved in the learned performance of circus animals, involves basic principles of operant conditioning. Although operant training has existed for centuries, the behaviorist revolution in psychology provided the first carefully delineated methods and procedures of operant conditioning so that such training could be accomplished most
efficiently.\textsuperscript{1} The key stimulus is reinforcement. Reinforcement refers to any consequence that increases the likelihood that a particular behavior will be repeated or that strengthens that behavior. Extinction involves the gradual decrease in the strength or tendency to perform a response due to the elimination of reinforcement. Based on these principles, what came to be known as the “Skinner box” was devised as an enclosed plexiglas box in which there was a light above a lever. The lever could be pressed down by the animal with its paws (rats were used in these early studies). Below the lever was a food tray into which food pellets could be dispensed. The task of the animal was to learn that pressing the lever (a certain number of times or at a certain rate, predetermined by the experimenter) resulted in food pellets being dispensed in the food tray. Thus, the animal learned to operate on the environment (the lever in the box) in order to receive reinforcement (food pellets).

Once the aforementioned response was learned, one could then introduce different reinforcement schedules in order to produce different patterns of responding. Reinforcement could now require variable numbers of bar presses or could be available every so often. Also, a discriminative stimulus could be introduced, so that the rat received reinforcement for pressing the bar only when the light was on in the box. The animal would soon learn not to respond when the light was off. In this manner, the rat’s bar-pressing behavior came under stimulus (e.g., light) control.

This same shaping procedure is used in training circus and other animals to perform complicated acts. Dolphins can be shaped to leap out of the water, and lions can be taught to jump through flaming hoops in order to receive some reinforcement. These techniques are used in virtually every zoo and marine animal show.

**OBSERVATIONAL LEARNING**

Finally, the third major form of learning is called observational learning. There has been a great deal of research indicating that learning can occur through simple observation without the presence of any form of tangible direct reinforcement. Such learning, besides being called observational learning, is sometimes called imitation learning, cognitive learning, vicarious learning, or modeling. Observational learning is defined simply
as that learning which occurs without any apparent direct reinforcement. Many behaviors can be acquired if an individual sees the particular behavior performed or modeled by another person. In addition, behavior is often strongly guided by social norms, resulting in a given individual being motivated to adopt a set of behaviors that are consistent with these norms. Observational learning is one such mechanism that transmits knowledge of these norms to the individual. These norms can be either explicit or implicit, and they can operate at the level of specific groups an individual may identify with, in addition to norms dictated at the larger societal level.

One of the earliest laboratory studies of observational learning involved nursery school children. One group of children observed an adult perform a series of aggressive acts, both verbal and physical, toward a large toy Bobo doll. Another group watched a nonaggressive adult, who simply sat quietly and paid no attention to the doll. A third group of children was not exposed to a model. Later, after being mildly frustrated, all children were placed in a room alone with the Bobo doll and their behavior was observed. It was found that the behavior of the two model groups tended to be similar to that of their adult model. That is, children who had viewed the aggressive adult performed more aggressive acts toward the doll in the free-play situation than the other groups and also made more responses that were exact imitations of the model’s aggressive behavior. Those children who had observed a nonaggressive adult model performed significantly fewer aggressive responses than the aggressive model group.

Operant Conditioning and Pain

THE HALLMARK WORK OF WILBERT FORDYCE

As discussed earlier, and as reviewed by Gatchel, operant conditioning refers to the strengthening of a response and behavior through reward or reinforcement. That is to say, the probability that a behavior will be performed again is increased if it is followed by some form of reinforcement. Behavior is controlled by its consequences. If a behavior is followed by a reward, it has a high probability of recurring; if it is ignored
or punished, it has a low probability of recurring. Obviously, a great deal of our everyday behavior is learned and maintained through operant conditioning. For example, most of us work because of the rewards (both tangible, such as money, and intangible, such as a pleasant work environment) that it produces.

In terms of pain, many times a person in pain will elicit a great deal of sympathy and attention (both of which are rewarding). In addition, suggestions are usually made by others to rest and stay inactive, pain-relieving medications are usually administered, and often financial compensation is provided. The longer these reinforcing consequences continue, the longer the patient is likely to display the maladaptive pain behaviors such as inactivity and avoidance of work. Thus, this type of learning or conditioning can significantly contribute to the maintenance of pain behavior.

As pointed out by Baum et al., this operant conditioning conceptualization of pain was systematically employed in the operant pain treatment program originally developed at the University of Washington’s Department of Rehabilitation Medicine by Fordyce and colleagues. This program involved a 4- to 8-week inpatient period, designed to gradually increase the general activity level of the patient and to decrease medication usage. The program was based on the assumption that, although pain may initially result from some underlying organic pathologic condition, environmental reinforcement consequences (such as attention of the patient’s family and the rehabilitation staff) can modify and further maintain various aspects of “pain behavior,” such as complaining, grimacing, slow and cautious body movements, requesting pain medication, and so on. Viewing pain as an operantly conditioned behavior, Fordyce and colleagues assumed that the potentially reinforcing consequences, such as the concern and attention from others, rest, medication, and avoiding unpleasant responsibilities and duties, as well as other events, frequently follow and reinforce the maladaptive pain behavior and, as a consequence, hinder the patient’s progress in treatment.

In their treatment program, Fordyce and colleagues systematically controlled environmental events (e.g., attention, rest, medication) and made them occur contingent on adaptive behaviors. A major goal of the
program was to increase positive behaviors, such as participation in therapy and activity level, while simultaneously decreasing or eliminating negative pain behaviors. It should also be noted that members of the patient’s family were actively involved in the treatment program and worked closely with the rehabilitation staff. They were taught how to react to the patient’s behavior in a manner that would reduce pain and to maximize the patient’s compliance with, and performance in, the rehabilitation program. Using this operant approach, the patient was basically taught to reinterpret the sensation of pain and tolerate it while performing more adaptive behaviors that would gain the attention and approval of others. Such a program was initially conducted in the hospital and would later be continued on an outpatient basis. These programs proved to be very successful at decreasing pain behaviors while increasing the levels of activities of daily living.

Of course, such examples do not imply that all pain is learned. The point being made is that our pain perceptions and responses often have a significant psychological learning component that directly and significantly contributes to these experiences of pain. Thus, psychological variables play a direct role in the pain experience. How one reacts to pain sensations is as important an issue as the specific physiologic mechanisms involved in transmitting and generating pain experiences. Pain is a complex behavior and not simply a sensory effect.

With the aforementioned view in mind, it is clear that one must conceptualize pain like any other form of complex behavior, consisting of multiple behavioral components. As Fordyce and Steger have indicated, in order to describe pain, “there must be some form of pain behavior by which diagnostic inferences and treatment judgments can be made.” A patient will signal the type of pain he or she is experiencing by describing the intensity, frequency, location, and type of pain experienced. In addition to these verbal cues available to the patient’s environment as an indication of his or her pain, there is a myriad of nonverbal signs used to communicate pain experiences. These include grimaces, sighs, moans, limps, awkward or strained body positions, the use of a cane or crutch, and many other symbols associated in our society with discomfort or physical problems.
Traditionally, in attempts to describe pain, the focus was only on the physiologic or structural mechanisms underlying the report of pain and not on other components such as behavioral indices and self-report. The reliance on strictly one component, such as structural measures, does not yield a valid or precise measure of an individual’s pain. Again, pain is a complex behavior and not purely a sensory event. One needs to consider multiple behavioral components in the assessment and treatment of this behavior.

OPERANT CONDITIONING AND CHRONIC PAIN: THE BASICS

Sanders⁹ has provided an excellent overview of the key ingredients involved in the use of operant conditioning methods when managing chronic pain. Of course, as he appropriately points out, operant conditioning methods should not be viewed as the only technique to use in managing chronic pain. Rather, it is just one of a number of behavioral science methodologies that can be used in combination/unison with other methodologies. Operant techniques can be used to help significantly decrease many common overt pain behaviors, such as the following:

- Verbal pain behaviors, such as overt expressions of hurting (e.g., moaning, sighing, complaining)
- Nonverbal pain behaviors, such as limping, grimacing, overreliance on a cane or brace, rubbing the affected area, etc.
- Overly sedentary activities, such as decreased activity level, sitting, and lying down
- Overconsumption of medications and the sole reliance on other therapeutic devices to control pain

Rather than engagement in the aforementioned maladaptive pain behaviors, the patient is encouraged and reinforced to engage in “well behaviors” that involve more positive activity and alteration away from the overfocusing on pain. Through a comprehensive approach, health care professionals, family members, and others reinforce and encourage these well behaviors, whereas other effective pain management techniques are learned by the patient, such as biofeedback, stress management, coping skills, and appropriate pharmacotherapy, which is closely maintained. The
overall goal is to increase function which will then be accompanied by a decrease in pain.6

Classical Conditioning and Pain

AVERSIVE CLASSICAL CONDITIONING AND PAIN
As discussed earlier in this chapter, Pavlov conducted studies demonstrating that when an initially neutral stimulus (such as a bell) was presented just prior to the presentation of an aversive, painful stimulus (such as electric shock) which will, in turn, produce negative emotional responses (such as whimpering, fear, avoidance, etc.), the bell itself will produce the negative emotional response when presented by itself. We then may generalize this to a patient who developed a sudden painful back problem at work, which does not go away after several days, after which just the act of going to work and anticipating lifting a heavy object may produce a negative emotional response such as fear of lifting and possible avoidance of the workplace because of pain.

CLASSICALLY CONDITIONED FEAR/AVOIDANCE AND PAIN
Figure 30.2 presents the conditioning sequence that a person may go through in the situation described earlier: (1) At first, before conditioning, there is no association between lifting an object at work and any avoidance of lifting because of fear of pain. (2) During conditioning, the individual now begins to experience some back pain while lifting objects at work. This pain becomes progressively worse over time, to the point that this person hesitates to lift anything because of fear of exacerbating the back pain he or she is already experiencing. (3) After conditioning, any prompting or requirement to lift an object automatically produces a fear response and active avoidance of any lifting to avoid pain. There is now a classically conditioned negative emotional response of lifting objects at work because of the fear of pain.
FIGURE 30.2 Classically conditioned fear and pain during a work task (lifting an object). CR, conditioned reflex; CS, conditioned stimulus; UCR, unconditioned reflex; UCS, unconditioned stimulus.

How can the aforementioned classically conditioned association between lifting and a fear of pain response be broken? As Pavlov’s experiments have shown, just as a conditioned association can be learned, it can also be subsequently extinguished or broken under the right situations. One such method would be to initially teach patients how to correctly lift while keeping their back muscles relaxed. The weight they are then asked to lift is kept relatively light and then progressively made heavier as the individual is able to lift a certain weight while relaxed and not experiencing any pain. The person is also taught appropriate pacing skills so that enough time is given between lifts for his or her back muscles to recuperate before performing the next lift. Thus, fear of lifting becomes “deconditioned” or extinguished in this work situation.

Observational Learning and Pain

Observational learning is defined simply as that learning which occurs without any apparent direct reinforcement. Many behaviors can be acquired if an individual merely sees the particular behavior displayed or modeled by another person. Examples of behaviors acquired by observational learning abound. For example, investigations of dental fears in children have revealed that the attitudes and feelings of a child’s family toward dental treatment are important in determining that child’s own
anxiety toward dental treatment. In one such study, it was found that children with anxious mothers showed significantly more emotionally negative behaviors during a tooth extraction than did children of mothers with low anxiety.\textsuperscript{10}

In our society, there is a great deal of potential observational learning that can negatively influence comprehensive pain management effects. We are constantly being bombarded by advertisements that certain medications or pills will make us feel better. This, in turn, produces an unfortunate iatrogenic effect on patients who assume that there is some magic “silver bullet” pill or procedure that will automatically make them feel better and take away their pain. Unfortunately, such expectations are often not realized. Thus, patient education is often initially needed to dissuade patients of the notion that there is an immediate magical cure for their pain, especially as it becomes more chronic in nature.

Social norms can also influence an individual’s response to pain, often through the mechanisms of observational learning. These normative influences play a role in behaviors associated with the reporting of pain, seeking treatment for pain, and level of pain tolerance. A study by Sternbach and Tursky\textsuperscript{11} was among the earliest investigations that illuminated our further understanding of how normative factors influence responses to pain. In this study, the results implied that cultural differences associated with ethnicity played a role in an individual’s tolerance of painful electrical stimulation. Parallel results in terms of ethnic differences were also demonstrated when physiologic indices (such as heart rate and palmar skin resistance levels) were measured in response to painful electrical stimulation despite relatively large intraethnic group variation.\textsuperscript{12}

Recent studies have also demonstrated the role played by ethnic differences. For example, ethnicity has been reported to account for differences in self-reported levels of pain, as well as for tolerance of induced ischemic pain, during a study on a sample of chronic pain patients.\textsuperscript{13,14} Cultural differences are also apparent in treatment preference and levels of health care utilization. A large population-based survey in the United States indicated that Caucasians had greater number of visits on average compared to African Americans and Hispanics and were more likely to have received complementary or alternative therapies for chronic
Early research on the association between gender and responses to pain also indicated that females had a lower tolerance level for experimentally induced pain and were also more likely to report pain within clinical settings. However, recent research has indicated that the extent of an individual’s identification with his or her own gender group norms moderates his or her tolerance of pain. Gender differences in the tolerance of experimentally induced pain are present only among individuals strongly identifying with social norms that dictate that men should tolerate more pain than women. Although it remains to be seen whether social norms also dictate gender differences in the probability of seeking treatment for pain, there is a demonstrable gender difference in health care utilization among chronic pain patients, with females being more likely to seek treatment for pain.

Integrating Learning Principles in the Treatment of Pain

COGNITIVE-BEHAVIORAL THERAPY AND PAIN

As Turk has highlighted in his discussion of the cognitive-behavioral therapy (CBT) approach to pain, there are important behavioral learning theory principles that are part of this overall therapeutic perspective. Certainly, classical conditioning (a focus on eliminating conditioned fear avoidance), operant conditioning (such as not reinforcing pain behavior), and observational learning (such as education about the negative iatrogenic expectation of immediate pain relief) are all important components. However, in addition, Turk appropriately points out the fact that cognitive factors, in addition to behavioral factors, need to be considered: “The critical factor for the C–B model, therefore, is not that events occur together in time or are operantly reinforced but that people learn to predict them based on experiences and information processing. They filter information through their preexisting knowledge and organized representations of knowledge (e.g., cognitive scheme) . . . and react accordingly . . . Because interaction with the environment is not a static process, attention is given to the ongoing reciprocal relationships among
physical, cognitive, affective, social, and behavioral factors” (p. 140). This perspective is in keeping with the biopsychosocial approach to pain, to be discussed later.

With this aforementioned perspective in mind, there is no doubt that CBT is an effective treatment modality for the management of pain. Morley et al., on the basis of their systematic review of the scientific literature and a meta-analysis of randomized controlled trials, found that CBT produced significantly greater changes in self-reported pain and cognitive coping, as well as reduced behavioral expressions of pain, relative to waiting list control patients and alternative treatment control conditions. In a more recent comprehensive review, Gatchel and Okifuji found comparable results. Table 30.1 provides a summary of some of the components of CBT, as delineated by Gatchel.

COGNITIVE-BEHAVIORAL THERAPY AS AN ESSENTIAL COMPONENT OF A COMPREHENSIVE INTERDISCIPLINARY APPROACH TO PAIN MANAGEMENT
The biopsychosocial perspective of pain is now accepted as the most heuristic approach to the understanding and treatment of pain disorders.\textsuperscript{6,23} It views physical disorders, such as pain, as a result of a complex and dynamic interaction among physiologic, psychological, and social factors that perpetuate and may worsen the clinical presentation. Moreover, each individual experiences pain uniquely. Therefore, the range of psychological, social, and economic factors can interact with physical pathology to modulate a patient’s report of symptoms and subsequent disability. As a consequence, a comprehensive biopsychosocial approach to assessment and treatment must be employed with each patient because of the unique interactions as well as to tailor the treatment to the specific needs of the patient. This is why comprehensive interdisciplinary pain management programs have proven to be more therapeutic and cost-effective than traditional unimodal treatment approaches.\textsuperscript{22}

Within an interdisciplinary treatment program, there is a comprehensive treatment team that consists of the following: physician–nurse team to deal with medical issues, psychologist or psychiatrist to deal with the psychosocial issues of patients, a physical therapist to address any issues related to physiologic bases of pain as well as any issues related to physical progression toward recovery, and an occupational therapist who is involved in both physical and vocational aspects of the patient’s treatment. For such a program to be effective, constant and efficient communication among all treatment personnel is imperative, during which patient progress can be discussed and evaluated. This is important so that patients hear the same treatment philosophy and message from each of the treatment team members. The overall goal is to produce an increase of functioning and the ability to manage pain and disability.

It is a major goal of the psychologist or psychiatrist to increase the patient’s understanding of pain as well as their coping skills required to manage the pain. This is where CBT plays a major role. Of course, in keeping with the biopsychosocial perspective, it is not a standalone treatment but must be integrated with the other components of therapy in order to yield the best long-term outcomes.\textsuperscript{6}

Conclusion
Pain is a complex behavior and is, therefore, subject to the general principles of learning and behavior change. The three major principles of learning include classical conditioning, operant conditioning, and observational learning. These principles play an important role in the development of pain behavior (e.g., social or environmental factors that can reinforce maladaptive pain behavior). However, these learning principles can also be effectively utilized in the treatment and management of pain. The biopsychosocial approach to the treatment and management of pain emphasizes interdisciplinary treatment modalities and eschews a “one-size-fits-all” approach in dealing with pain. Learning principles are therefore an important component in this approach due to its flexibility in addressing complex behavioral history at the individual level. CBT incorporates these learning principles and has been documented as an effective component of interdisciplinary pain management.

CHAPTER 31

Psychiatric Illness, Depression, Anxiety, and Somatic Symptom Disorder

JOSEPH GREGORY HOBELMANN, MARK D. SULLIVAN, MICHAEL R. CLARK, and AJAY D. WASAN

Chronic pain and psychiatric illness commonly occur together. Yet the high rates of psychiatric illness in patients with chronic cancer and noncancer pain are still poorly understood. Diagnostic hierarchies taught to physicians in medical school and residency, impairment rating strategies used by compensation systems, and the natural scientific method used by medicine that looks for objective causes for clinical symptoms force us into a mind–body dualism. George Engel helped develop our modern concept of “psychogenic pain.” Psychogenic pain has been defined as pain due to psychological factors in the absence of an organic basis for pain. If we cannot explain pain in terms of objective tissue pathology, Western biomedicine lures us to explain it in terms of patients’ psychopathology. This is not an evidence-based strategy but rather a reflection of what it means to explain a symptom in modern biomedicine.

The majority of patients with chronic pain and psychiatric illness have a physical basis for pain in the body, whose perception is made worse by overlying psychiatric illness. Epidemiologic evidence supports the use of inclusive rather than exclusive models of psychiatric diagnoses in medical settings that allows for the presence of both medical disease and mental disorders (i.e., a comorbidity model). Medical illness in no way excludes the possibility of a clinically important psychiatric illness. Medically ill patients are much more likely to have psychiatric illness than patients without medical illness. Psychiatric illness in no way precludes the possibility of a clinically important medical illness. Psychiatric illness is, in fact, associated with health behaviors and psychophysiologic changes
known to promote medical illness.

The structure of our clinical settings makes the integrated delivery of mental and physical health care difficult. Nowhere is this more important than in the care of the patient with chronic pain. Psychotherapeutic interventions for chronic pain are rarely effective in isolation from somatic treatments, and the success of somatic treatments is diminished by co-occurring mental illness. Distress, disuse, and disability are important facets of a chronic pain problem, and all require clinical attention by the pain practitioner. Neglect of one of these components can result in treatment failure even in the presence of excellent care for the other components. Research has indicated that psychiatric comorbidity has an adverse impact on treatments for chronic pain, such as rehabilitation, spinal cord stimulation, or opioid therapy.\(^3,7\) Although the details of these interactions are quite relevant to understand, this chapter concentrates on the recognition and diagnosis of psychiatric illness in patients with chronic pain, a sizable task in and of itself. Similarly, psychiatric comorbidity has shown to be particularly prevalent in and salient to the outcomes of a range of noncancer pain disorders (e.g., chronic low back pain,\(^8\) fibromyalgia,\(^9\) temporomandibular joint disorder,\(^10\) chronic daily headache,\(^11\) and chronic pelvic pain\(^12\)). However, the specific role that comorbid psychopathology plays in each of these disorders is beyond the scope of this chapter.

This chapter first outlines an approach to psychiatric diagnosis and to categorizing psychiatric symptoms in patients with chronic pain. Because of the breadth of psychiatric symptoms in pain patients, this section is substantial in order to provide a framework for organizing symptoms into diagnostic and treatment categories. Then, this chapter discusses the main illness categories of depression, anxiety, personality, and somatoform disorders. It is beyond this chapter to discuss to what extent a pain practitioner should evaluate and treat psychiatric problems and when to refer to a psychologist or psychiatrist.

**Psychiatric Nosology and Diagnostic and Treatment Approaches**

As noted, any discussion of psychiatric disorders in patients with chronic
pain is haunted by the concept of psychogenic pain. We are drawn to the concept of psychogenic pain because it fills the gaps left when our attempts fail to explain clinical pain exclusively in terms of tissue pathology. Psychogenic pain, however, is often merely a diagnosis of exclusion made solely on the basis of the inability to identify an objective cause for pain. Positive criteria for the identification of psychogenic pain, mechanisms for the production of psychogenic pain, and specific therapies for psychogenic pain are lacking. Furthermore, neuroimaging studies indicate that anticipated pain, imagined pain, or empathizing with the pain of another are associated with activations of the same brain areas involved in processing a painful stimulus, such as applied noxious heat (the lateral and medial pain systems).\textsuperscript{13,14} Thus, there is a dynamic interaction between our mental states (mind) and brain function. The dichotomy between mind and body (including brain) underlying the concept of psychogenic pain is hollow. As discussed later in this chapter, it may be more useful to frame the contributions of the mind to pain perception in terms of a process of central sensitization.

Psychiatric diagnosis of many disorders, such as depression, can be helpful to the clinician and patient by pointing to specific effective therapies. The Diagnostic and Statistical Manual of Mental Disorders (5th ed.; DSM-5) lists the current diagnoses treated by psychiatrists and the specific symptoms that serve as descriptive criteria for each condition.\textsuperscript{15} However, DSM offers only consistency and reliability of symptoms and does not take into consideration course of illness, which is essential in recognizing mental illness.\textsuperscript{16} This is particularly true of psychiatric disorders in those with medical illness. Most psychiatrists tend to use the DSM as a guide to the major diagnoses, not as a definitive diagnostic method. As a descriptive tool, many of the symptom lists for DSM diagnoses are quite complete and will be referred to throughout this chapter. However, when patients with chronic pain are in need of psychiatric care, they want to know the generative nature of their conditions and how to differentiate them for the sake of receiving prognoses and treatments.\textsuperscript{17} Multidisciplinary pain treatment functions with the same limitations.\textsuperscript{18,19} Without the method to determine a set of unique causes and direct specific treatments, the patient receives
symptomatic treatments with the expected “partial” response. Despite the involvement of more disciplines, the approach is clearly dualistic—cures for “organic” problems and management for “functional” problems. Cartesian dualism lives.

The DSM, although it has limitations, provides a taxonomy that serves as the basis for psychiatrists and psychologists to communicate and further study disorders. This has been historically lacking for the classification of chronic pain conditions. However, the Analgesic, Anesthetic, and Addiction Clinical Trial Translations Innovations Opportunities and Networks (ACTTION) has partnered with the U.S. Food and Drug Administration and the American Pain Society (APS) to develop an evidence-based chronic pain classification system called the ACTTION-APS Pain Taxonomy (AAPT). This classification incorporates available knowledge regarding both physiologic and biopsychosocial mechanisms contributing to pain conditions. It is important to recognize that psychological and social factors are not solely secondary consequences of chronic pain but rather play a complex role in the persistence and severity of pain conditions. These biopsychosocial factors can be risk factors, protective factors, and process variables within the dynamic system of forces that constitute a chronic pain condition. The AAPT classification system provides a framework that incorporates these complicated factors and could be very useful clinically if validated in future outcome studies.

Patients with chronic pain come to or are referred to a psychiatrist because they are ill. In some way, they are considered a diagnostic dilemma. Despite the utilization of extensive health care resources to perform an exhaustive evaluation, the patients remain ill. A temptation emerges to diagnose them with a psychogenic problem because no “good” cause can be found for their persistent pain and the accompanying disability and suffering. The cause for their illness cannot be found until the investigation expands to include the domain of personal meaning. This realm contains not only the diseases of the brain (cerebral faculties) but also the disruptions of the motivational rhythms of behavior, the psychological constitution of the individual, and the personal chronicle of desire and relationships. All mental disorders are expressions of life under altered circumstances that affect characteristic mental capacities and
generate particular expressions.\textsuperscript{26,27} These distinctions allow for independently informed perspectives about the nature of mental disorders and what may have happened to generate the disorder.

Four perspectives (diseases, behaviors, dimensions, and life stories) represent classes of disorders that each have a common essence and logical implications for causation and treatment.\textsuperscript{28,29} In this approach to patient care, diseases are what people have, behaviors are what people do, dimensions are what people are, and life stories are what people encounter. The formulation of a patient with chronic pain should address the contributions from each perspective to the overall presentation and inform the design of a treatment plan that can address each component of the patient’s illness. Although the basis for a mental illness may be dominated by one perspective (i.e., the disease perspective in schizophrenia), generally, each psychiatric diagnosis has contributions from each perspective that are responsible for the onset and maintenance of the disorder.

Diseases of the brain may manifest psychologically. The psychological faculties of the brain include, but are not limited to, consciousness, cognition, memory, language, affect, and executive functions. Abnormalities in the structures or their associated functions of these faculties are expressed in the symptoms typical of common diagnoses such as delirium, dementia, panic disorder, and major depression. However, the patient may describe deficits in these faculties with difficulty and rely on somatic symptoms (e.g., pain) as incomplete proxies for these criteria. The physical symptoms occur because the brain is malfunctioning and suggests pathology in the body. The unifying feature of diseases is a broken part within the individual that is causing the characteristic signs and symptoms typically manifested by the affliction.\textsuperscript{27} For the patient, only the symptoms and reduction of symptoms are of concern. Finding a cure may repair the broken part, prevent the initial damage from progressing, or compensate for the pathology through secondary compensatory measures.

The perspective of behavior encompasses a wide range of actions and activities. The complex behaviors of human beings are designed with purpose to achieve goals. Human consciousness is characterized by the regular, rhythmic alterations of attention and perception produced by
internal drives that increase a person’s motivation toward a particular activity.\textsuperscript{29,30} The drive pushes the individual into action. Then, after the actions, the drive is satisfied and a state of satiety emerges. Over time, drives reemerge with subsequent effects on the individual’s perceptual attitude toward his setting. In addition, personal assumptions or external opportunities increase the likelihood of certain behaviors. These present a choice to the person who must decide what action to take. After the choice is made and the behavior completed, external consequences emerge from the outcome and influence future actions. The person learns which choices are most effective. When aspects of choice and control over behavior become disrupted, physicians will be asked to address the distorted goals, excessive demands, damaging consequences, and a lack of responsiveness to negative feedback.\textsuperscript{31,32} Eating disorders and opioid use disorders are examples. Treatment of behavioral disorders begins with regaining temporary control of the situation by stopping the behavior.\textsuperscript{33} Restricting the patient’s actions and preventing these problematic behaviors eventually limits the chaos of destructive actions. This stable foundation is required for the patient to gain insight about and motivation toward appropriate choices that will result in less distress and more satisfaction.\textsuperscript{34} This is the basis for the effectiveness of behavioral approaches to chronic pain management as outlined in other chapters.

In contrast, many mental disorders emerge not from a disease of the brain or some form of abnormal illness behavior but a patient’s personal affective or cognitive constitution.\textsuperscript{29,30} Each individual possesses a set of personal dimensions such as intelligence, extraversion, and neuroticism. These traits describe who a person is, and they are carried into the world as a set of innate capabilities of their psychological makeup. Which traits are relied on and how much of them a person possesses will determine his potential to cope with different situations. Some circumstances are overwhelming and provoke a person’s vulnerability to distress. The patient cannot manage the situation and what is required because of who he is. Borderline personality disorder is an example (Table 31.1). It is probably the most severe personality disorder and generally is evident prior to the onset of pain. Assessment of personality traits is discussed at greater length in the following text. Treatment for disorders of the dimensional
type focuses on remediation of specific deficiencies and guidance about overcoming potential vulnerabilities through adaptations such as education about, assistance with, or modification of the particular stressors.\textsuperscript{19,33}

The life story perspective utilizes a narrative composed of a series of events that a person encounters and determines to be personally meaningful.\textsuperscript{29,30} These self-reflections are the means by which a person judges the value of his life as a whole. They impart a sense of self as the agent of a life plan unfolding in a social setting as well as the reflective subject experiencing and interpreting the outcome of such plans and commitments. If events are occurring as planned, then the person feels on track and successful. However, if the sequence of events results in an unexpected or disappointing outcome, the person will feel a sense of distress about this failure. Life story disorders are interpretive responses to life encounters such as grief from loss or anxiety due to expected threats.\textsuperscript{31,35,36} In patients with chronic pain, the demoralization resulting
from the inability to work or perform normal duties is a good example. Treatment begins with the expectation to forge a narrative of setting and sequence that suggests some role of the patient in his life, and that illuminates the troubled state of mind as the outcome of that role and course of events.\textsuperscript{19,33} The effective treatment of life story disorders requires reframing and reinterpretation to remoralize the patient by transforming the story into one with the potential for success and fulfillment.

The four perspectives provide a comprehensive yet flexible approach to the evaluation of a patient in distress with chronic pain and other somatic symptoms.\textsuperscript{29,37} The treatments prescribed are now designed from the individual formulation and relevant perspectives. If a patient’s symptoms and distress continue, the physician must consider other factors that may have been overlooked. Usually, these factors are within one of the perspectives initially thought to be less important. A new combination of therapies is then required to treat the patient successfully. Understanding the relevant contributions from each perspective is important to formulating treatment. In the discussion that follows, categories of psychiatric disorders as defined in the DSM-5 (2013) of the American Psychiatric Association are used as an organizing strategy. The DSM-5 is relatively new, and there are significant changes from the DSM (4th ed., DSM-IV), which was utilized for almost 20 years. As such, there is little research using the new criteria, so this chapter discusses concepts utilizing both DSM-IV and DSM-5.

Framework for Describing Psychiatric Symptoms

Figure 31.1 illustrates common psychiatric symptoms in patients with chronic pain. However, Figure 31.1 does omit substance use disorders, which are beyond the scope of this chapter. It is important to note that substance abuse or addiction in patients with chronic pain is estimated to range from 3\% to 48\% depending on the population sampled, with most estimates around 15\%.\textsuperscript{38} Psychiatry-based research and health psychology–based research have contributed important insights into characterizing the mental life of patients with chronic pain. The findings
from these epistemologies overlap significantly, and although lacking until recently, the new AAPT classification system for pain is a model for integrating these results.\textsuperscript{39} Common terms to describe the psychological condition in pain patients are heightened emotional distress, high negative affect, and elevated pain-related psychological symptoms (i.e., those that are a direct result of chronic pain, and when the pain is eliminated, the symptoms disappear). These can all be considered forms of psychopathology and psychiatric comorbidity because they represent impairments in mental health and involve maladaptive psychological responses to medical illness. This approach melds methods of classification from psychiatry and behavioral medicine to describe the scope of psychiatric disturbances in patients with chronic pain. Psychiatry is the field of medicine that is concerned with someone’s mental life, such as their emotions, experiences, thoughts, and behaviors. It is focused particularly on disruptive, disordered, or pathologic psychological states. Thus, the constructs from pain psychology are situated in Figure 31.1 as psychiatric symptoms, which in themselves can be at pathologic levels, just as depression symptoms can rise to a level considered abnormal.

**FIGURE 31.1** Common psychiatric symptoms in patients with chronic pain. DSM, Diagnostic and Statistical Manual of Mental Disorders; Gen, general; Rx, prescription; SUDs, substance use disorders. (Adapted from Wasan AD, Alpay M. Pain and the psychiatric co-morbidities of pain. In: Stern T, ed. Comprehensive Clinical Psychiatry. Philadelphia: Elsevier; 2008:1067–1080.)

In pain patients, the most common manifestations of psychiatric comorbidity involve one or more core psychopathologies in combination
with pain-related psychological symptoms. For instance, poor pain self-efficacy or high levels of pain catastrophizing are most often found in conjunction with high levels of depression or anxiety symptoms. These categories interact, and some component of each are part and parcel of other psychopathologies. In other words, “lumping” (a diagnostic approach) and “splitting” (a construct-based approach) are both valid approaches to psychiatric phenomenology. As described in the previous section, not all patients and their psychiatric symptoms fit neatly into DSM categories of illness. This is true not just of those with chronic pain, and hence, looking beyond DSM to broader and more specific methods of illness description and diagnosis is more prudent.

The pain-related psychological symptoms are described at length in other chapters, but it is important to understand how they interact with other psychiatric diagnoses. For example, pain-related anxiety (which includes state and trait anxiety-related to pain) is the form of anxiety most germane to pain. Elevated levels of pain-related anxiety (such as fear of pain) also meet DSM-5 criteria for an anxiety disorder due to a general medical condition. Because anxiety straddles both domains of core psychopathology and pain-related psychological symptoms, the assessment of anxiety in a patient with chronic pain (as detailed in the following discussion) must include a review of manifestations of generalized anxiety as well as pain-specific anxiety symptoms (e.g., physiologic changes associated with the anticipation of pain).

As indicated on Figure 31.1, elevated pain-related psychological symptoms have a clear, negative predictive relationship to many outcome areas. Poor coping skills often involve passive responses to chronic pain (e.g., remaining bed-bound and mistakenly assuming that chronic pain is indicative of ongoing tissue damage as a reason for inactivity). Poor copers employ few active self-management strategies (such as using ice, heat, or relaxation strategies for 10 to 20 minutes before resuming activities). Pain catastrophizing (cognitive distortions that are centered around pain) and low self-efficacy (a low estimate by the patient of what he/she is capable of doing) are linked with higher levels of pain and disability and worse quality of life. A tendency to catastrophize predicts poor outcome and disability, often independent of other psychopathology, such as major
depression. Duration of chronic pain and presence of psychiatric comorbidity are each independent predictors of pain intensity and disability. High levels of anger (which occur more often in men) can also explain significant variance in pain severity.42

**Depression**

One must begin by distinguishing between depressed mood and the clinical syndrome of major depression. It is important to note, especially when working with chronic pain patients, that depressed mood or dysphoria is not necessary for the diagnosis of major depression. Anhedonia, the inability to enjoy activities or experience pleasure, is an adequate substitute. It is common for patients with chronic pain to deny dysphoria but to acknowledge that enjoyment of all activities has ceased, even those without obvious relation to their pain problem (e.g., watching television for a patient with low back pain).

The DSM-5 criteria for major depressive episodes are listed in Table 31.2. These include psychological symptoms, such as worthlessness, and somatic symptoms, such as insomnia. The three core symptoms of major depression in patients with pain (which also holds true in those without pain) are low mood, impaired self-attitude, and neurovegetative signs.43 It is important to note that somatic symptoms count toward a diagnosis of major depression unless they are caused by “the direct physiologic effects of a general medical condition” or medication. The poor sleep, poor concentration, and lack of enjoyment often experienced by patients with chronic pain are frequently attributed to pain rather than depression. These should generally not be excluded as a direct physiologic effect of pain.

Given the high rates of depression in chronic pain patients, in the context of low mood complaints, it is best to attribute these symptoms toward a diagnosis of depression. Indeed, studies of depression in medically ill populations have generally found greater sensitivity and reliability with “inclusive models” of depression diagnosis than with models that try to identify the cause of each symptom.44 Similarly, just as in those without pain, those with depression and pain are very likely to also have high levels of anxiety.45,46
TABLE 31.2 Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Criteria for Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-wk period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly attributable to another medical condition.
1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). Note: In children and adolescents, can be irritable mood.
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation)
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or a decrease or increase in appetite nearly every day. Note: In children, consider failure to make expected weight gains.
4. Insomnia or hypersomnia nearly every day
5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
6. Fatigue or loss of energy nearly every day
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The symptoms are not caused by the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

D. The occurrence of the major depressive episode is not better explained by schizoaffective disorder, schizophrenia, schizoaffective disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.

E. There has never been a manic episode or hypomanic episode.

SUICIDAL IDEATION AND BEHAVIOR

Suicide accounts for 1.4% of all deaths in the world, making it the 15th leading cause of death. In the United States, 4.6% of the population surveyed had made a suicide attempt, and 13.5% reported a history of suicidal ideation. The majority of suicide attempts occur within a year of the onset of suicidal ideation. The risk of suicidality is greatest in patients
with affective disorders (e.g., depression and anxiety), personality disorders, substance use disorders, and chronic debilitating physical illnesses. Depression is the most consistent and strongest predictor of suicidal ideation. In one study of patients with major depressive disorder, 58% reported suicidal ideation during a current episode of illness. Suicide was attempted by 15% of these patients with 95% preceded by suicidal ideation. Hopelessness, low levels of function, perceptions of poor social support, and disorders of alcohol use predicted suicidal ideation.

Medical illnesses and chronic pain particularly, increase the risk of suicide. In a study of suicide in the elderly, medical conditions such as congestive heart failure, chronic obstructive lung disease, seizure disorder, and urinary incontinence were significantly associated with suicide with treatment for multiple illnesses increasing the risk. Yet, except for bipolar disorder, the highest risk of suicide was found in patients with severe pain (odds ratio [OR] = 7.52). Pain has been studied as a contributory factor in episodes of deliberate self-harm involving patients with medical problems admitted to a general hospital. Multiple studies have shown that patients with chronic pain are at greater risk for suicidal ideation, suicide attempts, and suicide completions.

Most clinical diagnoses of pain conditions have been associated with increased risk for suicide. A recent comprehensive review notes that the likelihood of death by suicide in patients with chronic pain is 2 to 3 times the rate described in the general population. The lifetime prevalence of suicide attempts in patients with chronic pain ranged from 5% to 14%, and the rate of suicide attempts is double that found in the general population. The lifetime prevalence of suicidal ideation associated with chronic pain is approximately 20%. The rate of suicidal ideation in patients with chronic pain is estimated between 5% and 24%. Although a number of methods are used to commit suicide, overdoses with medications are the most common. The relationship between chronic pain and suicidality is complex. Although the associations are consistent, the cause and effect pathways of transition from suicidal ideation to suicide attempt to suicide completion are more difficult to describe. At this time, no successful algorithm exists and only an in-depth and longitudinal evaluation of the patient with chronic pain offers the best strategy for detecting who is
considering suicide as a personal option. Although understandable, it is not the norm to be suicidal even in those with severe pain. Most commonly, suicidality in a patient with chronic pain is indicative of an underlying psychiatric disorder.\textsuperscript{57} Thinking one is better off dead (a passive death wish) is not the same as actively trying or wanting to kill oneself (suicidality). It is important to bear this distinction in mind in evaluating any patient with thoughts about death.

Part of the concern regarding the association between chronic pain and suicidality lies in whether chronic pain is an independent risk factor for suicidal behavior or the presence of depression completely explains this association. A thorough review described the evidence for eight pain-specific risk factors of suicidality, which is defined as suicidal ideation, suicide attempt, or suicide completion.\textsuperscript{50} The studies available suffer from significant limitations including inadequate assessments, retrospective designs, limited control groups, and the failure to distinguish between the potential risk factors of pain versus pain-related disability. However, the existing pain literature coupled with the general knowledge of suicide supports the following as the strongest predictors of suicidality: family history of suicide, previous suicide attempts, and presence of comorbid depression. Evidence exists for other risk factors including pain characteristics (intensity, location, type, duration), female gender, comorbid insomnia, catastrophizing and avoidance, desire for escape, helplessness and hopelessness, and problem-solving deficits.\textsuperscript{58–60} The prevention of suicide should remain a priority for the care of patients with chronic pain.

**WHICH CAME FIRST, DEPRESSION OR PAIN?**

Patients with chronic pain often dismiss a depression diagnosis, stating that their depression is a direct reaction to their pain problem. Psychiatry has long debated the value of distinguishing a reactive form of depression caused by adverse life events from an endogenous form of depression caused by biologic and genetic factors.\textsuperscript{61} Life events are important in many depressive episodes, although they play a less important role in recurrent and severe or melancholic or psychotic depressions.\textsuperscript{62} Determining whether a depression is a reasonable response to life’s stress
may be important to patients seeking to decrease the stigma of a depression diagnosis and has been of interest to pain investigators (for a review, see Fishbain and colleagues\textsuperscript{6}). It is not, however, important in deciding that treatment is necessary and appropriate. Indeed, no clinical benefit is gained from debating whether the depression caused the pain or the pain caused the depression, although such information may be useful in psychotherapy. If patients meet the diagnostic criteria outlined previously, it is likely that they can benefit from appropriate treatment. There is evidence that subsyndromal depression—depression symptoms not quite satisfying the threshold for major depression but debilitating nonetheless—also benefits from treatment and should be treated.\textsuperscript{63–65}

Prospective studies of patients with chronic musculoskeletal pain have suggested that chronic pain can cause depression,\textsuperscript{66} that depression can cause chronic pain,\textsuperscript{67} and that they exist in a mutually reinforcing relationship.\textsuperscript{68} One fact raised to support the idea that pain causes depression is that the current depressive episode often began after the onset of the pain problem. The majority of studies appears to support this contention.\textsuperscript{69} However, it has been documented that many patients with chronic pain (especially those disabled patients seen in pain clinics) have often had episodes of depression that predated their pain problem by years.\textsuperscript{70} Among patients presenting to chronic pain clinics, one-third to more than one-half meet criteria for current major depression.\textsuperscript{71} Depression in patients with chronic pain is associated with greater pain intensity, more pain persistence, application for early retirement, and greater interference from pain, including more pain behaviors observed by others.\textsuperscript{72} This has led some investigators to propose that there may exist a common trait of susceptibility to dysphoric physical symptoms (including pain) and to negative psychological symptoms (including anxiety and depression).\textsuperscript{73,74} They conclude that “pain and psychological illness should be viewed as having reciprocal psychological and behavioral effects involving both processes of illness expression and adaptation.”

It may be useful when initiating depression treatment to accept that the pain caused the depression because it builds rapport and is consistent with epidemiologic evidence about the current depressive episode. And most frequently, depression follows the onset of chronic pain and is not
DIFFERENTIAL DIAGNOSIS
When considering the diagnosis of depression in the patient with chronic pain, important alternatives include bipolar disorder, substance-induced mood disorder, and dysthymic disorder (particularly if accompanied by a severe personality disorder, such as borderline personality disorder). Patients with bipolar disorder have extended periods of abnormally elevated as well as abnormally depressed mood. These periods of elevated mood need to last more than one continuous day and include features such as inflated self-esteem, decreased need for sleep, and racing thoughts. A history of manic or hypomanic episodes predicts an atypical response to antidepressant medication and increases the risk of antidepressant-induced mania. Substance-induced mood disorders can also occur in those with pain. Patients with chronic pain may be taking medications such as opioids, corticosteroids, dopamine-blocking agents (including antiemetics), or sedatives (including muscle relaxants) that produce a depressive syndrome. Current medication lists should be scrutinized before additional medications are prescribed for any patient.

BIOLOGIC TESTS FOR DEPRESSION
A variety of biologic tests for depression have been investigated. These tests have included the dexamethasone-suppression test, thyrotropin-releasing hormone stimulation test, clonidine-induced growth hormone secretion, and rates of imipramine binding to platelet membrane serotonin transporters. Forty percent to 50% of patients with major depression do not show normal suppression of morning plasma cortisol after receiving dexamethasone the night before. However, high false-positive rates for this dexamethasone-suppression test exist in patients who are pregnant; patients with dementia, alcoholism, anorexia nervosa, and other chronic debilitating diseases; and patients who are taking medications that induce microsomal enzymes, including barbiturates and opioids. This has limited the clinical value of this test. The serotonin transport mechanism on platelet membranes is similar to that on serotonergic neurons. $^3$H-imipramine binding to this platelet receptor is reduced in patients with
major depression. It appears to be further reduced in patients who have both pain and depression. Lower level of serotonin in the cerebral spinal fluid have found in depressed patients and have been linked to suicidal ideation. Although patients show significant differences on these tests, when considered as a group, substantial variation between individual patients limits the usefulness of these tests in the clinical setting. In the future, they may be able to provide a better understanding of the biochemical links between pain and depression.

**DYSTHYMIC DISORDER**
Dysthyemic disorder is a chronic form of depression lasting 2 years or longer. The symptoms are generally less severe than those during an episode of major depression. Individuals with dysthyemia can develop major depression as well. This combined syndrome has often been called double depression. It is important to note dysthyemia because it is frequently invisible in medical settings, often being dismissed as “just the way that patient is.” Dysthyemia has been shown to respond to many antidepressants, including the selective serotonin reuptake inhibitors (SSRIs). Treatment of double depression can be particularly challenging because of treatment resistance and concurrent personality disorders. Psychiatric consultation should be considered when dysthyemia or double depression is suspected.

**EPIDEMIOLOGY OF DEPRESSION**
The prevalence of depression is much higher in medical settings and in patients with chronic illnesses than in the general population. It has been shown in studies using structured psychiatric interviews that a linear increase occurs in the prevalence of major depressive disorder when comparing community, primary care, and inpatient medical populations. Although 2% to 4% have major depression in the community, 5% to 9% of ambulatory medical patients and 15% to 20% of medical inpatients meet diagnostic criteria. Primary care patients with major depression have been found to have more severe medical illness than those who are not depressed. Even among community samples, the risk for depression appears to increase with worse perceived health status, number of chronic
medical conditions, and number of medications taken.\textsuperscript{84}

Depression is the most prevalent mood disorder associated with comorbid chronic pain.\textsuperscript{85} Prevalence rates of depression among patients in pain clinics have varied widely depending on the method of assessment and the population assessed. Rates as low as 10\% and as high as 100\% have been reported.\textsuperscript{86} The reason for the wide variability may be attributable to a number of factors, including the methods used to diagnose depression (e.g., interview, self-report instruments), the criteria used (e.g., DSM-5, cutoff scores on self-report instruments), the set of disorders included in the diagnosis of depression (e.g., presence of depressive symptoms, major depression), and referral bias (e.g., higher reported prevalence of depression in studies conducted in psychiatry clinics compared with rehabilitation clinics). The majority of studies report depression in more than 50\% of chronic pain patients sampled.\textsuperscript{87,88} There is a direct relationship between the duration of pain and the incidence of major depression. Certain chronic painful conditions are associated with higher rates of depression than others. For example, fibromyalgia, chronic daily headache, and chronic pelvic pain, each are associated with higher rates than arthritis.\textsuperscript{45,89}

Studies of primary care populations (in which generalization is less problematic) have revealed a number of other factors that appear to increase the likelihood of depression in patients with chronic pain. Dworkin and colleagues\textsuperscript{90} reported that patients with two or more pain complaints were much more likely to be depressed than those with a single pain complaint. Number of pain conditions reported was a better predictor of major depression than pain severity or pain persistence.\textsuperscript{90} Von Korff and colleagues\textsuperscript{91} developed a four-level scale for grading chronic pain severity based on pain disability and pain intensity: (1) low disability and low intensity; (2) low disability and high intensity; (3) high disability, moderately limiting; and (4) high disability, severely limiting. Depression, use of opioid analgesics, and doctor visits all increased as chronic pain grade increased. Engel and colleagues\textsuperscript{92} showed that depression was associated with high total health care costs but not high back pain costs among health maintenance organization patients with back pain. When dysfunctional primary care back pain patients are studied for a year, those
whose back pain improves also show improvement of depressive symptoms to normal levels. These epidemiologic studies provide solid evidence for a strong association between chronic pain and depression but do not address whether chronic pain causes depression or depression causes chronic pain. As indicated previously, this question has more importance in medicolegal contexts than clinical contexts. Overall, in most instances, depression follows the onset of pain.

**PAIN AND DEPRESSION: MECHANISMS OF ASSOCIATION**

Beyond documenting the association of chronic pain and depression lies the question concerning mechanisms by which they may interact. Biologic, psychological, and social mechanisms have been proposed to explain the high co-occurrence of chronic pain and depression. There is also substantial evidence (beyond the scope of this chapter to recount) that the following mechanisms underlie the other psychiatric comorbidities of pain, such as anxiety disorders.

**Biologic Theories**

**Pain Sensitivity**

It is well documented that patients with major depression, or even depressive symptoms, have more pain complaints than those without depression. Studies have shown that 30% to 60% of depressed patients complain of pain. These findings raise the possibility that depressed patients may have a greater sensitivity to noxious stimuli. In other words, depressed patients may have a reduced pain threshold. But many studies have shown that depressed patients and patients with other psychiatric disorders have an elevated, not reduced pain threshold. Depression appears to elevate pain threshold more for exteroceptive (e.g., cutaneous) stimulation than interoceptive (e.g., ischemic) stimulation, but there is significant heterogeneity in findings among different patient populations and stimulus modalities. Psychiatric patients with dissociation such as borderline personality disorder have reliably shown elevated pain thresholds to external noxious stimuli. Patients with posttraumatic
stress disorder (PTSD) show complex responses with higher pain thresholds and higher pain ratings to noxious stimuli than controls. Elevated pain thresholds were associated with dissociation levels, whereas elevated experimental and clinical pain ratings were associated with anxiety and anxiety sensitivity. Thus, there is an unexplained discrepancy between the higher experimental pain thresholds and the higher clinical pain complaints among patients with depression and other psychiatric disorders. But it is clear that the increased pain complaints of patients with psychiatric disorders cannot be explained by changes in pain thresholds.

Biogenic Amines, Cytokines, and Neural Pathways
The highly variable relationship between injury severity and pain severity has been known since Beecher’s studies of the soldiers at Anzio beach in World War II. Since the 1970s, great strides have been made in identifying the central nervous system mechanisms of endogenous pain modulation. Opioid and nonopioid branches to this system have been identified. Stimulation of the rostral ventromedial medulla or the dorsolateral pontine tegmentum produces behavioral analgesia in animals and inhibition of spinal pain transmission. The rostral ventromedial medulla is the principal source of serotonergic neurons that project to the spinal dorsal horn. The dorsolateral pontine tegmentum is the major source of noradrenergic neurons that project to the dorsal horn. Both neurotransmitters (serotonin and norepinephrine) inhibit nociceptive dorsal horn neurons when locally applied. The descending inhibitory system is modulated by serotonin and norepinephrine, which are also thought to modulate mood. This is perhaps best illustrated by the effects of selective serotonin norepinephrine reuptake inhibitors (SNRIs) on depression and pain. The two drugs approved for use in this class are duloxetine and venlafaxine. Both are FDA-approved antidepressants that have analgesic properties independent of their effects on mood. These medications enhance serotonergic and noradrenergic neurotransmission. Additional studies indicate that opioid analgesia is enhanced in the presence of antidepressant treatment and decreased after serotonin and norepinephrine depletion. Therefore, it appears that biogenic amines play a critical role in endogenous pain
modulation. To the extent that depletion or impaired function of amines such as serotonin and norepinephrine occurs in depression, this may contribute to the pain experienced and reported by those with major depression. Just as cytokine responses are important to the initiation and maintenance of chronic pain, they have also been implicated in the pathogenesis of depression. Depressed patients without pain have been found to have higher levels of proinflammatory cytokines and acute phase proteins. Administration of the cytokine interferon-α leads to depression in up to 50% of patients. Proinflammatory cytokines affect neurotransmitter metabolism, neuroendocrine function (particularly the hypothalamic-pituitary-adrenal axis), and synaptic plasticity.

Cortical Substrates for Pain and Affect
Advances in neuroimaging have linked the function of multiple areas in the brain which process pain and mood simultaneously, described at length in a previous chapter. This system is often termed the medial pain system or spinolimbic pain system. These cortical areas (e.g., the anterior cingulate cortex [ACC], the insula, amygdala, and the dorsolateral prefrontal cortex [DLPFC]) form functional units through which psychiatric comorbidity may amplify pain and disability (Fig. 31.2). They are also laden with opioid receptors. The ACC, insula, and DLPFC are less responsive to endogenous opioids in pain-free subjects with high negative affect (e.g., depression, anxiety, and anger symptoms). Thus, high negative affect may diminish the effectiveness of endogenous and exogenous opioids through direct effects on supraspinal opioid binding. The medial pain system runs parallel to the spinothalamic tract and receives direct input from the dorsal horn of the spinal cord. The interactions among the function of these areas, pain perception, and psychiatric illness are still being investigated. But the spinolimbic pathway is involved in descending pain inhibition, whose function may be negatively affected by the presence of psychopathology. This, in turn, could lead to heightened pain perception. Coghill and colleagues have shown that differences in pain sensitivity between patients can be correlated with differences in activation patterns in the ACC, the insula, and the DLPFC. The anticipation of pain—a form of anxiety for pain—is
also modulated by these areas, suggesting a mechanism by which anxiety about pain can amplify pain perception. Ploghaus and colleagues\textsuperscript{13} have demonstrated that anticipation for an acute painful stimulus in healthy volunteers is marked by brain activation patterns throughout the medial pain system.

**Sleep Disturbance**

Depression produces well-documented disturbances to sleep architecture. Polysomnographic recordings have documented reduced slow wave sleep, early onset of the first period of rapid eye movement (REM) sleep, and increased phasic REM sleep in patients with major depression.\textsuperscript{112} Sleep continuity disturbances and increased phasic REM sleep tend to normalize with depression remission, even with psychotherapeutic treatment. However, reduction of REM latency and decreased slow wave sleep tend to persist despite clinical recovery. In sum, there appear to be state and trait elements to the sleep disturbance associated with depression. Studies have also demonstrated that sleep disturbance may be a result of chronic pain, which, in turn, can make it worse.\textsuperscript{113} Fibromyalgia patients who were sleep deprived reported worsening pain and were found to be hyperalgesic (beyond their baseline pain) on pressure sensitivity testing.\textsuperscript{114} Thus, whether depression or pain precipitated or worsened a sleep disturbance,
its presence makes pain worse and is an important link between the two conditions.

**Psychological Theories**

**Psychodynamic Theory**

In classic psychoanalytic theory, depression is postulated to be derived from anger unconsciously turned inward, excessive dependence on others for self-esteem, and feelings of helplessness in achieving one’s goals. Some have suggested that the depression in some chronic pain patients is a manifestation of a personality style that draws from early developmental conflicts of guilt, anger, and masochism. From this perspective, chronic pain may be a symptom of depressive disorder.

Psychoanalytic theory stresses the fundamental parallelism between mental and physical pain and the possible displacement from the former to the latter. Intrapsychic links between pain and depression suggest that pain may function as a hysterical or conversion symptom that may prevent the breakthrough of more severe depression. These intrapsychic links largely correspond with the dynamics of pain proneness that were originally described by Engel and, in a further elaboration, connected with the concept of masked depression by Blumer and Heilbronn.

Blumer and Heilbronn proposed a new psychological disorder, the “pain-prone” disorder, building on Engel’s notion of the pain-prone patient. In this view, pain should be considered as a variant of depressive disease. The central explanation is unconscious core conflicts. Core issues include “strong needs to be accepted and to depend on others as well as marked needs to receive affection and to be cared for.”

Pain in the absence of organic pathology is considered by Blumer and Heilbronn to be a depressive spectrum disorder. According to this model, pain and depression are viewed as manifestations of a single, common disease process. Specifically, the pain-prone disorder is viewed as a masked “depressive equivalent . . . the prime expression of a muted depressive state.” No empiric research has supported the psychoanalytic formulation as presented by Blumer and Heilbronn.

A more modern variant of this theory sees chronic pain as an expression of repressed anger and rage toward others. This was initially advanced by
John Sarno, MD, a physiatrist practicing in New York City. This theory has not been thoroughly investigated empirically, but there is preliminary evidence of a significant relationship between forgiveness and pain, anger, and psychological distress in patients with low back pain.

Behavioral (Operant Conditioning) Theory

The behavioral model of depression concentrates on the most obvious symptom of depression, the motivational deficit characterized by a reduction in active behavior. A central feature of the behavioral model is response-contingent reinforcement (i.e., the responses from significant others to the individual’s behavior). From this perspective, depressive behavior and depression are associated with low rates of positive reinforcement from the environment. Lack of positive reinforcement leads to a decrease in the frequency of the individual engaging in these behaviors, and ultimately, they may be extinguished completely. These low rates of reinforcement may occur because (1) positive reinforcers in the environment may become less available, or aversive events in the environment may have become more prevalent; (2) the positive effect of previous reinforcers may have declined, or the negative impact of aversive events may have increased; or (3) the individual may lack the skills either to attain the available positive reinforcers or to cope with aversive aspects of the environment. When individuals experience low rates of positive reinforcement, they reduce the performance of those behaviors, unless they are self-reinforcing. The reduction of behavior decreases further opportunities to receive positive reinforcement.

In the case of chronic pain, the individual may reduce his or her behavior because of physical impairments or because of fear of additional pain or further injury. Thus, by the restriction in behavior and social contacts, chronic pain patients may reduce the opportunity to achieve positive reinforcement and to engage in previously rewarding activities and consequently become depressed. The family can also reinforce maladaptive behavior. Although many families of patients with chronic pain are supportive with the best of intentions, excessive catering to the patient at the expense of maintaining function can perpetuate illness behavior, leading to depression. In other words, patients can occupy the
sick role for reasons other than causal disease.

Cognitive Theory

According to Beck, people may be vulnerable to depression because, from an early age, they have possessed negatively biased conceptualizations (schemas) of themselves and their experiences. When they are challenged by stressful life events, these schemas become activated, which, in turn, elicits negative thoughts about themselves, the world, and the future (the negative cognitive triad). These patients view themselves as hopeless, hapless, and helpless (i.e., “my life is not going to get better, no one can help me, and I can’t help myself”). The latter can also be termed poor self-efficacy, or the belief that one is incapable of doing things to improve his or her life. Poor pain self-efficacy is the related belief that a patient cannot do anything to improve his or her pain or function.

In depressed patients, Beck suggests that the cognitive triad serves as a filter for incoming information. This filter creates a negative bias that serves to put a pessimistic light on information and reinforces the depressed state. It also creates low expectations about their ability and thus may lead to lack of effort. Moreover, these people tend to discount their performance, underestimating their accomplishments.

Beck’s cognitive theory of depression emphasizes the importance of peoples’ appraisal processes. In particular, it is believed that depressed persons show faulty information processing reflected by errors of logic. Through these cognitive errors (collectively referred to as cognitive distortions), depressed persons systematically misinterpret or distort the meaning of events so as to consistently construe themselves, their world, and their experiences in a negative way (the negative cognitive triad). According to this perspective, differences in cognitive errors and cognitive distortions, in general, should differentiate depressed and nondepressed patients. One of the most common cognitive distortions is catastrophizing, a tendency to view the most negative possible outcome as the only likely outcome. Pain catastrophizing (discussed at length in previous chapters) is the extension of this concept to patients viewing their pain as unbearable, uncontrollable, and leading to tissue damage. It has a significant co-
occurrence and conceptual overlap with other depression and anxiety symptoms in pain patients. In other words, when pain patients with depression or anxiety catastrophize, they most often catastrophize over their pain.

Cognitive-Behavioral Perspective
The cognitive-behavioral perspective is based on five central assumptions: (1) People are active processors of information and not passive reactors. They attempt to make sense of information and determine what constitutes positive reinforcers. (2) Thoughts (e.g., appraisals, expectancies, beliefs) can elicit and influence mood, affect physiologic processes, have social consequences, and serve as impetuses for behavior; conversely, mood, physiology, environmental factors, and behavior can influence the nature and content of thought processes. (3) Behavior is reciprocally determined by both the individual and environmental factors. (4) People can learn more adaptive ways of thinking, feeling, and behaving. (5) Individuals should be active collaborative agents in changing their maladaptive thoughts, feelings, and behaviors. From the cognitive-behavioral model, the way in which one thinks about pain and behaves in response to pain affects the extent of depression experienced. Like Beck’s cognitive theory, its essential difference from the purely behavioral model is its view of patients as active interpreters of their environment.

Depression in chronic pain patients is postulated to result from patients’ interpretations of the meaning and effect of their symptoms and their inability to exert any control over their symptoms. It is only when patients interpret their pain as interfering with important life activities and believe that they (or anyone) can do little to control the symptoms that they become depressed (i.e., they become depressed when they feel helpless and hopeless to exert any control, overwhelmed by the disruption of their lives, and unable to attain significant positive reinforcement from previous activities). Thus, the cognitive-behavioral approach integrates the principles of operant conditioning and behavioral techniques with the emphasis of cognitive theory on the patients’ appraisals, beliefs, and attributions.

Diathesis-Stress Model
This is discussed at length in other chapters but should be restated here because it is the dominant model for understanding the interactions between pain and comorbid psychopathology, including depression.\textsuperscript{3,127} This model frames the biologic and psychological mechanisms discussed earlier as diatheses or vulnerabilities. Under a condition of mental or physical stress, such as pain, the diatheses interact to produce the conditions of chronic pain and depression.\textsuperscript{128,129} One can rephrase this notion such that in any given person, genetic susceptibilities to chronic pain and/or mental illness interact with the environment (e.g., physical experience of acute pain, reinforcement from the family, inability to work) leading to changes in the functioning of mental processes (mind, such as negative cognitive schema) and brain (such as neurotransmitter systems and endogenous opioid response), resulting in chronic pain and psychiatric comorbidity.\textsuperscript{130}

**Anthropologic Theories**

Traditional and industrial societies appear to hold individuals less responsible for somatic symptoms than psychological symptoms. This difference may be especially prominent in modern Western biomedicine, in which symptom complexes are validated or invalidated through their correspondence with objective disease criteria.\textsuperscript{131} A somatic “idiom of distress” may become the favored means for communicating distress of any origin that is overwhelming or disabling.\textsuperscript{5,132} In other words, complaints about pain may be indicative of depression rather than a pain syndrome of a somatic origin. In many cultures including Western nations, pain is a more acceptable reason for disability than depression. Therefore, cultural incentives exist for translation of depression into pain. Because depressed patients have many physical symptoms, these can become the focus of clinical communication and concern. Giving patients with chronic pain permission to talk of distress in the clinical setting, using nonsomatic terms, can facilitate treatment as long as they do not feel that the somatic elements of their problem are being neglected or discounted.

This is one of the bedrock principles of narrative medicine,\textsuperscript{133,134} which through the patient’s description of their illness experience helps them to articulate the interrelationships between their physical symptoms,
psychological states, and their roles among family, coworkers, and within society. The physical symptoms of chronic pain and the pathophysiology underlying them can be thought of as the disease of chronic pain. Although the constellation of disease, a patient’s psychological state, and their experience of suffering can be termed, the illness of chronic pain. Questions from the practitioner, such as “What have you lost as a result of your pain?” “How do you manage with your pain?” and “Is it a lot of work to stay well despite having pain?” are important to evoking an illness narrative and describing these interrelationships.

**DEPRESSION TREATMENT**

Just as in the treatment of major depression in patients without chronic pain, the best quality treatment of depression in pain patients is to combine psychotherapy with medication management. One of the most effective psychotherapy modalities in chronic pain patients is cognitive-behavioral therapy (CBT), discussed in the following text and in further detail in other chapters.

**Pharmacologic Agents**

In choosing an antidepressant agent in a patient with chronic pain, an important principle is that the medication should have independent analgesic properties. This means that the medication can be helpful for pain independent of its effect on mood (i.e., it works as an analgesic in those with and without depression). The two main classes with this property are the tricyclic antidepressants (TCAs) and the selective SNRIs. In the United States, duloxetine, venlafaxine, desvenlafaxine, and milnacipran are the SNRIs currently available. The monoamine oxidase inhibitors (MAOIs) (such as selegiline or tranylcypromine) are excellent antidepressants which do also have analgesic properties. But they are rarely used anymore except by psychiatrists (due to their side effect profile and medication interactions), and their use is confined to a third- or fourth-line agent in treatment resistant depression. Antidepressant medication can effectively treat depression in the presence of chronic pain, but there is some evidence that depression with comorbid pain is more resistant to treatment. When depression accompanies chronic pain, as when it
accompanies other chronic medical disorders, there may be some extra hurdles for depression treatment to overcome. These include aversive physical symptoms, severe deactivation, vocational dysfunction, marital conflict, social isolation, and concurrent medications. Comprehensive assessment of these issues and formulation of a treatment plan that takes them into account increase the likelihood of successful depression treatment in the chronic pain patient. If depression can be relieved, many other aspects of rehabilitation, such as physical therapy, are often much more easily accomplished. Pain often subsides with improvement in depressive symptoms. Patients will typically report that they may still have pain but that “it doesn’t bother me anymore.” This statement is very telling that the affective component of pain has significantly improved.

All currently marketed antidepressants are equally effective for the initial treatment of depression. However, there is some evidence that medications with effects on dual neurotransmitter systems, such as serotonin and norepinephrine (the TCAs and SNRIs), are associated with a faster rate of improvement and lower rates of depression relapse. Overall, whatever differences may exist among antidepressants in efficacy for neuropathic pain do not appear to affect their ability to treat depression.

The clinical art of depression treatment for those with chronic pain consists of establishing a solid therapeutic alliance around the problem of depression and finding a medication regimen with independent analgesic properties and a side effect profile that the patient can tolerate. Because patients with chronic pain can be vigilant and catastrophic in thinking about somatic symptoms, care must be taken to educate them about antidepressant side effects. Sometimes, it becomes necessary to initiate an antidepressant regimen at the lower doses used for geriatric patients to ease habituation to side effects. Because of their analgesic properties, the SNRIs and TCAs are the treatments of choice for patients with chronic pain and depression.

Although the TCAs are considered first line, their side effect profiles and the slower rate of titration needed to reach a therapeutic dose limit their usefulness compared to SNRIs. The TCAs have more side effects (anticholinergic) and more therapeutic effects (sleep continuity and anxiolysis) than the SNRIs. However, because the TCAs are used
frequently in the management of neuropathic pain, it is very common to encounter a patient on lower doses of TCAs (10 to 75 mg). Typically, these patients have acclimated to many of the side effects, and gradual escalation of the dose to antidepressant ranges (approximately 100 to 300 mg, depending on the compound) can easily be performed in the pain management setting. In monitoring their use for depression, it is possible to obtain serum blood levels of TCAs to make sure that they are in the therapeutic range, but it is also appropriate to titrate to clinical effect.

Disadvantages of TCAs include a wide range of adverse effects, including anticholinergic effects, orthostatic hypotension, effects on the cardiac conduction system, weight gain, sedation, sexual dysfunction, restlessness, “jitteriness,” heightened anxiety on initial dosing, and cardiotoxicity in overdose. Before starting a TCA, in those over 45 years or in any patient with a history of cardiac disease, the QTc interval on an electrocardiogram (ECG) should be checked to see if it is <450 ms. Using TCAs in patients with QTc intervals >450 ms places them at a greater risk of developing torsades de pointes arrhythmia, even when lower doses of TCAs are used (10 to 75 mg), as is common in pain medicine. Of the TCAs, nortriptyline has the lowest incidence of side effects and thus is the preferred TCA for use in chronic pain patients, either for treatment of pain or depression. Although nortriptyline is more sedating than desipramine, it has a lower incidence of orthostatic hypotension and dizziness. Nortriptyline also has a comparable rate of analgesia to amitriptyline, despite the latter perhaps having broader effects on multiple analgesic mechanisms, such as sodium channel blockade. Nortriptyline is also twice as potent as amitriptyline, so it is much easier to get patients to therapeutic doses and to sustain use at these doses.

The SSRIs (those available in the United States include citalopram, escitalopram, fluoxetine, fluvoxamine, sertraline, and paroxetine) have become the most popular antidepressants because of their favorable side effect profiles but are more useful as second-line agents in a pain population because they do not have significant analgesic properties. Bupropion has effects on dopamine-norepinephrine reuptake inhibitors (DNRIIs). Because of its energizing effects, it is very useful in those with chronic pain because many experience fatigue and poor concentration,
either due to the pain itself or as side effects from pain medications. One study has shown that bupropion has analgesic properties in neuropathic pain. Another study showed equivocal results in back pain. More detailed information on prescribing antidepressants is available in one of the standard psychopharmacology manuals. In situations of treatment-resistant depression, studies have indicated that electroconvulsive therapy can be useful for treatment of depression and pain, across a variety of painful disorders. However, no carefully controlled studies demonstrate the effectiveness of electroconvulsive therapy for treatment of chronic pain.

Chronic pain is frequently associated with insomnia and anxiety. It is, therefore, common that patients are treated with benzodiazepines or other sedatives (e.g., the muscle relaxers). Some patients begin taking these medications during the acute phase of the pain problem and then continue to take them for many months or years. Assessing chronic pain patients who take benzodiazepines for depression is important. These medications mask some symptoms of depression (e.g., initial insomnia, agitation), but they are not adequate treatments for depression. Indeed, dangerous levels of depression can develop under the cover of benzodiazepines. It has been suggested that benzodiazepines can induce depression with chronic use, but the evidence for this is not strong. More important is the masking of depression by benzodiazepines.

Nearly, all patients with chronic pain should be tapered off benzodiazepines. Few conditions exist for which chronic benzodiazepines are the treatment of choice. Many patients with chronic pain are treated with opioids, and the combination of opioid and benzodiazepine therapy is associated with large increases in mortality risk. The Centers for Disease Control and Prevention (CDC) opioid guideline strongly recommends against simultaneous use of opioids and benzodiazepines in the treatment of patients with chronic pain. The treatment of choice for chronic anxiety disorders, which are almost always accompanied by depressive symptoms, is antidepressant medication. Buspirone (a 5-HT\textsubscript{1a} partial agonist) is marketed as an anxiolytic but is more similar to the antidepressants in its pharmacology and side effect profile. It is a reasonable alternative to the benzodiazepines for the treatment of
breakthrough anxiety, particularly for those who experience agitation on the antidepressants.

**PSYCHOTHERAPY**

**Psychodynamic Psychotherapy**

In general, psychodynamic theory emphasizes the long-term predisposition to depression rather than the losses that occur in the short term. Treatment of depression from the classical psychoanalytic perspective tries to help the patient achieve insights into the repressed conflict and often encourages outward release of hostility turned inward. In the most general terms, the goal of therapy is to uncover latent motivations for the patient’s depression. The psychodynamic approach to the depressed individual with chronic pain emphasizes the importance of individual differences in patients based on their developmental history, intrapsychic conflicts, interpersonal difficulties, and the subsequent failure to adapt to chronic illness. Patients’ premorbid characteristics are hypothesized to color their adaptation to their current situation and affect their vulnerability to depression.

Psychodynamic therapy emphasizes the need for patients to address unconscious conflicts that may contribute to and maintain the depression and makes use of the therapeutic relationship, assuming that the patient will transfer or project his or her feelings onto the therapist.\(^{154}\) This approach can be contrasted with treatment based on operant conditioning, in which it is assumed that the basic principles of learning apply to all individuals and the environmental contingencies of reinforcement can influence the reports of pain, distress, and suffering. As a treatment for depression, there is no good standardization of psychodynamic therapy, and thus, it is difficult to evaluate the studies of its effectiveness.

**Behavioral Model**

As noted, the behavioral model of depression concentrates on the reduction in active behavior that is a central feature of depression. Behavioral therapy for depression focuses on physical and social reactivation of patients.\(^{155}\) As long as avoidance behaviors are targeted, it has efficacy equal to that of CBT, without any focus on cognitions.\(^{156}\) The
focus of treatment for depression is on the shaping of behavior through the use of graded task assignments and response-contingent reinforcement. Depressed individuals are encouraged to engage in more activities and to behave in ways that are likely to be regarded more positively by others. In some instances, it is believed that depressed patients are deficient in certain skills necessary to achieve positive reinforcement. Social skills training may also be included when the therapist determines that the patient is deficient in specific skills (e.g., communication skills). Attention may also be given to assisting the patient in planning pleasant events that the patient will find reinforcing.

**Cognitive Model**

From the cognitive perspective, therapy is based on the rationale that an individual’s affect and behavior are largely determined by the ways in which he or she construes the world, and the therapeutic techniques were designed to identify, test, and correct distorted conceptualizations and the dysfunctional beliefs (schemas) underlying these cognitions. Beck’s therapy for depression is based on the assumption that the affected people engage in faulty information processing and reasoning and subscribe to schema that are self-defeating. In particular, depressed people are subject to the negative cognitive triad, in which they have feelings of pessimistic helplessness about themselves, the world, and their future. The aim of the cognitive therapist is to identify and then help patients to correct these distorted ideas and also to improve their information processing and reasoning. In contrast to psychodynamic therapy, the focus is on the here and now. Thus, attention to the origin of dysfunctional schemas in the cognitive model is limited.

The therapeutic procedures are highly structured and time limited and begin with the recognition of the connections between cognitions and affect, careful recording of these connections, collection of evidence for and against the ideas, followed by substitution of more adaptive and realistic interpretations. The cognitive approach is most frequently combined with behavioral techniques to treat patients with chronic pain, even though some debate exists about the compatibility of these approaches.124,125
Cognitive-Behavioral Model

No one cognitive-behavioral model exists but rather sets of models that share a perspective and incorporate some common features, namely (1) an interest in the nature and modification of patients’ thoughts, feelings, and beliefs, as well as behaviors, and (2) some commitment to behavior therapy procedures in promoting change (e.g., graded practice, use of homework, training in relaxation, coping skills training, problem solving, and relapse prevention).\textsuperscript{126}

Depressed people may focus attention selectively on and become preoccupied with somatic symptoms and their potentially ominous significance for their health and future. They may view themselves as helpless and their situation as hopeless and beyond their control. In depressed patients with chronic pain, the cognitive distortions often center around their pain, such as excessive fear of pain or fear of movement. To break this vicious circle, the cognitive-behavioral therapist applies a comprehensive approach to treatment that combines physical, psychological, behavioral, and social interventions. Coping skills training, problem-solving strategies, communications skills training, and directing patients to attend to their appraisals, interpretations, and beliefs surrounding pain are commonly used techniques. One of the most effective CBT methods in pain patients is to combine coping skills training focusing on fear of pain, reinjury, and movement with gradual activity and movement-based physical therapy.\textsuperscript{157}

The cognitive-behavioral therapist attempts to assist patients to try new behaviors and to adopt more adaptive modes of thinking. Alterations in behavior become information that the patients are encouraged to use as the basis for changing their views of their situation and themselves from being helpless, hopeless, and out of their control to being resourceful and capable of exerting at least some control over their plights. Changing the cognitive schema by cognitive and behavioral means is designed to result in different interpretations of information about themselves and their futures. Thus, changing behaviors and thoughts may be reciprocally related and mutually reinforcing. Neither attending exclusively to behavior, as in the behavioral model, nor only attending to patients’ thinking, as in the cognitive model, is adequate to alleviate depression.\textsuperscript{125}
The cognitive-behavioral approach has become a central component for treating depression in many multidisciplinary pain rehabilitation and functional restoration programs.

All of the psychological therapies emphasize patients’ active role in alleviating depression. In contrast to the psychodynamic model, in which the therapist plays a relatively passive role, in behavioral, cognitive, and CBTs, the therapist takes an active, directive role, attempting to guide patients into changing their behavior and reorganizing their thinking and actions. The behavioral, cognitive, and CBTs are all centered in the present, compared with psychodynamic therapy, which focuses on the past.

Anxiety Disorders

It is not unusual for patients with symptoms of pain to be anxious and worried. Up to 30% of chronic pain patients meet criteria for an anxiety disorder such as generalized anxiety disorder (GAD), panic disorder, agoraphobia, and PTSD.\(^\text{158}\) There may be stronger data for anxiety disorders preceding the onset of chronic pain than mood disorders.\(^\text{159}\) This is especially true when the symptoms are unexplained, as is often the case for chronic pain syndromes. For example, in a large-scale, multicenter study of fibromyalgia patients, between 44% and 51% of patients indicated that they were anxious.\(^\text{160}\) In other clinic samples, rates of an anxiety disorder ranged from 16% to 29% among pain patients.\(^\text{161,162}\) Most researchers agree that the prevalence of anxiety disorders in patients with chronic pain is underestimated by these data.\(^\text{1,55}\)

Anxiety and concern about symptoms are not synonymous with a psychiatric diagnosis of an anxiety disorder, necessarily. When anxiety is debilitating, it may meet criteria for an anxiety disorder. Anxiety disorders are a broad spectrum of disorders which include GAD, PTSD, obsessive-compulsive disorder, and panic disorder. As noted earlier in this chapter, pain anxiety is the most prevalent and salient form of anxiety in pain patients.\(^\text{163}\) Although distinct in some respects, there is significant overlap of pain anxiety symptoms with the constructs of fear of pain, fear of movement, and pain catastrophizing.\(^\text{164}\) High levels of pain anxiety (which
are impairing, maladaptive, and predictive of higher pain levels\textsuperscript{165} also meet DSM-5 criteria for anxiety due to a general medical condition.\textsuperscript{15} Although this diagnosis was intended originally for anxiety secondary to chronic hypoxemia or steroid use, for example, chronic pain is a medical condition primarily and falls within the scope of this diagnostic category. Fears, worries, and preoccupations about pain are all secondary to having pain, and if the pain resolves, so do these psychological symptoms.

Anxiety disorders frequently accompany other affective disorders, such as major depression, so clinicians should remain alert to the possibility of a mood disorder when patients complain of severe anxiety.\textsuperscript{1} In general, the approach is to diagnose and treat initially the most prominent mood disorder in a patient, whether it be depression or anxiety. For instance, in a patient with significant depression and anxiety symptoms, if the depression symptoms seem to be greater or more debilitating than the anxiety symptoms, the diagnosis is major depression with anxious features. In these situations, addressing the depression will also improve the anxiety symptoms. In a major depression with significant overlying anxiety, clinicians will often choose an antidepressant with significant antianxiety properties, such as the SNRIs or SSRIs.

**GENERALIZED ANXIETY DISORDER**

Table 31.3 outlines the criteria for GAD. GAD is characterized by excessive anxiety and worry (apprehensive expectation) and difficulty controlling the worry for at least 6 months, accompanied by at least three of the following symptoms: restlessness or feeling keyed up, being easily fatigued, difficulty concentrating, irritability, muscle tension, or sleep disturbance.\textsuperscript{1} There is significant debate whether a 6-month duration of symptoms is necessary to make the diagnosis, and many psychiatrists contend that this is unnecessarily lengthy.\textsuperscript{85} Often, there are significant associated depression symptoms, but they do not rise to the level of a major depressive disorder. It is very common for patients with GAD to also have panic attack symptoms or posttraumatic stress symptoms. There are trait and state (situational) components to anxiety disorder presentations in patients with pain. The trait components include excessive worry and concern, often about routine matters. The amount of worry and

1480
anxiety is out of proportion to the likelihood of the negative consequences occurring, and the patient has great difficulty controlling worry. In making a diagnosis of GAD, trait anxiety in this context does not imply that the symptoms or the tendency toward these symptoms have been present since the beginning of adulthood.

### TABLE 31.3 Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Criteria for Generalized Anxiety Disorder

| A. | Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 mo, about a number of events or activities (such as work or school performance) |
| B. | The person finds it difficult to control the worry. |
| C. | The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 mo). Note: Only one item is required in children. |
| 1. Restlessness or feeling keyed up or on edge |
| 2. Being easily fatigued |
| 3. Difficulty concentrating or mind going blank |
| 4. Irritability |
| 5. Muscle tension |
| 6. Sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep) |
| D. | The anxiety, worry, or physical symptoms cause significant distress or impairment in social, occupational, or other important areas of functioning. |
| E. | The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism). |
| F. | The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive-compulsive disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance in flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder). |

The situational (state) anxiety is often centered on the pain itself and its negative consequences (pain anxiety). Patients may have conditioned fear, believing that activities will cause uncontrollable pain, causing avoidance of those activities. Pain may also activate thoughts that a person is seriously ill.41 Questions such as the following can be helpful: “Does the
pain make you panic? If you think about your pain, do you feel your heart beating fast? Do you have an overwhelming feeling of dread or doom? Do you experience a sense of sudden anxiety that overwhelms you when you feel more pain?”

The best quality of treatment for GAD is CBT plus medications. The CBT is pain based as in major depression treatment. Psychotherapy alone is highly effective for anxiety disorders. Successful CBT in patients with obsessive-compulsive disorder has been shown on neuroimaging studies to correlate to changes in the functioning of frontal lobe limbic areas. As discussed, the most frequently chosen medication classes are the SNRIs or SSRIs. Unlike depression treatment and despite their lack of analgesic properties, in anxiety disorders, the SSRIs are considered first line because of their efficacy over most other antidepressant classes. The TCAs can be effective, but higher doses are often needed which are difficult for patients to tolerate. Benzodiazepines should almost always be avoided, especially in patients on opioid therapy. Breakthrough anxiety can be addressed with buspirone, hydroxyzine, or low-dose antipsychotics (which is beyond the scope of this discussion).

**PANIC DISORDER**

Panic disorder is a common, disabling psychiatric illness associated with high medical service use and multiple medically unexplained symptoms. The diagnosis of panic disorder requires recurrent, unexpected panic attacks (Table 31.4) followed by at least 1 month of worry about having another panic attack, the implications or consequences of the panic attacks, or behavioral changes related to the attacks. These attacks should not be the direct physiologic consequence of a substance or other medical condition. The panic attacks should not be better accounted for by another mental disorder, such as PTSD (see following discussion) or obsessive-compulsive disorder. At least two unexpected attacks are required for the diagnosis, although most patients have many more.

<table>

<tbody>
<tr>
<td>An abrupt surge of intense fear or intense discomfort that reaches a peak within minutes and during which time four (or more) of the following symptoms occur.</td>
</tr>
</tbody>
</table>
One of the most common problems with panic disorder is the fear of an undiagnosed, life-threatening illness. Patients with panic disorder can receive extensive medical testing and treatment for their somatic symptoms before the diagnosis of panic disorder is made and appropriate treatment initiated.

**EPIDEMIOLOGY**

Lifetime prevalence of panic disorder throughout the world is estimated to be 1.5% to 3.5%. One-year prevalence rates are from 1% to 2%. Panic disorder is 2 to 3 times more common in women than in men. Age of onset is variable, but most patients typically start between late adolescence and the mid-30s. Of all common mental disorders in the primary care setting, panic disorder is most likely to produce moderate to severe occupational dysfunction and physical disability. It was also associated with the greatest number of disability days in the past month. In some studies in pain patients, it has a prevalence of 5% to 8%, significantly higher than the general population.

The most common complication of panic disorder is agoraphobia, or fear of public places. Patients with panic disorder learn to fear places where escape might be difficult or help not available in case they have an attack. One-half to two-thirds of patients with panic disorder also suffer
from major depression. These patients are the most disabled panic disorder patients. The differential diagnosis of patients presenting with panic symptoms in the medical setting includes thyroid, parathyroid, adrenal, and vestibular dysfunction; seizure disorders; cardiac arrhythmias; and drug intoxication or withdrawal. Patients with panic disorder typically present in the medical setting with cardiologic, gastrointestinal, or neurologic complaints. These include chest pain, abdominal pain, and headaches.\textsuperscript{170}

Chest pain is one of the most common complaints presented to primary care physicians, but a specific medical etiology is identified in only 10\% to 20\% of cases. From 43\% to 61\% of patients who have normal coronary arteries at angiography and 16\% to 25\% of patients presenting to emergency rooms with chest pain have panic disorder. A number of these patients eventually receive the diagnoses of vasospastic angina, costochondritis, esophageal dysmotility, or mitral valve prolapse. High rates of psychiatric disorders have been found in some of these groups as well.\textsuperscript{171} Many of these patients remain symptomatic and disabled 1 year later despite reassurance concerning coronary artery disease.\textsuperscript{172}

Patients with documented coronary disease also have elevated rates of panic disorder. A number of studies have found nearly identical rates of panic disorder in chest pain patients with and without coronary disease. Increased mortality has been noted in those with anxiety and coronary disease. These data point to the importance of remaining alert to both medical and psychiatric diagnoses in those presenting with chest pain. Patients with unexplained chest pain who were given low-dose imipramine (50 mg per day) reported significant reductions in pain regardless of whether they had increased anxiety symptoms or another psychiatric disorder. This has been postulated to be caused by a visceral analgesic effect of imipramine.\textsuperscript{173} It is possible, however, that imipramine was treating subthreshold anxiety and depressive symptoms, because 63\% of the sample had a history of these disorders at some point in their lives.

Approximately 11\% of primary care patients present the problem of abdominal pain to their physician each year. Less than one-quarter of these complaints are associated with a definite physical diagnosis in the following year. Among the most common reasons for abdominal pain is
Irritable bowel syndrome. It is estimated that irritable bowel syndrome accounts for 20% to 52% of all referrals to gastroenterologists. Various studies have found that 54% to 74% of these patients with irritable bowel syndrome have associated psychiatric disorders. Walker and colleagues determined that patients with irritable bowel syndrome have much higher current (28% vs. 3%) and lifetime (41% vs. 25%) rates of panic disorder than a comparison group with inflammatory bowel disease. This suggests that the psychiatric disorder was not simply a reaction to the abdominal distress.

Among 10,000 persons assessed in a community survey who consulted their physicians for headache, 15% of female and 13% of male subjects had a history of panic disorder. Further studies have suggested that migraine headache is most strongly associated with panic attacks. Often, anxiety symptoms precede the onset of the headaches, whereas depressive symptoms often have their onset after the headaches. Some authors have suggested that a common predisposition exists with headaches (especially migraines and chronic daily headache), anxiety disorders, and major depression.

**TREATMENT**

Psychopharmacologic and psychotherapeutic treatments for panic disorder have been proven effective. The American Psychiatric Association has released a “Practice Guideline for the Treatment of Patients with Panic Disorder.” Panic-focused CBT and four classes of medications (SSRIs, TCAs, MAOIs, and benzodiazepines) have demonstrated effectiveness. These drugs may be used in combination with CBT. Panic-specific CBT includes psychoeducation, continuous panic monitoring, development of anxiety management skills, cognitive restructuring, and in vivo exposure. As discussed previously with depression, the SSRIs likely are the easiest antidepressants to use for panic disorder. However, starting doses should be halved to avoid any initial exacerbation of agitation or anxiety. TCAs and MAOIs are now reserved for those patients who do not respond to the SSRIs. Benzodiazepines should be avoided. It is possible to use them for early symptom control in conjunction with one of the other classes of effective medication, but subsequent tapering can be difficult.
Posttraumatic Stress Disorder

DIAGNOSIS

At the time of initial physical trauma, patients who develop chronic pain may also experience overwhelming psychological trauma. George Crile, a surgeon and experimental physiologist, laid the foundation for our modern concept of psychological trauma. He suggested that fear is the memory of pain. This fear holds an adaptive advantage in directing individuals to anticipate and avoid injury. Freud added anxiety to our modern conceptualization. Anxiety is the capacity to imagine pain and not merely to remember it. In other words, anxiety is memory of pain set loose.\textsuperscript{177}

After direct personal exposure to an extreme traumatic event, some individuals develop a syndrome that includes reexperiencing the event, avoidance of stimuli associated with the event, and persistent heightened arousal. PTSD was originally described after exposure to military combat but is now recognized to occur after sexual or physical assault, natural disasters, accidents, life-threatening illnesses, and other events that induce feelings of intense fear, hopelessness, or horror. Persons may develop the disorder after experiencing or just witnessing these events. DSM-5 diagnostic criteria are shown in Table 31.5.

\begin{table}[h]
\centering
\begin{tabular}{|p{\textwidth}|}
\hline
\textbf{Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Diagnostic Criteria for Posttraumatic Stress Disorder} \\
\hline
\textbf{Note:} The following criteria apply to adults, adolescents, and children older than 6 y.

\textbf{A.} Exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:
1. Daily experiencing the traumatic event(s)
2. Witnessing, in person, the event(s) as it occurred to others
3. Learning the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental.
4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remain, police officers repeatedly exposed to details of child abuse) \\
   Note: Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related.

\textbf{B.} Presence of one (or more) of the following intrusive symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:
\hline
\end{tabular}
\end{table}
1. Recurrent, involuntary, and intrusive memories of the traumatic event(s)
   Note: In children older than 6 y, repetitive play may occur in which themes or aspects of
   the traumatic event(s) are expressed.

2. Recurrent distressing dreams in which the content and/or affect of the dream are related to
   the traumatic event(s)
   Note: In children, there may be frightening dreams without recognizable content.

3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the
   traumatic event(s) were recurring (Such reactions may occur on a continuum, with the
   most extreme expression being a complete loss of awareness of present surroundings.)
   Note: In children, trauma-specific reenactment may occur in play.

4. Intense or prolonged psychological distress at exposure to internal or external cues that
   symbolize or resemble an aspect of the traumatic event(s)

5. Marked physiologic reactions to internal or external cues that symbolize or resemble an
   aspect of the traumatic event(s)

C. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the
   event(s) occurred, as evidenced by one or both of the following:
   1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or
      closely associated with the traumatic event(s)
   2. Avoidance of or efforts to avoid external reminders (people, places, conversations,
      activities, objects, situations) that arouse distressing memories, thoughts, or feelings about
      or closely associated with the traumatic event(s)

D. Negative alterations in cognitions and mood associated with the traumatic event(s), beginning
   or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the
   following:
   1. Inability to remember an important aspect of the traumatic event(s) (typically due to
      dissociative amnesia and not to other factors such as head injury, alcohol, or drugs)
   2. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the
      world (e.g., “I am bad,” “no one can be trusted,” “the world is completely dangerous,” “my
      whole nervous system is permanently ruined”)
   3. Persistent, distorted, cognitions about the cause or consequences of the traumatic event(s)
      that lead the individual to blame himself/herself or others
   4. Persistent negative emotional state (e.g., fear, horror, anger, guilt, shame)
   5. Markedly diminished interest or participation in significant activities
   6. Feelings of detachment or estrangement from others
   7. Persistent inability to experience positive emotions (e.g., inability to experience happiness,
      satisfaction, or loving feelings)

E. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning
   or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the
   following:
   1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as
      verbal or physical aggression toward people or objects
   2. Reckless or self-destructive behavior
   3. Hypervigilance
   4. Exaggerated startle response
   5. Problems with concentration
   6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep)

F. Duration of the disturbance (criteria A, B, C, D, and E) is more than 1 month.
G. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

H. The disturbance is not attributable to the physiologic effects of a substance (e.g., medication, alcohol) or another medical condition.

**EPIDEMIOLOGY OF POSTTRAUMATIC STRESS DISORDER IN CHRONIC PAIN PATIENTS**

Approximately 13% of all veterans returning from service in Iraq and Afghanistan receive diagnoses of PTSD. These constitute about half of all mental health diagnoses received.\(^{178}\) Up to 80% of Vietnam veterans with PTSD report chronic pain in limbs, back, torso, or head.\(^{179}\) Increased physical symptoms, including muscle aches and back pain, are also more common in Gulf War veterans with PTSD than in those without PTSD.\(^{180}\) The prevalence of PTSD in medical populations has been shown to be quite high. For example, a number of patients presenting at medical clinics with myocardial infarctions\(^{181}\) and cancer\(^{182,183}\) often meet the criteria for PTSD. Averaging the prevalence rates of PTSD across a number of studies reveals that after motor vehicle accidents sufficient to require medical attention, 29.5% of patients meet the criteria for PTSD.\(^{184}\) For more than one-half of these patients, the symptoms resolve within 6 months. In one study, 15% of idiopathic facial pain patients seeking treatment were found to have PTSD.\(^{185}\) In another study, 21% of fibromyalgia patients were found to have PTSD.\(^{186}\) Case reports have associated reflex sympathetic dystrophy (complex regional pain syndrome) with PTSD. Other studies suggest that 50% to 100% of patients presenting at pain treatment centers meet the diagnostic criteria for PTSD.\(^{186,187}\) Among adult urban primary care patients, 23% had PTSD, of whom 11% had it noted in the medical record. The prevalence of PTSD, adjusted for demographic factors, was higher in participants with chronic pain, major depression, and anxiety disorders.\(^{188}\)

Pain patients with PTSD have been shown to have more pain and affective distress than those without PTSD,\(^{189}\) so it is not surprising that PTSD rates among pain patients increase as treatment settings become
more specialized.

**POSTTRAUMATIC STRESS DISORDER AND ASSOCIATIONS WITH PAIN**

The relationship between pain and PTSD is multifaceted, as suggested by the early thinking by Crile and Freud discussed previously. Pain and PTSD may result from a traumatic event. Sometimes, acute pain can constitute the traumatic event, as described in a case of traumatic eye enucleation. In a nationwide survey of patients admitted after trauma, 23% of injury survivors had symptoms consistent with a diagnosis of PTSD 12 months after their hospitalization. PTSD symptoms have been significantly associated with greater levels of pain, emotional distress, interference, and disability. Greater levels of early postinjury emotional distress and physical pain were associated with an increased risk of symptoms consistent with a PTSD diagnosis. Pain may also be a consequence of PTSD or a manifestation of it. In a sample of patients admitted to an orthopedic hospital, back pain after major trauma was not associated with measures of injury severity or demographic factors but was significantly associated with the presence of PTSD, the use of a lawyer, the presence of chronic illnesses, and lower education levels. Compared with accident-related factors, PTSD symptoms and other psychological factors were the strongest predictors of the development of chronic pain in people who had severe accidents 3 years earlier. Functional brain imaging studies suggest altered processing of noxious signaling in the brain of patients with PTSD. In one study, patients with PTSD revealed increased activation in the left hippocampus and decreased activation in the bilateral ventrolateral prefrontal cortex and the right amygdala. Much research remains to be done on the relative contributions of physical trauma and psychological trauma to chronic pain problems.

**TREATMENT**

It is best to institute treatment for PTSD as close in time to the trauma as possible. Acute crisis intervention may reduce the development of chronic PTSD and other complications, including, possibly, chronic pain. This treatment should establish support, promote acceptance of what happened,
provide education and information about symptoms, and attend to general health needs. Beyond the acute phase, the CBT treatment described for panic disorder earlier has been shown to be effective with PTSD as well. The most evidence-based therapies for PTSD are prolonged exposure (PE) and cognitive processing therapy (CPT). Stress-inoculation training, implosive therapy, and systematic desensitization have also been reported to have some efficacy as have complementary and alternative techniques such as recreational therapy, yoga, acupuncture, and alternative delivery methods of psychotherapy.

Medications are rarely adequate as the sole treatment for PTSD. Controlled trials of TCAs, SSRIs, and MAOIs have demonstrated some benefit by 8 weeks at reducing core intrusive features. These benefits appear to be in addition to the antidepressant and antianxiety effects of these medications. Recent PTSD treatment trials have demonstrated effectiveness of venlafaxine ER and prazosin, but these trials have not specifically monitored the effects on pain. Propranolol has been shown to attenuate traumatic memory in primary and tertiary use.

**Personality Disorders**

**EPIDEMIOLOGY**

Several studies have reviewed the personality characteristics and disorders of patients with chronic pain. The prevalence of personality disorders among clinic populations ranges from 31% to 81% and is greater than in the general population or in populations with either medical or psychiatric illnesses. The Minnesota Multiphasic Personality Inventory (MMPI) is the most widely used personality assessment tool of patients with chronic pain but is probably not purely a personality trait measure. Previous studies have identified profiles defined by MMPI scale elevations that are proposed to be characteristic of chronic somatic symptoms such as pain. The hypochondriacal reaction, conversion “V,” and neurotic triad profiles exhibit different multivariate relationships between other constructs such as somatization, coping strategies, depression, pain severity, and activity level. However, although patients with chronic pain differ from nonchronic pain controls in their scale.
profiles on the MMPI, there is no single personality trait or disorder associated with medically unexplained chronic pain or chronic pain from “organic” diseases.

OVERVIEW OF PERSONALITY DISORDERS

Personality pathology is best thought of along a continuum of traits present to greater or lesser degrees. Personality disorders described in the DSM represent the pathologic extreme of personality traits. Patients with personality disorders are one type of “difficult patient” characterized by an inflexible, pervasive, and maladaptive inner experience and set of behaviors.\[^{15,135}\] Traits have been conceptualized as dimensional aspects of individual variation, whereas personality disorders are represented as categorical aberrations within the realm of psychopathology. This section presents an overview of personality pathology and not a discussion of the criteria for each specific personality disorder.

Analytic approaches undertaken to understand the features of temperament have described several core factors. The five-factor model is one of the most popular and characterized by the trait dimensions of neuroticism, extraversion, openness, agreeableness, and conscientiousness as described by the revised NEO Personality Inventory.\[^{211–213}\] In contrast, the Temperament and Character Inventory (TCI) is composed of four heritable and stable dimensions of temperament (harm avoidance [HA], novelty seeking, reward dependence, persistence) that represent individual differences in associative learning and three dimensions of character (self-directedness [SD], cooperativeness [C], self-transcendence) that develop over time as a function of social learning and maturation of interpersonal behavior.\[^{214}\] This psychobiologic model defines personality as the interaction of temperament and character. Studies have described three dimensions (HA, SD, C) as a core feature of all personality disorders.\[^{215}\] However, this profile has also been associated with other constructs such as depressive and anxiety disorders.\[^{216,217}\]

Only a portion of the variance in the factors or dimensions characterizing personality disorders is explained by core personality traits.\[^{218}\] Personality traits are generally considered to be enduring features of an individual. The stability of personality after age 30 years has been
Longitudinal studies also demonstrate that dimensional models of personality disorders may represent a manifestation of personality traits interacting with life events or illness consistent with the diathesis-stress model. Caution should be exercised in making the diagnosis of a personality disorder in the presence of any illness. Personality traits should be appreciated as sustaining or modifying factors that have the potential to complicate the treatment process rather than as causes of or the sole explanation for illnesses such as chronic pain. Personality vulnerabilities contribute to the degree of potential disability that individuals experience by modifying their response to pain. Although these patients are more likely to be “difficult” because of their complexity, their prognosis should not be viewed as hopeless or unresponsive to treatment.

The diathesis-stress model may partly explain the high rates of personality pathology but also the decreases in these rates that have been observed with chronic pain treatment. A comprehensive review of the effect of pain on the measurement of personality characteristics found substantial evidence that trait inventories are not pain state independent. Pain treatment resulted in improvement in trait scores across the majority of studies that utilized the MMPI and measures of trait anxiety, coping/self-efficacy, and somatization/illness behavior. In a significant number of the studies reviewed, the trait changes could be attributed to improvements in pain. This state–trait interaction contradicts the notion that personality inventories catalog only enduring aspects of the individual. Instead, there is increasing evidence that a state disorder (psychiatric, medical, stress-related pain) may distort the measurement of traits and that treatment of that condition will decrease the presumed trait disorder. Just as personality pathology may improve with adequate pain treatment, personality disorders may emerge in the context of chronic pain, even if prior to pain, there was no evidence of maladaptive personality traits. The explanation for this change may include several mechanisms or confounders including that trait measurements are being contaminated by state-specific questions; pain treatments (medications, CBT) directly alter traits; and pain treatments improve state disorders which were previously affecting trait measurement, test–retest-related problems; and that
PERSONALITY AND PAIN TREATMENT OUTCOME

Current research has focused on how personality relates to treatment outcome, the transition from acute to chronic pain, and the persistence of pain-related disability. However, results have been inconsistent and more likely to detect emotional distress and psychopathology. Recently, a disability profile based on elevations of four or more clinical scales of the MMPI-II has been proposed as more common than those described earlier. In a prospective investigation of almost 1,500 patients with chronic occupational spinal disorders, this disability profile was associated with 5 times the likelihood of having a personality disorder and 14 times the likelihood of having an Axis I disorder. Although associated with high levels of psychopathology, patients with the disability profile compared to those with neurotic triad, conversion V, and normal profiles showed no significant differences in response to treatment with an interdisciplinary rehabilitation program. In a 30-year longitudinal study of healthy college students, elevations on MMPI scales 1 and 3 were associated with increased reports of chronic pain conditions at midlife. However, the magnitude of this association was small, and the clinical significance was unclear.

In a similar study, patients with chronic pain due to nonspecific musculoskeletal disorders exhibited higher levels of HA and lower levels of SD on the TCI. This trait profile would characterize patients as cautious, insecure, pessimistic, lacking self-esteem and long-term goals, failing to accept responsibility, and struggling with their identity. Another study of patients with chronic pain of all types identified the same profile plus low levels of C. Low levels of SD have been associated with learned helplessness, poor self-efficacy, and an external locus of control. High levels of HA overlap with the construct of fear-avoidance behavior, fearful cluster C personality disorders, and the development of pain-related disability. The fear-avoidance model and expectancy model of fear provide explanations for the initiation and maintenance of chronic pain disability, proposing that anxiety sensitivity amplifies reactions such as avoidance of specific activities. Anxiety sensitivity is a significant predictor of
fear of and anxiety about pain. Fear of pain, movement, reinjury, and other negative consequences that result in the avoidance of activities promote the transition to and sustaining of chronic pain and its associated disabilities such as muscular reactivity, deconditioning, and guarded movement.

Fear-avoidance beliefs have been found to be one of the most significant predictors of failure to return to work in patients with chronic low back pain. Operant conditioning reinforces disability if the avoidance provides any short-term benefits such as reducing anticipatory anxiety or relieving the patient of unwanted responsibilities. In a study of patients with chronic low back pain, improvements in disability following physical therapy were associated with decreases in pain, psychological distress, and fear-avoidance beliefs but not specific physical deficits. Decreasing work-specific fears was a more important outcome than addressing general fears of physical activity in predicting improved physical capability for work among patients participating in an interdisciplinary treatment program. These studies suggest that certain personality traits or profiles should alert the clinician to the presence of psychological problems and psychiatric disorders that would benefit from more specific treatments as opposed to defining a group of patients with chronic pain who should be condemned to no treatment because of an expected poor outcome.

Somatic Symptom Disorders, Illness Behavior, and Sick Role

DEFINITIONS
Sickness is a complicated psychological and social state that has been understood from a variety of perspectives over the years. We consider those of sick role, illness behavior, and somatic symptom disorder (SSD).

The concept of the sick role was first introduced by Talcott Parsons in 1951 and was formulated more concretely 12 years later. The sick role is granted to an individual provided that he or she regards his or her condition as undesirable and is not held responsible for it (i.e., under his or her control and able to be reversed voluntarily). If granted, the individual is allowed exemption from his or her usual obligations to a greater or
lesser extent and is considered to be deserving of care and attention. Associated with the sick role are the obligations of seeking the advice and assistance of a person regarded as competent to diagnose and treat the condition and of cooperating with that person.

The basic concept of illness behavior was introduced by Mechanic and Volkart and later fully formulated by Mechanic. Mechanic’s concept of illness behavior complements the sick role because it delineates the contribution of the patient to the role-granting process. Illness behavior was originally defined as the ways in which individuals differentially perceive, evaluate, and respond to their symptoms. This concept proved to be an extremely useful one because it has facilitated the empiric study of behaviors that are of considerable importance to clinicians and other health care providers as well as to the individual’s family and society.

Although useful as it stands, health care providers find Mechanic’s definition restrictive because it refers to symptoms as the focus of behavior and consequently deemphasizes actions directed toward avoidance of the illness. A slightly modified definition describes illness behavior as “the ways in which individuals experience, perceive, evaluate, and respond to their own health status.” This definition recognizes the possibility that a person may be concerned about illness in the absence of symptoms.

Illness behavior is a concept more easily applied to individual patients than sick role and has therefore seen more use in clinical settings. However, it is dependent on social definitions of what constitutes legitimate illness. Although medical science determines what qualifies as disease based on objective changes in anatomy and physiology, society determines what qualifies as illness. These often follow each other quite closely, but there can be interesting discrepancies. Essential hypertension is a disease usually without symptoms. It has taken a concerted educational effort on the part of the medical profession to convince the public that it is an illness that should be monitored and treated. Chronic fatigue syndrome and fibromyalgia are illnesses increasingly recognized and accepted by the public. Because the medical profession has not been able to identify objective changes in physiology with these illnesses, many physicians question whether they qualify as legitimate diseases. Physicians, insurance companies, and compensation systems can find themselves in

1495
disagreement with patients experiencing chronic pain about whether a legitimate disease or illness is causing the pain.

Pilowsky\textsuperscript{243} introduced the concept of abnormal illness behavior for those situations in which physician and patient disagree about the applicability of the sick role to the patient’s condition. He contends that patients with truly abnormal illness behavior have extreme difficulty accepting the advice of any physician if it does not agree with their own appraisal of their health status. He cautions that misdiagnoses of abnormal illness behavior can occur when physician and patient do not share a common culture. We might add that it is also important to keep in mind the limitations of current diagnostic tests and disease criteria when diagnosing the patient’s disagreement with his or her physician as pathologic.

OVERVIEW OF SOMATOFORM DISORDERS AND SOMATIC SYMPTOM DISORDERS

Current psychiatric thinking frames the diagnoses of abnormal illness behavior or misuse of the sick role as SSDs. The categorization of these disorders has been significantly modified in the DSM-5. In the DSM-5, SSD appears in a new section, somatic symptoms, and related disorders. This section replaces the somatoform disorders of the DSM-IV. SSD is a single diagnostic entity that replaces three of the DSM-IV somatoform disorders: somatization disorder, pain disorder, and undifferentiated somatoform disorder. The DSM-5 criteria for SSD are listed in Table 31.6. Currently, there is scant available research about SSD as it was fairly recently adopted.

\textbf{TABLE 31.6} \textit{Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Diagnostic Criteria for Somatic Symptom Disorder}

\begin{itemize}
\item A. One or more somatic symptoms that are distressing or result in significant disruption of daily life
\item B. Excessive thoughts, feelings, or behaviors related to the somatic symptoms or associated health concerns as manifested by at least one of the following:
  \begin{itemize}
  \item 1. Disproportionate and persistent thoughts about the seriousness of one’s symptoms
  \item 2. Persistently high level of anxiety about health or symptoms
\end{itemize}
\end{itemize}
3. Excessive time and energy devoted to these symptoms or health concerns

C. Although any one somatic symptom may not be continuously present, the state of being symptomatic is persistent (typically more than 6 mo).

Specify if:
With predominant pain (previously pain disorder): This specifier is for individuals whose somatic symptoms predominantly involve pain.

Specify if:
Persistent: A persistent course is characterized by severe symptoms, marked by impairment and long duration (more than 6 mo).

Specify current severity:
Mild: Only one of the symptoms specified in criterion B is fulfilled.
Moderate: Two or more of the symptoms specified in criterion B are fulfilled.
Severe: Two or more of the symptoms specified in criterion B are fulfilled, plus there are multiple somatic complaints (or one very severe symptom).

The essential feature of the somatoform disorders is the presence of physical symptoms that suggest a general medical condition but are not fully explained by a general medical condition. The DSM-5 diagnosis of SSD eliminated the requirement that somatic symptoms be medically unexplained. In either case, these symptoms must cause impairment in social and occupational functioning. These disorders are distinguished from factitious disorders and malingering in that the symptoms are not intentionally or voluntarily produced in the somatoform disorders or SSD. Malingering is the deliberate feigning of symptoms for a clear gain, often financial. In factitious disorder, although there is a feigning of symptoms, the patient is only partially aware that they are doing so, and their gain or benefit is much less clear. In factitious disorder, the maintenance of symptoms is for the psychological benefits of the sick role, similar to the gain in somatoform disorders.

In the majority of patients with pain and somatoform illness, there is a physical basis (including functional or structural pathology, such as neuropathic pain) for at least a portion of the pain complaints, in which symptom reporting is magnified by somatizing. Somatization is best thought of as a process (vs. somatization disorder, discussed in the following text). The spectrum of somatization includes amplification of symptoms, which entails “focusing on the symptoms, racking with intense
alarm and worry, extreme disability, and a reluctance to relinquish them.” Pain-related psychological symptoms amplify pain perception and disability. Hence, there is a tremendous overlap between the somatoform component of a chronic pain syndrome and other psychiatric comorbidities. In other words, in a patient with pain and any psychiatric comorbidty, somatization is a ubiquitous, mediating process by which pain and disability are worsened. It has psychological and physiologic bases, which are still being elucidated. Similarly, pain complaints may become an “idiom of distress” in which psychological distress or needs are communicated through the proxy of pain reporting.

In the DSM-IV, four somatoform disorders may involve pain: somatization disorder, conversion disorder, hypochondriasis, and pain disorder (with or without a physical basis for pain). In the DSM-5, three somatic symptoms and related disorders involve pain: SSD, illness anxiety disorder, and conversion disorder (functional neurologic symptom disorder). Somatoform disorders without any physical basis for pain are estimated to occur in 5% to 15% of patients with chronic pain who receive pain treatment.

**Somatic Symptom Disorder**

The DSM-IV somatoform disorders were criticized for two main reasons: (1) the questionable importance of medically unexplained pain in pain disorder associated with psychological factors and (2) the lack of a definition of psychological factors or a description of when they are of sufficient importance to have a role in the experience of pain in the presence of a general medical condition, which made it a diagnosis of exclusion. If a medical cause for pain is discovered, it means the SSD diagnosis is discarded regardless of the evidence previously considered supportive of it. However, somatic symptoms that are not attributable to a medical condition are a substantial problem in primary care and pain specialty practice. It is estimated that 20% of visits to medical doctors are for this type of complaint. However, because somatoform disorders were restrictively defined, and many clinicians felt that giving patients a somatoform diagnosis could be interpreted as “everything is just in the
mind,” the diagnostic category was rarely used in the United States and Europe.248

The DSM-5 Somatic Symptoms Disorders Work Group tried to address these issues when developing the criteria for the new diagnostic group. The new category was named Somatic Symptoms and Related Disorders with SSD as the prototype. The common feature of this category is that individuals have “somatic symptoms associated with significant distress and impairment.” The major advance in the DSM-5 is that it uses positive criterion, namely, maladaptive reaction to a somatic symptom, rather than the earlier negative criterion, namely, that the symptoms should be medically unexplained. The new diagnosis of SSD is designed to cover not only patients with somatization but also patients with chronic pain conditions, most patients with hypochondriasis, and many patients with medical conditions that are accompanied by psychological features.248 The diagnostic criteria for SSD includes one or more physical symptoms lasting 6 months or longer that are associated with excessive thoughts, feeling, or behaviors. There are three specifiers that describe the nature, duration, and severity of the symptoms.

Despite these advances in the DSM-5, criticisms have emerged. The main criticism is the high probability of misdiagnosing a medical illness, such as a chronic pain condition, as a mental illness.249 The conditions that qualify for a diagnosis are highly variable and include patients with medically unexplained symptoms, medical patients with emotional stress, patients with typical chronic pain conditions, and patients with health-related anxiety.248 This results in a classification with high sensitivity but low specificity. Several authors have proposed modified criteria that reduce the likelihood of diagnostic inflation and this misdiagnosis of a medical illness as a mental disorder and suggested that adjustment disorder may be a safer and more accurate diagnosis when one is needed for someone who is medically ill and troubled by symptoms.246

Conversion Disorder (Functional Neurologic Symptom Disorder)

The essential feature of conversion disorder is an alteration in voluntary
motor or sensory function that suggests a neurologic or general medical disorder. Classic examples include hysterical paralysis, blindness, or mutism. Psychological factors must be associated with the initiation or exacerbation of this deficit. The name “conversion disorder” refers to a hypothesis based on a psychological etiology that has little supportive empirical evidence. As such, the DSM-5 has added the bracketed term, functional neurologic symptom disorder, to give a more proper and respectable definition to these symptoms. Diagnostic DSM-5 criteria are displayed in Table 31.7. In the new criteria, there is less emphasis on psychological and emotional events prior to the development of symptoms and emphasis on the need for positive diagnostic signs and symptoms. These changes may lead to a more collaborative approach between psychiatrists and neurologists and be more acceptable to patients.

</tr>
</tbody>
</table>

Despite these changes, great caution must be exercised in making the diagnosis of conversion disorder because the presence of relevant psychological factors does not exclude the possibility of a concurrent organically caused condition.

In “Psychogenic Pain and the Pain-Prone Patient,” George Engel proposed that psychogenic pain arose from guilt and an intolerance of success. He indicated that it functioned as a substitute for loss or a replacement for aggression. He further stated that “. . . patients with conversion hysteria constitute the largest percentage of the pain-prone population.” Others have also contended that pain is probably the most...
common conversion symptom encountered clinically. However, only case reports exist to support this contention. Pain is not a classic conversion disorder symptom, and it is controversial whether chronic pain can ever qualify as a conversion disorder by itself. Some, for example, have contended that reflex sympathetic dystrophy (complex regional pain syndrome) can be understood as a conversion reaction; however, this is highly controversial. Some elements of conversion disorders appear to be present in reflex sympathetic dystrophy/complex regional pain syndrome patients (e.g., indifference or neglect toward the affected body part), although it is highly unlikely that the condition is entirely psychogenic.

Rather than labeling some chronic pain problems as conversion reactions and others as not, it may be more useful to understand what components of conversion reaction may be present in chronic pain problems. Again, the emphasis should be on thinking about somatoform illnesses as a process. Being ill surely creates problems in living for those affected, but it can also solve problems in living. For example, being ill provides an excuse for not being at school or not meeting a deadline at work. These interpersonal advantages of illness were originally recognized by Freud and termed secondary gain.

The term secondary gain has been distorted and misunderstood in the care of chronic pain, probably because of medicolegal pressures. A number of corrections are in order. First, all illnesses are characterized by some secondary gain, not just illnesses considered to be psychogenic. Being sick always has advantages as well as disadvantages. Second, secondary gain includes all potential interpersonal benefits of illness, not just monetary advantages. Many of the advantages of illness are quite subtle and individualized. Third, secondary gain must be understood in the context of primary gain, the intrapersonal advantages of illness. For example, focusing on pain rather than depression may allow patients to avoid self-blame and thereby achieve primary gain. This is a common phenomenon in chronic pain. Indeed, blame avoidance has been hypothesized by some to be one of the main functions of somatization. Thus, traditional elements of conversion disorder may be present in many chronic pain problems without many pain problems qualifying as...
conversion disorders per se.

Purely psychogenic or conversion models of chronic pain have some questionable implications for diagnosis and therapy of chronic pain disorders. Interview of the patient with a suspected conversion disorder with the aid of a sodium amobarbital (Amytal) infusion has been a standard tool in psychiatric diagnosis. More recently, lorazepam interviews have been substituted. It is more common that motor and sensory deficits than pain resolve under sodium amobarbital (Amytal) or benzodiazepine sedation. Furthermore, some patients have had violent or suicidal reactions to abrupt resolution of their somatic symptoms under sodium amobarbital (Amytal), possibly caused by loss of face-saving primary gain aspects of the illness. Psychodynamic theories of the origin of conversion symptoms imply that psychological treatments alone will be effective.

Psychodynamic treatments for chronic pain, however, have little documented success. The most effective psychological treatments, such as CBT, include a reactivation component that addresses the profound disuse and deconditioning found in many patients with chronic pain.

ILLNESS ANXIETY DISORDER
Many patients with chronic pain resist their physician’s reassurance that “nothing is wrong” or that the “tests reveal nothing.” These patients know that they hurt and cannot accept that a bodily cause cannot be identified for their pain. This has been described as disease conviction in the chronic pain literature. Disease conviction has been measured with the Illness Behavior Questionnaire, and hypochondriasis is assessed with the MMPI. In DSM-IV, there also exists a disorder called hypochondriasis, which was changed to illness anxiety disorder in the DSM-5. The major change to the DSM-5 criteria was the addition, in criterion B, that somatic symptoms should not be present, and if they are present, they are only mild in intensity. This will lead to some patients with previously diagnosed hypochondriasis now being diagnosed with SSD. Otherwise, hypochondriasis and illness anxiety disorder are essentially the same in concept, that is, a persistent fear in having a medical illness.

The prevalence of hypochondriasis in primary care has been reported to
be 4% to 9%. The prevalence of hypochondriasis in pain clinic populations is difficult to determine but is likely to be high if patients are not excluded by qualifying for pain disorder because of the likelihood of disagreement between patient and physician about the cause of the pain problem.

Treatments of hypochondriasis have attempted to shift patient focus from cure of the disease causing the symptoms to strategies of symptom management. These strategies are common components of multidisciplinary pain treatment programs as well. It is indeed critical to achieve early in treatment some agreement with the patient about the cause of the pain that acknowledges the reality of the pain and yet points away from invasive attempts to cure disease or repair broken parts. The task is not to convince the patient that “nothing serious is wrong” because his or her pain may be severe and persistent. The task is to convince the patient that the appropriate treatment is different than the treatment he or she thought necessary.

**Conclusion: Pain and Suffering and Psychiatry**

Psychiatric diagnosis and treatment can add an essential and often neglected component to the conceptualization and treatment of chronic pain problems. The high rates of psychiatric comorbidity and the negative impact they have on chronic pain necessitate that a psychiatric assessment be part of any comprehensive pain evaluation. The expanse of psychiatric symptoms in patients with pain is broad and deep, and thus, a comprehensive framework for describing psychiatric symptoms and the relationships between them is essential to thorough diagnosis and treatment. Advances in neuroimaging have elucidated some of the interrelationships between pain perception and psychological states, underscoring that most painful conditions have an affective component to the pain experience.

It is this disordered affective experience of pain and, consequently, suffering that form a key interaction between pain and overlying psychiatric disorders. It is absolutely critical to avoid a dualistic model that postulates that pain is either physical or mental in origin. This model
alienates patients who feel blamed for their pain. It is also inconsistent with modern models of pain causation. Since the gate control theory of pain, multiple lines of evidence suggest that pain is a product of efferent as well as afferent activity in the nervous system. Tissue damage and nociception are neither necessary nor sufficient for pain. Indeed, it is now widely recognized that the relationship between pain and nociception is highly complex and must be understood in terms of the situation of the organism as a whole.

We are only beginning to understand the complexities of the relationship between pain and suffering. Pain usually, but not always, produces suffering. Suffering can, through somatization, produce pain. We have traditionally understood this suffering, as we have understood nociception, as arising from a form of pathology intrinsic to the sufferer. Hence, the traditional view that pain is caused by either tissue pathology (nociception) or psychological states (suffering). Psychiatric comorbidity represents an additional layer of suffering, which also magnifies the perception on pain. Yet this is still somewhat dualistic; an alternative model is to think of pain as a transdermal process with causes outside as well as inside the body. For humans, social pathology can be as painful as tissue pathology. We can investigate the physiology and the psychology of this sociogenic pain without losing sight of its origins in relations between people.

Psychiatric care for patients with chronic pain should occur within the medical treatment setting whenever possible. This is the most effective way to reassure patients that the somatic elements of their problems are not neglected. It also allows integration of somatic and psychological treatments in the most effective manner. The success of multidisciplinary approaches to pain underscores the value of psychiatric assessment and treatment by the pain medicine provider.

Substance use disorder (SUD), formerly called substance abuse, dependence, or addiction, is a prevalent chronic disease in our society, not only with implications for the health and quality of the life of the sufferers but also with often devastating consequences for the families and communities in which they live and for society. Perhaps unlike any other chronic illness, SUD has meaningful effects on all aspects of the pain experience, ranging from its perception to its management. Specifically, the neurologic and behavioral states associated with the disease tend to worsen the pain presentation and mitigate the efficacy of therapeutic interventions. These complications become particularly apparent in the case of opioid use disorder (OUD), where the abused substance is also a primary analgesic used to treat moderate to severe pain. The development of opioid tolerance, physical dependence, hyperalgesia, and/or relapse are all challenges clinicians face when attempting to manage the pain of persons with OUD.

This chapter provides a brief overview of SUD, conceptualizing it as a chronic, relapsing neurologic disease for which evidence-based treatments exist, however, with access to these treatments limited in part due to negative societal perceptions of the illness. The overlap in neurobiologic systems in pain and SUD is considered, and how the presence of an SUD in general, and OUD specifically, can affect the experience of pain is discussed. Finally, principles of acute and chronic pain management for the patient with SUD is outlined, differentiated by whether the patient is actively using, on medication-assisted therapy (MAT; i.e., methadone, buprenorphine, naltrexone), or in drug-free recovery. Evident in these
recommendations is the understanding that effectively and thoughtfully treating pain in the patient with SUD concomitantly benefits the recovery process regardless of the state of disease progression.

**Substance Use Disorder**

Misusing and abusing drugs and alcohol is endemic in the United States. The most recent national surveys suggest that approximately 8% (or 20 million) of Americans older than 12 years met diagnostic criteria for an SUD in the past year.¹ Being legal and readily available, not surprisingly, three quarters of these individuals meet criteria for alcohol use disorder (AUD). Among those with an illicit drug use disorder, the most common drug is marijuana (4 million people), followed by an estimated 2.1 million people with an OUD, which includes 1.8 million people with a prescription pain reliever use disorder and 0.6 million people with a heroin use disorder.¹ There is good evidence to suggest that the prevalence of SUD is higher in patients seeking medical care secondary to the toxic effects of the drugs themselves and/or the risky behaviors associated with the disorder.²–⁵

Like chronic pain, addiction is an extremely complex human condition, with strong behavioral and social components, that cannot be entirely understood by analyzing its physiology. SUD is defined as a chronic, relapsing disorder that is characterized by (1) a compulsion to seek and take drugs, (2) loss of control over drug intake, and (3) emergence of strong negative emotional states (e.g., dysphoria, anxiety, and irritability) when access to the drug is prevented (Table 32.1).⁶ The occasional, limited, recreational use of a drug is clinically distinct from the loss of control over drug intake and the emergence of compulsive drug-seeking behavior that characterize SUD.⁷ Because the disorder is primarily evident in behaviors, it is one of the few conditions in which the sufferer is the disease, as reflected in the pejorative labels ascribed to him or her (i.e., “drunk,” “druggie,” “addict,” “lush”).

¹

²–⁵

⁶

⁷
- More substance (drug, alcohol) is used than intended or planned.
- Inability to cut down or control substance use
- Much of time obtaining, using, or recovering from substance
- Craving or a strong desire to use substance
- Inability to fulfill role obligations at work, school, or home
- Continued substance use despite accumulating consequences
- Reduced participation in social, occupational, or recreational activities due to substance use
- Substance use in situations in which it is physically hazardous
- Continued substance use despite health problems caused or exacerbated by substance
- Need for increased amounts of substance to achieve desired effect (tolerance)
- Characteristic withdrawal syndrome for substance when not used (physical dependence)

Like all chronic disorders, SUD is never “cured,” but it can be effectively managed with lifestyle changes and, in some cases, medication. Similar to other chronic conditions, there are demonstrable pathophysiologic changes underlying the disorder, which, in the case of addiction, reside in subcortical and cortical neural pathways underlying reward and memory and, ultimately, the prefrontal cortex, driving behavior (Fig. 32.1). Without treatment, the disease will predictably progress and result in disability and ultimately death. Known risk factors for SUD in both patients with pain and in those without pain include a prior history of alcohol and/or illicit drug abuse (including nicotine addiction), a family history of substance abuse or SUD, a history of mood or anxiety disorder, early onset (age <14 years) of alcohol or drug use, a history of child sexual abuse or child neglect, involvement in the legal system, and significant psychosocial stressors. Furthermore, as with all chronic diseases, SUD is characterized by exacerbations (or relapses) over time, often at times of interpersonal or intrapersonal stress, and treatments are most effective when ongoing.
Adopting a chronic illness model for SUD provides the foundation for effective treatment; however, this model is inconsistent with societal perspectives. For example, SUD has been conceptualized as a moral failing, such that those who engage in problematic drug and alcohol use are often described as lacking honorable character or moral fortitude (i.e., “just say no”). Also, in the United States, illicit drug use is classified as a criminal behavior, with punishment, including incarceration, being the societal approach to treatment. Unfortunately, both the moral and criminal attributions to SUD result in significant shame and stigma for the sufferer, making them less likely to seek treatment and further isolating them from therapeutic supports. These negative perspectives are reflected in the relative paucity and marginalization of SUD treatment services in the United States, such that in 2016, only about 1 in 10 people (10.6%) aged 12 years or older who needed substance use treatment were able to receive it.\(^1\)

Fortunately, evidence-based treatments for SUD exist, and as a result of the current opioid abuse crisis, are becoming increasingly integrated into acute and primary care settings. For drugs of abuse with significant physiologic withdrawal syndromes (i.e., alcohol, opioids, benzodiazepines), treatment often begins with a taper or detoxification with a long-acting substitution agent. However, it is important to
appreciate that detoxification in and of itself is not a treatment for SUD; it simply readies the patient for the cognitive, behavioral, and group support interventions necessary to mitigate disease progression. Opioid medications may be utilized as adjuncts to treatment in the case of AUD (naltrexone) and should be routinely offered to all patients with OUD (methadone, buprenorphine, naltrexone) to allay craving and withdrawal; in all cases, medications to treat underlying psychiatric disorders are indicated. Related to previous stressful or traumatic experiences, especially those occurring in childhood, individual or group psychotherapy can be highly beneficial for patients in whom adverse events are an issue, but access to and reimbursement for these services can be limited.

Clinical Implications of Substance Use Disorders on Pain

Pain and SUD are not unrelated phenomena, and this overlap becomes significant at the clinical level. Pain and drug reward share common neuroanatomical and neurochemical substrates, and the physiologic sequelae of SUD (i.e., tolerance, dependence, and altered stress response) have clear effects on pain management. Drugs of abuse often have inherent analgesic properties, yet SUD can bring with it mood states, behaviors, and social losses that worsen the pain experience. The clinical intersection of pain and SUD is particularly complex in the case of OUD, as opioids have rewarding, analgesic, and hyperalgesic activity. Furthermore, accumulating genetic data suggest that pain severity, opioid analgesia, and OUD may share similar patterns of gene expression, which become evident in the response of the individual patient to a painful stimulus.

NEUROBIOLOGIC OVERLAP BETWEEN PAIN AND ADDICTION SYSTEMS

It is not surprising that pain and SUD responses are related in that both are modulated by the activity of the same neuropeptide—the opioids at the opioid receptor. Whether administered endogenously or exogenously, opioids engender both pain relief and psychoactive reward, the latter of which provides the neurobiologic foundation for SUDs. All drugs of
abuse, either directly or indirectly, activate opioid reward systems, which in individuals at risk can result in the compulsive behaviors diagnostic of SUD.

Of relevance to pain and pain treatment, the neurobiology of SUD is often characterized by two incompletely understood yet related allostatic states: tolerance and physical dependence. These neuroadaptations may be evident not only in those brain systems in which drugs of abuse exert direct actions but also in brain systems that oppose the actions of the drug. Importantly, the simple presence of these adaptations in the nervous system does not infer meeting the diagnostic criteria for SUD. Any individual using alcohol or opioids on a regular basis will become tolerant to or physiologically dependent on the effects of the drug; it is simply a neurobiologic outcome of drug exposure. As noted earlier, SUD is identified by a cluster of aberrant patterns of behavior that, although partially motivated by these physiologic changes, is evident in much broader functional domains (see Table 32.1).

**Tolerance**

Ongoing use of substances of abuse often results in the development of drug tolerance, even when they are used for analgesic purposes, which is defined as a reduction in response to a given dose of drug after repeated administration.\(^\text{10,11}\) The neuroadaptations associated with tolerance counter the acute drug effects to maintain system-level homeostasis. A theoretical explanation for the processes underlying tolerance is offered by the opponent process theory of acquired motivation.\(^\text{12,13}\) Reflecting homeostatic assumptions, the theory describes how, over the course of repeated exposures to a stimulus, a counteracting or opposing emotional or physiologic response develops, which eventually accounts for habituation to the stimulus and becomes the predominant state in its absence. In the case of drug reward, the model predicts that in order to maintain a “normal” or homeostatic level of reward system activity, “antireward” systems are recruited to counteract drug effects, which become stronger with each exposure and extinguish more slowly than the original response.\(^\text{14,15}\) Upon abrupt drug withdrawal, antireward or dysphoric processes are revealed. As described in the following discussion,
analogous opponent processes are theorized to underlie the development of opioid-induced hyperalgesia (OIH).

Physiologic tolerance involves adaptations that occur both at the site of drug action and in systems distal to the site of drug action.\(^{16-18}\) Because drugs typically act at selective receptors, tolerance has been conceptualized as a functional “uncoupling” of the receptor from its effector response (opening or closing an ion channel, initiating second messenger systems); in other words, a certain proportion of receptors are rendered less functional or nonfunctional, thus making the drug less effective.\(^{18,19}\) Clinically, the resulting tolerance provides a certain amount of protection for the user, such as with the respiratory depressant effects of opioids or the anesthetic effects of ethanol. However, tolerance does not develop to all physiologic drug effects; for example, in the case of opioids, tolerance to opioid-induced constipation and opioid-induced androgen deficiency does not develop over time.\(^{20,21}\)

**Dependence**

A related consequence of chronic drug use is physiologic dependence, defined as a physiologic adaptation to the continuous presence of a drug that results in symptoms of withdrawal when the drug effect significantly diminishes or stops.\(^{22}\) Physical dependence occurs not only to drugs with reward potential, such as opioids and benzodiazepines, but also to those with little or no reward potential, such as \(\alpha_2\)-adrenergic agonists (e.g., clonidine), \(\beta\)-blockers, and tricyclic antidepressants. It is associated with a drug class–specific withdrawal syndrome that can be produced in persons with prolonged exposure to the drug by abrupt cessation, rapid dose reduction, decreasing blood level of the drug (e.g., due to administration of an enzyme inducing medication resulting in accelerated metabolism to the drug), and/or administration of an antagonist. When a drug blood level falls below a critical point, the adaptive changes associated with tolerance predominate and become profoundly nonadaptive.\(^{23}\) Suddenly unopposed by drug effects, the sources of tolerance become evident as the characteristic drug-specific withdrawal syndrome\(^{22,23}\) and a more generalized negative emotional state. Such negative emotional states include malaise, anxiety, dysphoria, emotional pain, loss of interest in
natural rewards, and depression. These are common to withdrawal from all drugs of abuse, underlie drug craving and relapse, and are particularly relevant to the interface of SUD and pain.

**Analgesic Effects of Drugs of Abuse**

As interactions between the neurobiology of pain and SUD are considered, it is notable that many classes of abused drugs have analgesic properties, recruiting ascending and descending pain pathways to diminish the perception of pain. The opioids are defined by their direct analgesic effects, and, at high doses, alcohol is a potent anesthetic and analgesic. The sedative hypnotics, particularly benzodiazepines, are used to treat painful muscle spasms and muscle spasticity secondary to upper motor neuron damage and are a standard anxiolytic adjunct for procedural sedation and analgesia. Central nervous system stimulants, such as cocaine and caffeine, produce and potentiate analgesia, presumably by increasing neurotransmitter activity in descending inhibitory pain pathways. Notably, all drugs of abuse provide reward via activation of subcortical opioid systems, and withdrawal from these substances increases sensitivity to pain.

Of current interest are the effects of cannabinoids on pain perception. Mao and colleagues have provided good preclinical evidence for an independent tetrahydrocannabinol (THC)-responsive antinociceptive pathway that is particularly effective for pain of neuropathic origin. Interference with glutamate release at the level of the dorsal root ganglia or periaqueductal gray is a hypothesized mechanism by which cannabinoids provide analgesia. Although clinical trials of cannabinoids in multiple sclerosis have suggested an analgesic benefit, human studies of cannabinoid-mediated analgesia have been limited by study size, heterogeneous patient populations, subjective outcome measures, and variable drug pharmacokinetics. Recent meta-analyses do not support that cannabinoids effectively treat acute, fibromyalgia or rheumatic pain. There are reports of moderate efficacy to treat cancer pain, although insufficient evidence for its use as an adjunct in this context. It is identified as a fourth-line analgesic for the management of neuropathic pain, behind the more effective antiepileptics, tricyclic antidepressants,
serotonin norepinephrine reuptake inhibitors (SNRIs), and lastly opioids. However, all reviews note that the paucity of well-controlled clinical trials on the analgesic efficacy of cannabinoids limits comprehensive evaluation of benefit.

**EFFECTS OF SUBSTANCE USE DISORDER ON PAIN**

SUDs bring with them physical and psychological consequences which serve to worsen or facilitate the pain experience, including autonomic arousal and negative mood states. These changes are related to both the discrete effects of certain classes of drugs and the effects of all drugs of abuse on reward-relevant systems. For example, important psychological sequelae characteristic of SUD, including sleep and psychiatric disorders, can contribute to the experience of pain and decrease the efficacy of analgesic interventions. SUD commonly co-occurs with mood and anxiety disorders which—if not corrected—can increase the perception of pain. Depression has been demonstrated to increase the discomfort associated with pain and to impair function in studies of patients with chronic pain, and pain symptoms frequently improve with effective antidepressant treatment, in particular the selective SNRI antidepressants which appear to have direct effects on pain pathways.

Drug use in those with SUD is characterized by frequent and often rapid fluctuations in blood levels of the drug. Abused substances tend to be ingested in short-acting formulations and via routes with rapid onset (i.e., inhalation, intravenous [IV]) to boost psychoactive effect. These use patterns result in rapidly alternating states of intoxication and subtle (or sometimes full-blown) withdrawal. As detailed earlier, strong and persistent negative affective states accompany withdrawal from many drugs of abuse, including anhedonia, prolonged dysphoria, and irritability. Clearly, the negative feeling states associated with drug withdrawal can augment the subjective discomfort associated with pain.

Finally, and not insignificantly, the stress associated with interpersonal conflicts, role adjustments, and social support losses that characterize the lived experience of SUD can worsen the experience of pain, making the individual less able to manage or cope with discomfort, and to interfere with effective pain treatment engagement and implementation of active
pain treatment modalities. The chaotic and drug-oriented lifestyle of the sufferer make it difficult to comply with prescribed pain management regimens and engage in pain reduction activities (i.e., exercise, mindfulness meditation). Empirical support for a worsened pain experience in individuals with active SUD has been demonstrated in the case of experimental pain; subjects currently using addictive drugs are significantly less tolerant of cold-pressor (CP) pain than matched drug-free ex-abusers regardless of whether the primary drug of abuse was a stimulant (cocaine) or an opioid.49

The development of SUD and chronic pain appear to share epigenetic mechanisms, underscoring the interrelated nature of these phenomena. In the case of alcoholism, epigenetic modifications in the amygdala have been demonstrated to contribute to the negative affective states characteristic of the allostatic changes associated with SUD,50 whereas cocaine intake appears to alter gene expression in reward-relevant pathways in the nucleus accumbens.51 Such epigenetic regulation may be especially significant during windows of neurodevelopmental vulnerability (prenatal, adolescence)52 and explain the link between early substance abuse and SUD later in life. In the case of chronic pain, there is evidence that inflammation and tissue or neural injury can induce epigenetic modifications in the central nervous system resulting in pain hypersensitivity,53 including allodynia and hyperalgesia. Portending overlap between epigenetic mechanisms that mediate both chronic pain and SUD, Descalzi and colleagues54 describe chronic pain-induced modifications in brain reward systems which are analogous to those induced by exposure to drugs of abuse.

**EFFECTS OF OPIOID USE DISORDER ON PAIN**

Because the opioid class of drug abused is also a primary pharmacologic tool for the treatment of moderate to severe clinical pain, the effects of SUD on pain become particularly significant in the case of individuals addicted to opioid drugs. As noted earlier, OUD and opioid analgesia are dependent on agonist activity at the μ-opioid receptor; the reinforcing and analgesic effects of morphine, for example, can be blocked by the administration of μ-receptor antagonists and are absent in μ-opioid
receptor gene knockout animal models. In that the same receptor is central to both SUD and pain systems, it is reasonable to expect that alterations related to the latter might be evident in individuals chronically exposed to opioids (agonists or antagonists) in the context of the former. Although drug reward and analgesia are distinct processes, opioids activate their shared anatomical substrate, inducing the previously described interrelated adaptations of tolerance and dependence. Individuals with OUD may seek psychoactive effects yet are not immune to the effects of these drugs on central and peripheral opioid-relevant pain systems.

Early research in both human and animal models indicated that opioids are less rewarding in the presence of pain,\textsuperscript{55,56} suggesting that pain interfered with the reinforcing properties of the medication. This hypothesis is supported by reports from patients who say that opioids relieve their pain without psychoactive effects; furthermore, many patients experience dysphoria or other aversive feelings, rather than euphoria, when given opioids for their pain and often stop taking them for this reason alone. Nevertheless, based on our current understanding that a subgroup of patients treated with long-term opioids for chronic pain meet diagnostic criteria for OUD, the presence of pain cannot be considered a sufficiently protective factor against reward to occur and resulting OUD, particularly in those at risk.\textsuperscript{57,58}

**Genetics of Pain and Opioid Use Disorder**

Individual differences in pain perception and opioid response have long been appreciated in the clinical setting, and genetic factors, which underlie these differences, are increasingly elucidated. For example, heritable differences in hepatic P450 isoenzyme activity affect both the amount of reward and analgesia received from an opioid. Individuals who are extensive “metabolizers” of opioids (i.e., those with high P450 activity) receive less analgesia and reward from a given opioid dose\textsuperscript{59–61} theoretically putting them at decreased risk for SUD but increased risk for unrelieved pain.\textsuperscript{62} Preliminary data suggest that these extensive metabolizers of opioids are less tolerant of experimental pain, possibly due to defects in the endogenous synthesis of opioids.\textsuperscript{63}

The preclinical literature, primarily from the laboratories of Mogil et
al.,64,65 and Elmer et al.,66–68 shows that recombinant murine strains differ both in their baseline tolerance for pain and in the amount of reward or reinforcement they receive from opioids. Specifically, strains of animals with poor pain tolerance (i.e., C57, CXBK) find opioids to be highly reinforcing, whereas those with good pain tolerance (i.e., BALB/c, CXBH) receive little reinforcement from opioids.69–71 Furthermore, pain-tolerant murine strains receive robust opioid analgesia and demonstrate increased opioid receptor binding activity as compared to pain-intolerant strains.72

Investigators in both the pain and SUD fields have been focusing on polymorphisms in the µ-opioid gene receptor (OPRM) as candidates underlying phenotypes for pain sensitivity,73–75 opioid analgesic response,76 and SUD.77,78 Best characterized is the single nucleotide polymorphism A118G of the OPRM, such that normal human subjects with the variant allele have been shown to require almost twice as high as plasma level of morphine to achieve the analgesic response as those with the nonmutated allele.79,80 Other genes that have been linked to pain and opioid responses include those that code for the δ-opioid receptor, the capsaicin-sensing vanilloid receptor,81 the neurotransmitter enzyme catechol-O-methyltransferase,82 and the melanocortin-1 receptor gene.83

Patients with OUD may present for pain care with untreated disease (actively using illicit opioids), on MAT (methadone, buprenorphine, naltrexone), or in drug-free recovery. Principles of pain treatment for each of these groups are presented in subsequent sections of this chapter. Outlined in the following discussion are the effects of illicit or prescribed opioid agonist use on pain responses of patients with OUD.

**Tolerance**

Tolerance occurs differentially to opioid analgesic and rewarding effects as well as to such adverse effects as respiratory depression, sedation, nausea, sleep disturbance, or constipation. As noted earlier, the presence of tolerance does not presuppose the presence of SUD and is simply an adaptive outcome secondary to opioid exposure. Opioid tolerance can be innate due to inherent biogenetic characteristics of the individual, or it can be acquired in response to ongoing opioid exposure. Acquired opioid tolerance may be due to both pharmacokinetic factors, such as changes in
drug absorption and metabolism that reduce blood concentration, and to pharmacodynamic factors such as receptor desensitization or other density changes at the level of opioid receptors. Changes in central immune signaling and in N-methyl-D-aspartate (NMDA) receptor activity have been demonstrated in the development of opioid tolerance. As described earlier, behavioral opioid tolerance evident in mood and affect has been attributed to opponent adaptive processes in the mesocorticolimbic reward circuitry.

The incidence of analgesic tolerance in clinical settings has not been well described. Animal studies suggest that tolerance to the analgesic effects of opioids occurs in some contexts but not in others. Human studies of the management of acute pain document the development of progressive tolerance to the analgesic effects of opioids when they are administered on a continuous basis over a period of several days. However, over longer periods of time (weeks to months), evidence for the continuing development of progressive opioid analgesic tolerance is mixed. Interestingly, persons on MAT for OUD do not appear to develop tolerance to the opioids; patients can remain on the same dose of methadone or buprenorphine for years without a diminution of treatment effect. However, patients with OUD, whether actively using or on agonist MAT, do clinically present with notable opioid analgesic tolerance and in cases of acute obstetric, surgical, or traumatic pain require much larger doses of opioids to achieve relief than do opioid-naive individuals.

**Physical Dependence**

As is the case of opioid tolerance, physical dependence on opioids does not presume the active presence of SUD; persons with SUD on MAT are physically dependent despite being in a state of recovery, and individuals taking opioid analgesics on a regular basis can become physically dependent on medications without meeting the diagnostic criteria of SUD. Common symptoms of opioid withdrawal include autonomic signs and symptoms, such as diarrhea, piloerection, sweating, mydriasis, and mild increases in blood pressure and pulse, as well as signs of central nervous system arousal such as irritability, anxiety, and sleeplessness. The character and intensity of opioid withdrawal vary, depending on the dose
and duration of opioid administration and a variety of host factors, including previous experience with withdrawal, prior long-term administration of opioids, and the patient’s expectations regarding withdrawal.\textsuperscript{98} These negative emotional states and stress-like responses during withdrawal have been ascribed to diminished function of the dopamine reward system as well as activation of certain brain stress neurotransmitters, such as corticotropin-releasing factor (CRF) and dynorphin.\textsuperscript{99}

Craving for the medication is expected in the course of withdrawal, and pain—most often experienced as abdominal cramping, deep bone pain, or diffuse muscle aching—is common.\textsuperscript{100} Providing evidence for opioid withdrawal hyperalgesia, patients with chronic pain report intensified levels of their usual pain syndrome during withdrawal.\textsuperscript{101–103} In patients who are physically dependent on opioids, the use of short-acting opioids may result in intermittent withdrawal between doses, which may cause an increase in perceived pain.\textsuperscript{104,105}

**Opioid-Induced Hyperalgesia**

Finally, it appears that OUD brings specific hyperalgesic changes to pain systems, which can further complicate the experience and management of pain. Extensive preclinical evidence demonstrates that at the same time opioids provide potent analgesia, they paradoxically set in motion molecular processes that eventually result in OIH. OIH is defined as increased sensitivity to pain resulting from opioid administration and characterized by increase in pain sensitivity to external stimuli over time and spreading of pain to locations beyond the initial pain site. Broadly conceptualized as an opponent process, the hyperalgesia induced by opioids is theorized to counter the analgesia these drugs provide. As with tolerance and physical dependence, OIH is not diagnostic of OUD; rather, it is an outcome of ongoing opioid exposure.

OIH has been best demonstrated in animal models, wherein pain-free rodents have significantly decreased nociceptive thresholds from baseline following single or repeated administration of opioids. These preclinical studies have shown that OIH generalizes across nociceptive stimuli (thermal chemical, electrical), opioid agent (heroin, fentanyl, morphine),
and route of administration (IV, subcutaneous [SC], intrathecal [IT], intraperitoneal [IP], oral). The hyperalgesia is dose dependent (cumulative dose/cumulative exposure) and appears to resolve in a time course similar to its development, with increased magnitude of response correlated to its duration. It intensifies with antagonist precipitated withdrawal and worsens with repeated withdrawal episodes.\textsuperscript{106–110}

Links have been hypothesized to exist between the neural mechanisms responsible for the hypersensitive negative emotional states associated with OUD and OIH.\textsuperscript{47,48} For example, evidence suggests that the stress system neuroadaptations associated with SUD may overlap with substrates of emotional aspects of pain processing in the amygdala.\textsuperscript{15,111,112} Supporting these links, opioid (and alcohol) withdrawal in animal models produce increased anxiety-like responses and hyperalgesia, both of which are blocked by CRF antagonists.\textsuperscript{113,114}

Withdrawal Hyperalgesia
The phenomenon of hyperalgesia has long been recognized as a fundamental symptom of the opioid withdrawal syndrome in animal models of dependence,\textsuperscript{115–119} and although not extensively studied, hyperalgesia and spontaneous muscle and bone pain have long been considered cardinal symptoms of opioid withdrawal in humans.\textsuperscript{11,120} The time course, opioid dose–response relationship, and opioid pretreatment parameters of withdrawal hyperalgesia have been carefully characterized in preclinical models for over 30 years, such that it arises following single or chronic opioid exposure, can be detected up to 5 days following SC injection, and increases in intensity with pretreatment opioid dose or intrinsic efficacy.\textsuperscript{121,122}

Heightened pain perception has been observed in persons during opioid withdrawal.\textsuperscript{123} Individuals with OUD maintained on either methadone or buprenorphine showed increased sensitivity to CP pain.\textsuperscript{124} Indeed, Ren et al.\textsuperscript{125} found that a hyperalgesic state can persist for up to 5 months in abstinent individuals with a history of OUD, and those with more pain sensitivity also displayed greater cue-induced craving at follow-up. Thus, OUD individuals with poor pain tolerance may suffer a more severe form of SUD, have difficulty tolerating the discomfort (pain) inherent in
detoxification and early abstinence, and be more likely to relapse.

Opioid-Induced Hyperalgesia and Tolerance
The presence of hyperalgesia with ongoing opioid use provides an alternate conceptualization of analgesic tolerance. It is clear that similar systems are involved in the evolution of OIH and of opioid tolerance; however, the clinical and neurophysiologic relationships between opioid tolerance and OIH continue to be elucidated.\[16–19\] As eloquently hypothesized by Colpaert\[126,127\] and Célèrier et al.,\[128–130\] that which appears to be opioid analgesic tolerance, and therefore increased opioid need, may in fact be an organismic response to an opioid-induced hypersensitivity to pain or “apparent tolerance.” Essentially, opioids lose their analgesic effectiveness in the face of decreased tolerance for pain. That OIH might contribute to the phenomenon of analgesic tolerance in the clinical setting is a paradigm-shifting idea; analgesic tolerance may reflect underlying neuroadaptive changes that reflect the development of hyperalgesia.

In an important series of early preclinical studies exploring the molecular mechanisms of hyperalgesia, Mao and colleagues\[131–135\] demonstrated many similarities between opioid analgesic tolerance and OIH. These investigators provide credible evidence that the development of opioid analgesic tolerance via intermittent morphine dosing induces hyperalgesia, whereas animals made hyperalgesic via neuropathic injury concomitantly exhibit opioid analgesic tolerance (results replicated with heroin by Célèrier et al.\[129\]).

Mechanisms of Opioid-Induced Hyperalgesia
Various explanations for the development of OIH have been offered and include spinal, supraspinal, and cortical (learned) sites of action (Fig. 32.2).\[121,136–142\] Mao and colleagues\[131,132\] have demonstrated that the shared pathway for the development of morphine tolerance/hyperalgesia is activation of excitatory NMDA receptors on dorsal horn neurons, with subsequent intracellular increases in protein kinase C and nitric oxide. Like the hyperalgesia associated with neuropathic pain,\[132,141\] OIH is conceptualized as a variant of central sensitization and thus prevented by NMDA receptor antagonism and calcium channel blockers.\[131,143–147\] The
latter finding has spurred interest in the potential utility of NMDA receptor antagonists (i.e., ketamine) as a means to treat OIH and complements the ongoing work of addiction scientists on the utility of these agents to reverse opioid tolerance and dependence.

FIGURE 32.2 Theorized mechanisms of opioid-induced hyperalgesia. NMDA, N-methyl-D-aspartate. (Adapted from Angst MS, Clark JD. Opioid-induced hyperalgesia: a qualitative systematic review. Anesthesiology 2006;104[3]:570–587.)

Alternatively, Vanderah and colleagues provide good preclinical evidence that opioids activate descending pain facilitation systems arising in the rostral ventromedial medulla (RVM), resulting in OIH. Specifically implicated are opioid-induced increases in levels of cholecystokinin (CCK), a pronociceptive peptide, in the RVM; these increased CCK levels appear to play a role in the development of opioid analgesic tolerance as well. It is suggested that CCK activity in the medulla drives descending pain facilitatory mechanisms, resulting in spinal hyperalgesic responses to nociceptive input; notably, CCK is also involved in the opioid nocebo effect of hyperalgesia.

Various spinal neuropeptides, distinct from excitatory amino acid systems, have also been implicated in the development of OIH. Over a
decade ago, Simonnet’s laboratory showed that a single dose of parenteral heroin resulted in significant release of the antiopioid neuropeptide FF from the spinal cord in rats, an effect blocked by the subsequent administration of the opioid antagonist naloxone. This induced a hyperalgesia 30% below threshold baseline. More recent animal work in Porreca’s laboratory has demonstrated increased levels of lumbar dynorphin, a κ-opioid agonist with pronociceptive activity, following sustained spinal opioid administration. Interestingly, the hyperalgesic effects of opioids have been reversed by the administration of an antagonist to the neurokinin-1 receptor, which is the receptor mediating the nociceptive neuropeptide substance P. Particularly active in pain of inflammatory origin, substance P involvement suggests a neuroinflammatory component to the development of OIH.

A related inflammatory mechanism mediated by neuroimmune processes has been hypothesized in the development OIH. In this paradigm, peripheral immune cells activated in response to opioid administration are hypothesized to bind to astrocytes and induce specific classes of central proinflammatory (and therefore pronociceptive) cytokines, thus resulting in a state of heightened pain sensitivity. For example, within hours of heroin or morphine administration, mice demonstrate increased serum levels of interleukin (IL)-6, and splenocyte production of IL-1β, IFN-γ, IL-12, and TNF-α, effects antagonized by naltrexone. Proinflammatory consequences are suggested by parallel evidence for decreased expression of the anti-inflammatory cytokines, IL-10 and IL-4, following acute opioid exposure. Via toll-like receptors, opioids induce proinflammatory effects on spinal glial cells, which is thought to lead to increases in cytokines in the plasma. Reviewing the literature, Ossipov commented that, “opioid-induced abnormal pain may share a molecular signature with pain of inflammatory origin.”

Finally, a conditioned component to OIH was demonstrated by Siegel and colleagues more than 30 years ago. A robust hyperalgesia was observed in animals receiving saline in an environment previously paired with morphine administration. This work showed that rats receiving acute morphine doses (3 to 9 doses separated by 48 hours) in a specific
environment demonstrate significant hyperalgesia in the same setting as compared to rats receiving morphine unpaired with setting or saline control rats. Because conditioned responses to medications typically are opposite in direction to unconditioned drug effects, the learned responses were ascribed a causal role in the development of drug tolerance.

Clinical Evidence of Opioid-Induced Hyperalgesia

That hyperalgesic pain responses accompany OUD clinically is not a new idea. In an early essay describing his clinical observations on patients injecting morphine on a daily basis, physician and author Clifford Albutt asked, “Does morphia [sic] tend to encourage the very pain it pretends to relieve?” He continues, “I have much reason to suspect that a reliance upon hypodermic morphia only ended in a curious state of perpetuated pain.” As noted, descriptions of OIH have been principally established in animal models, making it difficult to extrapolate to the clinical setting. Not only is pain a much more highly modulated experience in humans than in animals, but it is not entirely clear how pain tolerance in humans (point of subjective intolerance of pain, an indicator of hyperalgesia) maps onto putative pain threshold or perception (point at which animal withdraws tail, jumps, on hotplate) in animals. Furthermore, the development of OIH has been better characterized in animals without pain or with acute pain; thus, its effect and relevance in the common condition of chronic pain remain incompletely described.

Evidence for OIH in humans has primarily been demonstrated in three distinct populations: patients with OUD on MAT (methadone, buprenorphine), patients administered opioids during the surgical period, and healthy volunteers administered opioids acutely and then evaluated with experimental pain assays. Less common, but of increased interest in the era of the prescription opioid crisis, are data to support the presence of OIH in patients with chronic pain on opioid therapy; the degree to which prescribed opioids worsen outcomes in chronic pain patients is an important area of investigation (see Fig. 32.3 for differential diagnoses of requests for increase opioid medication).
Patients on Medication-Assisted Therapy. Over 50 years ago, Martin and Inglis\textsuperscript{179} described significantly lower tolerance for CP-induced pain in a sample of incarcerated opioid-abusing women in comparison to matched nonaddicted controls. Ho and Dole\textsuperscript{180} found that both methadone-maintained (MM) and drug-free opioid-addicted individuals had significantly lower thresholds for CP pain than did matched nonaddicted sibling controls. Subsequent work supports that, prior to methadone dosing, CP pain threshold (defined as time when cold sensation becomes painful) does not differ between MM and drug-free individuals with OUD but is significantly lower for MM patients in comparison to matched normal controls.\textsuperscript{49,181,182} Under the same conditions, MM patients’ CP pain tolerance (defined as time when pain becomes subjectively intolerable) is less than that in both matched drug-free patients with OUD\textsuperscript{49} and matched controls.\textsuperscript{181–183} With respect to perceived pain severity, Schall and colleagues\textsuperscript{184} found no difference between MM and control subjects in their perception of pressure pain (measured on a scale of 1 to 10) immediately prior to methadone dosing.

Across nociceptive stimuli, methadone patients reliably demonstrate poor tolerance for experimental pain and are, on average, between 42% and 76%, less tolerant of CP pain than are normal controls matched on age, gender, and ethnicity.\textsuperscript{124,181,182,185,186} Pilot data suggest that degree of
hyperalgesia may vary with the intrinsic activity of the opioid maintenance agent, such that patients maintained on the partial agonist buprenorphine are less hyperalgesic than those maintained on methadone, a full agonist.\textsuperscript{124} Note that all these data are correlational in nature, resulting in controversy as to whether or not the diminished tolerance in pain noted in persons on MAT for OUD is in fact “opioid induced” (Table 32.2). It is possible that patients prone to OUD are pain intolerant by nature, which is therefore present while on MAT.

OUD, opioid use disorder; >, pain tolerance is greater than; <, pain tolerance is less than; =, pain tolerance is the same.

### Surgical Patients

Increasing evidence suggests that opioids administered in the intraoperative period induce postoperative hyperalgesia in patients without OUD undergoing surgery and perhaps in a dose-dependent manner. Data show that in patients undergoing various abdominal surgeries, postoperative reports of pain severity at rest and/or opioid consumption were significantly higher in those patients receiving IT or IV short-acting opioids (fentanyl and remifentanil) during surgery in comparison to those receiving placebo or low-dose opioids. The hyperalgesia is most pronounced early in the postoperative period (24 hours) and with high-dose remifentanil administration; patients receiving high-dose intraoperative opioids utilized approximately 18 mg more of morphine sulfate during the postoperative period and had larger margins of wound hyperalgesia than those in patients with lower intraoperative opioid exposure. The hyperalgesia was minimized if the cumulative intraoperative opioid dose was kept less than 40 µg/kg; if coadministered with ketamine, magnesium.
dexmedetomidine, pregabalin, propofol, nitrous oxide, and clonidine; or if tapered slowly. In that it is elicited with the abrupt offset of intraoperative remifentanil infusion suggests that rather than OIH, withdrawal hyperalgesia may be the source of increased sensitivity to pain. These findings have spurred current interest in evaluating opioid-sparing peri- and intraoperative procedures, such as preoperative administration of gabapentinoids; coadministration of nonopioid analgesics including nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, ketamine, magnesium, propofol, nitrous oxide, and clonidine; and nonpharmacologic strategies to minimize postoperative OIH. 

**Healthy Controls.** Similarly, in healthy controls, remifentanil or fentanyl administered by bolus or slow (90 to 100 minutes) infusion has been shown to increase the perceived severity of experimental heat pain and CP pain 2 hours following administration and wound (electric burn or topical capsaicin) hyperalgesia from 30 minutes to 7 hours following administration. Again, in these instances, hyperalgesia was evaluated following offset of acute opioid effect; thus, it is unclear if withdrawal hyperalgesia accounted for the findings. In fact, healthy controls receiving a single dose of parenteral morphine or hydromorphone evidenced significant hyperalgesia following an acute naloxone challenge.

**Patients with Chronic Pain.** Reports of OIH in patients with chronic pain are much less common and are primarily limited to individuals with malignant pain. Across a number of case studies, the emergence of hyperalgesia and allodynia has been reported in cancer patients on large or rapidly escalating doses of morphine or fentanyl, in at least one case resolving with discontinuation and switching to a weaker opioid. A similar pattern of OIH induced with IT sufentanil and clearing with opioid discontinuation has been described in a single case report of a woman with chronic nonmalignant low back pain (failed back syndrome), suggesting that regardless of the etiology of chronic pain (malignant vs. nonmalignant), OIH becomes evident in certain individuals in the context of high-dose opioid therapy. OIH in these patients often presents with constellation of neuroexcitatory signs, including agitation, myoclonus, and delirium.
In the case of chronic pain, few prospective studies exist. In this work, comparators typically include patients receiving low-dose opioids or placebo. As opioid dose increases (>100 mg morphine equivalent dose [MED]), hyperalgesia worsens, and “high-grade” tolerance is more likely to co-occur with OIH. There appears to be a negative correlation between OIH and opioid-derived analgesia, and OIH is more robust in the presence of neuropathic, as opposed to nociceptive pain. Unknown is the degree to which the presence of chronic pain accounts for baseline hyperalgesia, which is reflected in OIH responses. Interestingly, those chronic pain patients screened at higher risk for OUD were also more likely to report increased pain sensitivity to punctuate mechanical stimuli, regardless of whether they were receiving no opioids or low- or high-dose opioids, suggesting that hyperalgesia may be less related to opioid prescription and more related to propensity for SUD.

A single study by Chu and colleagues demonstrated the development of OIH in a small sample of patients with chronic nonmalignant low back pain following 1 month of oral sustained-release morphine treatment (median dose 75 mg per day). In these six individuals, 30 days of morphine at therapeutic doses not only resulted in analgesic tolerance to challenge doses of remifentanil but also diminished tolerance to CP pain by almost 25% from baseline. Similarly, Suzan and colleagues found that tolerance to heat pain diminished significantly following 4 weeks of oral hydromorphone therapy in patients with chronic pain, a finding that was not duplicated in matched healthy controls. In a sample of cancer patients with pain undergoing a standardized lidocaine injection, self-reported ratings of pain and unpleasantness as well as pain behaviors associated with the procedure increased by daily MED opioid dose. When evaluating chronic pain patients on methadone for the treatment of OUD, Hay and colleagues report diminished pain tolerance on the CP assay in both those with and without chronic pain. Most recently, a trend for increased pain severity in veterans with chronic pain assigned to receive opioid versus nonopioid therapy was reported. Despite appreciating analgesia, the experimental and clinical pain responses of these patients suggest the presence of opioid-induced hyperalgesic changes.
Several structured evidence-based reviews conclude that there is insufficient evidence to determine whether clinically significant OIH occurs in the context of long-term opioid use in clinical settings. Observational studies have long indicated that some individuals with pain who use opioids on a long-term basis experience improvement in pain after tapering or simple withdrawal of opioids, including patients in both pain treatment and addiction treatment settings. A 2017 systematic review of patient outcomes in dose reduction or discontinuation of long-term opioid therapy suggests that pain, function, and quality of life may improve with opioid dose reduction, but the degree to which these improvements can be attributed to decreased OIH is unknown.

Complicating isolating of the role of OIH in the maintenance of chronic pain is the understanding that there are many factors that may result in hyperalgesia and sensitization, including the long-term presence of pain itself and physiologic and psychological stressors such as sleep deprivation, possibly mediated by aberrant glial activation. In fact, some chronic pain disorders are understood as central sensitization syndromes, with hyperalgesia a typical or defining feature of these conditions (e.g., fibromyalgia).

Genetics and Opioid-Induced Hyperalgesia
Interestingly, genetic differences in opioid response appear to predict the propensity of the individual to develop OIH. In a series of preclinical studies, Kest and colleagues reported murine strain differences in the development of opioid tolerance and withdrawal severity, both of which have been ascribed a role in the presentation of OIH. Liang et al. evaluated 16 different strains of inbred mice for the development of thermal hyperalgesia following 4 days of morphine pretreatment and found significant variation among strains. Reduction percentage in nociceptive thresholds ranged from 4% (LP/J strain) to 36% (AJR/J strain) in these experiments, and interestingly, a strain found to be relatively pain intolerant (C57BL/6J) in previous work also developed a notable degree of hyperalgesia (24%) following chronic morphine administration.

In a related study, this investigative group evaluated the effects of chronic inflammatory pain on thermal pain perception and opioid
responses across strains of mice. Despite considerable variation, chronic pain induced thermal hyperalgesia and increased sensitivity to morphine analgesia across animals tested. Furthermore, following 4 days of opioid administration, those both with and without pain demonstrated dependence and tolerance, albeit with significant strain variation. Suggesting a shared mechanism for OIH, opioid tolerance, and physical dependence, haplotypic genetic analyses revealed that differential expression of a gene coding for the nonspecific P-glycoprotein transporter (Abcb1b gene) best accounted for strain-related differences in the development of thermal hyperalgesia following morphine administration. Activity of this glycoprotein, which is a transporter for morphine, appears to play an important role in opioid response across domains.

Ongoing work provides evidence that OIH may arise from the epigenetic modifications associated with opioid tolerance. For example, He and Wang suggest that microRNA activity regulates the expression of µ-opioid receptors, thereby interfering with both opioid analgesic and reward activity. Furthermore, to the degree that histone modification underlies the development of neuropathic pain, these mechanisms are likewise implicated in the initiation and maintenance of opioid tolerance and OIH. Human studies of patients taking opioids for the treatment of OUD or chronic pain suggest that opioid-induced DNA methylation is related to increased chronic pain severity, which at the level of the patient is expressed as OIH.

**Pain Management in Persons with Substance Use Disorder**

Consideration of the physiologic bases of pain and SUD, and how they overlap, provides direction for the management of pain in this population. Clearly, the human experiences of pain and SUD are not separate but interrelated; knowledgeable management of the former must reflect the extent to which, even at the physiologic level, its expression and response are affected by the latter.

Patients with SUD may present for pain management in different phases or states of the disorder; for example, they may be actively using drugs of
abuse and not engaged in treatment; they may be in MAT taking an opioid agonist (methadone), partial agonist (buprenorphine), or antagonist (naltrexone) for the treatment of the disorder; or they may be in drug-free recovery with variable engagement in SUD treatment. The pain requiring management may be of acute, perioperative, cancer, or nonmalignant chronic origin. Each of these different situations requires slightly different pharmacologic and nonpharmacologic approaches to provide relief; however, the overall guiding principles remain the same. These include effective treatment of pain; avoiding potential withdrawal; utilization of opioid-sparing approaches; reinforcement or introduction of SUD treatment, including relapse prevention strategies; careful documentation of treatment plan; and active involvement of the patient and family in the plan of care.

PREVALENCE OF SUBSTANCE USE DISORDERS IN PATIENTS WITH PAIN

In light of the well-publicized links between opioids prescribed for chronic pain and the current opioid crisis, the true prevalence of SUD in patients with pain has received increased scrutiny. As noted earlier, current estimates indicate that the population prevalence of SUD is approximately 8%,\(^1\) suggesting that 1 in every 12 patients encountered suffers from active disease. However, these data do not reflect the patients whose disease is in good control or remission, but at constant risk for relapse, especially in the face of the stressors associated with pain (loss of work and family roles, social isolation, depression). Furthermore, related to the toxic effects of abused substances on body tissues, the risky behaviors in which sufferers may engage, and the high rates of comorbid psychiatric disease, persons with SUD are highly likely to present to medical settings and therefore requiring pain care. Although one cannot state with certainty how many patients with pain have a history of SUD, these factors suggest that it should be assessed in all patients presenting with a need for pain management.

Most evaluations of SUD in pain patients have focused on those with chronic nonmalignant pain (CNMP) receiving opioid therapy. Early studies in the 1900s led to a perception that iatrogenic addiction through
the medical use of opioids was a very frequent occurrence,\textsuperscript{234,235} whereas a number of retrospective surveys in the 1980s of never-addicted medical patients suggested that the development OUD in the course of long-term opioid therapy for pain was negligible,\textsuperscript{236,237} leading to an underappreciation of the risks and overprescribing of opioids. Albeit not evidence based, recent guidelines regarding long-term opioid therapy for chronic pain are based on the assumption that any exposure to opioid medication for pain may increase the risk of developing OUD,\textsuperscript{92,93} which is an oversimplification of the complexity of pain and SUD.

Studies on the incidence and prevalence of SUD in the context of chronic pain treatment have generally examined a wide variety of “aberrant behaviors” rather than specifically assessing for SUD. In addition, many studies that assess opioid use and misuse in pain populations excluded the highest risk group, those with a prior history of SUD, or were sampled from pain clinics which tend to have a disproportion of patients engaging in aberrant drug-related behaviors (ADR). A 2008 structured clinical review sought to estimate the risk of development of a clinically significant SUD in the course of long-term opioid therapy of pain and to distinguish these from misuse or ADRs.\textsuperscript{238} The review identified 67 scientifically acceptable studies of opioid use and misuse and divided them into those that excluded persons with history of SUD and those that identified “aberrant behaviors” versus those in which clinicians more formally identified Diagnostic and Statistical Manual of Mental Disorders (4th ed.; DSM-IV)–defined SUD. The review found that across these studies, in patients with no history of SUD, the risk of de novo opioid SUD was 0.19% and the risk of ADRBs was 0.59%. In studies that included persons with a history of SUD, the risk of OUD was 3.27%, whereas the risk of ADRBs was 11.9%. The review also examined five studies that included urine drug screening and found that up to 20% of samples had unexpected findings, suggesting that actual rates of ADRBs and SUD may be higher than suggested based on behavioral observation and clinical assessment and supporting the value of urine drug screening in identifying misuse or addiction in the context of opioid therapy.

More recently, Boscarino and colleagues\textsuperscript{57} assessed patients with CNMP receiving long-term opioid therapy within a large US health care
system for diagnosis of OUD using the DSM (5th ed.; DSM-5) criteria. In their population, the lifetime prevalence of OUD by DSM-5 was 41.3%, with 28.1% for mild symptoms, 9.7% for moderate symptoms, and 3.5% for severe symptoms. Campbell et al.\textsuperscript{239} examined the prevalence of OUD in patients on opioid therapy for CNMP according to International Classification of Diseases, 11th revision (ICD-11), DSM-5, and the pain medicine concept of “addiction” (defined as behavior including one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and cravings).\textsuperscript{240} Past 12-month prevalence was 19% for ICD-11, 18% for DSM-5, and 24% for “addiction,” with “substantial” concordance between “addiction” and both DSM-5 use disorder and ICD-11 dependence, noting that the definition of “addiction” captures a larger group of patients than other classification systems and includes people with fewer “risk” behaviors.\textsuperscript{239} One could also argue that the criteria for establishing a diagnosis of OUD in both the DSM-IV and DSM-5 are not completely applicable to patients receiving long-term opioid therapy. Well-conducted meta-analyses of the literature support that estimates of SUD in the chronic pain populations hover at 8% to 10%,\textsuperscript{97} not unlike the past year rates of SUD in the US population in general (7.8%),\textsuperscript{1} suggesting that the same factors that put an individual at risk for developing SUD (family history, psychiatric comorbidity, early onset of use) are also involved in the development of the same in persons with chronic pain and receiving opioid therapy.\textsuperscript{8,241,242}

Conversely, the prevalence of pain among persons with SUDs may be significantly higher than that of the general population, with studies suggesting that up to 50% to 60% of patients on MAT report chronic pain, in which 25% to 35% of cases, the pain is rated as severe.\textsuperscript{243,244} Higher severity of chronic pain in patients with SUD is associated with more chronic illness; poorer psychosocial, physical, and social functioning; and high rates of mental illness (primarily major depression).\textsuperscript{245–251} The presence of chronic pain portends poorer OUD treatment outcomes, such that patients with pain are more likely to engage in continued polydrug use, require higher doses of methadone, experience higher ratings of opioid craving, and are more likely to relapse to opioid use.\textsuperscript{252–254} Persons with alcohol and other SUDs are vulnerable to traumatic injury,\textsuperscript{255} which
may contribute to a relatively higher prevalence of chronic pain in persons with SUD.\textsuperscript{256}

**PRINCIPLES OF PAIN TREATMENT IN PATIENTS WITH SUBSTANCE USE DISORDERS**

Principles of care for the patient with pain and a history of SUD include the provision of thoughtful and effective pain treatment, including the accommodation of opioid tolerance and avoidance of withdrawal when present and an emphasis on opioid-sparing approaches. In addition, directly addressing the presence or history of SUD is necessary to optimize pain outcomes. Finally, critical to effective pain management in this population is the development of a clearly documented pain treatment plan, including the involvement of the patient, family, and addiction treatment providers as possible.

**Provide Effective Pain Relief**

For acute, perioperative, and chronic pain, treatment approaches are increasingly utilizing effective multimodal nonopioid- or opioid-sparing regimens, which should be heavily relied on to provide pain relief for those with SUD. In general, these include utilization of nonpharmacologic interventions including heat, cold, massage, bracing and stretching, and behavioral interventions such as distraction, graded exercise, cognitive-behavioral therapy (CBT), and relaxation or mindfulness-based meditation. Nonopioid pharmacotherapies focus on around-the-clock use of acetaminophen or NSAIDs, with more specific medication adjuvants utilized for specific pain indications (described in the following discussion). In some cases, regional procedures with lidocaine or steroid injections can be an important component of the pain management plan. Increasingly, peripheral nerve blockade and regional anesthesia are temporarily continued during the initial phase of the postoperative period to reduce the need for systemic analgesia.\textsuperscript{257,258}

It is important that patients with SUD who are experiencing pain receive adequate pain control in an effective and timely manner. Without adequate pain control, development of a therapeutic alliance is thwarted, and it is unlikely that the patient will be motivated or able to effectively engage in
SUD or pain treatment. In addition, undertreated pain may create craving for pain-relieving medications as well as anxiety, frustration, anger, and other negative affect states that worsen pain and fuel drug seeking. Persons with a history of SUD have valid concerns that their reports of pain will not be believed; therefore, reassurance and actions to indicate otherwise are especially important with this patient population.

Acute Pain
As described in the following discussion, an acute painful event can provide a golden opportunity for motivational interviewing toward change. Hospitalization for a traumatic event or surgery can provide the patient respite from the drug-using lifestyle and an opportunity to connect with supportive others. Referral to treatment can be provided prior to discharge, and in some acute care settings, patients can be introduced to addiction specialists and interventions while hospitalized. For patients on MAT or in drug-free recovery, aggressive management of acute pain is likewise important to support treatment efforts and gains. Underscoring this need, acute pain exposure has been negatively correlated to SUD treatment retention related in part to insufficient pain relief. Key strategies for managing acute pain in patients with SUD are outlined in Table 32.3.

BID, two times a day; NSAIDs, nonsteroidal anti-inflammatory drugs; PCA, patient-controlled analgesia; TID, three times a day.

Patients using opioids (prescribed or illicit) or on opioid agonist (methadone) or partial agonist (buprenorphine) MAT present with opioid tolerance and hyperalgesia, thus will require higher doses of opioids to provide anesthesia and analgesia than the opioid-naive patient. In that opioid withdrawal is likely to aggravate hyperalgesia, these patients must have their baseline opioid requirements met to avoid the emergence of withdrawal. For those abusing prescribed or illicit opioids, the average baseline daily dose of opioid therapy should be determined or estimated and either the same drug provided at that dose or an alternative opioid provided at a lower than calculated equianalgesic dose. It is permissible under the US Controlled Substances Act to provide opioids to prevent withdrawal in a patient who is hospitalized for a diagnosis other than SUD. For example, if a patient with heroin use disorder is hospitalized for subacute bacterial endocarditis, the treating physician can legally provide opioid medications, including methadone, to prevent...
withdrawal, as well as additional medications for pain. Although opioids for pain treatment can be continued after discharge, opioids cannot be provided for treatment of SUD after discharge, except from a federally licensed methadone maintenance treatment program or from a federally certified/waivered buprenorphine provider.261

Not uncommonly, the patient with SUD will be abusing more than one substance. A patient physically dependent on alcohol or sedative-hypnotic medications (either from long-term medically appropriate prescribing or alternatively from SUD) should have withdrawal symptoms treated when they occur in the course of pain treatment. Unrecognized alcohol or sedative-hypnotic withdrawal will make pain control difficult to achieve, and physical signs of withdrawal (such as hypertension and tachycardia) may be misinterpreted as reflecting acute pain. The short-term use of a long-acting benzodiazepine may be used for treatment of withdrawal symptoms; however, the combination of benzodiazepines with opioid medication greatly increases the risk of respiratory depression and fatal overdose, and the concurrent prescription should be avoided whenever possible.92,93

For patients with SUD, multimodal opioid-sparing techniques should be emphasized. In addition to acetaminophen or NSAIDs, ketamine administered in a low dose as a continuous IV or SC infusion has been demonstrated to treat acute pain for the hospitalized patient on MAT. Recommended dosing regimens include a starting dose of 100 to 200 mg over 24 hours, using a mixture of 200 mg ketamine and 5 mg midazolam made up to a total volume of 48 mL with normal saline and a rate of infusion of 1 to 2 ml per hour or 0.1 mg/kg/hour.94,262 A regional anesthetic blockade should be implemented where possible.263

If opioids are required, immediate-release (IR) opioids can be utilized, titrated to analgesic effect and ideally administered via patient-controlled analgesia (PCA) to enable self-titration and minimize perceived drug-seeking behaviors or cues.264 When used in addition to MAT (methadone, buprenorphine), it is important to remain vigilant for signs of toxicity with naloxone readily available should these emerge. Supplementation with a different opioid for acute pain has been recommended, as the use of the same medication for SUD and for acute pain management may confuse the
issues of pain treatment and SUD treatment when the acute pain resolves, and it is time to taper the analgesic. If managed appropriately (see the following discussion), there is no evidence that opioids provided for acute pain exacerbate or worsen OUD outcomes, and as noted earlier, there is concern that untreated pain may precipitate relapse.

For those on opioid MAT (methadone or buprenorphine), it is important that the maintenance MAT dose be continued during pain treatment, which should be verified with the MAT provider; the state prescription drug monitoring program (PDMP) should also be consulted to determine if other opioids are being consumed. If the methadone dose cannot be confirmed, it is safest initially to give the patients reported dose in three or four divided doses of no greater than 30 mg total per day, so that doses can be modified according to patient response. Although both methadone and buprenorphine have intrinsic analgesic properties, the daily dosing regimen for OUD only treats the symptoms of withdrawal and craving, thus cannot be considered as providing any measurable pain relief. Patients on methadone should be continued on methadone rather than being switched to an alternative opioid; there is incomplete cross-tolerance of methadone with other µ-agonists, and methadone withdrawal has been observed in some patients despite calculated equianalgesic doses of alternative µ-agonists. In recognition of the significant risk of relapse in patients with OUD, in experienced hands, titration of methadone for acute pain can be effective, and dosage splitting to BID or TID dosing or an additional lower dose later in the day may be used as a strategy to provide analgesia around the clock.265,266

Strategies for managing acute pain in individuals with prescribed buprenorphine are emerging as experience accumulates. Buprenorphine binds tightly to the opioid receptor and thus tends to block the action of other opioids; thus, it is sometimes challenging to obtain analgesia by adding another opioid.267 µ-Opioids can usually be titrated to higher doses to overcome the buprenorphine blockade; use of IV fentanyl or IV or oral hydromorphone, which bind with relatively high affinity to µ-opioid receptors, is often recommended, although morphine and others have been used effectively.268 Opioid titration in this setting should be done by an experienced clinician with close monitoring of the patient with naloxone.
available. When acute pain can be predicted in persons on buprenorphine, such as after elective surgery, some experts suggest discontinuing buprenorphine a few days prior to surgery.\textsuperscript{269–271} However, other experts note the challenges of reinducing patients on buprenorphine once acute pain has resolved and report good results with continuation of buprenorphine and titration of an alternative opioid to achieve analgesia in the same manner as for unanticipated acute pain.\textsuperscript{272} Early recommendations that patients on buprenorphine be rotated to methadone or other full agonists (fentanyl or morphine) to enable more predictable IR opioid-analgesic response appear unnecessary and may expose the patient to greater risk of withdrawal or relapse than continuing the usual buprenorphine dose. Alternatively, a patient on a low-dose buprenorphine (2 to 8 mg per day) may receive acceptable analgesia from a temporarily increased daily dose administrated BID to achieve around-the-clock analgesia. Because of its partial agonist properties and its near full receptor occupancy at relatively low doses, buprenorphine has traditionally been thought to have a ceiling effect for analgesia\textsuperscript{94}; however, this view has been challenged by recent studies and observations.\textsuperscript{273,274}

Patients on naltrexone MAT present a particular challenge if opioid analgesia is required. There have been no clinical studies to guide opioid dosing or efficacy. It can be expected that patients will receive little to no opioid analgesia while opioid receptors are fully occupied; however, as the naltrexone formulation approaches half-life, case studies suggest that pain relief can be appreciated, and patients may even be supersensitive to opioid effects related to receptor resetting with antagonist treatment.\textsuperscript{262} It has been demonstrated that the competitive blockade of naltrexone can be overcome with opioid agonists, but the required doses are on the order of 10 to 20 times the usual doses by weight.\textsuperscript{94} This becomes particularly hazardous as naltrexone dissociates from the opioid receptor and subsequent receptor supersensitivity puts the patient at risk for opioid toxicity. Close monitoring and availability of naloxone become paramount when opioids are provided to those receiving naltrexone MAT. If IR opioid administration cannot override the receptor blockade, in cases of severe pain, patients on naltrexone therapy may require general or regional anesthesia.
For patients who were in drug-free recovery prior to the acute pain experience, it is critical that opioids provided for pain are tapered cautiously with close observation prior to discharge; nonopioid analgesics and strategies should be used early on and continued as clinically indicated after discontinuation of opioid analgesics. The emergence of withdrawal symptoms can precipitate relapse; thus, these should be assessed and managed aggressively. If the opioid taper is anticipated to continue after discharge, dosing should be highly structured on a scheduled basis with supervised dispensing of medication or issuing in short-term intervals. In addition, links to recovery resources, such as a sponsor or counselor, should be initiated to help the patient remain abstinent following discharge. It is important to note that tapering and discontinuation of opioids used for pain can be legally supervised by any clinician with a Drug Enforcement Administration (DEA) license; however, detoxification from opioids as a component of addiction treatment can only be done by a waivered buprenorphine provider or federally licensed methadone maintenance treatment center.

Perioperative Pain
Related to the general health consequences associated with addiction behaviors, patients with SUD are likely to suffer acute painful conditions (i.e., dental, infections, trauma), which may require surgical intervention. In that opioids have been a mainstay in the perioperative setting, utilized both intraoperatively and postoperatively to manage pain, providing pain care for patients with SUD undergoing surgical procedures requires mention. Although no specific practice guidelines exist to address surgical pain-relief interventions in this population, the general principles outlined earlier can be implemented.

**Preoperative Management.** Preoperative substance use assessment is critical to effective anesthesia and postoperative analgesia. Types and amounts of substances abused should be evaluated. If the patient is on MAT, the dose should be verified with the provider and the PDMP consulted. It is also important to determine if the patient is regularly using benzodiazepines or alcohol to avoid/manage associated withdrawal syndromes. The patient and family should be included in the management
plan (admission to discharge) as well as other health care professionals (i.e., pain medicine, psychiatry, nursing, social work).  

If the patient on MAT will be NPO for greater than 24 hours postsurgery, plans to convert the patient from oral methadone or buprenorphine to IV equivalent should be instituted. Methadone can be administered parenterally; doses of half to two-thirds of the total daily oral dose can be given in three to four divided doses by intermittent intramuscular or SC injection or by continuous infusion. Some clinicians opt to convert to morphine or another full agonist first, and when performing an opioid rotation, it is recommended to reduce the calculated equianalgesic dose by 30% to 50% due to the possibility of incomplete cross-tolerance. Although it has been suggested that patients on buprenorphine be rotated to methadone prior to surgery, there is no evidence that this improves pain management as opposed to keeping on their usual MAT. Others recommend that patients on higher dose buprenorphine maintenance (i.e., 16 mg to 32 mg per day) be titrated down to 12 mg per day prior to surgery to minimize potential dose-dependent opioid antagonism effects. If possible, it is recommended that oral naltrexone be discontinued 72 hours prior to surgery so that opioids can be utilized if necessary; however, this becomes impractical for patients on naltrexone XR or with unplanned procedures. In these cases, nonopioid approaches that should be utilized in all patients become essential.

**Intraoperative Management.** As noted, baseline opioid, alcohol, or benzodiazepine requirements should be met, and if on methadone or buprenorphine, the usual prescribed MAT dose be taken on the day of surgery using a take-home dose provided by the MAT provider. Effective multimodal opioid-sparing anesthetic techniques, which differ across surgical procedures, are highly recommended and may include preemptive administration of acetaminophen, celecoxib, or pregabalin; preloading the incision sites with local anesthetic before incision; and placement of an epidural catheter for intraoperative and postoperative use. Local and regional analgesia techniques are preferred when suitable. If opioids are used, higher opioid requirements can be anticipated due to tolerance and hyperalgesia; in spontaneously breathing patients,
maintaining a respiratory rate of 12 to 14 can be used as a guide.\textsuperscript{95} Instillation of long-acting lidocaine in the surgical wound prior to closure has been shown to significantly decrease pain and opioid requirement for several days following surgery. Local anesthetic techniques include wound infiltration or regional or neuroaxial block; local anesthetic catheters can prolong the benefits of regional anesthesia into the postoperative period.\textsuperscript{278}

**Postoperative Management.** Postoperative pain management should proceed for acute pain as outlined above, with the goals of providing effective analgesia while maintaining opioid coverage as needed and relying on multimodal, opioid-sparing approaches as possible. Nonopioid analgesics, including around-the-clock NSAIDs, acetaminophen, and selective cyclooxygenase-2 (COX-2) inhibitors, as well as ketorolac administration,\textsuperscript{263,276} can be utilized; these are available in parenteral and other forms of administration and associated with a reduction in postoperative opioid use and improved analgesia. Less well-tested agents include clonidine and dexmedetomidine, which elicit analgesia by agonism of the $\alpha$-adrenergic receptor, and gabapentin and pregabalin, which inhibit pain transmission via binding to the $\alpha_2\delta$-1 subunit of voltage-gated calcium channels.\textsuperscript{280} Regional blockade with local anesthetics can be useful in the early postoperative period because it theoretically removes the need for additional systemic analgesia; although neuroaxial opioids allow for lower doses of opioid exposure, these may not prevent opioid withdrawal, and additional systemic opioids are often required\textsuperscript{257}; furthermore, it may be difficult to estimate an appropriate or safe dose.

When regional analgesia is not applicable and/or IR opioids are indicated, an IV PCA administration system is highly recommended because it allows for individual dose titration and reduces workload for staff. Related to opioid tolerance and hyperalgesia, doses that are higher than those usually prescribed may be needed (including higher PCA bolus dose) for those on physically dependent on opioids. Similarly, it can be anticipated that their pain scores will be higher and decrease more slowly and that review and adjustment of dosing will be required more frequently. Several studies indicate that after a variety of surgical procedures, first 24-hour PCA morphine requirements were, on average, three times greater in
the opioid-tolerant than opioid-naive patients. Determining the appropriate setting of bolus size and lockout interval may be challenging; one recommended method is to begin with the patient’s usual 24-hour opioid requirement and base the size of the bolus dose at 50% of the hourly background infusion rate with a 5-minute lockout. Concerns that IR opioid provision may result in respiratory depression in patients with OUD are not supported by clinical experience, likely related to the development of cross-tolerance; however, evidence of opioid toxicity should be carefully monitored for and naloxone made readily available.

As postoperative pain subsides, it is important to bring the patient on methadone or buprenorphine therapy back to the usual MAT dose as soon as possible. Similarly, for those who were in drug-free recovery prior to the surgical experience, a gradual taper of opioids with recovery supports initiated or strengthened is critical to the maintenance of abstinence.275

Progressive Cancer-Related or Terminal Pain
Early studies reported low rates (5%) of SUD in oncology patients,281–283 whereas more recent examination of Medicare data found that the prevalence of SUD in men with advanced prostate cancer to be 10.6%,284 and another review found an OUD prevalence rate of 7.7% in patients with cancer pain of all types.285 Increased rates of oncologic disease in patients with AUD are suspected due to the known injurious effects of abused substances on cells and body tissues. Inflammatory or other repair responses to cellular injury can result in DNA mutations that play a role in inducing neoplastic changes. A chart review of 598 patients with advanced cancers found that 17% were positive for DSM-IV (text revised; DSM-VI-TR)–defined AUD on the cut down, annoyed, guilty and eye-opener (CAGE) screening tool, and only 13% were identified as with the same diagnosis before their palliative care consultation.286 They were also more likely to be taking potent opioids at the time of referral than patients who screened negative for SUD. Although not diagnostic, 39% to 43% of cancer patients on opioids scored as medium to high risk for DSM-IV–defined opioid abuse on standard opioid abuse screening tools.

Treatment of advanced cancer-related pain in the patient with addictive disease is usually similar to that in the person without addictive disease;
the comfort of the patient should be the primary goal. Opioids generally should not be withheld in patients with terminal illness when they are needed and effective because of concerns regarding addiction. However, if SUD-related problems are diminishing the patient’s quality of life, it can be necessary to maximize external controls (e.g., having medications dispensed daily by others) and to insist on concomitant SUD recovery work or to rely on nonopioid treatments.\textsuperscript{287,288}

Cancer may be accompanied by significant distress arising from fear, grief over impending losses, depression, anger, and spiritual conflict, which patients may try to self-medicate with opioids. However, in the case of the patient with SUD, such use causes further declines in function and quality of life. Directed, evidence-based nonpharmacologic and pharmacologic means of addressing such stressors should be employed. For many individuals in SUD recovery, appropriate resources may provide meaningful support. Therefore, it is helpful for the clinician to assess the patient’s experience with recovery and to help sustain participation in or reengaging with recovery groups, sponsors, and programs if these have been meaningful to the individual in the past.\textsuperscript{5}

Chronic Nonmalignant Pain
As promulgated by the recent Centers for Disease Control and Prevention (CDC) guideline for prescribing opioids for chronic pain\textsuperscript{92} and U.S. Department of Veterans Affairs/U.S. Department of Defense (VA/DoD) guidelines for opioid therapy in patients with chronic pain\textsuperscript{93} and for low back pain,\textsuperscript{289} it is increasingly appreciated that opioids are not first-line therapy for the management of CNMP, and that in some cases, functionality improves when opioids are tapered. The VA/DoD opioid guideline provides a strong recommendation against initiation of long-term opioid therapy; if opioids are prescribed for patients with CNMP, a short duration is recommended.\textsuperscript{93} This is particularly pertinent in the case of patients with a history of SUD. Conceptualized as a chronic illness for which complete remission is not expected, nonpharmacologic approaches become central to the treatment of CNMP and include evidence-based interventions such as acupuncture, physical therapy, transcutaneous electrical nerve stimulation (TENS), graded exercise, weight loss,
cognitive-behavioral/acceptance therapy, mindfulness mediation, and yoga. Nonopioid pharmacotherapies with demonstrated efficacy are the NSAIDs and acetaminophen; the anticonvulsants gabapentin and pregabalin; and the SNRIs, duloxetine and venlafaxine. Certain tricyclic antidepressants have also been recommended but are typically less useful due to associated adverse side effects. These same strategies are indicated for chronic pain patients with SUD; in fact, several of these (acupuncture, CBT, mindful meditation, antidepressants) are likely to provide support for recovery efforts.

However, there is a subpopulation of patients with chronic pain whose functionality and quality of life improve with opioid therapy, at least temporarily, which may include patients on MAT and in stable recovery (patients with active SUD are never candidates for opioid therapy as controlled use and functional improvements will not be realized). Although there is scant data supporting the efficacy of high-dose opioids in patients with CNMP, there is evidence that low-dose opioids in well-selected patients can be beneficial. In veterans with chronic pain assigned to receive opioid versus nonopioid therapy over 1 year, there was no therapeutic advantage of opioids over those receiving NSAIDs or acetaminophen, although the opioid group reported a higher side effect burden. In general, it is now believed that long-term opioid therapy likely carries greater risks than benefits in most patients and risks increase with duration and dosage, which may be particularly high in patients with SUD. Risk mitigation strategies utilized for all patients with CNMP on opioid therapy, including the use of treatment agreements and/or written informed consents, random urine toxicology, and monitoring of PDMPs, should be implemented. Because patients with a history of SUD are at high risk for relapse, opioid provision to these patients requires expansion of the chronic pain treatment plan to include the integration of relapse prevention strategies, frequent assessment for evidence of misuse, and the expectation that they maintain good standing and engagement in addiction treatment. Due to ongoing opioid blockade, opioid provision is not an option for patients on naltrexone MAT.

Because the risk of opioid misuse for a given patient cannot be absolutely determined, it is prudent to view all patients who consume
opioids as having some level of risk and to employ a set of universal precautions (Table 32.4).\textsuperscript{92,93,292–294} With respect to assessment of risk for opioid misuse, it is important to be aware that no screening tools have been specifically validated for use in populations with identified SUDs. Although not a screen for risk per se, the Addiction Behaviors Checklist (ABC)\textsuperscript{295} or Prescription Drug Use Questionnaire (PDUQ)\textsuperscript{296} can be used to track behaviors of concern between clinic visits. Another promising tool to detect opioid misuse is the Current Opioid Misuse Measure (COMM), which has demonstrated 77% specificity and 77% sensitivity in identifying current prescription OUD in a primary care setting.\textsuperscript{297} These tools assess risk of ADRB which is not necessarily a surrogate for SUD but can also reflect undertreatment of pain or self-treatment of concomitant mood, anxiety, or sleep disorders. Due to the limitations associated with the predictive and concurrent validity associated with these screeners, composite indices have also been described combining scores from tools with urine toxicology results. For example, Jamison and colleagues created the Aberrant Drug Behavior Index (ADBI) and the Drug Misuse Index (DMI) which combine PDUQ or ABC scores with urine toxicology to predict relative risk.\textsuperscript{298} With respect to naloxone provision to persons using opioids for analgesia, a small survey study of veterans on opioids for chronic pain indicated that they underestimated their risk for opioid overdose.\textsuperscript{299} Importantly, 21% reported having previously experienced an opioid overdose, and most desired a naloxone rescue kit to enhance their safety.\textsuperscript{300}

Making opioids available in quantities that relieve pain, while not inviting misuse, may be a key factor in successful opioid therapy for pain in persons with SUD. The number of units of opioid medications available to the patient and the frequency with which they are dispensed are two variables that can be controlled. In persons with SUD, it is prudent to dispense smaller quantities more frequently, sometimes weekly, or even daily. Frequent dispensing of small doses can also preserve safety by ensuring that the patient does not have a potentially lethal supply of medications available. For patients at risk for OUD, transdermal buprenorphine for pain, which requires only weekly changes and may pose less risk of respiratory suppression if misused, may be a good option that allows close monitoring, even weekly dispensing of single patches. Also, oral buprenorphine with or without naloxone is effective in patients not currently using opioids in controlling acute pain\textsuperscript{301,302} and thus may be advantageous to full µ-agonists in patients with history or at risk of OUD. Keeping the total dose dispensed sublethal may be an important strategy in some patients, but no method fully protects a patient who is at risk for major overuse. Frequent dispensing can be done by a pharmacy, a clinician’s office, or a trusted other such as a family member, although care must be taken that this does not interfere with personal relationships that sustain the social support system needed by patients.

Several recent studies have suggested that, with the addition of structure and active programs to address substance misuse, opioid analgesia can be brought under control in some patients who demonstrate ADRBs and substance misuse. A US VA study utilized consultations with clinical pharmacists, signing of second-chance agreements, and simple limit-setting interventions (e.g., more frequent visits, limited supplies of opioids, urine toxicology screening) in patients manifesting ADRBs. Of those referred for this consultation, 45% were able to remain in pain management and had their behavior come under reasonable control, whereas about 38% self-discharged, indicating the likelihood of SUD among other issues (see Fig 32.3).\textsuperscript{303} Another study of persons with active substance misuse and pain demonstrated that intensive psychological
interventions, including adherence monitoring, motivational techniques, and cognitive-behavioral techniques added to a methadone-based pain management program led to a diminution in use of nonprescribed opioids and trends toward decreases in nonopioid drug use. And a third study of patients with chronic pain and opioid misuse behaviors found that the addition of substance and motivational counseling, compliance checklists, and regular toxicology screening to standard care reduced the prevalence of drug misuse among high-risk, drug-misusing patients to that of low-risk patients receiving standard care.

Reinforce or Introduce Substance Use Disorder Treatment

An open and nonjudgmental approach to the discussion of substance use concerns facilitates information exchange with patients; often, health professionals discuss concerns about a patient’s substance use among themselves, without bringing the patient into the discussion. When SUD is understood as a medical disorder, it becomes easier to address it in the same manner as any other medical condition, with respectful and nonjudgmental, but matter-of-fact, concern. Patients with SUD often justifiably fear that awareness of their problem will negatively affect the manner in which their providers approach their care. Therefore, they may not be immediately forthcoming about their problematic use. As noted earlier, it is important to allay the anxiety by reassuring the patient that the SUD diagnosis will not impede efforts to treat their pain.

As noted earlier, the patient who is hospitalized for an acute medical problem may be more receptive to intervention for SUD than would otherwise be as an outpatient. It is important to consider the hospitalization as a window of opportunity to bring patients into recovery. SUD treatment should be offered when the disorder is detected in the course of pain treatment. If the patient does not accept SUD intervention at the time it is offered, it may be helpful to use the acute pain problem to begin to explore the patient’s motivation for recovery and to follow-up at future visits.

Critical to managing pain in patients with SUD is the understanding that the chronic nature of the disease requires continuous management; a single-mindedness focus on treating the former may allow the latter to progress unchecked. The presence of pain, be it acute or chronic, is a
stressor, and even if opioids are not prescribed for its management, the associated anxiety, functional losses, sleep disturbances, and general discomfort can set the patient up for a relapse to use of the drug which in the past has reliably provided psychic relief. For the patient in recovery, most important to ensuring that an exacerbation of SUD does not occur is the establishment of a collaborative treatment relationship between the addiction treatment provider and the pain care provider, with regular communication about the patient’s response to each.

Persons with SUD who require opioids for pain benefit from active cultivation of their recovery and implementation of relapse prevention interventions in the plan of care. What constitutes meaningful recovery activities vary between individuals but may include attendance at self-help meetings, close interaction with a sponsor, work with a counselor, or active participation in a faith community, among others. SUD professionals may provide an important service to patients and their pain treatment providers by making recommendations on enriching recovery and by supervising the recovery plan while patients are using opioids for pain. In persons with other conditions that put them at risk for misuse of medications, such as psychiatric disorders or cognitive impairment, engagement of appropriate professionals to assist in management of or accommodation to these disorders may be needed.

Although not addiction treatment providers, there are specific strategies the pain clinician can utilize to support the goals of SUD treatment. As noted earlier, continued and active engagement in addiction treatment should be encouraged; even if the patient is hospitalized, virtual 12-step meetings, visits from sponsors or the MAT provider, or access to readings or web-based programming can be facilitated. It is necessary to continuously evaluate the presence and severity of stressors that might precipitate relapse (such as unrelieved pain, sleep disturbance, withdrawal symptoms, psychiatric symptoms, interpersonal conflicts, craving) as well as identify protective factors against relapse and to support/strengthen these to the extent possible; the validated Defense and Veterans Pain Rating Scale (DVPRS) screening tool can be easily administered in the clinical setting to this end. If it becomes apparent that a relapse has occurred, it is critical that recovery providers be notified as soon as
possible to minimize the extent of the exacerbation and reinforce recovery efforts.

**Document Pain Treatment Plan and Involve Patient and Family in the Plan of Care**

It is important to achieve pain relief with methods that do not confuse, stress, or frustrate the staff or the patient. This requires clear communication regarding the pain treatment plan to all staff involved in caring for a patient with SUD. Stigma and misunderstanding are widespread among health care personnel and too often lead to inadequate pain management when the primary treating clinician is not available and the plan is not clearly documented. In the absence of a clear and consistent structure, the patient’s behaviors may foster confusion of pain and addiction issues. Written documentation of the plan, displayed in a prominent and accessible location, may be necessary.

Shared decision making is based on the foundation of a patient-centered assessment of risks and benefits and a clinical synthesis performed by the provider.\(^\text{92}\) To be effective, the patient (and often family) must be included in the decision-making process regarding the choice of treatment options including medication, dosing, and scheduling. This provides a sense of control and allays the anxiety and fear that worsens pain perception. It also may afford information that is useful in designing an effective treatment regimen. Patients with OUD often know the doses they require to meet their basic physical dependence needs as well as the additional levels required to treat their acute pain. If a patient becomes intoxicated or sedated at the prescribed dose, medications should be adjusted to avoid the observed side effects while continuing to provide analgesia.

**Pain, Substance Use Disorder, and Suicide**

There has been a great deal of scholarly activity devoted to the burgeoning rate of opioid misuse/abuse and opioid-related fatalities. State and federal policy makers have made a priority to develop risk mitigation strategies such as opioid prescribing guidelines, PDMPs, and educational programs to curb the rising rate of opioid abuse. However, these important efforts have overshadowed the equally devastating silent epidemic of suicidal
ideation (SI) and suicidal behavior (SB), particularly in vulnerable populations. Suicide has become a global health crisis. The World Health Organization published an executive summary, Preventing Suicide: A Global Imperative.\textsuperscript{308} In this document, there were disturbing facts: Every 40 seconds someone in the world dies of suicide; an estimated 804,000 suicide deaths occurred worldwide in 2012; in the age group of 15 to 29 years, it is the second leading cause of death, and suicide constitutes 54\% of the 1.5 million violent deaths per year globally.

Pain and Suicide

There is substantial literature indicating that there is a high prevalence of SI in patients suffering from CNMP, ranging from 18\% to 50\%.\textsuperscript{309–324} A systematic review by Tang and Crane\textsuperscript{321} revealed that the risk of successful suicide doubled in patients with CNMP as compared to nonpain controls. Ilgen and his colleagues\textsuperscript{322} evaluated a large cohort from the VA database (n = 260,254) and discovered that veterans experiencing severe pain were more likely to end their life by suicide than veterans with no, mild, or moderate pain (hazard ratio [HR]: 1.33; 95\% confidence interval [CI]: 1.15 to 1.54). Campbell et al.\textsuperscript{323} examined data from a nationally representative household survey of 8,841 individuals. Results revealed that the odds ratio (OR) of lifetime and past 12-month SI and SB was two to three times greater in individuals with chronic pain than those without chronic pain.

Substance Use Disorders and Suicide

Individuals suffering from SUDs, like ones with pain, are at substantial risk for SI and SB. Greater than 40\% of persons seeking treatment for their SUD endorse having a history of suicide attempts.\textsuperscript{325–327} Individuals with an AUD are almost 10 times more likely to die by suicide and those who inject drugs are approximately 14 times more likely to commit suicide as compared to the general population.\textsuperscript{328} These individuals tend to have multiple risk factors for SB including having depressive symptoms and significant numbers of severe stressors such as loss of relationships, jobs, health, and financial problems. Yuodelis-Flores and Ries\textsuperscript{329} reviewed the literature examining the characteristics of SB in patients with SUDs and
found that a history of attempted suicide was a strong predictor of future suicide which is very common in all populations, not just patients with an SUD. History of impulsiveness, aggression, pessimism, and hopelessness, along with acute stressors such as loss of relationships or income and a history of childhood sexual abuse all were important factors that contribute to the risk of suicide for patients with SUD. Certain mental disorders also strongly affected the risk for suicide attempts in patients with SUD, in particular, major depressive disorder, bipolar disorder, posttraumatic stress disorder (PTSD), and borderline personality disorder.

Pain, Substance Use Disorder, and Suicidal Ideation and Behavior

Pain and SUD are independent risk factors for SI and SB, putting patients with co-occurring pain and SUD at particularly high risk for ending their lives by suicide.

**Risk Factors.** There are general, nonpain-specific risk factors and pain-specific risk factors for SI and SB. General, nonpain-specific risk factors include gender (female); age (>45 years old); having co-occurring mental disorders (especially depression and SUD); acute losses and stressors (relationships, job, finances); enduring chronic medical illnesses; sleep disturbance; experiencing conflict, disaster, and discrimination; past psychiatric hospitalizations; frequency of SI; severity of psychiatric disorder; and poor social support; and the strongest predictor of suicide is a previous suicide attempt. Although patients with pain and SUD commonly have a number of these risk factors (e.g., loss of vocational and home roles, isolation, depression), pain-specific risk factors include pain type, pain duration, pain intensity, sleep disturbance, and opioid dosing.

**Possible Mediators.** Both catastrophizing and burdensomeness/social isolation have been identified as potential mediators for suicide in patients with chronic pain. Many patients with pain engage in a pain-related catastrophizing, which can be defined as magnified, exaggerated negative focus on pain that can contribute to depression and disability and in turn exacerbate an individual’s experience of pain and suffering. The association between SI and individual differences in the use of pain-related
coping strategies and pain catastrophizing was assessed in a large cohort of 1,515 patients with CNMP. In this sample, 32% reported recent SI. It was revealed that the extent of depression and pain catastrophizing best predicted the occurrence and the degree of SI. Demographic variables, pain intensity, and pain duration were not particularly robust predictors of SI.\(^\text{320}\)

With respect to burdensomeness and social isolation, the interpersonal theory of suicide by Joiner and colleagues\(^\text{333,334}\) proposes that there are two primary factors that significantly contribute to the context that leads to SI and possible SB. These two factors are thwarted belongingness, which is defined as the unfulfilled need for social interaction and connectedness, and perceived burdensomeness, which perceives oneself as a burden or a liability to others, particularly family members. Kanzler and colleagues\(^\text{335}\) evaluated 113 patients with CNMP, and a logistic regression model revealed that one question measuring perceived burdensomeness was the only predictor of SI. Cheatle et al.\(^\text{319}\) discovered that social withdrawal and isolation were predictive of SI in a cohort of 466 patients referred to a pain center.

According to the interpersonal theory of suicide, whereas the confluence of burdensomeness and thwarted belongingness can lead to the desire for suicide, the capability for suicide attempts develops in response to repeated exposure to physically/emotionally painful and/or fear-inducing experiences. This theory of SI and SB is very relevant to patients with pain and those with an SUD because in both populations individuals tend to become isolated and often perceive that they are a burden on their friends and families and are often subjected to emotionally and, at times, physically painful events due to their disease and related disabilities.

Screening for Risk of Suicide

Screening for risk of suicide in patients with chronic pain and SUD should include general mental health screening, assessing sleep disturbance, and the use of specific tools to assess SI and SB.

**Mental Health Screening.** A number of well-validated screening tools for depression and anxiety have been used, both clinically and in research. The Beck Depression Inventory (BDI)\(^\text{336}\) and the Profile of Mood States
are the two measures recommended by Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) consensus group to assess emotional function in chronic pain. The BDI is a 21-item self-report measure of the severity of depressive symptoms over the past week, whereas the POMS assesses six distinct mood states including depression, anxiety, and anger, thought to be the most relevant factors in the pain population. A frequently employed depression screening tool for use in primary care is the Patient Health Questionnaire (PHQ-9), which is a self-rating instrument derived from the Primary Care Evaluation of Mental Disorders (PRIME-MD) project which includes nine symptoms of depression based on the DSM-IV-TR criteria, including one item specifically inquiring about self-harm (SI). The Patient Reported Outcome Measurement Information System (PROMIS)-depression item is another brief instrument (five questions) to screen for and assess depression severity. Finally, the PHQ-4 is a four-item screening tool for depression and anxiety that can be easily administered in a busy primary care practice.

Screening Tools for Sleep Disturbance. Sleep disturbance is a risk factor for both increased pain and SI. Measures for insomnia predominantly include patient self-report in questionnaire and daily sleep diary to capture the subjective experience of sleep disturbance but may also include objective measures such as actigraphy and polysomnography to assess sleep patterns and possible concomitant sleep disorders (e.g., sleep apnea, restless leg syndrome/period limb movement disorder, narcolepsy). Self-report measures assess different aspects of sleep disturbance. Clinically useful tools typically assess sleep quality such as the Pittsburgh Sleep Quality Index, Insomnia Severity Index, PROMIS-sleep disturbance and sleep-related impairment item. Moul and colleagues provide a review of the various sleep assessment scales.

Screening Tools for Suicide. Although the majority of depression screening tools have a question assessing SI, there are a number of suicide screening tools that provide more granular information on risk of suicide and intentionality. For example, the P-4 Brief Assessment assesses
suicide attempts, a **plan** for suicide, probability of completing suicide, and **preventive factors**. The Columbia-Suicide Severity Rating Scale (C-SSRS) measures a number of suicide domains including ideation, intensity, behaviors, severity of self-injury, and potential lethality of suicide attempts. The C-SSRS provides greater precision in the assessment of SB and SI but due to its length can be cumbersome with regards to clinical practice and is typically used in clinical trials during medication development.

The Suicide Assessment Five-Step Evaluation and Triage (SAFE-T) assessment tool was developed in collaboration with the Substance Abuse and Mental Health Services Administration (SAMHSA). The SAFE-T includes assessment of risk factors including SB, current and past psychiatric disorders, key symptoms, family history, change in treatment, and access to firearms; protective factors, both internal, such as the ability to cope with stress, spiritual or religious beliefs, and frustration tolerance, and external, such as responsibility to children or others and having a positive therapeutic relationship and good social supports; suicidal inquiry with specific questions about thoughts, plans, behaviors, intents, risk level, and intervention; and the risk level based on the clinical judgment after completing the first three steps. Patients are stratified into low, moderate, and high risk, with specific interventions indicated for each risk level. The last step is documenting the risk level and rationale for the treatment plan to address or reduce the risk.

**Suicide Risk Reduction and Interventions**
Reducing the risk of developing SI and of engaging in SB possibly resulting in death by suicide relies in part on managing comorbidities commonly seen in patients with pain and SUD (mood disorders, sleep disturbance, catastrophizing). Patients who present with complaint of moderate to severe depression with or without acknowledging SI, if possible, should be comanaged with a mental health specialist. Patients who express active SI may require immediate inpatient treatment which is contingent on certain dynamics including severity of depression and SI, lack or presence of a specific plan for completing suicide, access to means (potentially lethal medications such as opioids and benzodiazepines or...
own a gun), and history of past SB or impulsivity.

Certain factors mitigate the need for inpatient care, such as patients having a robust social support system, having a history of demonstrating good impulse control, are willing to contract that they will go to a local hospital or call emergency assistance if SI intensifies, and having a collaborative relationship with their health care provider. In these cases, patients may be able to be managed as an outpatient. During an acute suicidal phase, the patient will require both pharmacotherapy and intensive psychotherapy. The pharmacotherapy strategy should include managing depressive symptomatology, sleep disturbance, and pain. If opioid or benzodiazepine use is necessary, these medications should be prescribed judiciously, in small amounts and held and administered by a family member or close friend or sponsor. Patients determined to be high risk for engaging in SI and SB or have chronic SI should be involved in ongoing psychotherapy and remain under psychiatric care.

**Pharmacotherapy.** There are no specific pharmacologic agents that have been identified to directly reduce SI, so the general strategy is to treat comorbid conditions that can contribute to increased risk of suicide, including depression, anxiety, sleep disorder, and poorly controlled pain. Typical pharmacologic agents might include a combination of antidepressants and antiepileptic drugs and sleep aids. There is, however, equivocal data that antidepressants and antiepileptics can actually increase the risk of SI/SB in a subgroup of patients. With this in mind, treating patients with pain, SUD, and comorbid suicidality, it is critical to closely monitor for ongoing suicide risk with any changes or additions to therapy. When treating sleep disturbance in this patient population, avoidance of benzodiazepines is advised especially if the patient is on opioid therapy and to rely on nonbenzodiazepine agents with low abuse potential and low risk of respiratory depression.

**Nonpharmacologic Interventions.** Individuals with pain and especially ones with both pain and concomitant SUD often experience co-occurring mood, anxiety, and sleep disorders, which can increase the risk of SI and SB. In a subgroup of patients, pharmacotherapy can improve mood, anxiety, and sleep which can in turn reduce the risk of SI/SB in a subgroup
of patients, but the combination of appropriate pharmacotherapy and nonpharmacologic interventions, CBT in particular, is the most efficacious approach.

**Cognitive-Behavioral Therapy for Pain.** Patients experiencing persistent pain often engage in maladaptive behaviors for example kinesiophobia (or fear of movement) and dysfunctional thought patterns, most commonly catastrophizing. As noted previously, catastrophizing has been identified as a potential risk factor for SI/SB in patients with chronic pain. The goal of CBT is to assist and support the patient in identifying maladaptive behaviors and/or dysfunctional thought patterns that may reduce the patient’s ability to adjust to and cope with their chronic pain, thus contributing to their related depression and anxiety.

The process of CBT typically involves the patient acquiring specific skills which can include mindfulness-based stress reduction, progressive muscle relaxation training, behavioral pacing, effective communication, cognitive restructuring, followed by skill consolidation, rehearsal, and relapse training.\(^{350}\) There is persuasive research supporting the clinical efficacy and cost-effectiveness of CBT in improving mood, anxiety, and functionality in a number of chronic pain disorders, including chronic low back pain,\(^{351,352}\) arthritis,\(^{353}\) lupus,\(^{354}\) fibromyalgia,\(^{355}\) and sickle cell disease.\(^{356}\)

**Cognitive-Behavioral Therapy for Insomnia.** CBT personalized to treat insomnia has been effective in improving sleep disturbance. Sleep disturbance is highly prevalent in patients with CNMP and patients with SUD. Pain and sleep are bidirectional with pain leading to sleep disturbance and sleep disturbance causing increased pain.\(^{357,358}\) There is evidence that CBT-insomnia (CBT-I) in patients with chronic primary insomnia is equally effective or even superior to pharmacotherapy in multiple outcomes.\(^{359}\) A course of CBT-I typically includes psychoeducation about sleep and insomnia, stimulus control, sleep restriction, sleep hygiene, relaxation training, and cognitive restructuring. CBT-I can be delivered in an individual, group, and computer-assisted format with generally equal effectiveness.
Cognitive-Behavioral Therapy, Pain, and Substance Use Disorder. As noted, there has been a burgeoning rate of prescription opioid misuse/abuse and opioid-related fatalities. There is emerging evidence that CBT can reduce the risk of prescription opioid misuse and abuse in high-risk patients indirectly by improving mood, anxiety, sleep, and pain coping skills and also in improving outcomes in patients with pain who have a history of an SUD. In a recently published pilot study, patients with hepatitis C who also experienced chronic pain and had a history of SUD were enrolled in an eight-session integrated group CBT program for chronic pain and SUD. Results revealed improvement in key outcomes including pain-related interference, reduction in cravings for alcohol and other substances, and a decrease in past-month alcohol and substance use.

Opioid Tapering and Suicide. Given the current concern over the opioid “epidemic” and the burgeoning rate of opioid misuse/abuse and opioid-related fatalities and fanned by the recent opioid prescribing guidelines, there is a trend to taper patients off opioids, even in the absence of evidence of ADRB. The findings of a recent opioid tapering study at a single pain clinic at a community hospital showed that a substantial fraction of patients on high-dose opioid therapy long-term wished to engage in voluntary opioid dosage reduction and was able to do so successfully without increase in pain intensity or pain interference. Combining patient education about the benefits of opioid reduction with a plan that reduces opioids slowly (in this study, over 4 months) with close clinician follow-up may help patients engage and succeed in voluntary outpatient tapering.

However, tapering in patients with CNMP and SUD must be initiated cautiously. In a recent study, veterans with CNMP who were discontinued from opioid therapy were selected from a national cohort. The sample included patients with SUD and matched controls. Results indicated that in both groups, there was a high rate of SI (9.2%). These results underscore the importance of individualizing treatment, and being cognizant that those patients with pain receiving opioid therapy can be unnecessarily vilified, and increase the risk of SI and SB.
Future Directions
Predicting future SI and SB is a herculean endeavor even for seasoned mental health clinicians. There is emerging science on biomarkers of SI and SB. For example, there is evidence that patients with diminished central serotonin have a higher risk of SB. In particular, low concentration of 5-hydroxyindoleacetic acid (5-HIAA) in the cerebral spinal fluid was found to predict future SB and was discovered in depressed suicide attempters and in the brainstems of autopsied patients that committed suicide. Further implicating the serotoninergic system is polymorphism of the gene coding for the serotonin transporter (5-HTTLPR) and brain-derived neurotropic factor.

Conclusions
Patients with pain commonly present with comorbid disorders. Unlike other diseases or illnesses, comorbid SUD puts patients with pain at unique and increased risk of a worsened experience of pain and a limited response to pain management interventions. These poor outcomes are related not only to the behavioral manifestations of the disorder but also to the neurophysiologic processes which underlie its development. SUDs disrupt motivational systems encoding reward; stimuli that are by nature stressful and unrewarding, such as pain, are likely to be preferentially affected by the presence of SUDs. These issues become particularly salient in the case of OUD, where tolerance, physical dependence, craving, and hyperalgesia complicate the provision of opioid analgesia.

Despite the challenges associated with managing their pain, it is critical that the pain suffered by patients with SUD be treated effectively, if not aggressively. Untreated pain puts them at risk for relapse or escalation of substance use, disengagement from treatment, and worsened morbidity, including overdose and suicide. The therapeutic alliance developed when pain reports are believed and relieved can be a powerful motivator or reinforcer of recovery. Fortunately, the current emphasis on, and growing evidence base for, multimodal pain treatment and opioid-sparing strategies provide tools for effective pain management in patients with SUD which do not engage addiction systems. Furthermore, with thoughtful and
judicious oversight, opioids can be provided to individuals with acute and chronic pain of severity requiring their potent analgesic effects. Doing so requires vigilance on the part of the provider to monitor for withdrawal, relapse, and toxicity as well as ensuring that SUD treatment resources are included in the plan of care. By its very nature, effective pain care for the patient with SUD concomitantly benefits the recovery process, thus provision of such is critical in this vulnerable patient population.

Pain management physicians commonly have to deal with doctor–patient conflicts because of the nature of persons with chronic pain, the personalities of the pain practitioners who treat them, and added pressures stemming from the health care system. Persons with chronic pain frequently present with psychosocial stressors including sleep disturbances, loss of function, disability issues, and depression, which affect their ability to cope. Medical conditions such as diabetes, hypertension, asthma, gastrointestinal distress, and other comorbidities such as substance abuse and psychiatric disorders make these patients challenging to manage. Patients with chronic pain can be time-consuming when doctors are under increasing pressure to see more patients in a shorter amount of time. The need to provide detailed documentation and written justification of each treatment decision and to remain current with the latest treatments adds further time pressure for the pain practitioner. All of these conditions can add to difficulties that set up doctor–patient conflicts.

Between 10% and 60% of patients treated in health care settings exhibit “difficult behavior,” which can include extreme aggression, threats of homicide and suicide, and behavior related to substance abuse. Patients with chronic pain can be especially difficult because they have a tendency to be angry, mistrustful, anxious, and depressed. Depression and anxiety disorders are 2 to 3 times more prevalent among patients with chronic pain than in the general population, and patients with pain can frequently
present with added behavioral symptoms of inflexibility, negativity, or entitled behavior. The aim of this chapter is to describe difficult doctor–patient relationships in a pain center or primary care setting and focus on communication issues that may be useful in avoiding treatment dissatisfaction and possible legal reprisals. In this chapter, I first review the reasons that patients can be difficult and identify those patients who are prone to exhibit problems. Next, I discuss some of the major issues that lead to doctor–patient conflicts and review possible communication strategies to help the pain specialist successfully manage these patients. Finally, I outline common clinical scenarios leading to potential doctor–patient conflicts and give appropriate responses that may be beneficial in dealing with difficult patients. As implied in the title, this chapter focuses on the doctor–patient relationship, although it should be noted that this same information could easily be applied to any clinician and any person receiving treatment.

Difficult Patients and Difficult Doctor–Patient Relationships

In a study of over 500 adults presenting to a primary care clinic, Jackson and Kroenke\textsuperscript{13} found that treating physicians rated over 15% of their patients to be difficult. In a comparable study of 750 subjects, Hinchey and Jackson\textsuperscript{14} perceived 17.8% of patients to be difficult. These difficult patients tended to have a depression or anxiety disorder, poor functional status, unmet expectations, reduced satisfaction, and a greater use of health care services. These studies also showed that physicians who were less experienced and were less empathic were more likely to experience encounters with these patients as difficult. In another study, Jackson and Kroenke\textsuperscript{15} found that patients’ unmet expectations were common in those individuals experienced as difficult by the clinicians. These patients were also likely to have a mental disorder, with somatic symptoms, poorer function status, greater expectations for care, less satisfaction, and higher use of health services than patients who were not difficult (P < .001). Every clinician will encounter at least one extremely difficult patient who
may require behavioral limit-setting and possible hospitalization and/or psychotropic medication. Patients with chronic pain are known for being particularly difficult. In a recent survey study of 56 primary care physicians, 83.9% agreed that patients with chronic pain can be very stressful to deal with.

Vegni and colleagues, after analyzing difficult doctor–patient relationships, concluded that the doctor’s personal and professional issues as well as changes in the health care system are the chief contributors to conflicts. Likewise, Haas and others identified the fact that difficult doctor–patient relationships can be based on (1) patient factors (medical, psychiatric, personality, and substance abuse risk), (2) physician factors (workload, communication skills, personality, level of experience, quality of training and practice setting), and (3) the health care system (financial and productivity pressures, fragmentation of care, availability of outside resources, and documentation and treatment guidelines). In a survey of 750 patients and 200 physicians performed by Roper Starch Worldwide Inc, the qualities of physicians that were most frustrating to patients were being too rushed (30%), hard to reach (19%), and not down to earth (11%). The qualities that described the most difficult patients were hostility or anger (49%), noncompliance (19%), and being too demanding or needy (19%).

Hahn and others developed the Difficult Doctor–Patient Relationship Questionnaire (DDPRQ) and established its reliability and validity. The results of the DDPRQ, completed by physicians who had just concluded a patient encounter, showed that 10% to 21% of patient encounters were labeled as difficult. Most of these patients showed signs of psychosomatic symptoms and psychopathology. In subsequent studies by this same group conducted in four primary care clinics, physicians rated 96 patients (15%) out of 627 to be difficult. Compared with patients who were described as not difficult, difficult patients had more functional impairment, higher health care utilization, lower satisfaction with care, and more psychiatric disorders of somatization, panic, dysthymia, anxiety, depression, and alcohol abuse or dependence.

**PSYCHIATRIC AND PERSONALITY ISSUES**

Difficult patients with pain can display destructive psychiatric behaviors
such as suicidal ideation, self-mutilation, extreme noncompliance with treatment, or opioid misuse, and most pain specialists have little training in psychiatric assessment and treatment.\textsuperscript{12} Many clinicians avoid pain medicine practice altogether because of the emotional challenge of working each day with demanding and draining patients. Patients with pain can be fearful of flare-ups and worry that their clinic will be unresponsive to the urgency of their condition. Their heightened anxiety adds to a need for frequent contact with their doctors, resulting in endless e-mails and phone messages. Patient–relations departments of hospitals and the state boards of registration and medical examiners are notified most often by patients who complain that their doctor is unresponsive to their care. As a result, physicians are watchful about the perception of inadequately treating or abandoning their patients.\textsuperscript{21}

Epidemiologic studies indicate that 35\% of chronic back and neck pain sufferers in the United States have a comorbid depression or anxiety disorder\textsuperscript{22} and up to half of all patients with chronic pain can have a comorbid psychiatric condition.\textsuperscript{11,23} Further studies also report that patients who are most difficult frequently have a personality disorder, which includes psychotic episodes, impulsivity, superficiality, problems with interpersonal relations, and affective disorders.\textsuperscript{24} Surveys of chronic pain clinic populations as a whole indicate that 50\% to 80\% of patients with chronic pain have some signs of psychopathology, making this the most prevalent comorbidity in these patients.\textsuperscript{25,26} Persons with fibromyalgia, chronic daily headache, and chronic pelvic pain have the highest rates of depression compared to patients with other chronic pain conditions.\textsuperscript{27–29} Patients with two or more pain complaints are more likely to be depressed than those with a single pain complaint, and the number of pain conditions is a better predictor of major depression than pain severity or pain duration.\textsuperscript{30} Patients with borderline and antisocial personality disorders can be commonly found in a pain management clinic. Taken together, these studies provide support for the association between chronic pain and having a mood disorder.\textsuperscript{31} These patients often trigger the strongest negative reaction among their providers.\textsuperscript{12}

Outcome studies highlight the poor response of patients with psychiatric comorbidity to many different treatments for chronic pain,\textsuperscript{32} especially
those patients with chronic low back pain. Boersma and Linton have shown that patients with chronic pain with a combination of anxiety and depression have a 62% worse return to work rate at 1 year than those with no psychopathology.

**OPIOID THERAPY**
Patients with chronic pain who have a mood disorder are likely to be prescribed opioids more often than those without a mood disorder, which can lead to doctor–patient conflicts. In a study of 50 Veterans Administration (VA) patients and 50 patients treated in outside primary care practices with opioids for noncancer pain, Reid and colleagues found a 50% prevalence of major depression and a 20% prevalence of an anxiety disorder. In a similar study, Breckenridge and Clark determined a high prevalence of mood disorder among patients with pain who were prescribed opioids. In a study of 191 patients examining factors that led pain physicians to prescribe opioids for noncancer pain, Turk and Okifuji concluded that neither pain severity nor objective physical pathology influenced the decision to prescribe. Rather, greater affective distress and pain behaviors drove the decisions. Thus, patients with chronic pain and psychopathology are likely to be prescribed opioids, and these patients report greater pain intensity, more pain-related disability, and a larger affective component to their pain than those without psychopathology.

In terms of the impact of mood disorders on opioid response, a study examined the effects of intravenous (IV) opioid analgesia in patients with chronic pain with high and low levels of psychiatric comorbidity. Sixty patients with low back pain stratified into three groups of severity of psychological symptoms (low, moderate, and high) were given IV morphine and placebo in random order on separate visits and completed pain ratings over 3 hours at each session. The low-psychopathology group had a 40% greater reduction in pain with IV morphine than the high-psychopathology group (P < .01). This study found that patients with chronic pain who had a high degree of negative affect benefited less from opioids in controlling their pain than those with a low degree of negative affect, a finding replicated by subsequent studies.
DIFFICULT “NORMAL” PATIENTS

Not all patients with difficult behavior exhibit significant psychopathology, such as major depression or anxiety or a personality disorder. Patients who are otherwise “normal” can be perceived as difficult, for example, when they arrive at a pain center for treatment with unrealistic expectations about what should happen. They may have had problems with previous health care settings in which they were accused of exaggerating their pain. Lack of sleep, extreme fatigue, poor eating habits, and long travel to their appointments can also contribute to volatile and unstable behavior. They may experience their physicians as dismissive or skeptical of their pain rather than being understanding and sympathetic. Even comparatively well-adjusted patients can sometimes develop the idea that their pain physician should be able to eliminate all of their pain and that failure to do so is tantamount to withholding treatment. This becomes critical when medication regimens involving opioids are concerned. Patients may worry about being prescribed adequate amounts of medication or undergoing withdrawal if they are to be tapered off opioids.

Some patients with pain are entitled consumers who are no longer willing to be passive in their treatment but rather prefer to take control of their medical care. Medical information through the Internet is more accessible than ever, and patients frequently come to their appointments armed with information about a particular therapy. Patients are increasingly opinionated about their care. They look to have a mutually respectful relationship with their health care providers and want to take an active role in the decision-making process. They become dissatisfied with their treatment when their provider is unresponsive to their suggestions and not willing to hear their own ideas. Cultural and ethnic differences can also act as barriers to an effective doctor–patient relationship.

COMORBID MEDICAL CONDITIONS

Most persons with chronic pain also have significant medical conditions that impact treatment decisions. Some are medically challenging as well as being interpersonally difficult. Patients with pain may report asthma, chronic obstructive pulmonary disease (COPD), diabetes, coronary artery disease, hypertension, ulcers, kidney, bladder and liver problems, and
history of cancer. Persons with chronic pain often smoke cigarettes, have gained weight, and have lost bone density. Multiple providers can prescribe multiple medications including blood thinners, blood pressure and heart disease medications, inhalers, and antidepressants. These patients are also noted for allergies and reactions to certain medications. Occasionally, they have implanted medical devices (e.g., pacemakers, rods, stimulators) or wear prostheses. Some of the most challenging patients tend to be older, take many medications, have multiple psychosocial problems, have poor social support, limited education, and come from disadvantaged backgrounds.³

Kenny⁴³ points out in a survey study of 20 patients with chronic pain and 22 pain specialists that differences in communication interactions—especially when patients embrace a medical model to explain their pain and physicians perceive a psychogenic etiology of pain—can significantly negatively affect the doctor–patient relationship. In a study of how and why physicians dismiss patients from their practice, 25 general practitioners identified two types of patients who tend to be dismissed over others: (1) patients who break the rules of the doctor–patient relationship or clinic practice and (2) patients whose difficult personality makes it hard to care for them.⁴⁴

**SUBSTANCE USE DISORDERS**

There are notable links between chronic pain and substance abuse.⁴⁵,⁴⁶ Studies show that 10% to 16% of patients treated in a general practice and 25% to 40% of hospitalized patients have problems related to drug or alcohol addiction.⁴⁷,⁴⁸ Other studies indicate that patients with pain and high rates of mood disorders are at high risk for alcohol or opioid abuse.⁴⁹–⁵¹ Hasin and Liu⁵² found some patients abuse opioid pain medication in an attempt to alleviate their psychiatric symptoms. Thus, comorbid depression and/or anxiety disorders are associated with greater opioid misuse, even in those with no history of a substance use disorder. Wasan and colleagues⁵³ also found that increased craving for prescription opioids was associated with a greater urge to self-medicate the anxiety and depression that precede the sensations of craving. These individuals with a mood disorder who self-medicate negative affective symptoms are at
increased risk for substance abuse.\textsuperscript{51,54} Physicians are often in the difficult position of providing appropriate pain relief while minimizing the inappropriate use of pain medications by being ever watchful of substance use disorders.\textsuperscript{55} Inappropriate use can include the following: selling and diverting prescription drugs, seeking additional prescriptions from multiple providers, concurrently using other illicit drugs, and manipulating the formulation to snort or inject the medications or use them in a manner in which they were not intended. It is important for the successful treatment of chronic noncancer pain to be able to frequently monitor patients on opioid regimens and to identify those patients who exhibit ongoing abuse behaviors, which can be an added burden to providers.\textsuperscript{56,57}

Unfortunately, physicians can be deceived, which is all the more reason that steps are needed to perform a thorough evaluation for risk factors and to closely monitor patients on opioid therapy.\textsuperscript{58} History of substance abuse further complicates treatment because it increases the potential for inadequate treatment of pain.\textsuperscript{59} Thus, encounters with patients can be made difficult by underlying issues of substance abuse and addiction.

**Physician Factors**

Difficult doctor–patient relationships are not completely due to the patient. The attitudes and behavior of the physicians play an important role as well. Some doctors take patient behavior personally instead of realizing that this is how the patient responds and behaves in other situations as well. An understanding of the patient’s situation helps in depersonalizing any reactions that they may experience. Doctors who show disrespect or have inward anger toward their patients transmit negative emotions that lead to distrust. Some physicians have hidden feelings of inadequacy or poor self-esteem, and others have an inability to listen to what the patient is saying.\textsuperscript{60} Those personality and behavior qualities of doctors can lead to difficult relationships, including inward anger, impatience, lack of empathy, depression, poor self-esteem, and feelings of vulnerability.\textsuperscript{61,62}

For health care providers, treating patients with chronic pain can also lead to reactive feelings of being manipulated, which, in turn, can lead to extreme dislike for certain patients.\textsuperscript{63} Because physicians are frequently
under pressure to see patients within a short period of time, pain patients who show vague symptoms and who are unresponsive to many different interventions can be particularly frustrating, especially when the burden of providing treatment is shouldered alone instead of being shared by an interdisciplinary team. More problematic patient issues, including verbal abuse or physical threats to the clinician and staff, stalking, criminal behavior, and gross noncompliance, can trigger negative reactive emotions in the provider.

Krebs et al. interviewed 1,391 physicians to assess personal and practice characteristics associated with greater frustration with patients. Physicians who were younger, worked more hours, had symptoms of depression and anxiety, were under higher stress, and had more patients with psychosocial and substance abuse problems reported increased frustration with their jobs. In a qualitative study, Mathias and colleagues interviewed 20 providers at a Veterans Affairs medical center. They concluded that the providers’ needs should not be ignored and that improving the providers’ patient-centered communication skills, including demonstrating empathy and encouraging shared decision making, would ultimately lead to improved patient care. Tam and Su point out that pain clinicians may have extensive training in their area of expertise but have had little instruction in communication skills.

Health Care System Factors

Health care system factors also indirectly contribute to doctor–patient conflicts. Physicians frequently report being overworked and under constant pressure to be productive. The demands of the job include reading reports, meticulously documenting treatments and reconciling medications in the electronic medical records. Many have also witnessed changes in health care financing and fragmentation of care. Commercial insurance carriers and The Joint Commission Centers for Medicare & Medicaid Services frequently revise regulations in medical record documentation. Physicians are more than ever being asked to expand their role in the identification and management of psychiatric conditions and addictive disorders. Keeping abreast of the latest pharmacologic therapies and
screening devices can also be daunting. Advances in information technology can radically transform decision-making and treatment processes, although there is no indication of whether they decrease the physician workload. It has been suggested that the use of the Internet can have a negative effect on doctor–patient relationships by discrediting conventional therapies, misleading patients, and adding to consultation times. Thus, productivity pressures from hospitals and medical centers, changes in health care financing, threats of legal repercussions related to treatment decisions, fragmentation of care, and the rising use of information technology can place burdens on the provider and add to additional external stress.

Patient Interaction Strategies

It is surprising to some outsiders when patients cherish their pain provider even though their treatment outcomes are not always successful. These patients may openly admit that their pain was made worse by a particular surgery or procedure but still feel that their doctor did all that could have been done without placing fault or blame on him or her. Conversely, other patients may hold their physician directly at fault for a negative outcome in what they perceive was inadequate or faulty treatment, even though the treatment technique was appropriate without evidence of complications. The differences may lie in the interpersonal skills that the physician used to help deal with the poor outcome, diffusing conflicts and building patient rapport. These same skills may have been lacking in another provider who was accused of causing further problems. Thus, the medical expertise and competence of the clinician is not the only quality needed for acceptance and satisfaction of treatment, regardless of the outcome, but rather the nonspecific effects of the doctor–patient relationship play an important role. Here, I review the components of positive doctor–patient relations, especially when dealing with challenging, difficult patients.

Much has been written on useful strategies in dealing with difficult patients, and an exhaustive review of the literature is beyond the scope of this chapter; however, a brief review of some studies will be useful. Elder and colleagues interviewed 102 physicians who were identified as
having excellent skills in interacting with difficult patients about how they identified, managed, and coped with these patients. The authors concluded that the key ingredients of changing a difficult encounter into a successful one included the use of empathy, appropriate use of power, and an understanding of the need for doctor–patient collaboration. Lown\textsuperscript{74} also proposed strategies to deal with anger in the clinician–patient relationship, suggesting that clinicians who cultivate personal awareness, practice self-monitoring, understand the reasons for patient anger, demonstrate specific communication skills, set clear boundaries, and seek personal support are best at managing difficult patient encounters.

Halpern\textsuperscript{63} also describes ways for physicians to manage difficult patients: recognize one’s own emotions, attend to negative emotions, attune to patients’ verbal and nonverbal emotional messages, and become receptive to negative feedback. These steps allow clinicians to reduce anger through increased empathy and ultimately increase therapeutic impact. Finally, Nisselle\textsuperscript{75} felt that by considering the difficulties in the relationship, doctors would be less prone to labeling patients as difficult. Strategies in managing difficult patients included acknowledging the problem, setting boundaries, using communication skills, and including external resources when necessary.

**PATIENT-FOCUSED CARE**

In a study on physicians’ communication style and perceptions of patients, Street et al.\textsuperscript{76} audiotaped and coded interactions among 29 physicians and 207 patients. They concluded that more positive communication from one participant led to similar responses from the other and that reciprocity and mutual influence had a strong effect on quality of care. Klitzman\textsuperscript{77} interviewed 50 doctors who had experienced a serious illness in which they were required to be hospitalized as patients. Because of their own experiences as a patient, these physicians acknowledged increased sensitivity to patients’ experiences and the importance of empathy in the doctor–patient relationship. They included hospital practice recommendations of charting with the patient present, acknowledging whenever they keep a patient waiting, and being sensitive to nonverbal aspects of care. Their conclusions are in keeping with the differences
described by Irwin and Richardson\textsuperscript{78} between patient-focused care and a disease-centered model of care. They loosely define patient-focused care as care we would like those we care most about to receive. Having a disease-focused management approach does not exclude having a good bedside manner; however, patient-focused care takes in the whole person’s experience in a way that suggests understanding and caring. This point is well illustrated in a study of 316 cancer patients among whom satisfaction with pain management was strongly related to the doctor–patient relationship and not related to the severity of the pain.\textsuperscript{79} Likewise, studies of postoperative satisfaction with pain have been found to be more related to perception of care than actual report of pain.\textsuperscript{80,81}

It has been suggested that poor communication style is the underlying problem in most medical–legal cases.\textsuperscript{82} In a sample of 45 physician-related plaintiff dispositions, relationship issues appeared to be central to 71\% of the lawsuits.\textsuperscript{83} In fact, it has been suggested that the majority of negligence cases are not related to quality of care but are brought on by inadequate doctor–patient communication—often occurring before the incident that leads to a claim.\textsuperscript{84} By concentrating more on the medical than the human needs of the patient, there is an increased chance of breakdown in communication and a greater perception of inadequate care. Those physicians who are less prone to legal action demonstrate skills in listening, empathy, and expressing understanding.\textsuperscript{82} Gafaranga and Britten\textsuperscript{85} believe that the opening statement made by the physician during the first patient encounter may have a lasting impression on the relationship. Roy and others\textsuperscript{86} have also shown that doctors who inform their patients of changes that impact their care in person rather than by mail have greater patient satisfaction. Back et al.\textsuperscript{87} identified some common pitfalls of doctor–patient communication that they label as blocking, lecturing, depending on a routine, collusion, and premature reassurance. They encourage instead employing open-ended communication skills they label as “ask-tell-ask” and “tell me more.” Caregivers who show good patient communication skills are ones who speak in a caring way with an open body posture and do not transmit the impression of defensiveness or indifference when they engage in conversation with their patients. Thus, as pointed out in some training
programs, the secret of caring for patients is really caring for patients.

Pomm, et al.\textsuperscript{60} suggest that clinicians also need to understand the patient’s perspective, attempt to actively listen to their patients, recognize what they can or cannot change, and get help from colleagues and friends for support if problems occur. They describe this as the CALMER (Catalyst for change, Alter thoughts to change feelings, Listen and then make a diagnosis, Make an agreement, Education and follow-up, Reach out and discuss feelings) approach to dealing with difficult patients. The literature on stages of change\textsuperscript{88,89} also indicates that patients go through stages in which they are more prone to make positive behavioral changes than at other times. Physicians who recognize when a patient is not ready to change, despite the patient’s giving lip service to what needs to be done, are less inclined to transmit disappointment when no changes are made.

**Communication Framework: WIPS and E’s**

Different models have been promoted to improve doctor–patient communication. Kathleen Gordon (Connecting with Care, unpublished manual, 2006) identified what she believes are needs and expectations of all patients with pain and used the letters WIPS (welcome, important and informed, perspective, and secure) to help remember what all patients expect during each doctor–patient encounter (Table 33.1). First, patients want to feel welcome. They like to believe that their provider is happy to see them and is concerned about their condition. Second, patients want to feel important and to be informed about what is going on and what will take place. The impression that there is mutual respect and collaboration is key to meeting these needs. Third, patients need to believe that their perspective is understood, which necessitates listening skills and body posture that convey a sense of caring. Fourth, the patient wants to feel secure that his or her doctor is competent and knows what needs to be done. To this end, patients like to have the expectation that their needs will be met as well as possible.

2. Feel **important** and informed  
3. Believe their **perspective** was understood  
4. Feel **secure** that their needs will be met

The Bayer Institute for Health Care Communication adopted a consensus model for essential elements of physician–patient communication.\(^9\) Even if the encounter is brief, those clinicians who follow particular interaction strategies are able to improve patient rapport. These strategies are remembered as the 4 E’s: (1) Engage, (2) Empathize, (3) Educate, and (4) Enlist. A revised version is presented in Table 33.2.

First, the clinician connects with the patient and builds rapport by greeting the patient warmly, having good eye contact, showing interest, and addressing any physical barriers by using nonverbal posturing that improves options for engagement (Engage). Second, the clinician listens to the patient and shows attentiveness by repeating the information back to the patient. The clinician acknowledges feelings and shows understanding. When appropriate, humor is also used (Empathize). Third, the clinician assesses the patient’s understanding and informs the patient and answers any questions that might arise in order to address concerns and to alleviate anxiety (Educate). Fourth, the clinician seeks the patient’s input about the treatment plan. Priorities are negotiated and different scenarios are discussed in order to address realistic expectations (Enlist). Finally, the clinician ends the encounter by summarizing the plan and outlining the next steps. Reassuring comments as well as positive concerns are expressed. The effective clinician will also be sure to follow through with what was discussed.

</table>
Clinical Scenarios

The following are some common scenarios encountered in a pain management clinic. How the clinician responds to these situations is important in preventing escalating problems and potential litigation. Although at times, patients present with a borderline personality disorder or have an underlying substance use disorder, employment of communication techniques can make clinicians more adept at managing these situations and improving outcomes. The following brief scenarios were chosen to address some of the points raised earlier. As you read them, try and picture what you might do in these situations.

**SCENARIO 1**

You are seeing a patient for the first time. You begin to ask questions about the patient’s medical history. The patient becomes very angry.

PATIENT: “I sent you all of my records and medical notes. Didn’t you even bother to read them? I keep having to repeat myself over and over again.”
CLINICIAN: “I am sorry that I have to ask you the same questions as everyone else, but I want to make sure that we do not miss anything. It is also important that I get a fresh look at how you are doing and what the main issues are. The goal is to improve your quality of life as best as possible and your patience and cooperation are important.”

Main issues: This interaction might happen with a patient who has had many previous problematic contacts with health care providers. The clinician’s appearing impatient and demanding will not help the situation. Rather, maintaining an open empathic stance, acknowledging the patient’s frustration that the first session may be repetitive and tedious, and showing caring will encourage the patient to cooperate.

As with any initial interview, listening and understanding are vital. It is important to summarize the major concerns and to help reconcile the issues. Many physicians choose to ignore anger for fear that addressing it will bring out more anger or for worry that it will lead to greater time involvement. However, addressing the situation early will pay dividends later on. Appearing impatient or demanding cooperation is an invitation for patient dissatisfaction and increased difficulties later on.

SCENARIO 2
It is late afternoon, and you have had several patients in the clinic with time-consuming complications. You are running 1 1/2 hours late. You enter the room to see your next patient, and you can tell this patient is very upset about having to wait so long.

CLINICIAN: “Hello Mrs. Black.”
PATIENT: [noticeably upset] “I have been waiting a long time and I have to get back home. Can we hurry this up?”
CLINICIAN: “I recognize that you have been waiting a long time and I am sorry that you have had to wait so long. I hate it when anyone must be kept waiting. As with all my patients, I want to spend as much time with you as you need.”

Main points: Apologizing ahead of time for any delay, even if it is for a short period, will acknowledge that you recognize that this person’s time is valuable and he or she may be legitimately irritated. Validating the
feelings of the patient first helps to defuse the situation. When running late, some clinicians make a point to quickly acknowledge that the patient is there and waiting and to let them know that they will be with them shortly.

**SCENARIO 3**

A patient is expecting to have a procedure, but the scheduler failed to put it in the schedule. You are running behind, and you can tell that this patient is very upset about the scheduling error.

CLINICIAN: [Sits down facing the patient with good eye contact and caring body posture.] “I need to apologize that there has been a mix-up about the schedule. I am afraid that we will not be able to do your procedure today.”

PATIENT: “What? I have had this appointment for weeks and I brought a friend with me to drive me home. Why can’t you just do it?”

CLINICIAN: “I can appreciate how upsetting this is especially when you have someone along with you. We simply can’t do this today. Mistakes like this don’t happen very often, and I am sorry that this happened to you. We will try and sort this out as best we can. I will have the scheduler set up another time as soon as possible.”

Main issues: It is important to reflect the patient’s perspective. If a mistake was made, it is always best to admit it and apologize without making excuses or directing the blame at others. Coming up with excuses or reasons for the problem right away without listening would not help to defuse the situation. It is important to use active listening techniques when patients are angry, including repetition, summary, validation, and empathy. Acknowledging that something will be done to help resolve the situation is important.

**SCENARIO 4**

A patient who calls and pages you often is pleasant when with you but is extremely disruptive while in the clinic. This patient is known to yell at the schedulers and the receptionist. Your receptionist insists that you speak to this patient.
CLINICIAN: “Mrs. Smith, I need to speak to you about your behavior in the clinic. I am aware that you get angry and raise your voice with staff at the front desk. We need to follow a protocol in our clinic, which means that everyone must respect each other. We cannot permit shouting or swearing in the waiting room.”

PATIENT: “But your receptionist has been rude to me and has accused me of coming just to get drugs. I don’t put up with that from anybody.”

CLINICIAN: “The staff here has difficult jobs to do, but we try and treat others with respect by not raising our voice or causing a scene. We expect the same from everyone who is being served here, including you. I am afraid that if you persist in this behavior we will not be able to continue to see you.”

PATIENT: “I don’t have a problem with you, doctor. But I can’t stand some members of your staff.”

CLINICIAN: “Whether you like them or not, you cannot be disruptive while you are here.”

Main issues: Some providers have difficulty in setting limits with difficult patients, but this is a case when firm limit setting is needed. Stating that it is difficult to work with anyone who is disruptive in the clinic and identifying the expected behaviors without showing anger or being demanding or blaming is best. For patients who are very disruptive in the waiting room, inviting them to come to a clinic room and to meet to discuss the issues privately would help to prevent further escalation of behavior.

SCENARIO 5

An elderly patient becomes combative and delusional following a procedure. This patient requires sedation and restraints. Family members see this patient in restraints and are very angry.

FAMILY MEMBER: “What are you doing to my mother? Is this a hospital or a prison? You should have notified us first. I want to transfer care to another facility.”

CLINICIAN: “I can see why you would be upset seeing your mother in restraints. I want to reassure you that she is being cared for with her safety in mind.”
FAMILY MEMBER: “But this can’t be the way you are supposed to handle patients.”
CLINICIAN: “I am sorry that you are upset, but we are doing this for her own safety. We try and take the greatest care with all our patients. Although your mother has been experiencing some of the effects of the medication, she will be fine.”

Main issues: It is important to be reassuring and matter of fact without reacting in a negative way. By acknowledging how the person may be feeling and checking to see if this is accurate, you allow the person to share his or her feelings. Helping the person to get some understanding of what is happening and why things are done according to protocol can also be valuable.

SCENARIO 6
A middle-aged man develops an infection following the implantation of a device. His goal was to decrease his opioid medication. Now, he has more pain, is taking more opioids, and is very angry at the outcome. He returns with his wife and demands to know what will be done for his pain.

PATIENT: [Noticeably angry and upset] “I am a lot worse off now since that failed procedure. What are you going to do about my pain?”
CLINICIAN: “I know that you had hope that this would help your pain, and it must be frustrating that you are experiencing more pain. Having a set-back like this is difficult for all of us. We need to work together to get you back to a better state.”
PATIENT: “But things are even worse now than ever.”
CLINICIAN: “I wish we could be 100% successful every time, but unfortunately that is not the case. I am afraid that this did not work out as we expected, but we will keep working on this and hopefully we will be able to turn this around soon.”

Main issues: In this case, underneath the anger, the patient is worried that he will be abandoned, and acknowledging this fear and worry as well as offering some reassurance is important. At first, allowing the patient to vent and express anger without becoming defensive or being angry in return can set the stage for greater partnership in the treatment process. It
is important to speak slowly and calmly and to clarify expectations of treatment and limitations in the treatment process. Spending time with an angry patient despite levels of discomfort and helping to get the patient to commit to maintaining a mutual relationship in the treatment process are also important.

**SCENARIO 7**

A 42-year-old man was referred for treatment of his chronic back pain. He had two back surgeries following a work-related injury and has been taking opioids for his pain. His primary care provider has been prescribing his medication, and he was referred because he had been running out of his medication early and had an abnormal urine toxicology screen. This patient was seen on follow-up after having completed a comprehensive set of screening questionnaires, a structured interview with a psychologist, and a toxicology screen.

PATIENT: “My doctor referred me to you because she no longer wants to write for my pain medication. She thinks that you should take over writing for my pain medication since you are at a pain center.”

CLINICIAN: “Your interview and questionnaire information suggest that you are at high risk for having problems with opioids. This means that we will need to be very cautious. So, if I manage your medication, I am going to have to require that you see me every 2 weeks, sign an opioid agreement, give a urine screen once a month, and participate in substance compliance counseling. We may also find in the end that you are not a good candidate for opioids to treat your pain.”

PATIENT: “You are just punishing me for being truthful about my drug history. Don’t you realize that I have real pain and I need pain medication?”

CLINICIAN: “If you had heart problems, I would not be giving you treatments that would cause problems for your heart. Your test results suggest that these medications can be a problem for you, and as a result, we need to be very careful—for your sake and ours.”

Main issues: The physician does not talk down to the patient or accuse him of being a drug abuser but instead educates him about the best course of treatment for someone with his risk factors. The suggestion is that there
must be an up-front doctor–patient agreement and that cooperation will be needed. Ultimately, the physician is expressing the final authority to decide what will be the best course of treatment.

**Summary and Conclusions**

Many things can contribute to patient conflicts when treating chronic pain: Patients with personality disorders, a busy work schedule, and ever-demanding regulations all can create problematic encounters. Despite the many patient factors that contribute to doctor–patient conflicts, some clinicians know how to recover from difficult patient interactions without long-term repercussions. Much is due to their skills in interpersonal relations and the effects these skills have on patients’ perception of their caregiver. Certain patients are difficult because of issues of psychiatric comorbidity and a substance use disorder, but the doctor’s use of tested interpersonal communication skills can help to prevent the escalation of conflicts. It is important to have access to mental health professionals who can assist in working with the most difficult patients. Increased coordination and adequate communication among the other providers is also important. Ultimately, the employment of positive communication strategies can improve doctor–patient relations and minimize conflicts within a pain management practice.

**ACKNOWLEDGMENT**

Special thanks are extended to Kathleen Gordon and Edith Mariano from the Patient Family Relations Triaging Program, Brigham and Women’s Hospital (BWH), for their invaluable assistance, and to the patients and staff of the Pain Management Center, BWH, Boston, for their inspiration and support.

This chapter contains a discussion of the common causes of joint pain encountered in clinical practice. These include osteoarthritis (OA), rheumatoid arthritis, the spondyloarthropathies (ankylosing spondylitis, psoriatic arthritis, and reactive arthritis), and crystalline forms of arthritis (gout and pseudogout). In addition, there will be a brief discussion of two other rheumatologic conditions: septic arthritis and polymyalgia rheumatica.

Basic Considerations

PROBLEM IN PERSPECTIVE

In December 2012, a study on the Global Burden of Disease and the worldwide impact of all diseases and risk factors reported that musculoskeletal conditions, including arthritis and back pain, affect more than 1.7 billion people worldwide and are the second greatest cause of disability worldwide.\textsuperscript{1} Musculoskeletal conditions have the fourth greatest impact on the overall health of the world population with regard to death and disability.

In the United States, the Bone and Joint Decade took place from 2002 to 2011, and data reported in 2012 found that 54% of adults (126 million) in the United States reported a chronic musculoskeletal condition that year. This is much higher than those reporting a circulatory problem (31%), respiratory problem (28%), diabetes (13%), or cancer (9%). Approximately 75 million Americans report neck or low back pain, 52 million arthritis, and 4.5 million Americans will have an activity-related
musculoskeletal injury each year. In addition, it is expected that 1 in 2 women and 1 in 4 men over the age of 50 years will have an osteoporosis-related fracture during their remaining years. Rheumatoid arthritis, an autoimmune form of arthritis, affects over 1.5 million adults in the United States, whereas over 300,000 children are afflicted with juvenile inflammatory arthritis. Both of these conditions not only affect mobility and quality of life but can also shorten life expectancy.

The economic burden is significant with an estimated $874 billion being spent both for treatment of musculoskeletal condition and in lost wages of affected workers.

**JOINT ANATOMY**

Joints in the extremities are synovial (diarthrodial) joints that permit movement over a wide range ([Fig. 34.1](#)). The joint is held together by a capsule of dense fibrous tissue and ligaments and gains further support from overlying muscle and tendons. The inner surface of the joint capsule is covered by synovium, which consists of an intimal layer of specialized cells called synoviocytes, and an outer layer of highly vascularized connective tissue. Synoviocytes comprise one to three cell layers and are of two basic types: A and B. Type A synoviocytes are active in phagocytosis, and type B cells synthesize hyaluronate, which is primarily responsible for the high viscosity of normal synovial fluid. Synovial fluid in a normal joint lubricates the surfaces of synovium and cartilage. The synovium is folded along the inside of the joint capsule and does not cover the load-bearing surface of articular cartilage. The connective tissue layer of synovium blends with periosteum, which does not cover the bone within the joint. The synovium has a rich network of capillaries, venules, and lymphatics, and it is innervated by sympathetic nerve fibers. The knee and the sternoclavicular and radiocarpal joints contain disks of fibrocartilage that help to stabilize these joints when they rotate. The fibrocartilage meniscus of the knee also helps improve joint congruity which is important in the normal distribution of weight with joint loading. The intervertebral facet joints are diarthrodial joints and are covered by synovium.
Amphiarthrodial joints are only slightly movable and include the symphysis pubis and the joints between vertebral bodies. The joint surfaces are separated by intervertebral disks. The sacroiliac joint has elements of both a diarthrodial and an amphiarthrodial joint.

Articular cartilage is composed of type 2 collagen and proteoglycans. Type 2 collagen is unique to joints and provides cartilage with form and tensile strength. Proteoglycan molecules are linked noncovalently to a long chain of hyaluronic acid and are interwoven within the network of collagen fibers. Proteoglycan molecules bind most of the water present in cartilage, which represents approximately 70% of the total weight of articular cartilage. The proteoglycan molecules are constrained within the meshwork of collagen fibers and are responsible for the resiliency of cartilage. Chondrocytes secrete collagen, proteoglycans, and enzymes that degrade the cartilaginous matrix. The process of remodeling and degradation is kept in balance unless the microenvironment of these cells is altered. Joints normally contain a small amount of synovial fluid, which is viscous and clear and does not clot spontaneously. Normal synovial
fluid contains fewer than 200 white blood cells per cubic millimeter; most of these cells are mononuclear.

**Nerve and Blood Supply**

Joints are supplied partly by articular nerves, which are branches of major peripheral nerves, and partly by branches of nerves supplying adjacent muscles as well as vasomotor sympathetic fibers. Nerve endings are distributed in the interstitial and perivascular tissue located in the subsynovium fibrous capsule, in the articular fat pads, and in the adventitial sheaths of arteries and arterioles supplying the joints. The periosteum is innervated, but articular cartilage and subchondral bones are not and thus not a direct source of pain in arthritis.

There are four types of receptors that supply joints. Type I receptors are ovoid corpuscles with a thin connective tissue capsule, and each is supplied by a small myelinated nerve fiber (5 to 8 mm in diameter) that arborizes within the capsule. The type I receptor occurs almost exclusively in the fibrous joint capsule, acts as a slowly adapting mechanoreceptor (stretch receptor), and resembles both structurally and functionally the Ruffini endings in the dermis. The type II receptor is approximately twice as large as the type I receptor and is supplied by a somewhat thicker myelinated fiber (8 to 12 mm in diameter) that usually ends as a single terminal within a rather thick laminated capsule. These receptors, which resemble the pacinian corpuscles, occur only in the fibrous joint capsule and have been shown to be rapidly adapting mechanoreceptors (acceleration receptors) that are sensitive to rapid movements. Type III receptors, which are the largest, are supplied by thick myelinated fibers that branch profusely. These receptors, which resemble the Golgi organs, are present in extrinsic and intrinsic ligaments (and not in the joint capsule) and adapt slowly and at high thresholds. Type IV receptors are represented by plexuses of fine unmyelinated fibers that occur in the fibrous joint capsules, ligaments, and subsynovial capsules and fat pads; they are considered to be the joint nociceptors.

An anastomotic plexus of blood vessels called the periarticular anastomosis, together with these nerves, surrounds the capsule, and its branches penetrate the capsule. The periarticular anastomosis is fed by
branches of arteries passing the joint and is the source of blood to the capillary bed in the synovial membrane and also to the epiphysis.

Clinical Approach to Joint Pain

A variety of disorders, both systemic and local, can involve the joints. The process of arriving at a diagnosis begins with a thorough history which should initiate a differential diagnosis. The physical examination and subsequent laboratory and imaging testing continue the process of narrowing the differential.

HISTORY

The musculoskeletal history begins by determining the pattern or patterns of joint complaints. The rheumatologist often divides joint complaints into three different types: inflammatory, mechanical, and fibromyalgia-type discomfort. Inflammatory conditions, such as rheumatoid arthritis, are characterized by joint stiffness in the morning lasting at least 30 minutes but often several hours. Patients generally feel better after activity as the fluid accumulated during inactivity is pumped out of a swollen, stiff joint by the lymphatics, thus reducing the sensation of stiffness. The presence of inflammatory cytokines such as interleukin (IL)-1 or tumor necrosis factor (TNF) may cause fatigue, anorexia, or a loss of the sense of well-being. Joints may initially be stiff and painful but with time typically demonstrate swelling on examination. There is a subtype of inflammatory pain caused by the presence of microorganisms (usually bacteria), blood, or crystals. These conditions typically have an acute onset and cause severe joint pain. The affected person keeps the joint at 30 to 40 degrees of flexion and resists movement of the involved joint. This is the position of maximum joint volume and attempts to flex or extend the joint leads to decrease joint volume and thus an increase in joint fluid pressure leading to pain (Boyle’s law). Joint contractures form in part because of this principle as chronic immobility can lead to capsular contraction even when the fluid in no longer present.

Mechanical joint pain, typified by OA, generally causes only 5 to 10 minutes of morning stiffness, but affected joints become progressively more painful with activity. There may be discomfort for some period of
time following use as well. Swelling may or may not be present or only present following stress. There are no systemic symptoms in patients with mechanical forms of arthritis.

Fibromyalgia-associated pain is characterized by all over morning stiffness or pain, a period of loosening up late morning or early afternoon, followed by fatigue and increased pain as the afternoon progresses. Sleep is poor, memory may be reported to be poor, and activity and exercise are poorly tolerated, and in fact, patients will report being in bed for 1 or 2 days following a strenuous physical or even emotional event. The diagnosis of fibromyalgia should be considered when a patient reports that they have one or two days of feeling severe fatigue and pain after an episode of significant physical activity or emotional distress. Even doing household chores may exacerbate the discomfort. Patients often describe their pain in dramatic terms such as the sensation of hot pokers or ice picks being driven into a particularly painful area. Patients with fibromyalgia often have other somatic complaints such as chronic low back pain, temporal mandibular jaw pain, or chronic headaches.

With experience, the clinician can with some ease categorize a patient’s joint complaints into one of these three major types. It is important to remember that Occam’s razor (the simplest explanation is usually correct) is usually best to follow, but it is not uncommon for patients with inflammatory disease to have one, two, or all three patterns simultaneously (Hickam’s dictum: the patients can have as many diseases as they darn well please). For example, a patient with rheumatoid arthritis can have active inflammatory arthritis (inflammatory pattern), have a rheumatoid arthritis associated damaged knee with secondary OA (mechanical pattern), and, because sleep and usual exercise activities may be disturbed by both former patterns, have fibromyalgia as well. With experience, a clinician can learn to distinguish the single-pattern from the multiple-pattern patient and help the patient understand that there is more than one cause to the pain. Patients generally adhere to Occam’s razor until taught otherwise.

**Number of Joints Affected**
The next step in developing a differential diagnosis is determining the
number of joints involved. There are three categories in joint number as well and include monoarthritis, pauciarticular (two to five joints affected), and finally polyarthritis (six or more joints). Tables 34.1, 34.2, and 34.3 give a general differential diagnosis inflammatory or mechanical joint pain pattern and number of joints involved. It is important to recognize that these are general guidelines because a polyarticular condition such as rheumatoid arthritis might initially present with less than six affected joints but progress over time to be polyarticular in character. Once a disease has been established for several weeks/months, these patterns tend to be more fixed.

Pattern Recognition
A helpful historical and examination finding is the pattern of joint involvement. For example, OA affects the spine, the hands, hips, knees, and first metatarsophalangeal (MTP) joints. In the hand, the distal interphalangeal (DIP) joints, proximal interphalangeal (PIP) joints, and base of the thumb joint (first carpometacarpal [CMC]) are affected. **The metacarpophalangeal (MCP) joints are spared in primary OA.** For rheumatoid arthritis, the pattern of involvement is cervical spine only, shoulders, elbows, wrists, hands, hips, knees, ankles, and MTP joints. In the hand, the PIP joints and MCP joints are affected, but the DIP joints are spared. Noting the distribution of affected joints is very helpful in developing a differential diagnosis. This will be discussed further when the individual conditions are presented.

Systemic Features of Arthritis
A variety of systemic or demographic features of illness also provides clues to the underlying diagnosis and is discussed with the individual
PHYSICAL EXAMINATION

When a patient reports that he or she has “joint pain,” it may be the result of tendon, ligament, muscle, bone, joint, or nerve abnormalities. The clinician needs to keep this in mind during the examination. For example, “knee pain” may be caused by an L4 radiculopathy or hip pain may radiate to the area of the knee. Joints should be examined for evidence of synovial proliferation, fluid, and bony enlargement as well as a range of motion. Tenderness, warmth, and any limitation of range of motion should be noted. Pain on passive motion of a joint suggests the possibility of inflammation or damage to the joint. Even though a patient may complain about a particular joint or joints, make sure to examine all joints. Milder abnormalities that may be present in nonpainful joints could add to the information on the number of joints involved and the pattern, thus helping with the differential diagnosis. Comparing an affected to a nonaffected joint often confirms the presence of swelling or deformity.

EXAMINATION OF SYNOVIAL FLUID

Examination of the joint fluid is helpful in patients who have undiagnosed arthritis. Diagnosis of infectious or crystal-induced arthritis is established by analysis of joint fluid. Characteristics of the joint fluid in various rheumatic conditions are shown in Table 34.4. Normal joint fluid usually contains fewer than 200 white blood cells per cubic millimeter, and these cells are predominantly mononuclear. In inflammatory effusions, the white blood cell count is usually elevated (typically over 2,000 white blood cells per cubic millimeter) with predominantly neutrophils present on cell count. Traditionally, cell counts greater than 75,000 per cubic millimeter suggest an infectious arthritis, but cell counts of this magnitude are also seen in noninfectious inflammatory joint diseases such as reactive arthritis or urate gout. Data suggested that a synovial fluid cell count over 25,000 cell per cubic millimeter should be evaluated for possible infection as the likelihood ratio of infection is greater than one; less than this level is unlikely to be related to a septic arthritis.
### Clinical Considerations

**OSTEOARTHRITIS**

OA is characterized by progressive loss of articular cartilage leading to joint pain and limitation of movement. Weight-bearing and frequently used joints are most often affected. The disease is divided into a primary (idiopathic) form, in which no predisposing factors are apparent, and a secondary form, which is associated with trauma, sequela of an inflammatory joint disease, a metabolic disease such as hemochromatosis, or a congenital structural abnormality. Primary OA is the more common form, but pathologically, the two forms are indistinguishable.

**Epidemiology and Pathophysiology**

OA is the most common form of arthritis worldwide and is the leading cause of disability in seniors. The disease occurs in all races and geographic areas. Prevalence and severity increase with age. Under age 55 years, the frequency and joint distribution of OA in men and women are approximately the same. After age 55 years, OA of the knee is more common in women and OA of the hip in men. OA can be demonstrated radiographically in almost all persons over the age of 75 years. Weight-bearing joints such as the hips, knees, feet, and cervical and lumbosacral joints are most often affected. The DIP and PIP joints of the hands are also commonly involved. Certain occupations have been shown to predispose a

WBC, white blood cell; PMN, polymorphonuclear leukocytes.
person to OA. In coal miners, for example, OA of the shoulders and knees is more frequent, presumably because of the forces placed on these joints during work. Prizefighters are more likely to develop OA of their MCP joints, football players of their knees, and ballet dancers of their ankles. Hereditary factors also exist: Heberden’s nodes are twice as frequent in mothers of affected persons and 3 times more frequent in sisters. A single-point mutation in the complementary DNA (cDNA) coding for type II collagen was found in family members with an inherited form of OA associated with a mild chondrodysplasia. Previous major trauma and repetitive use of a joint increase the risk of developing OA. Age alone is a risk factor, with the prevalence of OA increasing after age 45 years. Obesity has been shown to be a definite risk factor for developing OA of the hips and knees.

The progressive change within the joint in OA is well known. The cartilage initially shows fissuring and pitting, which eventually progress to erosions and denuded areas. The proteoglycan content of cartilage and the number of chondrocytes decrease in proportion to the degree of disease. Subchondral bone becomes thickened and has an eburnated, or ivory-like, appearance. Cysts appear in the subchondral bone, and the formation of new bone at the joint margins produces osteophytes or spurs. The synovium is thickened and contains a modest infiltration of lymphocytes, plasma cells, and an occasional multinucleated giant cell. The joint capsule and ligaments are hypertrophied. Figure 34.2 shows the arthroscopic appearance progressive nature of OA in the knee.
Research in OA has identified a variety of factors associated with the development of OA. These include aging (older more at risk), gender (females have a higher prevalence and severity than males), joint trauma, inflammation (inflammatory cytokines such as IL-1 are thought to contribute to joint damage), mechanical factors (weight/alignment issues), genetics (may account for as much as 60% of hip OA), and obesity (via a variety of factors including adipokines such as leptin). An interesting observation is that obesity leads to OA of the weight-bearing joints as might be expected but also to an increase risk of OA of the hand joints. In individual patients, all these factors may be contributing to a greater or lesser degree. Ultimately, prevention and treatment approaches will require that these factors be addressed in a more holistic fashion.
Symptoms and Signs

OA may be limited to one or two joints or may occur in a generalized form involving many joints. Involved joints are stiff for 30 minutes or less in the morning and after periods of inactivity. Pain typically develops with use. The involved joints also can ache at night affecting the quality of sleep. Night pain is caused in part by increased intraosseous venous pressure. As the disease progresses, pain becomes a constant feature of physical activity and can persist for several hours afterward. Eventually, restricted motion and joint deformities develop.

Primary OA most frequently affects the DIP joints, the first CMC joint, the scaphotrapezoid joint, the hips, knees, first MTP joint, and the cervical and lumbar spine.

Heberden’s nodes usually develop after age 40 years and are associated with OA of the DIP joints. Similar nodes, called Bouchard’s nodes, appear at the PIP joints (Fig. 34.3). At times, these nodes become red and painful to touch. Bony enlargement, small effusions, restricted motion, and angulation can be seen on physical examination. Radial subluxation of the first CMC joint gives a square appearance to this joint (shelf sign). A form of OA, referred to as primary generalized OA, appears most often in middle-aged women and affects the DIP and PIP joints of the hand, the first CMC joint, knees, hips, and the first MTP joint. Episodes of inflammation are characterized by warmth, pain, and swelling of these joints.

FIGURE 34.3 Osteoarthritis of the hands. Note Heberden’s nodes (distal interphalangeal joints) and Bouchard’s nodes (proximal interphalangeal joints) in this patient with classic hand osteoarthritis.
OA of the hip is usually unilateral, but the opposite side is also affected in approximately 20% of patients. Congenital or developmental abnormalities such as slipped capital femoral epiphysis, Legg-Calvé-Perthes syndrome, or hip dysplasia underlie many of the cases. OA follows avascular necrosis, which can be related to deep-water diving, glucocorticosteroid therapy, alcohol, or sickle cell disease. Hip pain is experienced in the groin, over the greater trochanter, in the buttock, or down the anterior and inner thigh. Pain might be referred to the distal thigh and upper knee because the obturator nerve and its branches supply both hip and knee. As noted earlier, hip disease can be mistaken for knee arthritis or trochanteric bursitis because hip pain can be referred to those locations. The pain of hip disease is often described as dull and aching and is initially experienced with physical activity. Later, night pain is also experienced. Patients might limp and have difficulty rising from a sitting position. Functional shortening of the leg caused by adduction and flexion contractures causes the patient to walk with a shuffling gait. Examination of the hip shows initially decreased internal rotation that is followed later by decreased extension, abduction, and flexion as well as a flexion contracture.

Previous injury such as a torn meniscus or ligament predisposes the knee to secondary OA. The presence of an alignment abnormality such as genu varum (bow legs) or genu valgum (knock knees) increases the force directed through either the medial or lateral side of the knee and can lead to OA. These deformities are also acquired in OA as a result of destruction of either the medial or lateral articular cartilage. Obesity predisposes the knees to OA by the additional weight and by the thigh thickness, which places the legs in a genu varus position and increases the pressure on the medial compartment. In addition, obesity leads to the production of a variety of cytokines and adipokines that may affect the quality or quantity of cartilage. Pain also can be localized to either the medial or lateral aspect of the joint depending on which compartment is primarily involved. Atrophy and weakness of the quadriceps muscle develop with progression of the arthritis. Crepitus might be noted with bending of the knee as well as an effusion. With more severe disease, a contracture may be present which increases the energy required to stand upright. With loss of
ligamentous and muscle support, the knee becomes unstable, and the patient may be hesitant to walk on uneven surfaces. The knee might suddenly give way because of a pain reflex. A loose cartilaginous fragment, sometimes referred to as a loose body, can prevent the joint from being fully extended.

Patellofemoral arthritis occurs alone or in conjunction with arthritis of the other knee compartments, especially in older patients. The term chondromalacia patellae is often used interchangeably with patellofemoral arthritis, although some restrict this term to a self-limiting disorder occurring in adolescents and young adults. Patellofemoral arthritis is caused in some patients by improper tracking of the patella through the patellofemoral groove (trochlea). The patella is pulled to the lateral margin of the groove by a tight lateral patellar retinaculum or a relative weakness of the vastus medialis compared with the vastus lateralis of the quadriceps muscle. Lateral subluxation of the patella can also be caused by an increased Q angle resulting from rotational misalignment of the femur and tibia.

In the spine, intervertebral disks and apophyseal (facet) joints are sites for OA. Involvement of intervertebral disks is referred to as spondylosis, whereas disease in the apophyseal joints is considered true OA. OA also affects the joints of Luschka (uncovertebral joints), which are located in the cervical spine between the superior process of one vertebral body and the inferior process of the vertebral body above it.

Symptoms of spine involvement are localized pain and stiffness, referred or dermatomal pain, and radicular pain from nerve root compression. Nerve root involvement produces paresthesias, decreased sensation, loss of muscle strength, and diminished or absent deep tendon reflexes. OA of the cervical spine causes either localized pain or pain referred to the occiput, shoulder, interscapular area, or arm, depending on the level affected. With upper cervical disease, the pain tends to be referred to the occiput, and with lower cervical involvement, it is referred to the shoulder, upper arm, or interscapular area. Neurologic manifestations are also caused by compression of the spinal cord by posteriorly directed osteophytes and by occlusion of the anterior spinal artery by a herniated disk. Cervical spine diseases are discussed in Chapter
SECONDARY OSTEOARTHRITIS

OA can develop in joints that have been damaged. A torn knee meniscus or ligament can lead to incongruity of the joint surfaces resulting in OA. In addition, ligaments contribute to proprioceptive input and injury to these structures may increase the risk of developing OA. OA may follow joint damage produced by infectious arthritis or an inflammatory arthritis such as rheumatoid arthritis. Neuropathic joint disease is a severe form of OA resulting from the loss of pain sensation, proprioception, or both. Without these protective mechanisms, joints are subjected to repeated trauma, leading to progressive cartilage damage. Diabetes is the most common cause of neuropathic joint disease. Other causes include tabes dorsalis, syringomyelia, amyloidosis, meningomyelocele in children, and leprosy.

OA occurs in patients with excessively hypermobile joints. Patients with Ehlers-Danlos syndrome, a hereditary disorder of connective tissue, develop OA of their hands, shoulders, knees, and ankles usually before age 40 years. Debate exists regarding whether patients with idiopathic joint hypermobility are at risk of developing premature OA.

Several metabolic disorders are associated with the development of OA. These include hemochromatosis, ochronosis, and acromegaly. Arthritis occurs in 20% to 50% of patients with hemochromatosis and may appear before other overt clinical manifestations. Hands, knees, and hips are most commonly affected. A particularly characteristic finding is involvement of the second and third MCP joints, which are rarely affected in primary OA. A person, especially a male with early onset OA or OA in unusual locations such as the MCP joints or the shoulder should be investigated for a metabolic disorder especially hemochromatosis. Look for >60% saturation of total iron binding capacity or a markedly elevated ferritin. Ochronosis is a rare disorder caused by a hereditary deficiency of homogentisic acid oxidase, leading to accumulation of homogentisic acid in connective tissue. Deposits of homogentisic acid impart a blue-black hue to the sclerae and external cartilage of the ears. Arthritis appears in middle age and involves most often the knees, shoulders, hips, and spine.
These patients frequently have calcified intervertebral disks. Approximately 60% of patients with acromegaly develop OA, which most often involves the spine, knees, hips, shoulders, and, occasionally, ankles. The increased growth of articular cartilage causes joint surface incongruity and abnormal wear.

**Laboratory Findings**
Routine laboratory work is normal in patients with primary OA. The synovial fluid in OA is straw-colored and has good viscosity. The cell count is usually less than 2,000 white cells per cubic millimeter, and the cells are predominantly mononuclear. Radiographs in early OA are usually normal, but as the disease progresses joint space narrowing, subchondral bone sclerosis, subchondral cysts, and osteophytes are observed (Fig. 34.4). Erosive OA is characterized by erosions on the joint surface, sclerosis of subchondral bone, and later by bony ankylosis. Radiographic abnormalities do not always correlate with clinical symptoms.

**FIGURE 34.4** Osteoarthritis of the hip. The features of osteoarthritis are well illustrated in this x-ray including joint space narrowing, subchondral cysts, osteophytes, and subchondral sclerosis (thickening of the bone where cartilage has been lost).

**Treatment**
Think about the treatment of OA as a program especially when the weight-
bearing joints are involved. Basically, the program consists of three parts: physical modalities, medications, and surgery. The goal in OA should not necessarily be 100% pain relief, as absence of pain in a biomechanically abnormal joint may not be a good thing. The goal should be to reduce pain to a level that promotes quality of life and activity.

Physical modalities include education, weight loss if needed, joint protective aerobic exercises, range of motion exercises especially focusing on reduction of contractures, muscle-strengthening exercises, assistive devices such as a cane, and attempts to affect alignment with off-loading knee braces or patellar taping, if needed. The Arthritis, Diet, and Activity Promotion Trial demonstrated the benefit of promoting both exercise and weight loss in an 18-month-long program that examined both together versus either one alone.\textsuperscript{21} The control group was healthy lifestyle. The combination group lost more weight than the weight loss group alone (5.7% of body weight vs. 4.9%), and the combination group had a 24% improvement in physical functioning and a 30% decrease in knee pain over the study period. The exercise group only showed improvement in walk time while the weight loss group showed no significant improvement in any of the variables related to the arthritis. Correct use of a cane can off-load a joint by up to 24% and has been shown to reduce pain in OA of the hip or knee. There is evidence for a modest benefit with the use of an off-loading knee brace designed to realign either a varus or valgus knee misalignment.\textsuperscript{22}

The first-line pharmacologic therapy for OA is over-the-counter analgesics (e.g., acetaminophen, 1,000 mg four times a day or even less if it is effective). If the patient remains symptomatic after 2 to 4 weeks, low-dose ibuprofen or nonacetylated salicylates are indicated. If the response is still inadequate after 2 to 4 weeks, the patient should be placed on a full dose of a nonsteroidal drug. In the patient with risk factors for upper gastrointestinal bleeding or ulcer disease, a proton pump inhibitor should also be provided. There is one cyclooxygenase-2 (COX-2) inhibitor currently on the market, celecoxib, which could be used for patients as significant risk of gastrointestinal bleeding if other options do not work. Because of a concern for cardiac toxicity from the COX-2 agents, use the recommended dose of no more than 200 mg per day. There was for a time
some excitement about glucosamine based on a European trial (sponsored trial) published in the Lancet in 2001.\textsuperscript{23} The data suggested not only a clinical benefit over placebo but also a possible disease modification of OA. A publicly funded U.S. five-arm trial (glucosamine, chondroitin, combination, nonsteroidal anti-inflammatory drug [NSAID], and placebo) did not demonstrate an impressive effect of either nutraceutical in OA, although the placebo response was impressive.\textsuperscript{24,25} In the 2012, American College of Rheumatology (ACR) treatment guidelines for OA includes a recommendation that these not be used.\textsuperscript{26}

Intra-articular corticosteroid injections are effective in OA and can be used as part of the overall program. How often can injections be given? For many years, these were limited due to the concern about the development of Charcot joints. Again, the comments about not being too effective in controlling pain should be remembered. Data suggested that corticosteroid injections can be given every 3 months for at least 2 years with clinic benefit without structural change. In the absence of data, injections should probably not be given more frequently than this.\textsuperscript{27} Injectable hyaluronic acid is approved for use on OA of the knee. A meta-analysis of data on hyaluronic acid injections in knee OA suggests a small benefit especially for the higher molecular weight compounds.\textsuperscript{28} Treatment with hyaluronic acid requires three to five injections and can be used in patients who fail more conservative therapy. Other options in the 2012 ACR guidelines include use of topical NSAIDs for hands and knees such as diclofenac and tramadol.

When a joint is severely damaged and painful, joint replacement should be considered. Total hip replacement has provided dramatic relief of pain and improvement of function. Placement of a knee or shoulder can also be quite helpful. Correction of a valgus or varus deformity by osteotomy of the knee improves weight distribution and extends the functional life of the joint. Rebuilding the first CMC joint and replacement of the PIP joint with a prosthesis are now possible. Surgery is generally suggested for patients with a level of pain that is not controlled with physical modalities or medications and the patient is willing to endure a period of hospitalization and physical therapy.
RHEUMATOID ARTHRITIS

Rheumatoid arthritis is an inflammatory polyarthritis of unknown etiology that involves peripheral joints in a symmetric distribution. The worldwide prevalence varies from 0.097 to 2.900 per 1,000. In the United States, the prevalence is 1% to 2%. Women are more commonly affected: The average ratio is 3:1. Certain Native American populations in the United States can have prevalence rates as high as 7%.

Etiology and Pathophysiology

Even though the etiology of rheumatoid arthritis remains unknown, significant advancements have been made in the understanding of the inflammatory events leading to joint injury and extra-articular manifestations. It is a disease process where genes and environment interact in pathologic dance that leads to autoimmune disease. The genetic contribution is polygenic, and currently, there are 100 or so risk genes identified. It is estimated that 40% to 65% of the risk in rheumatoid arthritis is associated with genetic factors. The strongest genetic association exists with the HLA-DR4 antigen that is present on the surface of cells of the immune system. The so-called shared epitope (SE), which is carried by the vast majority of people with rheumatoid arthritis, is a five-amino acid sequence found on the third allelic hypervariable region of the HLA-DRβ chain of the HLA DR4 molecule. The presence of the SE confers not only disease risk but also severity. One of the earliest events in the development of rheumatoid arthritis is the appearance of anti-citrullinated antibodies. These antibodies appear as a result of inflammation causing the deamination of the amino acid arginine and the formation of the amino acid citrulline. Citrulline is not a normally occurring amino acid in the human body and its appearance in human proteins constitutes neoantigen formation to which the immune system responds. The HLA-DR4 molecule with its HLA-DRβ on T cells interacts with processed antigen (i.e., proteins that contain citrulline) from antigen-presenting cells, and if the HLA-DRβ happens to contain the SE, it is perfectly shaped or charged to interact with citrullinated peptides. The active T cells then produce inflammatory cytokines and also interact with B cells to produce antibodies against the citrulline-containing peptides.
(anti-CCP antibodies). There is typically a period of time when only the anti-CCP antibodies are present with no articular symptoms. This may be as long as 14 years.\textsuperscript{32} Then, at some point, the anti-CCP antibodies, joined often by rheumatoid factor, gain access to the joint and lead to inflammation. Rheumatoid factor is produced in the setting of immune complex disease and may serve as a protective mechanism to remove these from circulation. The hallmark of rheumatoid arthritis is the proliferation of synovium, which spreads over the articular surface as a pannus and damages cartilage, bone, and joint capsule. This process leads to eventual joint damage/destruction with the classic changes on examination.

The environmental exposure that may lead to lung inflammation and production of citrullinated peptides is smoking. An interesting piece of evidence in this light is the fact that rheumatoid arthritis was rare in the Old World before European exploration of the New World and seems to have appeared in Europe after this period.\textsuperscript{33} Rheumatoid arthritis has been diagnosed via skeletal remains in certain Native American population antedating the age of exploration, leading some to speculate that the disease is a New World phenomenon that was transmitted back to the Old World. One of the New World products taken back to Europe was tobacco. There is a very strong relationship between smoking and the development of and severity of rheumatoid arthritis.\textsuperscript{34}

**Symptoms and Signs**
The typical patient with rheumatoid arthritis is a young to middle-aged woman who presents to her physician with a history of 2 to 3 months of joint pain and stiffness in her hands. Constitutional symptoms of fatigue, weight loss, and low-grade fever might also be present. The hands and other involved joints are stiff on arising in the morning. Stiffness might last from 30 minutes to 2 hours or longer. In severe disease, the patient might remain stiff most of the day.

Patients with involvement of the hands and wrists might have difficulty performing tasks such as lifting pots, washing their hair, and opening jars or doors. A firm handshake can be quite painful. Tingling and numbness of the thumb and index and middle fingers, which often occur at night, indicate compression of the median nerve by synovial tissue in the carpal
tunnel (carpal tunnel syndrome). At times, the carpal tunnel syndrome produces pain radiating up the forearm and down into the hand. Rheumatoid arthritis can begin in the feet in the MTP joints. It is not unusual for a patient to attribute metatarsalgia to improperly fitting shoes before seeking medical attention.

On physical examination, the joints are swollen, tender to palpation, and warm but not hot. The combination of synovial proliferation and fluid gives the joint a boggy sensation on palpation (Fig. 34.5). Synovial proliferation in the flexor tendons of the fingers fills in the palm, giving it a flat appearance. The skin over the small joints often has a bluish discoloration resulting from venous engorgement. The hands may be cool and clammy. The range of joint motion is initially limited by pain and later by contractures. Ulnar deviation of the fingers at the MCP joint is a common deformity in established disease and results from radial deviation of the wrist and slippage of the extensor tendons to the ulnar side of the MCP joints. Another common deformity of the hand that develops in chronic disease is the swan-neck deformity. This appearance results from flexion of the DIP joint and MCP joint with hyperextension of the PIP joint. The boutonniere deformity is caused by avulsion of the extensor hood over the PIP joint, leading to a flexion deformity of this joint and hyperextension of the DIP joint. In advanced disease, subluxation and flexion deformities are common and involve the knees, ankles, elbows, wrists, shoulders, hands, and feet.

**FIGURE 34.5** Example of rheumatoid arthritis of the hands. Distal interphalangeal joints are spared, whereas the metacarpophalangeal and proximal interphalangeal joints are swollen. There is
beginning to be some early ulnar deviation on the left hand.

The natural history of rheumatoid arthritis is highly variable. Fifteen percent of patients may go into complete remission, whereas 10% or less go on to destructive disease that responds poorly to all forms of therapy. Most patients fall between these two groups with variable periods of remission and relapse. Some patients experience significant disability, whereas others respond to treatment and function quite well throughout their lifetimes. Prognostic factors for more severe disease include the presence of high titers of rheumatoid factor, elevated anti-CCP antibodies (see discussion later), presence of HLA-DR4, and more joints initially involved. Patients with seronegative rheumatoid arthritis (negative for anti-CCP and rheumatoid factor) are a different disease genetically and risk factor–wise and generally have a better prognosis that seropositive rheumatoid arthritis.

**Laboratory Findings**

Patients often have a normocytic normochromic anemia and an elevated erythrocyte sedimentation rate (ESR). Approximately 80% of patients have a positive rheumatoid factor test result. In the last several years, the anti-CCP has emerged as an important diagnostic and prognostic test. It detects the presence of antibodies to citrullinated peptides and is 75% sensitive and 96% specific for rheumatoid arthritis. The higher levels are correlated with more erosive disease and may appear before overt arthritis has appeared. Radiography in early disease reveals only juxta-articular osteopenia and soft tissue swelling. In more advanced disease, one finds narrowing of joint spaces, erosions at the margins of the joint, and eventually subluxation (Fig. 34.6). The synovial fluid usually has a white blood cell count that varies from 5,000 to 25,000 cells per cubic millimeter (most of the cells are neutrophils), decreased viscosity, and a low glucose level, although this is rarely measured anymore (see Table 34.4).
Treatment Philosophy
The treatment of rheumatoid arthritis has undergone considerable rethinking over the years. The time-honored approach to the treatment of rheumatoid arthritis has been based on the pyramid, in large part because of the philosophy that rheumatoid arthritis was a disabling but otherwise benign disease. Following the treatment pyramid philosophy, patients would receive NSAIDs or salicylates along with education and physical and occupational therapy, and as the disease progressed, more aggressive therapy with immunomodulating drugs known as disease-modifying antirheumatic drugs (DMARDs) of increasing toxicity would be used. In 1965, up to 120 months would pass before a DMARD would be started. Because a majority of patients with rheumatoid arthritis develop erosions by 2 years of disease and it has been found not to be the benign disease it was once thought to be, it has been suggested that we invert the pyramid; that is, begin with aggressive therapy up front to prevent erosive changes to joints that are generally not reversible and thus prevent the disability and potentially the mortality caused by unchecked rheumatoid arthritis. There has been a dramatic change in the level of disability and prognosis of rheumatoid arthritis in the last 10 to 20 years with the philosophy of early aggressive therapy and treating to target to prevent joint damage. Most patients who accept therapy will never know how
sick they can be. Currently, rheumatologists start a DMARD as soon as the diagnosis of rheumatoid arthritis is made and medication-induced remission rates in rheumatoid arthritis are now approaching 50% with the combination of methotrexate and biologic agents that will be discussed later.

Current Management of Rheumatoid Arthritis
Disease-Modifying Agents
Current therapy of rheumatoid arthritis is early diagnosis and early aggressive therapy especially for patients who have factors indicative of a poor prognosis, namely, high titer rheumatoid factor or CCP and a high number of joints involved at presentation.\textsuperscript{29,40–42} Disease activity scores are routinely monitored and therapy changed to lower rheumatoid arthritis disease activity into remission or low disease activity level. Patients with features that suggest more severe disease are typically started on methotrexate or even combination therapy from the outset, whereas patients with features or low disease activity may be started on less-potent DMARDs such as hydroxychloroquine or sulfasalazine. If after 3 to 6 months of therapy, if there is incomplete control of the disease, other agent(s) are added to the regimen. These can include triple therapy which is a combination of methotrexate, sulfasalazine, and hydroxychloroquine or methotrexate plus a biologic especially one of the anti-TNF agents.

Patients with early mild synovitis could be started on hydroxychloroquine. This agent takes 8 to 12 weeks before it begins to affect the synovitis. Its mechanism of action is thought to be on the basis of increasing the pH of the vacuoles in antigen-presenting cells and gently disrupting the interaction of the major histocompatibility complex with antigen, thus affecting the way antigen is presented to T cells.

Hydroxychloroquine is dosed by weight at 6.5 mg/kg/day in divided doses. Doses higher than this increase the risk for ocular toxicity. Common side effects include diarrhea, gastrointestinal upset, and rash. Serious side effects are listed in Table 34.5 as well as a monitoring schedule. Improvement in morning stiffness and pain, as well as a decrease in the number of tender and swollen joints, and a reduction in acute-phase reactants (i.e., ESR or C-reactive protein [CRP]) are measures of success.
Patients with more significant synovitis may be candidates for either sulfasalazine or methotrexate as single agents.

Sulfasalazine is another DMARD used for less severe disease. It is a combination of sulfapyridine and 5-aminosalicylic acid, which is cleaved by gut bacteria into two compounds. It is thought that the sulfapyridine moiety is the active one in rheumatoid arthritis. It is dosed generally at
2,000 mg in two divided doses. It takes 4 to 8 weeks for an effect to be apparent in most patients and in some may be up to 12 weeks. Common side effects include gastrointestinal upset, diarrhea, and rash. Severe agranulocytosis can occur and is idiosyncratic. Drug cessation resolves the cytopenias in most cases, but there have been a few cases requiring granulocyte colony-stimulating factor therapy. Glucose-6-phosphate dehydrogenase (G6PD) deficiency may lead to severe anemia in affected patients and should be checked before starting therapy if suspected.

Methotrexate is the current “workhorse” drug for rheumatoid arthritis. It is used by itself or more and more frequently in combination with other agents. In rheumatoid arthritis in particular, methotrexate plus something else seems to work better than either agent alone. The dose range and other characteristics are presented in Table 34.5. Methotrexate is a dihydrofolate reductase inhibitor. Its mode of action is uncertain but may be caused by an increase in adenosine, an anti-inflammatory compound. Methotrexate has the advantage of being given once a week and can be given both orally and subcutaneously. Methotrexate begins to be effective generally in 3 to 8 weeks after initiation of therapy. Common side effects include stomatitis, nausea, gastrointestinal upset, and mild hair thinning. Stomatitis in particular might respond to the addition of 1 mg of folic acid daily without affecting its activity in rheumatoid arthritis.

Leflunomide is a newer DMARD. The usual dose is 10 to 20 mg per day. Data indicate that it is similar to methotrexate in efficacy as well as toxicity. It has had, if you would, the misfortune to come to market at the same time as the anti-TNF biologic agents and thus somewhat overshadowed by the impressive results of these agents.

Biologic Disease-Modifying Antirheumatic Drugs
There are currently five anti-TNF DMARD on the market. Etanercept, infliximab, adalimumab, certolizumab, and golimumab are anti-TNF agents that have been shown to be quite effective in not only controlling inflammation in rheumatoid arthritis but also preventing joint damage. In fact, data from the early anti-TNF studies for rheumatoid arthritis called the TEMPO trial indicated that the combination of methotrexate plus etanercept can prevent new erosion in 76% of patients over 3 years and
even lead to filling in of previous erosions.\textsuperscript{29,40,43} In addition to anti-TNF therapy, there is anti–T cell therapy with abatacept, anti–B cell therapy with rituximab, anti–IL-6 therapy with tocilizumab, and the first of likely many oral agents that affect cytokine activity, tofacitinib, a janus kinase inhibitor. Table 34.5 has a list of DMARD therapies, including name, mechanism of action, dose, and common side effects.

Glucocorticoids
The anti-inflammatory mechanisms of glucocorticoids include altering leukocyte traffic and function, stabilizing lysosomal membranes of neutrophils and monocytes, and inhibiting the secretion of destructive enzymes including collagenase and elastase.\textsuperscript{44} They also inhibit the products of arachidonic acid metabolism including prostaglandins and leukotrienes.

A 2012 study of methotrexate plus 10 mg of prednisone compared to methotrexate alone for 2 years showed the combination therapy had less joint damage, needed less methotrexate to control disease activity, and needed to change therapy less often than those on methotrexate alone.\textsuperscript{45} The study reported no more side effects in the combination group compared to the methotrexate alone group. Low-dose prednisone treatment can be especially beneficial during initiation of treatment with a DMARD. Glucocorticoids are often used as bridge agents for patients diagnosed with rheumatoid arthritis (i.e., 5 to 10 mg per day until the DMARD begins to work). In patients on corticosteroids, it is important to give calcium in the range of 1,000 to 1,500 mg per day and vitamin D 400 units a day. Patients should be monitored closely for evidence of hypercalcemia and hypercalcinuria. A bisphosphonate (e.g., alendronate) may also reduce the bone loss of calcium in patients on corticosteroids.

Judicious intra-articular administration of corticosteroids can be quite useful in the treatment of rheumatoid arthritis. In a badly damaged joint or one that is soon to be replaced by a prosthetic joint, corticosteroids should probably not be injected within 6 weeks of surgery.

Surgery
Indications for orthopedic surgery in rheumatoid arthritis are twofold: pain unresponsive to medical management and loss of function. Synovectomy
of selected joints provides alleviation of symptoms and improvement of function in the first year after operation but may not provide a long-term effect. Removal of synovial tissue from the wrist and dorsal tendon sheath and resection of the ulnar head might prevent rupture of the extensor tendon. Patients with severely deformed hands can benefit from MCP arthroplasty. Patients with severe pain and loss of function can benefit from total joint replacement, especially the knee or hip. Metatarsal head resection can be of tremendous help in patients with painful metatarsal heads. Intermittent splinting of selected joints is beneficial.

**Important Complications of Rheumatoid Arthritis Presenting with Pain**

Carpal Tunnel Syndrome
Carpal tunnel syndrome is a common problem in rheumatoid arthritis caused by wrist synovitis that can lead to median nerve compression. Therapy is generally directed at the rheumatoid synovitis with DMARDs and anti-inflammatory agents. A wrist injection with corticosteroids may be helpful in many cases. Carpal tunnel release may be necessary in some cases.

Rheumatoid Vasculitis
This is a potentially life-threatening complication. Patients with long-standing, seropositive, erosive rheumatoid arthritis are generally at risk for this small to medium vessel vasculitis similar to polyarteritis nodosa. Patients may present with digital gangrene or symptoms of mononeuritis multiplex (i.e., foot drop). More serious complications include intestinal perforation or cardiac involvement. Kidneys are less commonly involved than in polyarteritis nodosa. Treatment is traditionally with cyclophosphamide and high-dose prednisone, but even with aggressive therapy, historical survival rates were only 60% at 5 years. More recently, there has been some experience with rituximab in rheumatoid vasculitis with reported high rates of success in induction and maintenance, although the data is at the level of retrospective case series and case reports. Fortunately, with the current approach to early aggressive treatment of rheumatoid arthritis, complications such as rheumatoid vasculitis are now
relatively rare.

Cervical Spine Disease
The synovial portions of the cervical spine can be involved in rheumatoid arthritis. This can lead to C1–C2 instability or subaxial instability. Symptoms may be caused by cord or vascular compression and may include neck pain, shock-like sensation up or down the spine, and intermittent loss of consciousness when vertebral artery compression occurs. Before surgery, all patients with long-standing rheumatoid arthritis should have a set of lateral flexion and extension views of the cervical spine taken to evaluate the cervical spine for C1–C2 subluxation.

Septic Arthritis
Patients with rheumatoid arthritis are at increased risk of septic arthritis caused by abnormal joint architecture, use of immunosuppressive drugs, and skin breakdown over high-pressure, biomechanically abnormal sites such as the feet. Patients often present with one joint out of proportion to the others in terms of pain or swelling and may have a paucity of systemic symptoms typical in non–rheumatoid arthritis patients. Detection is imperative because of the high mortality in such patients (i.e., 20% mortality if a single joint is infected and over 50% in patients with multiple joints involved).48

THE SPONDYLOARTHROPATHIES
Ankylosing Spondylitis
Ankylosing spondylitis is an inflammatory arthritis involving sacroiliac joints and the spine. Inflammation also occurs at sites of tendon and ligament insertions (enthesitis). Hips and shoulders are the most common peripheral joints involved, but rarely, the joints of the hands and feet can be affected as well. Onset of disease is usually in the second or third decade, and men are predominantly affected. The histocompatibility antigen HLA-B27 is found in 90% or more of patients.49 The normal frequency of HLA-B27 in the white population is approximately 7%.

Pathophysiology
Synovitis occurs in the apophyseal and costovertebral joints of the spine
and peripheral joints and is characterized by synovial hyperplasia with focal accumulation of lymphoid and plasma cells. Inflammation also involves cartilaginous joints, which include the intervertebral disks, manubriosternal joint, and symphysis pubis. With progression, ossification of the outer layers of annulus fibrosus of the disk and the inner layers of the longitudinal ligaments forms syndesmophytes that eventually interconnect to give the spine the appearance of bamboo.

In recent years, the enthesis (insertion of tendons, ligaments, and joint capsule to bone) has become an important tissue in the understanding the pathophysiology of spondyloarthropathies. These are common sites of inflammation, and it appears that inflammation may begin on the bone side at areas rich in fibrocartilage such as enthesis and extend to surrounding tissues. The knee has some 32 entheses alone, and the concept of enthesitis explains the clinic finding of dactylitis or sausage digits in the spondyloarthropathies (Fig. 34.7).

**FIGURE 34.7** Classic example of dactylitis, a.k.a. “sausage digit,” in a patient with a spondyloarthropathy (psoriatic arthritis in this case).

Symptoms and Signs
The patient initially notes low back pain and stiffness, especially at night when trying to sleep and on arising in the morning. The stiffness of the back lasts for several hours in the morning and occurs after periods of inactivity during the day. The pain might radiate into either buttock, extend down the back of the leg to the knee, and can be mistaken for the pain caused by herniated disk. The pain might alternate from side to side.
The back symptoms can be continuous or may be episodic. Involvement of the hips and shoulders causes pain, stiffness, and decreased motion. Costovertebral joint arthritis can cause chest pain similar to that of angina pectoris or pleurisy. Spine ankylosis typically develops insidiously over 10 years or more of disease activity. The extent of involvement varies among patients and ranges from bilateral sacroiliitis to complete ankylosis of the spine. The spondylitis sometimes skips segments of the back. Atlantoaxial subluxation (with the potential danger of spinal cord compression) can occur, but this is observed less often in ankylosing spondylitis than in rheumatoid arthritis. The fused spine, especially the neck, is susceptible to fractures with even limited trauma.

Acute iritis occurs in approximately one-third of the patients. It is typically unilateral and episodic and can rarely lead to vision-altering changes. A rare manifestation of ankylosing spondylitis is fibrosis of the upper lobes of the lung, which occurs late in the course of the disease. Also with long-standing disease, dilatation of the proximal aorta may lead to insufficiency of the aortic valve and inflammation of the atrioventricular bundle can produce cardiac conduction abnormalities. Patients occasionally have significant constitutional symptoms of fever and weight loss.

On physical examination, sacroiliac tenderness is elicited by direct palpation or by maneuvers that stress the joint. A loss of normal lumbar lordosis occurs, giving the lumbar area an ironed-out appearance. Flexion is limited and can be documented by performing a modified Schober test. The test is performed marking the midpoint between the posterior superior iliac spines and measuring and marking 10 cm vertically. When the patient bends forward to touch toes with the knees straight the top, mark should move 5 cm or now measure 15 cm total. Tenderness can be present over costovertebral joints, iliac crests, greater trochanter, and heels. Chest expansion is limited. In advanced disease, the spine becomes rigid, fusing in varying degrees of flexion.

Laboratory Findings
The sedimentation rate or CRP can be elevated, and a mild hypoproliferative anemia can occur. The rheumatoid factor test result is negative, and one would rarely mistake rheumatoid arthritis and
ankylosing spondylitis. The synovial fluid is inflammatory (see Table 34.4). Radiography of the sacroiliac joints in early disease shows blurring and irregularity of the joint margins, followed later by subchondral erosions, sclerosis, and eventually fusion (Fig. 34.8). Bony spurs appear at tendinous insertions such as the sites of attachment of the Achilles tendon and plantar fascia. Radiography shows a straight lumbar spine, squared vertebrae, and syndesmophytes. Syndesmophytes extend along the outer aspect of the intervertebral disk and eventually form a bridge between adjacent vertebrae (bamboo spine).

FIGURE 34.8 Ferguson view of the pelvis showing reactive bone changes around the sacroiliac joints as well as an indistinctness to the joints caused by erosions.

Treatment

Nonsteroidal Anti-inflammatory Drugs. NSAIDs are especially useful in reducing inflammation and relieving pain, and there is some evidence of mild disease-modifying behavior for high-dose NSAIDs. It is speculated that NSAIDs may encourage the patient to be more mobile and possibly lessen the chance of spine fusion, but NSAIDs also influence bone metabolism. Preferred agents include indomethacin or a once-a-day agent such as piroxicam because of their anti-inflammatory activity. Any anti-inflammatory agent chosen usually needs to be dosed at an anti-inflammatory level (i.e., upper limit of dosing range) for benefit.

Disease-Modifying Antirheumatic Drugs. Sulfasalazine has been shown to be beneficial for the peripheral joint in ankylosing spondylitis but not the spine. Methotrexate may also be helpful for peripheral joint disease.
The anti-TNF agents have a significant impact on disease symptoms and also diminish both bone edema and enthesitis by serial magnetic resonance imaging (MRI) scan. Anti-TNF agents may have disease-modifying activity if used early in the course of the illness. Once the patient has some degree of ossification, the anti-TNF agents may not halt further ossification. The newest agent for treatment of ankylosing spondylitis is secukinumab, an anti–IL-17 agent. It is given by subcutaneous injection every week for 1 month and then monthly thereafter. Anterior uveitis or iritis can be treated with topical or intraocular corticosteroids, and in severe cases, methotrexate or the monoclonal anti-TNF agents such as adalimumamab (officially approved for treating uveitis) or infliximab can be used. Etanercept, a fusion protein, is not effective for uveitis.

**Physical Therapy and Surgery.** Physical therapy is directed at maintaining the erect posture of the patient. Patients should be encouraged to sleep in the prone position and to avoid using a pillow when sleeping on their backs. Patients with severe hip or shoulder disease can benefit from total shoulder replacement, and in extreme cases, vertebral osteotomies with rod placement may change someone who can only look at the feet to someone in an upright forward looking position.

Important Complications of Ankylosing Spondylitis Presenting with Pain

**Cauda Equina Syndrome.** Patients with cauda equina syndrome generally have long-standing ankylosing spondylitis. The patient generally presents with progressive lower extremity weakness, pain, and loss of sensation in the lower extremities and perineum. Impotence and overflow incontinence are also frequently occurring problems. Radiographically, large dorsal diverticula are seen on myelography or MRI. Electromyography demonstrates multi-root involvement. Neurosurgery needs to be involved with the treatment of these patients. Data regarding appropriate therapy is sparse.

**Spondylodiskitis**

Spondylodiskitis is a rare complication of long-standing ankylosing spondylitis. Patients have persistent mechanical-type back pain (pain with activity) rather than inflammatory low back pain (pain in the morning or
with rest). It is caused by a mobile vertebral segment surrounded by fused segments. The focus of activity at the one segment may lead to significant inflammation and damage to the adjacent vertebral bodies, simulating infection. Infection generally needs to be ruled out, and treatment is directed to immobilizing the segment either via brace and allowing it to fuse or refuse; occasionally, it may need to be surgically fused.56

Vertebral Fracture
Vertebral segments connected by syndesmophytes are subject to fracture with even minor trauma.56 The usual location for such fractures is the C5–C7 vertebral segments; the fractures are typically caused by a hyperextension injury. Patients suspected of fracture should be evaluated by computed tomographic scan or bone scan to try to identify a potential fracture site, as plain radiography may not be able to demonstrate the fracture. Patients with such fractures have a relatively high morbidity and mortality even if identified because of surgery or prolonged immobilization usually required for treatment. Only 40% of such patients return to their former level of activity.

Chronic Enthesitis
Enthesitis of the Achilles tendon, plantar fascia, and, occasionally, the ribs can be a chronic source of pain and may be more resistant than spondylitis to usual therapies. In such cases, indomethacin at maximum dose or use of a DMARD such as methotrexate, sulfasalazine, anti-TNF therapy, or anti–IL-17 agent may be warranted.

**REACTIVE ARTHRITIS**
Reactive arthritis (formally Reiter’s syndrome) is defined as an asymmetric arthropathy involving predominantly joints of the lower extremities plus one or more of the following: urethritis or cervicitis, dysentery, mucocutaneous lesions, and inflammatory eye disease. It is also defined as an episode of arthritis lasting longer than 1 month that is associated with urethritis or cervicitis. The histocompatibility antigen HLA-B27 is present in approximately 80% of patients.57 The reasons for the change in nomenclature for Reiter’s to reactive arthritis is due to the involvement of Hans Reiter with the Nazi regime and the fact that the
same syndrome had been described previously by others.

There appears to be a relationship between certain infections and a specific genetic background. Reactive arthritis can follow infections with Shigella, Salmonella, Campylobacter, or Yersinia.\textsuperscript{58,59} An association also exists with urethritis associated with Chlamydia or Mycoplasma infections. In addition, reactive arthritis has been associated with HIV infection. Reactive arthritis develops in patients without these infections, however, and most patients with nonspecific urethritis do not develop this syndrome. The risk of an individual who has a positive result for HLA-B27 with nonspecific urethritis developing reactive arthritis is in the range of 20%. Up to 3% of individuals with nonspecific urethritis have been shown to develop a reactive arthritis. Reactive arthritis has a worldwide distribution and occurs more often in men. In post dysenteric reactive arthritis, the gender distribution is equal.

**Symptoms and Signs**

Arthritis affects several joints in an asymmetric fashion; knees and ankles are most often involved.\textsuperscript{59} Patients also experience pain in the feet and ankles secondary to inflammation at the insertion of the Achilles tendon and plantar fascia. Joints can remain swollen for several months. Swelling of two adjacent interphalangeal joints and adjoining tendon sheath results in a sausage digit or dactylitis. In approximately 20% of patients, spinal involvement occurs. Sacroiliitis is usually unilateral, and spine involvement mild. Patients can also experience chest pain caused by inflammation at the tendinous insertions of the intercostal muscles.

The mucocutaneous lesions of reactive arthritis include oral ulcers, balanitis, and keratoderma blennorrhagica. The oral ulcers are shallow and irregular and have a slightly erythematos base. These lesions are only present for several days. Balanitis usually begins as small painless vesicles on the glans penis that become hyperkeratotic. These lesions are painless and remain crusted in the circumcised patient. In the uncircumcised patient, lesions are moist and can become secondarily infected. Keratoderma blennorrhagica consists of hyperkeratotic lesions/plaques that may coalesce and most commonly involves the feet soles of the feet. It can also involve the palms of the hands and rarely the trunk.
Conjunctivitis involves one or both eyes. Uveitis also occurs and again is unilateral and self-limited. Urethritis can precede or accompany the arthritis, and prostatitis may be an issue. As with ankylosing spondylitis, some patients may develop dilatation of the proximal aorta, leading to aortic valve insufficiency. The course of reactive arthritis is recurrent or persistent, with some patients experiencing a single transient, self-limited bout of disease.

**Laboratory Findings**

Routine laboratory test results are usually normal. The sedimentation rate is quite variable and does not correlate with disease activity. Synovial fluid shows an elevated white cell count ranging from 5,000 to 50,000 white blood cells per cubic millimeter, predominantly neutrophils. Radiography shows juxta-articular osteopenia, joint space narrowing, and bone erosions. Periostitis is present adjacent to the involved joints and at the insertion of tendons and fasciae. Erosions, sclerosis, and irregularity of the sacroiliac joint can be present and are usually unilateral. Changes of spondylitis are usually asymmetric, occur at various levels of the spine, and are similar to those seen in psoriatic arthritis. Testing for HLA-B27 is not necessary for diagnosis. This test should be reserved for patients who have asymmetric arthritis without other evidence of reactive arthritis.

**Treatment**

Treatment of reactive arthritis is similar to that of ankylosing spondylitis. NSAIDs are first-line therapy followed by sulfasalazine in refractory cases. Methotrexate or azathioprine can be used in more severe disease. Intra-articular corticosteroid can also be useful. The anti-TNF agents are less well studied but are reported to be effective in case series and case reports. Combination antibiotic therapy with doxycycline, rifampin, and azithromycin was reported to be efficacious in patients with chronic reactive arthritis due to Chlamydia.

**Complications of Reactive Arthritis Associated with Chronic Pain**

Rare patients may have more persistent inflammatory eye disease
requiring continuous ophthalmology care. Enthesitis can be severe in some cases of reactive arthritis. Chronic foot involvement can lead to erosive disease at the MTP joints.

**PSORIATIC ARTHRITIS**

Arthritis appears in up to 30% of outpatients with psoriasis depending on the population studied. Genetics play a role as an increased prevalence of psoriatic arthritis occurs in first-degree relatives with psoriasis. An association with HLA-B27 is seen in psoriatic arthritis with spondylitis but not in patients with peripheral arthritis. Onset of psoriatic arthritis is usually in the third or fourth decade, and the gender ratio is approximately equal. In most patients, psoriasis precedes the arthritis by several years, but arthritis may be the presenting manifestation. Most patients with psoriatic arthritis have oligoarthritis, and overall, the prognosis tends to be better than in rheumatoid arthritis.

**Symptoms and Signs**

Several patterns of arthritis are observed in patients with psoriasis. The majority of patients have an asymmetric oligoarthritis that can involve the proximal joints of the hands and feet, the knees, the wrist, and ankles. In approximately 10% of patients, arthritis affects predominantly the DIP joints and is usually accompanied by psoriatic changes of the adjacent nail. Other patients have a symmetric polyarthritis similar to that seen in rheumatoid arthritis. These patients usually have negative results for rheumatoid factor. If the rheumatoid factor test or the CCP result is positive, the patient may have both rheumatoid arthritis and psoriasis. Patients can also have sacroiliitis and variable degrees of spine involvement. A few patients have a severe, destructive, and deforming polyarthritis referred to as arthritis mutilans.

Joints are swollen, warm, and tender, and a digit may have the appearance of a sausage. Contractures and ankylosis of joints occur with long periods of persistent joint inflammation. In most cases, there appears to be no definite correlation between the degree of skin involvement and joint disease.
Laboratory Findings

Laboratory findings include an elevated sedimentation rate and a hypoproliferative anemia. The rheumatoid factor test result is negative. The synovial fluid shows evidence of inflammation with elevated white cell counts; the cells are predominantly polymorphonuclear. A somewhat characteristic radiographic finding is that of the pencil-in-cup deformity caused by osteolysis, or whittling of the distal end of the middle phalanx, which produces a pencil point that projects into a widened cup-like erosion in the adjacent surface of the distal phalanx (Fig. 34.9). Radiography shows joint space narrowing, erosions, osteolysis, and ankylosis, depending on the degree of clinical severity. The radiographic findings of the spine are similar to those found in patients with reactive arthritis.

![Figure 34.9](image)

**FIGURE 34.9** X-ray of the left foot in psoriatic arthritis demonstrating fusion of the fourth metatarsophalangeal joint and a developing pencil-in-a-cup deformity of the fifth metatarsophalangeal joint.

Treatment

Initial treatment of psoriatic arthritis with one to two joints involved and little impairment may be an NSAID alone. In patients with progressive disease, methotrexate, cyclosporine, leflunomide, hydroxychloroquine, and sulfasalazine have been used successfully for peripheral arthritis. Only

1653
methotrexate and cyclosporine are useful for the skin as well. None of these medications address spine involvement with present. Low-dose oral corticosteroids as well as intra-articular corticosteroids can also be used. Placing a patient on moderate- to high-dose prednisone and then tapering may exacerbate the skin disease. Prednisone doses if needed should be kept to 10 mg or less, if possible. There are a variety of biologic agents that are now available to use to treat psoriatic arthritis. The anti-TNF agents have an impressive effect on both skin and joints, including the spine. Ustekinumab is an IL-12/IL-23 inhibitor that has effects on skin and joint disease as does secukinumab, a newer anti–IL-17 agent, and apremilast, an oral phosphodiesterase-4 inhibitor.

ARTHRITIS ASSOCIATED WITH INFLAMMATORY BOWEL DISEASE
Both ulcerative colitis and regional enteritis (Crohn’s disease) are associated with peripheral arthritis spondylitis and enthesitis. Peripheral arthritis occurs in approximately 10% to 20% of patients with inflammatory bowel disease. Type I peripheral arthritis affects one to five joints typically large weight-bearing joints and/or the MTP joints. This arthritis is present with active bowel disease and is acute, lasts several days to several weeks, and leaves no residual damage. In some cases, the arthritis may precede obvious bowel involvement. The knees and ankles are most frequently affected. Type II peripheral arthritis is a polyarthritis that affects the small joints, and MCP joints are commonly involved and may mimic rheumatoid arthritis.

Spondylitis is also associated with inflammatory bowel disease and is seen in 5% to 12% of patients with inflammatory bowel disease. The gender distribution is 3:1 male to female. The majority (70%) of patients with spondylitis associated with inflammatory bowel disease has positive results for HLA-B27. Asymptomatic bilateral sacroiliitis can be found in up to 15% of patients with inflammatory bowel disease. Frequency of HLA-B27 is not increased in patients with only peripheral arthritis.

Enthesitis typically occurs at the heel (plantar fasciitis, Achilles tendonitis) or the knee. Calcification may be seen at tendon insertions.
**Treatment**  
Peripheral joint symptoms if mild can be managed with NSAIDs. NSAIDs, however, may lead to an exacerbation of the inflammatory bowel disease. Peripheral arthritis often in ulcerative colitis can disappear after colectomy. Many of the drugs used to treat inflammatory bowel disease also affect peripheral arthritis such as sulfasalazine, azathioprine, or methotrexate. The TNF agents, with the exception of etanercept, are useful for the bowel disease, peripheral arthritis, and spondylitis.

**ARTHRITIS CAUSED BY CRYSTALS**  
**Calcium Pyrophosphate Deposition Disease**  
Deposition of calcium pyrophosphate (CPP) dihydrate in the joint produces both an acute and chronic form of joint disease. The acute or subacute form is historically referred to as pseudogout because of its similarity to gout, but the suggested term for such arthritis is acute CPP crystal arthritis.\(^{64}\) Chondrocalcinosis refers to CPP crystal deposits in articular tissue that are detectable radiographically. It is thought that the presence of the crystals can lead to low-grade inflammation and joint damage. If the crystals are recognized by the innate immune system, an attack of acute arthritis can occur. Acute CPP crystal arthritis affects persons over the age of 40 years and in men predominately. The knee is the most frequent site of acute arthritis, but the hip, shoulder, ankle, wrists, and bursae can be affected. It affects approximately 4% to 7% of the adult population in Europe and the United States.  

Three forms of calcium pyrophosphate deposition disease (CPPD) are recognized: a hereditary form, CPPD associated with metabolic and other diseases, and an idiopathic form. The frequency of OA in CPPD varies from 40% to 70%. CPPD occurs in 41% of patients with hemochromatosis and in 5% to 15% with hyperparathyroidism.\(^{65}\) An association is suspected in patients with diabetes mellitus, hypophosphatemia, Wilson’s disease, ochronosis, and hypothyroidism.

**Pathophysiology**  
The initial site of crystal formation is in articular cartilage. In idiopathic CPPD, it is not clear whether the primary event is deposition of crystals in
cartilage or whether the crystals develop as a consequence of disturbed cartilage metabolism. Increased inorganic pyrophosphate is found in the synovial fluid and probably reflects a local disorder of pyrophosphate metabolism possibly due to overactivity of the ANKH membrane protein leading to deposition of CPP crystals in the joint.\textsuperscript{64,66} Elevated levels are also found in patients with OA. Acute arthritis is brought on by shedding of crystals into the joint space. The mechanism for crystal shedding is the lowering of either calcium or pyrophosphate ions in synovial fluid. The decreased concentration of ionized calcium results in movement of crystals from cartilage into synovial fluid. Crystals can also be shed into the synovial fluid as a consequence of mechanical disruption of cartilage. Attacks can follow trauma. In addition, crystals can be released as a result of degradation of cartilage by enzymes from neutrophils during episodes of bacterial arthritis or other forms of inflammatory arthritis.

**Symptoms and Signs**

Several patterns of joint disease are recognized.\textsuperscript{64} In approximately 25\% of patients, CPPD presents as an acute arthritis (pseudogout) involving a single joint or a few joints at any given time. The clinical picture mimics that of acute gout in intensity. The onset of joint swelling and pain is abrupt and severe and usually reaches a peak within 24 to 36 hours. An attack can last up weeks to months as opposed to gout that typically last a few days to a week.\textsuperscript{64} The joint is swollen, red, and tender. The most common site of involvement is the knee, but attacks can involve other large joints such as the ankles, wrists, elbows, or hips. Also, the lumbar and cervical spine can be involved. Trauma, surgery, or severe medical illness can precipitate an attack. The same joint is often involved in subsequent attacks. Radiographic evidence of chondrocalcinosis is usually present in affected joints.

Approximately 5\% of patients with CPPD have a form of disease that mimics rheumatoid arthritis (pseudorheumatoid disease). Involvement of multiple joints, synovial proliferation, limitation of joint motion, and joint deformity can develop. Patients experience fatigue and morning stiffness. To further confuse the issue, CPP deposition can occur in rheumatoid arthritis.
CPPD also occurs in a chronic form that is similar to OA. Multiple joints are involved and include the knees, wrists, MCP joints, hips, shoulders, elbows, and ankles. The disease involves middle-aged to elderly patients, predominantly women. CPPD can mimic neuropathic arthropathy (pseudo-Charcot) with a more severe joint destructive pattern.

The diagnosis of CPP disease is established by identification of CPP crystals in synovial fluid, both free and in neutrophils. The crystals appear as short rods, rhomboids, and cuboids, and they have a sign of weakly positive birefringence under compensated polarized light. X-rays show calcification in articular hyaline cartilage that is parallel to and separated from the subchondral bone. Calcifications in fibrocartilage are thick and irregular densities and are found in the menisci of the knee, symphysis pubis, annulus fibrosus, and the triangular cartilage of the wrist. Calcifications also occur in the Achilles, supraspinatus, and triceps tendons but can involve any tendon. Changes in the joint are similar to those seen in OA with sclerosis of subchondral bone, joint space narrowing, and large subchondral cysts.

**Treatment**
The NSAIDs are effective in the treatment of acute and chronic joint disease. An NSAID is given for 10 to 14 days in patients with acute CPP crystal arthritis. The drug can be continued indefinitely in patients with chronic CPP disease associated with OA. When an NSAID is contraindicated, another method of treatment for an acute attack is prednisone, starting with 40 mg the first day and gradually tapering over a 7-day period. Colchicine, 0.6 mg twice a day, is started on day 3 or 4 and continued for several weeks to avoid a flare of arthritis after prednisone is discontinued. An IL-1 inhibitor, anakinra, can be given subcutaneous for 1 to 3 days and will also treat an acute attack in patients who cannot use the aforementioned agents. Anakinra is not approved for this indication yet but has been effective in case series and case reports. Colchicine, 0.6 mg twice a day, can also be given prophylactically to reduce the number and length of attacks (see colchicine in section on gout). Aspiration of the involved joint followed by an injection of glucocorticoids reduces pain and swelling.
URATE GOUT

Urate gout is characterized by elevated serum urate levels, recurrent attacks of acute arthritis involving a single joint or a few joints at any given time, and deposition of monosodium urate dihydrate (tophi) in and around joints, leading in some patients to a deforming and crippling arthritis. Monosodium urate can serve as a nidus for calcium oxalate to form renal stones or form renal stone in their own right.

Recognized since ancient times, gout has been depicted in caricatures as affecting well-fed aristocrats overindulging in rich foods and wines. The disease has been referred to as the king of diseases and the disease of kings. Currently, it is estimated that 6.1 million adults in the United States have gout.

The normal serum urate concentration depends on several factors including age (increases with maturity), gender (women generally have lower levels than men), body habitus (those with metabolic syndrome will generally have higher levels), and genetic background. As noted, the upper limit of urate level is 6.8 mg/dL, but with the “super size” of the population in the United States, normative data which take the mean plus two standard deviations on either side has upper limit of normal as high in some labs as 8.5 mg/dL, which is above the level of urate solubility.

Both genetic and environmental factors play a role in the expression of hyperuricemia and gout. For example, higher serum urate levels are found in Filipinos living in the United States compared with racially identical persons living in the Philippines. These persons are unable to excrete the greater uric acid load resulting from the higher purine content of the diet eaten in the United States.

Etiology and Pathophysiology

Uric acid is a product of purine metabolism. The serum urate concentration depends on the rate of uric acid production and excretion. Approximately two-thirds of uric acid is excreted in the urine and one-third into the gastrointestinal tract. Normally, uric acid is completely filtered through the glomeruli and completely reabsorbed in the proximal tubule. Secretion of uric acid occurs in the proximal tubule, followed by a second reabsorption in the proximal tubule.
Primary gout is defined by the absence of other diseases or conditions such as drugs that lead to hyperuricemia and gout. Approximately 90% of patients with primary gout have decreased renal clearance of uric acid resulting from reduced glomerular filtration, increased tubular reabsorption, reduced tubular secretion, or combinations of these factors. Evidence for a molecular renal defect is still lacking in the majority of patients.

Approximately 10% of patients are overproducers of uric acid. Overproduction is defined as the urinary excretion of more than 800 to 1,000 mg of uric acid in 24 hours while the patient is on a regular purine diet.

Two inborn errors of purine metabolism make up a small number of primary gout patients who are overproducers of uric acid. The first disorder is caused by a partial deficiency of the enzyme hypoxanthine-guanine phosphoribosyltransferase, which catalyzes conversion of hypoxanthine to inosinic acid and guanine to guanylic acid. The second disorder is caused by increased 5-phosphoribosyl-1-pyrophosphate synthetase activity leading to elevated levels of intracellular 5-phosphoribosyl-1-pyrophosphate and overproduction of uric acid. These patients usually experience the onset of gouty arthritis in the second or third decade and have a high frequency of uric acid stones. Both diseases are inherited as an X-linked disorder, therefore affecting male subjects, with women as carriers. Some of these patients also have dysarthria, hyperreflexia, lack of coordination, and mental retardation. A severe form of the first disorder with almost a complete deficiency of this enzyme, referred to as the Lesch-Nyhan syndrome, is characterized by self-mutilation, choreoathetosis, and mental retardation. This disorder is classified under secondary hyperuricemia or gout because the neurologic disorder is predominant.

Secondary gout is defined as gout or hyperuricemia occurring in patients with other disorders. Overproduction of uric acid results in hyperuricemia in patients with disorders associated with increased cell proliferation and turnover of nucleic acids. These disorders include myeloproliferative and lymphoproliferative diseases, multiple myeloma, polycythemia, pernicious anemia, hemoglobinopathies, and some carcinomas. The hereditary
disorder glucose 6-phosphatase deficiency (von Gierke’s glycogen storage disease) is also manifested by overproduction of uric acid. Secondary hyperuricemia can also result from renal failure or the effects of drugs or toxins on renal clearance of uric acid. Diuretic agents, low doses of aspirin (less than 2 g per day), alcohol, ethambutol, cyclosporine, and lead are some of the agents that decrease the clearance of uric acid and thereby raise the serum urate level.

**Pathophysiology of Acute Gouty Arthritis**

Acute gouty arthritis results from the inflammatory reaction to urate crystals that form in the joint space or are released into the joint from synovium or articular cartilage. Plasma becomes supersaturated with urate at concentrations of approximately 6.8 mg/dL.\(^6\) Factors in addition to supersaturation of plasma urate are necessary for crystal precipitation because most patients with hyperuricemia do not develop gout. The lower temperatures found in peripheral joints or tissues might contribute to urate precipitation at these sites. Urate is less soluble at 32° C, which is the temperature observed in a normal knee, compared with the core body temperature of 37° C.\(^7\) Another mechanism for urate precipitation might be the faster reabsorption of extracellular fluid than urate from the joint space, resulting in a transient increased urate concentration and crystal formation.\(^7\) Trauma or impact loading of a joint that breaks crystals loose from the joint surface is yet another possible mechanism and might explain the high frequency of gout at the base of the great toe, which is a joint subjected to great stress.

Urate crystals induce inflammation by several mechanisms.\(^6\) Urate crystals activate Hageman’s factor in joint fluid, leading to the formation of kinins that induce vasodilatation and increased vascular permeability. Urate crystals activate the complement system with the generation of leukocyte chemotactic factors and also stimulate the formation of leukotrienes from arachidonic acid. Furthermore, urate crystals can activate platelets, which secrete several inflammatory mediators including prostaglandins. Urate crystals can also stimulate synovial lining cells and macrophages that secrete prostaglandins and collagenase.

The key to urate-induced inflammation is the polymorphonuclear white
cell. Urate crystals activate toll-like receptors on the surface of cells that lead to the activation of the inflammasome inside the cell which in turn leads to the release of inflammatory mediators such as IL-1. Crystals also bind immunoglobulin G (IgG), leading to their attachment to and phagocytosis by polymorphonuclear white cells. This process mediates the production of superoxide anions, which damage tissue. In addition, ingestion of crystals results in the release of chemotactic factors from the polymorphonuclear white cells, thus attracting more polymorphonuclear white cells. On ingestion by polymorphonuclear white cells, crystals are incorporated into phagosomes, which fuse with lysosomes. The rupture of phagolysosomes inside polymorphonuclear white cells damages these cells. Lysosomal and cytoplasmic enzymes are released into the joint space, resulting in tissue inflammation and injury.

Gouty arthritis often develops with fluctuation of serum urate levels. A rapid increase in serum uric acid results in precipitation of crystals in tissue or fluid. A rapid decrease in serum urate brings about release of urate from the joint surface into the joint space.

Drinking of alcohol is also associated with the precipitation of gouty attacks. Metabolism of ethanol results in an increased concentration of blood lactate, which blocks the renal excretion of uric acid by inhibiting tubular secretion and raising the serum urate level. Alcohol consumption also leads to accelerated degradation of adenosine triphosphate to adenosine monophosphate with accumulation of adenine nucleotides that are degraded to uric acid and other purine metabolites. Beers and ales in particular increase the risk of gout due to the amount of purines these contain. The drinking of moonshine whiskey is associated with gouty arthritis and is referred to as saturnine gout. Moonshine whiskey is often distilled in automobile radiators containing a lead core. Lead reduces the excretion of urate and decreases its solubility. In addition, lead may affect renal mechanisms for handling urate, leading to elevated levels.

Gout follows periods of fasting. During fasting, the increased plasma level of acetoacetate and hydroxybutyrate interferes with renal excretion of urate. Overindulgence of food and wine has often been associated with gout. When a large protein- and purine-rich diet is ingested along with copious amounts of wine or other liquor, the uric acid serum concentration
rises because of increased formation and decreased excretion of sodium urate. Acute gouty arthritis attacks occur when drugs increase or lower the serum uric acid level. Attacks are precipitated by allopurinol, which lowers the uric acid concentrations, and thiazides or low doses of aspirin, which raise the level. Cyclosporine interferes with the renal excretion of uric acid and induces hyperuricemia and gout. An increased frequency of gout is seen in transplant recipients receiving cyclosporine and may affect atypical joints such as the hips, sacroiliac joints, or shoulders.

**Signs and Symptoms**

Gouty arthritis occurs mainly in middle-aged and older men and after menopause in women. Approximately one-fourth of the patients have a family history of gout. Nephrolithiasis precedes the first attack of arthritis in approximately 10% of patients. The first attack occurs most often in the MTP joint of the great toe (podagra) or ankles. Subsequent attacks might be separated by several months or even years. The involved joint usually returns to normal between attacks. In untreated cases, the attacks become more frequent and involve other joints, such as wrists, elbows, olecranon bursae, and the small joints of the hand. Gouty arthritis can occur in DIP joints already involved with OA and Heberden’s nodes (Figs. 34.10 and 34.11). Gout can be overlooked in these joints because acute inflammation can also occur with Heberden’s nodes. Gouty arthritis of intervertebral joints, sacroiliac joints, and shoulders and hips is uncommon.

![Tophaceous gout affecting the distal interphalangeal joint.](image)

**FIGURE 34.10** Tophaceous gout affecting the distal interphalangeal joint.
FIGURE 34.11 X-ray of same patient with tophaceous gout. Note erosions in the middle phalanx of the index finger caused by gout.

The typical attack of gout comes on acutely, often during the early hours of morning. Attacks also occur after surgery. Pain and swelling reach a peak within 24 hours. The joint is exquisitely tender, and overlying soft tissue is swollen and erythematous even to the degree that it could be mistaken for cellulitis. Pain is intense and throbbing. Patients are unable to tolerate even a light sheet touching the involved great toe. Jarring of the bed can make the patient wince with pain. The patient might even dread the landing of a fly on the involved toe. Both a low-grade fever and leukocytosis can accompany the attack, especially in polyarticular gout. An untreated attack of gout usually lasts for several days to 2 weeks.

Chronic tophaceous gout develops in patients if hyperuricemia is not corrected. Before the effective control of hyperuricemia, approximately one-half of the patients with episodes of gouty arthritis eventually developed deposits of monosodium urate dihydrate in and around joints as well as in other tissues. These deposits, referred to as tophi, usually become apparent at least 10 years after the onset of gouty arthritis. They develop in the olecranon, infrapatellar and prepatellar bursae, Achilles tendons, synovium, subchondral bone, and, infrequently, cartilage of the ear. Tophi can ulcerate and drain material that contains microscopic needle-shaped crystals of monosodium urate. Patients with tophaceous gout have frequent episodes of acute gouty arthritis or may have
continuous joint inflammation. Joint deformity and destruction leading disability can be quite severe in the untreated patient.

There is recent data that suggests patients with hyperuricemia and chronic kidney disease may accelerate loss of kidney function more rapidly than those whose hyperuricemia is controlled. Likewise, patients with coronary artery disease and hyperuricemia have an increased all-cause mortality compared to those without hyperuricemia.

Treatment of patients with underlying myeloproliferative or lymphoproliferative disorder results in extremely high levels of serum urate that can precipitate in the renal tubules, producing obstruction and oliguria. Patients should be treated with allopurinol and colchicine before treatment of the blood dyscrasia.

Renal calculi develop in approximately 20% of patients with gout. Hypertension, diabetes mellitus, and hypertriglyceridemia occur more frequently in patients with gout.

**Laboratory Findings**
Radiography of the affected joint in acute gouty arthritis is usually normal. When the first MTP joint is involved, radiography might show underlying changes of OA. The typical erosion caused by urate deposition is sharply defined and has a thin shell-like overhanging edge at the margins of the erosion. The diagnosis of gout is established by demonstration of the characteristic crystal of monosodium urate monohydrate in the synovial fluid or from tissue deposits. Crystals are found both in the polymorphonuclear white cells and free in fluid. The crystals in joint fluid are usually rod-shaped and 7 to 10 µm in length. They are identified by use of polarized microscopy. With use of a first-order red compensator, crystals have a sign of strongly negative birefringence.

**Treatment**
Treatment of a patient with gout has two components: treatment of the acute gouty arthritis and treatment of hyperuricemia. Each is treated independently. Even though they are closely interrelated, the drugs used for each are different. In fact, the indiscriminate use of a drug to lower the uric acid can exacerbate or prolong an attack of gouty arthritis.
Anti-inflammatory Drugs
For the acute attack of gouty arthritis, the patient is given indomethacin 50 mg three times a day for 7 days, or naproxen 500 mg twice a day for 7 days has also been successful. NSAIDs for the treatment of acute gout should be avoided or used with caution in patients with symptomatic heart failure, renal failure, oliguria, or peptic ulcer disease. Glucocorticoids are also quite effective in treatment of acute gout. Prednisone is given over a 7-day period with an initial dose of 40 mg as a single dose and then gradually tapered over a 7-day period or 35 mg daily for 5 to 7 days has also shown to be effective. Intra-articular corticosteroids can also be used to treat gout in a large joint such as the knee. Colchicine can be used if started within 24 hours of the initial symptoms with 1.2 mg given the first hour and 0.6 mg the second hour. Anakinra 100 mg subcutaneously for 1 to 3 days has also been shown to be very effective in patients who cannot tolerate these other therapies, but it is not yet approved for gout by the U.S. Food and Drug Administration.

In patients who experience frequent attacks of acute gouty arthritis, colchicine, 0.6 mg once or twice a day, is effective in preventing attacks. Colchicine is also used to prevent flares of gout when hypouricemic therapy is initiated.

Myopathy and polyneuropathy may occur on maintenance doses of colchicine in patients who have renal insufficiency. Myositis manifests as proximal muscle weakness, and serum creatine kinase becomes elevated. These abnormalities return to normal 3 to 4 weeks after stopping the drug. Polyneuropathy also disappears on discontinuing colchicine. In addition, agranulocytosis or aplastic anemia can occur in patients with renal insufficiency who are on regular doses of colchicine because the plasma drug levels in these patients greatly increase.

Hypouricemic Medications
Treatment of hyperuricemia in patients with gout is directed at lowering uric acid levels with a target serum level of 5 to 6 mg/dL in patients without tophi and 4 to 5 mg/dL in patients with tophi. Lowering serum uric acid levels will prevent the formation of tophaceous deposits and eventually resolve existing tophi.
The uric acid concentration can be lowered by probenecid, which is a uricosuric agent. In patients with normal renal function and no renal stones, probenecid is an effective agent. The dose of probenecid is 1 to 3 g per day given twice a day. It is given generally at mealtime to coincide with fluid intake and relative alkaline urine. Dumping uric acid in the urine when there is low urine flow and acidic urine will foster the development of renal stones.

Serum uric acid level is effectively reduced by allopurinol, which is a potent inhibitor of xanthine oxidase. This drug blocks the conversion of hypoxanthine to xanthine and xanthine to uric acid. This leads to the accumulation of other oxypurines in the blood. The daily dose of allopurinol is 100 to 800 mg per day, which is regulated to reduce uric acid to a concentration below 6 mg/dL as noted. It is suggested that allopurinol be started at a low dose (i.e., 100 mg or even less in patients with chronic kidney disease) and slowly increased until serum uric acid levels are reached. Allopurinol administration can precipitate an acute attack of gout, presumably because of fluctuation of sodium urate between tissue and blood. Colchicine, 0.6 mg once or twice a day, is given along with the allopurinol to prevent an acute attack. In general, current guidelines suggest the use of allopurinol over probenecid for ease of use and compliance.

Transient leukopenia and abnormalities of liver function are observed in some patients. In patients treated for many years, xanthine stones may occur. These tend to occur in patients who are overproducers and hyperexcretors of uric acid. A serious side effect of allopurinol is a rash that occasionally progresses to a severe life-threatening Stevens-Johnson syndrome/toxic epidermal necrolysis. This is particularly true in Asian patients who are HLA-B5801–positive. This allele is found in Han Chinese, Koreans, and Thai patients but low in Europeans and Japanese. These patients are also at risk for the most serious complication of allopurinol use which is the allopurinol hypersensitivity syndrome. This occurs in patients with chronic kidney disease and those on thiazide diuretics. The hallmarks of this hypersensitivity syndrome include fever, a serious rash, eosinophilia, hepatic abnormalities, and acute renal failure. The allopurinol hypersensitivity syndrome has a high mortality. It is
thought to be avoided by starting with low doses of allopurinol and slowing increasing over time. Allopurinol potentiates the action of 6-mercaptopurine and azathioprine. The dose of the cytotoxic agent is usually reduced by at least one-third in patients on allopurinol.

There is another xanthine oxidase inhibitor available for use called febuxostat dosed 40 to 80 mg a day, and the advantage is that it is cleared by the liver and less so by the kidney. It can be used in patients with allopurinol associated rashes, but the use of febuxostat with 6-mercaptopurine or azathioprine still requires dose reduction of these agents as noted earlier.

Finally, a pegylated uricase inhibitor called pegloticase is available in intravenous (IV) form to treat patients with a significant tophaceous burden. Uricase metabolizes uric acid to the more soluble allantoin and will drop serum uric acid levels precipitously. It has a high immunogenicity but can be effective in selected patients.

**INFECTIONOUS ARTHRITIS**

**Nongonococcal Bacterial Arthritis**

Acute bacterial or septic arthritis is a serious problem that requires prompt treatment to avoid joint damage. Bacteria usually reach the joint by hematogenous spread from a primary infection elsewhere. Often, however, no primary source of infection is found. An infection in the adjacent bone or soft tissue can extend directly into the joint. Acute bacterial arthritis is most often caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Staphylococcus pyogenes*, or *Haemophilus influenzae*, with *Staphylococcus* spp. being the most common causative organisms. Gram-negative organisms include *Escherichia coli*, *Salmonella*, and *Pseudomonas* and are usually seen in patients who are immunosuppressed or use IV drugs. In the past, *Neisseria gonorrhoeae* was at the head of this list, but its importance has waned over time.

Patients with diabetes mellitus or blood dyscrasias or those receiving glucocorticoids or immunosuppressive drugs are more susceptible to joint infection. Septic arthritis is more likely to occur in joints previously damaged by trauma or inflammatory arthritis. Patients with rheumatoid arthritis in particular have an increased risk of septic arthritis and an
increased mortality rate.$^{48}$

Pathophysiology
The synovium is edematous and infiltrated by neutrophils. As the disease progresses, small abscesses are present in the synovium and subchondr al bone. Proteolytic enzymes from neutrophils damage the cartilage, bone, and joint capsule. Healing is manifested by proliferation of fibroblasts, which can lead to ankylosis.

Symptoms and Signs
The onset of bacterial arthritis is usually abrupt and associated with severe pain and fever. A shaking chill occasionally accompanies the onset. Any motion of the joint causes excruciating pain. The overlying skin is usually erythematous. In elderly patients and those who are on glucocorticoids, the symptoms can be less severe.

The joint affected most frequently by septic arthritis is the knee, which is involved in at least one-half of the cases. Other commonly involved joints are hips, shoulders, wrists, ankles, elbows, and sternoclavicular and sacroiliac joints. Involvement of the latter two joints has been noted in IV drug users. The small joints of the hands and feet are rarely infected. In the spine, the intervertebral disk space and adjacent vertebral bodies are infected. Infection in the hip is more difficult to recognize because swelling is less evident. Patients with hip infection might hold the thigh in adduction, flexion, and internal rotation. Pain is felt in the groin or thigh and is also referred to the anterior surface of the knee.

An overlying infected bursa or cellulitis can be mistaken for septic arthritis. It is important in aspirating a joint not to insert the needle through an infected bursa or cellulitis and possibly infect a normal joint.

Laboratory Findings
Joint fluid usually shows increased numbers of neutrophils ranging from 10,000 to greater than 100,000 per cubic millimeter. The white cell count in infected bursa fluid is not as high as observed in the joint. Data from a study taking place in the emergency room suggests that a white count in the synovial fluid over 25,000 per cubic millimeter has a likelihood ratio over one and should raise suspicion for an infected joint.$^{86}$ A peripheral
blood leukocytosis might also be present. Gram stain performed on synovial fluid often shows bacteria except in gonococcal infections. Culture results of synovial fluid as well as blood are positive in over 90% of cases and are important to send if infection is suspected.

Radiography of the joint initially shows swelling as manifested by distension of the joint capsule, followed later by juxta-articular osteoporosis. As the process continues, destruction of articular cartilage leads to joint space narrowing followed by bony erosions. Juxta-articular bone destruction might indicate osteomyelitis. In the spine, the initial change consists of narrowing of the disk space and proliferation of bone at vertebral margins. Osteolytic lesions in adjacent vertebrae are seen later. MRI can be helpful in identifying infection in certain joints such as the hip, shoulder, spine, and sacroiliac joints.

Treatment
An infected joint requires immediate aspiration and rapid initiation of parenteral antibiotic therapy. It has been reported that joint outcome is best when patients are seen within 7 days of initial symptoms. Joint fluid should be immediately cultured and a Gram stain performed. Vancomycin is the current suggested antibiotic for gram-positive infections (especially where methicillin-resistant S. aureus [MRSA] infection is common) and generally a third-generation cephalosporin for gram-negative organisms. (The details of antibiotic therapy are beyond the scope of this text.) Antibiotics should be given intravenously for 2 to 4 weeks depending on the organism. Antibiotics do not need to be infused into the joint. The joint should be adequately drained to prevent damage. Usually, drainage can be accomplished with a large-gauge needle. Drainage reduces intra-articular pressure and removes white cells, which is a source of proteolytic enzymes. Repeated aspirations are only necessary during the first 5 days of treatment. Surgical drainage is required when the joint cannot be adequately aspirated and irrigated by needle or when the cell count in the synovial fluid does not decline in spite of what appears to be adequate drainage. Surgical drainage via arthroscopy should also be considered in patients with underlying arthritis and those with prolonged symptoms (i.e., longer than 7 days). During the first few days of treatment, splinting of the involved joint in extension makes the patient more comfortable and
reduces the possibility of a flexion contracture. Daily physical therapy, once the acute process has resolved, improves the range of motion. In a severely damaged joint, bony fusion might be required.

**Gonococcal Arthritis**

Gonococcal arthritis was once considered the most frequent of bacterial arthritis in young adults. Women are more susceptible to gonococcal arthritis during menses and pregnancy. Persons who have a homozygous deficiency of complement component C5, C6, C7, or C8 are also susceptible to disseminated neisserial infections. Patients with low complement levels caused by consumption of complement might also be more susceptible to disseminated neisserial infections.

**Symptoms and Signs**

Patients typically present with fever and migratory arthritis or arthralgias that evolve in several days into monoarticular arthritis. Patients also directly present with monoarticular arthritis. Wrists and knees are common sites of involvement, but any joint can be affected. Arthritis is manifested by swelling, erythema, and severe pain as in other bacterial arthritides. Skin lesions can accompany gonococcal arthritis. These lesions can be pustular, vesicular, or hemorrhagic and can ulcerate.

**Laboratory Findings**

Joint fluid shows increased numbers of polymorphonuclear white cells, but the white cell count might not be as high as in other bacterial infections. The joint fluid glucose is also not decreased to the low levels found in other bacterial joint infections.

**Diagnosis**

Gonococcal arthritis is suspected in a patient presenting with fever, typical skin lesions, and polyarthritis or arthritis that evolves into monoarticular arthritis. Diagnosis is confirmed by positive culture results from synovial fluid or from blood, but culture results from these sites are positive in fewer than 50% of cases. Cultures from skin lesions are also usually negative. Gram stain or culture results from cervix, urethra, or rectum might be positive when joint, skin, and blood culture results are negative.
Polymerase chain reaction (PCR) may be useful if patients with suspected gonococcal arthritis where the organism cannot be demonstrated by direct culture of the synovial fluid.

**Treatment**

The patient should be admitted to the hospital and receive parenteral antibiotics. Currently, the recommendation is to start a third-generation cephalosporin such as ceftriaxone because penicillin-resistant strains are now widespread. The dose of ceftriaxone is 1 g IV every 24 hours for daily for 2 to 4 days. Most patients can be converted to oral antibiotic therapy in 48 hours. The patient is placed at bed rest for the first 2 days. Splinting of the affected joint provides pain relief. The infected joint should be immediately aspirated. The frequency of aspirations depends on the degree of inflammation. In most patients, residual joint damage does not occur.

**POLYMYALGIA RHEUMATICA**

Polymyalgia rheumatica (PMR) is an inflammatory disease affecting people over the age to 50 years and typically those of Northern European ethnic background. Patients can generally remember the day or the week the symptoms began and the symptoms include marked stiffness of the shoulders and hip girdle regions, fatigue, and low-grade fever. A clue to PMR is a senior patient with bilateral “rotator cuff tendonitis.” Patients may have rotator cuff signs and symptoms, but it is unusual to have bilateral rotator cuff tendonitis. PMR is a synovitis, and the tenosynovitis around the shoulder may lead to rotator cuff symptoms and signs. The general stiffness is often profound, and a patient will describe significant difficulty getting out of bed. Patients will relate that they had to roll out of bed in order to get up. A related illness, giant cell arteritis (GCA), can present with manifestations of PMR but also includes headache and may include visual changes, jaw pain with chewing, and more pronounced systemic symptoms. It is important to recognize the difference between isolated PMR versus PMR plus GCA. If GCA is untreated, it may lead to permanent visual loss in up to 50% or stroke in up to 10% of patients. More recently, modern imaging techniques have identified subclinical vascular inflammation in up to one-third of patients with isolated PMR.
Additional information will be necessary to determine if these patients are treated more aggressively than those with isolated PMR.

The laboratory hallmark of PMR is a markedly elevated ESR or CRP, with the CRP being more sensitive than the ESR in PMR. A few patients though (10% to 15%) may have normal levels and still have PMR so that the history is the key as well and the response to prednisone. Patients can also have mild anemia typical of other inflammatory diseases.

Treatment is prednisone and has been for almost 50 years. If suspected, an initial of dose of 15 to 20 mg is sufficient in most patients with PMR especially if a small portion is given in the evening. The initial dose is maintained for 4 to 6 weeks and then slowly tapered. One taper regimen is to reduce the prednisone by 1 mg a week to 10 mg, 1 mg every 2 weeks to 5 mg, and then 1 mg every month until completely tapered off, but there are may be many small ups and downs on the prednisone dose. It must be recognized that the average length of disease duration is 24 months. If GCA is suspected, start the patients on high-dose prednisone (40 to 60 mg per day) and refer to a rheumatologist. The patient will need to have temporal artery biopsy scheduled as soon as possible and may need additional therapy. Methotrexate may offer steroid sparing therapy in patients who cannot reduce prednisone.

Muscle pain is a common manifestation of many chronic pain conditions and is described as a diffuse, difficult to pinpoint, aching pain that may refer to deep somatic structures. Muscle pain is common in all age groups, but chronic muscle pain is more frequent in the elderly than in younger populations. Muscle-referred pain involves nociceptive-specific neurons in the spinal cord and in the brainstem. Wall and Woolf have shown that muscle nociceptive afferents are especially effective in inducing neuroplastic changes in the spinal dorsal horn. Muscle pain activates specific cortical structures, such as the anterior cingulate gyrus, which is also involved in the emotional, affective component of pain. Muscle pain is inhibited strongly by descending pain-modulating pathways, and under normal circumstances, there is a dynamic balance between the degree of activation of dorsal horn neurons and the descending inhibitory systems. Prolonged input from muscle nociceptors can be misinterpreted in the central nervous system and eventually can lead to allodynia, hyperalgesia, and an expansion of receptive fields.

Although muscle pain is very common, there is considerable controversy regarding its nature, existence, and relevance. Some clinicians consider muscle pain only secondary to other diagnoses, such as tendonitis, muscle strain, inflammation, degeneration, or injuries to joints and nerves. Others view persistent muscle pain primarily as a manifestation of a presumed somatoform disorder. Yet, others deny the existence of muscle pain all together as, in their view, all pain is produced by the brain, and focusing on peripheral tissues would be counterproductive. With the development of orthopedic and manual medicine, many physicians, chiropractors, and physical therapists directed their attention mostly to articular dysfunction, although early manual
medicine pioneers did include muscle dysfunction in their thinking.\textsuperscript{11,12} In this context, it is noteworthy that although skeletal muscle comprises nearly half of the body’s weight, it is the only organ in the human body that is not linked to a particular medical specialty. This led Simons\textsuperscript{13} to suggest that muscle is an orphan organ, further evidenced by the fact that muscle research and the development of a knowledge base of muscle-specific ailments, pathophysiology, and diagnostic and treatment options have not evolved until fairly recently. The literature on myofascial pain is scattered among the literature of many different disciplines. One could wonder why persistent muscle pain and dysfunction have largely been ignored by the medical professions, but such contemplations are outside the scope of this chapter.

**Brief Historical Overview**

Muscle pain has been described by many different terms, including fibrositis, interstitial myofibrositis, myogeloses, nonarticular rheumatism, myofascial pain, idiopathic myalgia, myofasciitis, perineuritis, myodysneuria, and fibromyalgia.\textsuperscript{14} Publications by Kellgren describing referred pain patterns from muscles and other soft tissues strongly influenced physicians James Cyriax in England and Janet Travell in the United States. At the time of Kellgren’s first publications, Travell was a cardiologist and researcher. Initially, she was interested in the applicability of Kellgren’s findings to cardiac pain, but soon, she became interested in musculoskeletal medicine.\textsuperscript{15} In 1942, she coauthored the first of many articles about the diagnosis and treatment of muscle pain.\textsuperscript{16} In 1952, Travell and Rinzler\textsuperscript{17} published an article of observed pain referral patterns of 32 muscles (Fig. 35.1).
FIGURE 35.1 Examples of trigger point referred pain patterns. **A:** Referred pain patterns of the multifidi muscles. **B:** Referred pain patterns of the hamstrings muscles. **C:** Referred pain pattern of the pectoralis major muscle.

At that time, there was virtually no research on muscle pain, and many of Travell’s writings were based on her empirical observations and ability to establish clinical correlations. For example, Travell and Rinzler observed that the fascia generated similar referred pain patterns as the contractile elements of the muscle; she subsequently modified her
terminology to myofascial pain to encompass both the fibrous and contractile aspects. The similarities between referred pain patterns of fascia and muscle and the mechanical relationships between fascia and muscle were not further investigated until much later.\(^{18}\)

Travell’s work culminated in the publication of a two-volume textbook on myofascial pain, which she coauthored with Simons.\(^{19,20}\) These books became known as the Trigger Point Manuals, and they have been translated in multiple languages. The term trigger point was introduced by Steindler in 1940 in a paper on muscle pain.\(^{21}\) Travell and Rinzler\(^ {17}\) introduced the terms myofascial trigger point and myofascial pain syndrome, which are now intricately linked to a particular theoretical model, referred to as the “integrated trigger point hypothesis.”\(^ {22}\) Although muscle pain and myofascial pain are sometimes used interchangeably, muscle pain is really a descriptive term, whereas myofascial pain, as introduced by Travell, is a more specific entity.\(^ {23}\)

In 1981, Simons and Travell\(^ {24}\) developed the “energy crisis hypothesis,” which postulated that direct trauma and subsequent damage to the sarcoplasmic reticulum or the muscle cell membrane leads to an increase in intracellular calcium (Ca\(^ {2+}\)) concentration, increased activation of actin and myosin, a relative shortage of adenosine triphosphate (ATP), and an impaired calcium pump, which in turn would increase the intracellular calcium concentration even more, perpetuating the cycle. Under normal physiologic conditions, the calcium pump is responsible for returning intracellular Ca\(^ {2+}\) to the sarcoplasmic reticulum against a concentration gradient, which requires a functional energy supply. Eventually, the energy crisis hypothesis developed into the integrated trigger point hypothesis and more recently developed hypotheses, which incorporate newer electrodiagnostic, histopathologic, and pain science research.\(^ {25–27}\) It is now acknowledged that actual tissue damage is not required for the development of trigger points. This chapter provides an updated review of the etiology, mechanisms, pathophysiology, and clinical implications of myofascial trigger points.

**Basic Myofascial Pain Concepts**
Over time, research in the etiology, epidemiology, pathophysiology, diagnosis, and clinical management of myofascial pain has grown exponentially. Although the integrated trigger point hypothesis is not a perfect theoretical concept, it quickly became the most comprehensive evidence-informed model to explain the role of muscle tissue in acute and persistent pain conditions. Researchers around the world are conducting basic trigger point research, prevalence studies, and clinical outcome studies. Their findings show that trigger points are associated with virtually all painful musculoskeletal problems, including migraines, tension-type headaches, craniomandibular dysfunction, epicondylalgia, low back pain, postlaminectomy syndrome, neck pain, disk pathology, carpal tunnel syndrome, osteoarthritis, radiculopathies, whiplash-associated disorders, fibromyalgia, postherpetic neuralgia, and complex regional pain syndrome, among others. Trigger points have also been associated with visceral dysfunction, including endometriosis, interstitial cystitis, irritable bowel syndrome, urinary/renal and gallbladder calculus, dysmenorrhea, and prostadynia. Although trigger points are reportedly the most common diagnosis responsible for chronic pain and disability, they are frequently overlooked in the clinic. Trigger points have been reported in all age groups except infants.

A trigger point is defined as “a hyperirritable spot in skeletal muscle that is associated with a hypersensitive palpable nodule in a taut band”. Palpating for trigger points begins with identifying this taut band by palpating perpendicular to the fiber direction (Fig. 35.2). Taut bands are stiffer than relaxed muscle fibers, and the degree of stiffness can be assessed by phase-contrast analysis of vibration-induced cyclic shear waves.
FIGURE 35.2 Palpation of trigger points. As the palpating finger of the examiner moves from normal areas of muscle (A) and encounters a painful trigger point (B), a local twitch response often occurs within the muscle surrounding the trigger point. (Redrawn after Simons DG, Travell JG, Simons LS. Upper Half of the Body. 2nd ed. Baltimore, MD: Lippincott Williams & Wilkins; 1999. Travell & Simons’ Myofascial Pain and Dysfunction: The Trigger Point Manual; vol 1.)

An active trigger point can spontaneously produce local tenderness and pain, referral of pain or other paresthesia to a distant site, and peripheral and central sensitization. A latent trigger point is only painful when stimulated. Motor phenomena associated with trigger points include disturbed motor function, muscle weakness as a result of motor inhibition, muscle stiffness, and restricted range of motion. Nociceptive input can perpetuate altered motor control strategies and lead to muscle overload or disuse. Subjects with latent trigger points in several shoulder muscles featured altered shoulder abduction patterns when compared to healthy subjects. Autonomic aspects may include, among others, vasoconstriction, vasodilatation, lacrimation, and piloerection.

To discuss the current research and the clinical implications of myofascial trigger points and contemporary trigger point hypotheses, a brief review of muscle physiology, the role of the motor endplate, muscle pain, dorsal horn, and central sensitization is provided in the context of
myofascial trigger points. The motor phenomena of trigger points are best explained by understanding the functions and structure of the motor endplate and the sarcomere assembly.

**Muscle Physiology**

Skeletal muscles consist of groups of fascicles, which are made of muscle fibers and myofibrils, accountable for contraction and relaxation of the fiber. The myofibril is approximately 1 to 2 µm in diameter and is separated from surrounding myofibrils by the mitochondria, the sarcoplasmic reticulum, and the transverse tubular systems or T-tubules.

The T-tubules lie perpendicular to the long axis of the muscle fiber with two zones of transverse tubules to each sarcomere. T-tubules conduct impulses from the exterior to the interior of the muscle fiber and activate voltage-dependent L-type calcium channels in the transverse tubular membrane, including type 1 sarcoplasmic reticulum calcium release ryanodine receptors and surface membrane calcium channel dihydropyridine receptors. Activation of these channels and receptors results in the release of Ca\(^{2+}\) into the myoplasm. The sarcoplasmic reticulum is a store for the release and uptake of Ca\(^{2+}\). Muscle contractions occur after actin and troponin are activated by Ca\(^{2+}\). Calcium allows tropomyosin to shift its position and expose myosin-binding sites on actin, thus regulating the cross-bridge interactions between actin and myosin. ATP-dependent processes are responsible for muscle force generation, which implies that both calcium and ATP are critical for the maintenance of the actin-myosin cross-bridges. The organization of thin actin and thicker myosin filaments are responsible for the striated patterning observed when viewed under longitudinal electron micrograph scanning. In addition to actin and myosin, there are several other important proteins, such as titin, nebulin, desmin, tropomyosin, troponin, and tropomodulin, among others, which together maintain the architecture and stability of the sarcomere (Fig. 35.3).
Titin is the largest known vertebrate protein. It connects the Z-line with myosin filaments and cross-links with titin molecules of adjacent sarcomeres. Titin positions the myosin filaments at the center of the sarcomere as a spring. One particular section of titin, referred to as the PEVK segment, is able to interact with actin filaments in close proximity to the Z-line, which may limit the degree of sarcomere contraction as the tip of the myosin filament may literally bounce back against a “viscous bumper” of the actin-titin interaction, comparable to a dragnet. Titin filaments are responsible for passive tension generation when sarcomeres are stretched and provide muscle stiffness by virtue of their spring mechanism in the I-band. During sarcomere contractions, titin filaments are folded into a sticky gel-like structure at the Z-line, which is an important contributor to the force generated by a contracting muscle. It is conceivable that myofascial trigger points have a damaged sarcomere assembly; myosin filaments may have broken the actin–titin barrier and gotten stuck in the sticky titin substance at the Z-line.

Single molecules of nebulin span the full length of the actin filaments, and nebulin dictates the architecture of actin with direct involvement of titin and the Z-line protein myopalladin. Titin and nebulin interact at many levels, especially during myofibrillogenesis. Nebulin connects to the proteins myopalladin and desmin in the Z-line. Myopalladin binds to α-actinin, which in turn connects to actin and to titin. Desmin filaments link adjacent Z-lines and interconnect the myofibrils with the sarcolemma, the nuclei, the T-tubules, the mitochondria, and possibly the
Nebulin acts as a stabilizing structure through its specific binding sites at different places on actin, tropomyosin, troponin, and tropomodulin. It regulates muscle contractions by inhibiting the cross-bridge formation until actin is activated by Ca\(^{2+}\). Troponin is a Ca\(^{2+}\)-receptive protein that sensitizes actomyosin to Ca\(^{2+}\) in association with tropomyosin, among other functions. Of interest is that tropomyosin and tropomodulin can influence molecular processes related to synaptic signaling and modulate neuronal morphology.

A key feature of the integrated trigger point hypothesis is the presence of excessive acetylcholine (ACh) at the neuromuscular junction, which stimulates voltage-gated sodium (Na\(^+\)) channels of the sarcoplasmic reticulum and ultimately results in a continuous increase of intracellular Ca\(^{2+}\) levels. This results in ongoing activation of nebulin, troponin, and tropomyosin and causes persistent muscle contractures consistent with taut bands and myofascial trigger points. The role of the motor endplate is reviewed in the next section.

### The Motor Endplate

The terms neuromuscular junction and motor endplate are used interchangeably, although technically, the neuromuscular junction refers to function, whereas the motor endplate refers to structure. A motor endplate is the synapse between the terminal ends of motor neurons and skeletal muscle. The terminal branches of a single motor neuron terminate in multiple presynaptic boutons containing many ACh vesicles.

When nerve impulses from a α-motor neuron reach the motor nerve terminal, voltage-gated Na\(^+\) channels are opened, which trigger a Na\(^+\) influx that depolarizes the terminal membrane. Voltage-gated Ca\(^{2+}\) channels are opened, which causes an influx of Ca\(^{2+}\) and a quantal release of ACh and other molecules, such as ATP, from the nerve terminal into the synaptic cleft (Fig. 35.4). When two ACh molecules bind to a nicotinic ACh receptor (nAChR) across the synaptic cleft, the nAChR opens a cation-specific pore, which facilitates a Na\(^+\) influx and a potassium (K\(^+\)) efflux across the muscle cell membrane. Each single quantum of ACh will depolarize the postsynaptic cell and trigger a miniature endplate potential.
A sufficient number of MEPPs will produce a depolarization and an action potential, which travels along the T-tubules, triggers the ryanodine receptor in the sarcoplasmic reticulum, and causes a release of Ca\textsuperscript{2+} from the sarcoplasmic reticulum.

**FIGURE 35.4** The motor endplate.

As stated, the release of Ca\textsuperscript{2+} triggers tropomyosin to shift its position and nebulin to allow cross-bridges to form between the actin and myosin filaments, resulting in a muscle contraction. The K\textsuperscript{+} efflux restores the resting membrane potential. During the brief period before the actual muscle contraction, ACh is hydrolyzed by the enzyme acetylcholinesterase (AChE) into acetate and choline. Choline is reabsorbed into the nerve terminal, where it is synthesized into ACh by acetyltransferase by combining choline and acetyl coenzyme A from the mitochondria. ACh release is not only activated by motor nerve stimulation, but it is also modulated by the concentration of AChE. Inhibition of AChE will cause an accumulation of ACh in the synaptic cleft, which may stimulate motor
nerve endings and tonically activate nAChRs.

A 1993 publication illustrating spontaneous electrical activity in myofascial trigger points initiated a new line of research into the role of motor endplates.\textsuperscript{75} Initially, the electrical activity was assumed to be the result of dysfunctional muscle spindles, but soon, multiple human, rabbit, and even equine studies confirmed that the activity was in fact abnormal endplate noise related to an excess of ACh at the motor endplate.\textsuperscript{22,76–83} It is conceivable that in myofascial trigger points, the contractures resulting from excessive ACh may cause myosin filaments to get stuck in sticky titin gel at the Z-line, thereby damaging the sarcomere assembly. The persistent contractures compromise local blood vessels, reducing the local oxygen supply, resulting in hypoxia, a lowered pH, and hypoperfusion, which all contribute to muscle pain, tenderness, dysfunction, and peripheral nociceptor sensitization.\textsuperscript{84}

The reduced oxygen levels in myofascial trigger points and an increased metabolic demand result in a local energy shortage and a local shortage of ATP.\textsuperscript{25} Under normal physiologic circumstances, presynaptic ATP inhibits the release of ACh. Inversely, a decrease in ATP leads to an increased ACh release. Insufficient postsynaptic ATP results in a failure of the calcium pump, increased levels of Ca\textsuperscript{2+}, and a Ca\textsuperscript{2+}-induced Ca\textsuperscript{2+} release. An increase in the Ca\textsuperscript{2+} concentration will reinforce muscle contractures. The local energy crisis is likely related to the finding of abnormal mitochondria in the nerve terminal and ragged red fibers, which are an indication of structural damage to the cell membrane and the mitochondria.\textsuperscript{85}

The presence of excessive ACh can be the result of AChE insufficiency, an acidic pH, hypoxia, a lack of ATP, certain genetic mutations, drugs and particular chemicals, such as calcitonin gene-related peptide (CGRP), diisopropyl fluorophosphate, or organophosphate pesticides, and increased sensitivity of the nAChRs.\textsuperscript{26,86,87} Myofascial tension or muscle hypertonicity, as seen in trigger points, may also enhance the excessive release of ACh.\textsuperscript{88,89} There are many possible vicious cycles capable of maintaining the resulting contractures and trigger points. For example, hypoxia leads to an acidic milieu, muscle damage, and an excessive local release of multiple nociceptive substances, including CGRP, bradykinin
(BK), and substance P (SP). Hypoxia may even trigger an immediate increased ACh release at the motor endplate. CGRP stimulates the release of ACh from the motor endplate, decreases the effectiveness of AChE, and upregulates the nAChR. An acidic pH enhances the release of CGRP, downregulates AChE, and causes hyperalgesia.

There are many similarities between the mechanisms and consequences of myofascial trigger points and eccentric loading or eccentric exercise. Eccentric training or exposure is frequently characterized by a certain degree of cytoskeletal muscle damage. Even very short bouts of eccentric exercise can result in a disorganization of the A-band, streaming of the Z-line, and a disruption of several cytoskeletal proteins, including titin, nebulin, vimentin, fibronectin, and desmin. By comparison, postmortem histologic studies of myofascial trigger points show pathologic alterations of the mitochondria as well as an increased width of A-bands and decreased width of I-bands in muscle sarcomeres of trigger points. A biopsy study of trigger points in a dog gracilis muscle revealed a similar pattern of severely shortened sarcomeres in the center and lengthened sarcomeres outside the immediate trigger point region. The diagnosis of trigger points in animals is comparable to that in human subjects. Although an animal cannot verbalize recognition of pain, skilled palpation combined with an analysis of dysfunctional movement patterns will direct the investigator or clinician to clinically relevant trigger points.

In addition to these similarities, eccentric loading and myofascial trigger points also involve local hypoxia, impaired local circulation, and local and referred pain. Eccentric contractions in unconditioned muscle or unaccustomed eccentric contractions are likely sources of myofascial trigger point development. Itoh and colleagues confirmed that eccentric exercise triggers the formation of taut bands and myofascial trigger points in exercised muscle.

There are other possible causes of trigger points. Patients commonly report an onset of pain associated with trigger points following either acute, repetitive, prolonged, or chronic muscle overload. Piano students developed significantly decreased pressure thresholds over latent trigger points after only 20 minutes of continuous piano playing.
operators developed trigger points after as little as 30 to 60 minutes of continuous typing. In other words, low-level muscle contractions can contribute to the development of trigger points, which is best explained by the so-called Cinderella hypothesis. According to the Cinderella hypothesis, low-level muscle contractions follow stereotypical patterns, where smaller motor units are recruited before and derecruited after larger motor units, which means that smaller type 1 fibers may be continuously activated during prolonged low-level contractions. Low-level contractions have been shown to lead to muscle fiber degeneration, an increase in Ca\textsuperscript{2+} release, energy depletion, and the release of various cytokines, which all have been associated with the formation of trigger points. During low-level contractions, the intramuscular pressure increases considerably especially near the muscle insertions, which may impair the local circulation, cause hypoxia, and eventually lead to trigger point formation. As noted, motor phenomena associated with trigger points include disturbed motor function, muscle weakness as a result of motor inhibition, muscle stiffness, and restricted range of motion.

**Sensitization and Activation of Muscle Nociceptors**

To better understand the sensory aspects of myofascial trigger points, including local and referred tenderness, pain, and other paresthesia, as well as peripheral and central sensitization, a brief review of the current understanding of muscle nociceptors, spinal cord mechanisms, and sensitization is necessary.

Muscle nociceptors are dynamic structures that can be activated mechanically by deforming the axonal membrane of the nerve ending, as for example, following a blow to a muscle. Many receptors are susceptible to chemical activation by nociceptive substances released from the surrounding tissues and immune cells. Matched receptors at the nociceptor exist for a variety of substances including BK, prostaglandins (PGs), serotonin (5-HT), protons (H\textsuperscript{+}), ATP, glutamate, and others, including the so-called purinergic and vanilloid receptors. Purinergic receptors bind ATP and stimulate nociceptors accordingly. Vanilloid receptors are especially sensitive under conditions of lowered tissue pH.
and muscle ischemia. Pain during tension-type headaches, tooth clenching, and bruxism is partially mediated by the vanilloid receptor molecule. BK, 5-HT, and PG interact at many levels at the vanilloid receptors, potentially synergistically producing local muscle pain. When injected together into the temporals muscle of normal volunteers, BK and 5-HT produced more pain than when each stimulant was injected alone.

The mechanism of chemical activation is of clinical interest, especially in evaluating chronic pain states where often there is little gross swelling evident. Endogenous substances such as BK, PG, and 5-HT not only are very effective at sensitizing or activating muscle nociceptors but also cause local vasodilation. Therefore, the release of these substances can lead to mechanoreceptor activation by distorting the normal tissue relationships. A sensitized muscle nociceptor has a lowered stimulation threshold into the innocuous range, such that it will respond to harmless stimuli like gentle pressure and muscle movement.

The nociceptor terminals contain neuropeptides, such as SP and CGRP. When these substances are released, they stimulate local vasodilation, plasma extravasation, and liberation of sensitizing substances from the surrounding tissue. Upon activation by a noxious stimulus, the nociceptor releases the stored neuropeptides, which directly influence the local microcirculation by stimulating vasodilation and increasing the permeability of the microvasculature. More importantly, the secretion of the neuropeptides in sufficient quantity leads to a cascade of events, including the release of histamine from mast cells, BK from kallidin, 5-HT from platelets, and PGs from endothelial cells. The cumulative effect is the increased production and release of sensitized substances in a localized region of edema in the muscle tissue. Therefore, the muscle nociceptor is not merely a passive structure designed to record potentially noxious stimuli. Rather, muscle nociceptors play an active role in the maintenance of normal tissue homeostasis by sensing the peripheral biochemical milieu and mediating the vascular supply to peripheral tissue. With tissue injury, the secretion of SP and CGRP increases, leading to the response outlined earlier that can alter the responsiveness of the nociceptor. Muscle tenderness is mainly due to the sensitization of muscle nociceptors by BK, PG, and 5-HT, which may account for the exquisite
tenderness found when firm pressure is applied over an active trigger point.\textsuperscript{124,125}

As noted before, the activation of a nociceptive terminal is not primarily due to a nonspecific damage of the nerve ending by a strong stimulus but rather the binding of specific substances, including BK, PG, and 5-HT, to their paired receptors on muscle nociceptors. Receptor responsiveness is dynamic. For example, inflammation alters the population of BK G protein-coupled metabotropic receptors at the nociceptive terminal. In normal muscle tissue, the B2 receptor is more prevalent. With tissue inflammation, an additional BK receptor (B1) is synthesized in the cell body of the ending in the dorsal root ganglion and inserted into the nociceptor terminal membrane. Unlike the B2 receptor, which is constitutively expressed, the B1 receptor is inducible and is involved in sensitization of the peripheral nociceptor. The B2 and B1 receptors are mediators of several physiologic and pathologic responses via the kallikrein–kinin system.\textsuperscript{126} Induction and binding of the B1 receptor can also lead to the production of pro-inflammatory mediators, including tumor necrosis factor-α (TNF-α) and interleukin-1 β (IL-1β). Stimulation of B2 receptors leads to only transient increases in the intracellular calcium concentration, making nociceptor sensitization unlikely; however, the B1 and B2 receptors do influence each other on many levels.\textsuperscript{127}

Stimulation of the B1 receptor results in prolonged elevation of intracellular Ca\textsuperscript{2+} concentration, which can lead to sustained peripheral sensitization.\textsuperscript{128} If the conformational change of the BK receptor persists after the inflammation subsides, this maladaptive change may herald the transition from acute to chronic pain. Therefore, the degree to which muscle nociceptors in a trigger point become sensitized or activated will vary according to the balance of sensitizing substances in the muscle tissue and the threshold of their respective receptors. There may be a spectrum of nociceptor irritability based on this balance that distinguishes a normal muscle from a muscle with a latent or active trigger point.

\textbf{Central Sensitization}

In addition to sensitization of the peripheral nociceptors, pain and
dysfunction induced by trigger points may also be related to alterations in the responsiveness of the dorsal horn.\textsuperscript{129,130} A chronic active trigger point may contribute to inflammatory exacerbation of the fascia and be a source of ongoing noxious input that sensitizes dorsal horn neurons and generates increased or referred pain to other spinal cord segments via central sensitization.\textsuperscript{131} Conversely, a sensitized central nervous system may lead to a lowering of the activation threshold of the peripheral nociceptors in a trigger point, inducing the transition from latent to active. The latter may occur when trigger points develop secondary to referred pain from viscera or joints or as a result of psychological stress.\textsuperscript{104,130} Giamberardino et al.\textsuperscript{132} have established that visceral referred pain with hyperalgesia is usually associated with cutaneous hyperalgesia and trigger points.\textsuperscript{132} Vecchiet et al.\textsuperscript{133} measured significantly lower pain thresholds with electrical stimulation over active trigger points in the muscles and the overlying cutaneous and subcutaneous tissues. With latent trigger points, the sensory changes did not involve the cutaneous and subcutaneous tissues.\textsuperscript{133,134}

Sensitization in the central nervous system can occur both segmentally and multisegmentally at the spinal level and also involve changes in activity of higher brain centers. Clinical characteristics of central sensitization include spontaneous pain, allodynia and hyperalgesia, and widespread pain.\textsuperscript{129,130} Spontaneous pain is often related to increased background activity in nociceptive neurons in the spinal cord and higher brain centers. When background activity is great enough to elicit an action potential, pain may be sensed without specific visceral or peripheral nociception. The central mechanisms for allodynia, hyperalgesia, and widespread pain are discussed in more detail in the following text.

The primary peripheral sensing apparatus in muscle involves group III (thinly myelinated, low-threshold fibers) and group IV (unmyelinated, high-threshold fibers) afferent nerve fibers. These fibers cause aching, cramping pain when stimulated with microneural techniques. The central projections of these fibers share several important characteristics especially when compared to cutaneous nociception. First, a reduced spatial resolution, because of a lower innervation density of muscle tissue, makes it harder to localize muscle pain. Second, convergence of sensory.
input from skin, muscle, periosteum, bone, and viscera into lamina IV and V of the dorsal horn onto wide dynamic range neurons can blur the identification of the origin of the pain. Third, divergence of sensory input into the dorsal horn–sustained noxious stimulation as demonstrated, for example, in group IV fibers in animal models can open previously ineffective synapic connections in the dorsal horn such that these fibers begin to respond to lower levels of stimulation, leading to mechanical allodynia, hyperalgesia, and secondary hyperalgesia.

Compared to normal muscle and muscle with latent trigger points, a muscle with active trigger points is more tender and mechanically sensitive, suggesting that peripheral nociceptors are already sensitized. Once sensitized, the group IV afferent nerve fibers fire at lower thresholds, even though they are normally high-threshold nociceptors. For example, in animal models, injection of BK into muscle causes the group IV afferents to respond to much lower levels of stimulation, suggesting they have become sensitized. Because muscle tenderness is mainly due to the sensitization of muscle nociceptors by BK, PGs, and 5-HT, peripheral sensitization by these substances presumably contributes to the tenderness seen in active trigger points and may contribute to the pain that individuals with active trigger points describe. Studies on the biochemical milieu of trigger points in the upper trapezius muscle have shown that active trigger points are associated with elevated levels of inflammatory mediators, neuropeptides, pro-inflammatory cytokines, and catecholamines. These chemicals can act to sensitize and activate local nociceptors. It is important to note that active trigger points are associated with elevated levels of these biochemicals compared to both normal muscle tissue and that with latent trigger points, which suggests that the presence of these biochemicals is related to the pain experience.

Central sensitization is more readily induced as the activation threshold is lowered for peripheral muscle nociceptors. In animal models of pain, a nociceptive input from skeletal muscle is much more effective at inducing neuroplastic changes in the spinal cord than cutaneous input. Experimentally induced myositis in animal models causes a marked expansion of the response of second-order neurons beyond the muscle’s target area of the dorsal horn. Hoheisel et al. found that after a localized
inflammatory reaction was created, noxious input from the gastrocsoleus muscle (L5 segment) also activated second-order neurons in the L3 segment. This segment would not ordinarily be activated by noxious stimulation of the gastrocsoleus in noninflamed muscle. This study demonstrated an expansion of the receptive field in the dorsal horn as a result of a central sensitization. The L3 dorsal horn neurons became hyperexcitable after continuous nociceptive input from the inflamed L5 muscle. The sensitized surrounding segments caused the L3 segment to respond to previously ineffective afferent input. This model of referred pain combines peripheral input and central processing and is known as the central hyperexcitability theory.\textsuperscript{140}

Several supraspinal mechanisms contribute to referred pain or secondary hyperalgesia.\textsuperscript{4,5,141} Pain from myofascial trigger points is associated with increased activity in the somatosensory and limbic regions and suppressed hippocampal activity. The limbic regions of the brain are responsible for the emotional/affective component of pain, whereas the hippocampus modulates stress.\textsuperscript{5} Increased cortical and subcortical activity spurred by disinhibition can disrupt function in descending pain-modulating pathways, which may lower pain thresholds peripherally.\textsuperscript{142–144} Trigger points and myofascial pain are also associated with widespread microstructural changes concentrated in limbic system gray matter that may indicate damage.\textsuperscript{145} A recent study showed that disinhibition of the motor cortex, consisting of either decreased intracortical inhibition or increased intracortical facilitation, is a marker of myofascial pain.\textsuperscript{146}

Until recently, pain has been considered primarily related to neuronal activity; however, recent work has uncovered the contribution of microglia to the pain experience.\textsuperscript{147–149} Microglia are not static cells; rather, they are capable of releasing a number of neuroexcitatory substances that modulate local neuronal activity.\textsuperscript{150} Studies by Chacur and colleagues have helped characterize the role of microglia in spinal sensitization.\textsuperscript{151} After experimentally induced myofascial inflammation, microglial cells evince morphologic changes both ipsilaterally and contralaterally to the inflamed tissue without activating the contralateral microglia cells to the point of inducing measurable effects of central sensitization. Inhibition of microglia through application of minocycline is sometimes effective at
attenuating hypersensitivity in animals with muscle pain, which supports
the role of microglia in mediating the pain experience.\textsuperscript{152}

Expansion of the receptive field in the spinal cord with myositis-induced excitation is clinically relevant, helping to explain the unusual referral patterns seen in myofascial pain. For example, trigger points in the suboccipital muscles may refer to the frontal region of the head, and trigger points in the piriformis may cause pseudosciatica. Expansion of the receptive field may also explain the symptomatic hyperalgesia reported by many patients, as many of these neurons become hyperexcitable. It is likely that these myositis-induced changes in the spinal cord occur due to a rewiring of dorsal horn neurons in response to sustained peripheral drive from an irritable, sensitized muscle nociceptor, such as that found in an active trigger point.\textsuperscript{153}

Visceral dysfunction can also manifest through central sensitization as trigger point development. For example, trigger points in the abdominal wall can be used for diagnostic purposes. Jarrell\textsuperscript{154} found that the presence or absence of a trigger point in the abdominal wall helps to determine whether there is evidence of current or previously treated visceral disease. The presence of an abdominal wall trigger point predicted evidence of visceral disease in 90\% of subjects. However, the absence of a trigger point was associated with no visceral disease in 64\% of the subjects.\textsuperscript{154,155} A cohort study of men with chronic pelvic pain syndrome found that abdominal pain or tenderness was present in 51\% of patients, compared to only 7\% of healthy controls.\textsuperscript{156}

Trigger points may also be associated with joint dysfunction. Trigger points in the upper trapezius were found to correlate with cervical spine dysfunction at the C3 and C4 segmental levels, although a causal relationship was not established.\textsuperscript{157} A single spinal manipulation induced changes in pressure pain sensitivity in latent trigger points in the upper trapezius muscle.\textsuperscript{158} It is important to add that referred pain is not unique to muscle tissue or myofascial trigger points. All tissues, including fascia, intervertebral disks, internal organs, ligaments, and zygapophyseal joints are capable of referring pain.\textsuperscript{132,159–162} Referred pain patterns from cervical zygapophyseal joints are very similar to those of trigger points in cervical muscles.\textsuperscript{163} Clinically, referred pain phenomena can be rather
confusing as patients frequently complain of pain in an area of the body where the pain did not originate.\textsuperscript{164,165} For instance, pain in the elbow region, often considered a local problem due to epicondylitis, may in fact be referred pain from shoulder muscles.\textsuperscript{166} Hsieh et al.\textsuperscript{167} demonstrated that inactivating trigger points in the infraspinatus muscle using dry needling inactivated trigger points in the anterior deltoid muscle. Similarly, pain in the region of the masseter muscle can be resolved by treating trigger points in the trapezius muscle.\textsuperscript{168} Headley\textsuperscript{169} suggested that trigger points in a particular muscle can inhibit other muscles especially in the area of referred pain. For example, trigger points in the infraspinatus muscles may weaken the extensor carpi radialis muscles.\textsuperscript{167,169} In other cases, muscle pain and trigger points may be secondary to other, nonmuscular disorders, such as internal organ, joint, or disk pathology. This finding underscores the necessity of an excellent and comprehensive differential diagnostic process to uncover the nuances of referred pain.\textsuperscript{170} Patients with osteoarthritis of the hip or knee joint were found to have significantly higher numbers of trigger points in muscles crossing these joints than healthy controls.\textsuperscript{171} The correlations between pathologic conditions and an increased number of trigger points may partially explain why localized painful conditions can become more widespread.\textsuperscript{23}

There are several hypotheses of the causal relation between trigger points and central sensitization.\textsuperscript{130} Hoheisel and colleagues studied central sensitization in the dorsal horn through histologic, electrophysiologic, and behavioral studies.\textsuperscript{172} Experimentally induced fascial inflammation in animal models leads to an increase in input from the fascia to the dorsal horn, which may be due to the activation of ineffective or silent synapses. Increased input to the dorsal horn increases afferent bombardment and background activity leading to spinal sensitization. The synaptic changes observed at the dorsal horn after induced fascial inflammation make a clear connection between fascial dysfunction and central nervous system structure and function.

The integrated trigger point hypothesis is a popular model, but it is not without flaws.\textsuperscript{27} Notably, it fails to account for trigger points observed with nonmusculoskeletal pathologies. The neurogenic hypothesis attempts
to address the observation of trigger points in regions without local injury by suggesting a neurogenic incitement of trigger point formation after primary pathology, local or remote, within the common neurometric field. According to Srbely, trigger points do not simply perpetuate central sensitization but are its neurogenic manifestations. Central sensitization, spurred by the primary pathology, results in neurogenic inflammation and sensitization of peripheral nociceptors. These in turn may lead to the formation of the characteristic discrete tender nodule or trigger point.

Hocking maintained that an upregulation of L- or N-type voltage-dependent calcium channels and $\alpha_1$-adrenergic receptors combined with a downregulation of calcium-activated $K^+$ channels would lead to an increase in the motor terminal cytosolic $Ca^{2+}$ concentration. According to Hocking, sympathetic activity would facilitate these phenomena because $\alpha_1$-adrenergic receptors are linked to L-type voltage-dependent calcium channels.

Furthermore, the integrated trigger point hypothesis does not include other pertinent mechanisms, such as the role of reactive oxygen species (ROS). Recently, Jafri expanded the integrated trigger hypothesis by incorporating mechano-activation of ROS signaling to destabilized calcium signaling. Striated muscle generates ROS, especially superoxide that usually is produced by mitochondria. Under stressful or pathologic conditions, the enzyme xanthine oxidase and phospholipase A2-dependent processes have been shown to also produce ROS. During repetitive contractions, nicotinamide adenine dinucleotide phosphate oxidase 2 (NOX2), located within the sarcoplasmic reticulum, the sarcolemma, and the transverse tubules, is the major source of superoxide ROS. In patients with Duchenne muscular dystrophy, the mechano-activation of NOX2-dependent ROS production plays a significant role in the pathogenic calcium and ROS signaling. Jafri hypothesized that mechanical stress can trigger an excessive release of calcium in muscles through X-ROS signaling. According to Jafri, mechanical deformation of the microtubule network can activate NOX2, which would produce ROS. The ROS oxidizes ryanodine receptors leading to increases in $Ca^{2+}$ release from the sarcoplasmic reticulum. The $Ca^{2+}$ mobilization resulting from mechanical stretch through this pathway is
referred to as X-ROS signaling. In skeletal muscles, X-ROS sensitizes Ca\(^{2+}\)-permeable sarcolemmal transient receptor potential or TRP channels, which may be a source of nociceptive input and inflammatory pain.\(^{27,183}\) Activating the transient receptor potential vanilloid 1 (TRPV1) leads to a quick increase in intracellular Ca\(^{2+}\) concentrations.\(^{184,185}\) Jafri\(^{27}\) suggested that myofascial pain is likely due to a combined activation of several ligand-gated ion channels, including the TRPV1 receptor, other acid-sensing ion channels (ASIC3), BK, and purinergic receptors, among others.

The Biochemical Milieu of Myofascial Trigger Points

Until recently, myofascial pain was characterized primarily by a physical finding and symptom cluster without demonstrable pathology. Research in the upper trapezius muscle has characterized the unique biochemical milieu of myofascial trigger points and has even identified quantitative differences between active and latent trigger points.\(^{138,186}\) The presence and possible effects of these biochemicals are discussed in the following sections. It has not yet been determined whether the unique biochemical environment develops before and perhaps causes trigger points or is somehow a result of trigger point formation. Further study of the biochemical milieu of trigger points may not only lead to an improved biochemical characterization of trigger points but may also identify those who are at risk for developing persistent symptoms. Discovering if and which measurable substances are predictive of pain could lead to focused therapies in the future.

pH and Muscle Pain

A previous study demonstrated a positive correlation between pain and local acidity.\(^{187}\) Sluka et al.\(^{91}\) demonstrated that an acidic milieu without muscle damage is sufficient to cause profound changes in the properties of the pain matrix such that alterations in pH would be sufficient to modify the threshold sensitivity of the nociceptor. An acidic pH stimulates the
production of BK during local ischemia and inflammation; therefore, a local acidic milieu may explain some of the pain associated with an active trigger point. Mechanical hyperalgesia is a hallmark of a trigger point; however, ongoing nociceptive activity is not necessary to cause mechanical hyperalgesia. In a rat model, repeated injections of acidic saline boluses into one gastrocnemius muscle produced bilateral, long-lasting mechanical hyperalgesia of the paws. Furthermore, the study showed that the persistent hyperalgesia does not require muscle tissue damage nor continued nociceptive input from the injection site, demonstrating that secondary mechanical hyperalgesia may be maintained by neuroplastic changes in the central nervous system, such as dorsal horn and thalamic neurons.

Specific ASICs on muscle nociceptors can be sensitized and activated by acidic pH. For example, ASIC3 knockout mice do not develop hyperalgesia following repeated bolus injections of acidic saline. Hong et al. suggest that an integrative mechanism at the spinal cord level in response to sensitized nociceptors plays a role in the development of active trigger points and should be considered in any pathogenetic hypothesis. In an expansion of Simons’s integrated hypothesis, Gerwin et al. proposed that the acidic pH may also modulate the motor endplate by inhibiting AChE. This would result in increased concentration of ACh at the synaptic cleft, promoting sarcomere contraction and formation of the taut band characteristic of trigger points.

Neuropeptides, Inflammatory Mediators, and Tissue Injury and Pain

Significantly elevated levels of SP and CGRP are found in the vicinity of active trigger points. The orthodromic and antidromic release of these substances is greatly increased in response to nociceptor activation, for example, by protons and BK binding to their matched receptors. This may lead to neuroplastic changes in the dorsal horn and profound changes in neuronal activity and the perception of pain. In the studies by Shah et al., SP and CGRP were the only two analytes at active trigger points with concentrations significantly below their original baselines in the
recovery period following a local twitch response. These biochemical changes correspond with the commonly observed decrease in pain and local tenderness after the inactivation of a trigger point by dry needling (Fig. 35.5).\textsuperscript{191}

**FIGURE 35.5** Concentrations of calcitonin gene-related peptide and substance P across time. A local twitch response was elicited at 5 minutes.

SP causes mast cell degranulation with the subsequent release of histamine, 5-HT, and upregulation of both pro-inflammatory cytokines, including TNF-\(\alpha\) and IL-6, and anti-inflammatory cytokines, including IL-4 and IL-10. TNF-\(\alpha\) is the only cytokine restored in the mast cell and is released immediately following mast cell degranulation.\textsuperscript{192,193} The finding of elevated levels of 5-HT, BK, norepinephrine, and pro-inflammatory cytokines in active trigger points is consistent with biochemical pathways involved in tissue injury and inflammation.\textsuperscript{137,138}
Catecholamines and the Autonomic Nervous System

Significantly elevated levels of 5-HT and norepinephrine are found in the vicinity of active trigger points, supporting the effect of the elevated TNF-α. The increased levels of norepinephrine may be associated with increased sympathetic activity in the motor endplate region of trigger points. In one study, sympathetic activity was recorded from rabbit myofascial trigger spots. Intra-arterial injection of phentolamine, an α-adrenergic antagonist, decreased the spontaneous electrical activity from a locus of a myofascial trigger spot in rabbit skeletal muscle. Conversely, the nAChR antagonist curare had no effect on the spontaneous electrical activity. Elevated levels of norepinephrine in the local milieu of active trigger points suggest that the autonomic nervous system is involved in the pathogenesis of spontaneously painful trigger points. A study by Ge et al. provides evidence of sympathetic facilitation of mechanical sensitization of trigger points. The presence of α- and β-adrenergic receptors at the endplate may provide a possible mechanism for autonomic interaction, for example, stimulation of the α- and β-adrenergic receptors stimulated the release of ACh in the phrenic nerve of rodents.

Cytokines and Pain

A unique cascade of cytokines is released following tissue injury and inflammation. For example, BK stimulates the release of TNF-α, which leads to the release of IL-1β and IL-6. These two cytokines stimulate the cyclooxygenase (COX) nociceptive pathway, which leads to the production of PGs. TNF-α also stimulates a separate nociceptive pathway via the release of IL-8, which mediates sympathetic pain by stimulating the liberation of sympathetic amines.

TNF-α, IL-1β, IL-6, and IL-8 have been found at elevated levels at active trigger points in the upper trapezius. TNF-α produces a time- and dose-dependent muscle hyperalgesia within several hours after injection into the gastrocnemius or biceps brachii of a rat. The hyperalgesia is completely reversed by systemic treatment with the nonopioid analgesic metamizol. Furthermore, TNF-α does not cause
histopathologic tissue damage or motor dysfunction. One day after injection of TNF-α, elevated levels of CGRP, nerve growth factor, and prostaglandin E2 are found in the muscle. According to Schafers et al., TNF-α and other pro-inflammatory cytokines such as IL-1β may play a role in the development of muscle hyperalgesia, and the targeting of pro-inflammatory cytokines might be beneficial for the treatment of muscle pain syndromes.

In rat model studies, Loram et al. measured the tissue and plasma levels of cytokines following injection of carrageenan into the hind paw compared with intramuscular injection into the gastrocnemius muscle. They demonstrated, for the first time, that the initiation of primary muscle hyperalgesia is not associated with elevated levels in local muscle of TNF-α, IL-1β, or IL-6. Loram et al. also showed that IL-1β and IL-6 are elevated at a time interval when there is no hyperalgesia. One possible explanation, they suggest, is that elevated intramuscular levels of IL-1β and IL-6 induce central sensitization but do not contribute to the initiation of hyperalgesia.

Cytokines that lead to PG release via the COX pathway have been targeted for pharmacologic intervention because of their roles in the inflammatory response. IL-1β is the major cytokine stimulus for central COX-2 expression during inflammation. Loram et al. found that IL-1β was the only cytokine that reached a higher concentration in the muscle compared to the hind paw after carrageenan injection in the rat. Furthermore, IL-1β was significantly elevated 24 hours after inducing muscle inflammation at a time when secondary hyperalgesia was induced. IL-1β also stimulates IL-6 production during muscle injury. Together, both cytokines are necessary for repair and regeneration of muscle. In light of the importance of cytokines to muscle regeneration, Loram et al. suggest that pharmacologic interventions preferentially target action of IL-1β and not IL-6 in order to reduce secondary muscle hyperalgesia and still conserve the cytokines’ regenerative qualities.

Moreover, which cytokines and when to target them may depend on the time course of the muscle injury and inflammatory response. Whereas some groups have found that TNF-α produces a time- and dose-dependent
muscle hyperalgesia within several hours after injection into rat muscle, others have found that injection of TNF-α into a rat’s gastrocnemius muscle does not excite but rather has a short-term desensitizing action on group IV muscle afferents.\textsuperscript{205} The data suggest that TNF-α has a dual action when released intramuscularly. Initially, it suppresses neuronal excitability, but in a later stage, it contributes to neuronal hyperexcitability.\textsuperscript{205} Therefore, the elevated levels of TNF-α, IL-1β, and IL-6 found in active trigger points may mediate secondary hyperalgesia and central sensitization via the COX pathway.

A second distinct nociceptive pathway moderates the inflammatory hyper-nociception following tissue injury. Rat cytokine-induced neutrophil chemo-attractant 1 (CINC-1) and its homolog in humans, IL-8, coordinate the sympathetic components of hyper-nociception. Loram et al.\textsuperscript{199} demonstrated that of the four cytokines—TNF-α, IL-1β, IL-6, and CINC-1—measured in muscle after carrageenan injection, only levels of CINC-1 were elevated at the time of primary hyperalgesia.\textsuperscript{199} Moreover, CINC-1 and IL-8 induce a dose- and time-dependent mechanical hyper-nociception. Therefore, the elevated levels of IL-8 found in active myofascial trigger points may mediate inflammatory hyper-nociception, muscle tenderness, and pain via this pathway. Furthermore, this pathway is inhibited by β-adrenergic receptor antagonists, although not COX antagonists.\textsuperscript{196}

Clinical Management

TRIGGER POINT DIAGNOSIS

The literature on the clinical management of patients with myofascial pain is scattered over multiple specialties and disciplines, including algology, physiatry, dentistry, otolaryngology, urology, neurology, osteopathy, orthopedics, gynecology, physical therapy, chiropractic, acupuncture, and massage therapy, among others. No medical specialty has claimed muscle as its organ of focus; therefore, the term myofascial pain may have different meanings among different disciplines, making understanding across disciplines challenging. In dentistry, for example, “myofascial pain dysfunction syndrome” is commonly used for nonspecific muscle pain
with or without limited mouth opening. The finding of trigger points should not preclude other aspects of the differential diagnosis, including neurologic examinations, biomechanical assessments of posture and movement patterns, and assessments of other possible contributing factors.

Trigger points may elicit symptoms similar to those of other conditions. Some trigger point–referred patterns are very similar to radicular pain patterns. For example, referred pain patterns of trigger points in the teres minor muscle or gluteus minimus muscle resemble a C8 or L5 radiculopathy, respectively. However, the presence of myofascial trigger points does not rule out a radiculopathy and vice versa. Trigger points may also be associated with lumbar disk lesions or contribute to symptoms of thoracic outlet syndrome. Even in fibromyalgia, which is considered a central sensitization disorder, myofascial trigger points play an important role in the perception of pain and sensitization.

As part of the diagnostic process, clinicians should consider other diagnoses, which may feature widespread pain, including but not limited to hypothyroidism; systemic lupus erythematosus; Lyme disease; babesiosis; ehrlichiosis; Candida albicans infections; myoadenylate deaminase deficiency; herpes zoster; complex regional pain syndrome; hypoglycemia; parasitic diseases such as fascioliasis, amoebiasis, and giardia; systemic side effects of medications including any of the statin drugs or even glucosamine sulfate; and metabolic or nutritional deficiencies or insufficiencies of vitamin B₁₂, vitamin D, and ferritin. Having patients complete standardized pain questionnaires at the time of the initial examination allows for objective outcome measurements. Because individual clinicians may not be familiar with discipline-specific differential diagnoses outside their own specialty, a multidisciplinary approach to assessment and treatment is preferred especially for more complex patients. However, the underlying mechanisms and principles of muscle dysfunction, described earlier in this chapter, apply to all disciplines.

A significant problem in the myofascial pain literature is the inconsistent use of criteria to identify trigger points. Palpation is the criterion standard for identifying myofascial trigger points in spite of the lack of research-validated definitional criteria. Simons et al. defined
empirically derived criteria, which have been applied to a number of interrater and intrarater reliability studies.\textsuperscript{219–231} A recent Delphi study of 60 experts from 12 countries revealed that more than 70\% of the experts considered only two palpatory findings and one symptom as essential criteria for the diagnosis of myofascial pain, namely, a taut band, a hypersensitive spot, and referred pain.\textsuperscript{232} The presence of a taut band and spot tenderness has been shown to be a reliable indicator of myofascial trigger points in one comprehensive study, although in a more recent study, referred pain and a jump sign were the most reliable indicators.\textsuperscript{219,221} The local twitch response is more difficult to elicit manually and has not been shown to be a reliable feature of trigger points. A systematic review in 2017 found that the overall interrater reliability of palpation for myofascial trigger points was moderate.\textsuperscript{233} Experienced and inexperienced clinicians reached different levels of agreement when identifying trigger points.\textsuperscript{234,235}

Occasionally, the concept of myofascial pain is challenged because acceptable interrater reliability is only achieved with experienced and well-trained clinicians.\textsuperscript{234,236} However, the fact that trigger point palpation has to be learned is no different than most other clinical skills and procedures. Palpation and, more specifically, trigger point palpation is not taught in the vast majority of medical, physical therapy, and chiropractic schools, and it should come as no surprise that clinicians do not necessarily master trigger point palpation without specific training.\textsuperscript{237} It is encouraging that several recent studies indicate that there has been much progress in the quality of myofascial pain studies, but there is always a need for better and higher quality research.\textsuperscript{238,239}

**PHYSICAL EXAMINATION AND DIAGNOSIS**

The physical examination of myofascial trigger points is performed with either a flat or pincer palpation technique. With the flat palpation technique, the taut band and trigger point are compressed in between a finger or thumb against the underlying tissue or bone (Fig. 35.6). With the pincer palpation technique, the taut band and trigger point are held in between the clinician’s fingers and thumb (Fig. 35.7). The initial palpation focuses on the presence of taut bands as, by definition, trigger points are
always located within a band of contracted muscle fibers. Palpation for trigger points is performed perpendicular to the fiber direction, which requires good anatomical knowledge of muscles and their fiber directions. Whether a muscle should be shortened, lengthened, or kept in a resting position depends entirely on the individual muscle, the tension in connective tissues and fascia, and available range of motion. The muscle needs to be placed in a position where the taut band can optimally be palpated. For patients with very tight and restricted muscles, the muscle may need to be placed in a relaxed position, whereas in hypermobile patients, the muscle may need to be prestretched to facilitate identification of taut bands.\textsuperscript{28}

FIGURE 35.6 Flat palpation technique.
Familiarity with referred pain patterns of trigger points is essential in guiding clinicians to clinically relevant muscles and trigger points. Recent studies have established new and confirmed previously suggested referred pain patterns, especially in the head and neck region. Prolonged pressure on trigger points for as long as 10 to 15 seconds may elicit referred pain patterns, and the patient’s familiar pain complaint. Local twitch responses may be elicited by strumming the taut band, but this has little utility as part of the diagnostic process. The minimum criteria for identification of an active trigger point are the presence of a taut band with exquisite spot tenderness and patient-recognized pain. The physical examination for myofascial trigger points should be a standard component of the diagnostic process but does not preclude any other part of the standard examination process. In addition to trigger points, there are many other possible sources of nociception and pain. A detailed history is critical. There are also several predisposing or perpetuating factors that need to be assessed in addition to possible medical diagnoses.

Mechanical perpetuating factors are relatively easy to identify by clinicians across disciplines and include forward head posture, which frequently contributes to migraines or tension-type headaches, neck pain, and upper thoracic pain, decreased spinal mobility, structural misalignments, such as leg length discrepancies or pelvic torsions, or systemic or local hypermobility. The combination of static and
awkward postures, excessive force, and repetitive tasks predisposes a patient to the development of trigger points.\textsuperscript{107,108} Ergonomic measures often play a vital role in correction and prevention of myofascial pain problems.\textsuperscript{253}

Psychological arousal has a direct impact on the electrical activity of myofascial trigger points, although autogenic relaxation reduces the electrical activity.\textsuperscript{254–256} Whether specific regions of the brain, such as the anterior cingulate gyrus and periaqueductal gray, which have been linked to nociceptive input from muscles and to depression, anxiety, and anger, can explain at least part of the association of psychological factors and trigger points remains to be seen.\textsuperscript{4,257} In 2013, Gerber et al.\textsuperscript{170} found that patients with cervical pain secondary to active myofascial trigger points had significantly poorer health status and quality of life compared to individuals with latent or no trigger points. Their poor health status was characterized by higher rates of depression, fatigue, tension, confusion, mood disturbances, and sleep disruption as well as greater disability.

Adequate treatment of myofascial pain involves consideration not only of the physiologic cause of pain but also of the psychosocial deficiencies patients may experience. Depending on the severity of these symptoms, it may be prudent to include psychologists or social workers in a patient’s long-term treatment plan.

Any nutritional or metabolic condition that interferes with the energy supply of muscle tissue can contribute to the development of myofascial trigger points.\textsuperscript{216} Laboratory levels can be within the “normal” range yet be insufficient for a given individual. The connection between the insufficiency and an individual’s pain may be difficult to appreciate, but it is no less important than in individuals with “abnormal” results. Empirically, common nutritional and metabolic deficiencies or insufficiencies include vitamins B\textsubscript{1}, B\textsubscript{6}, B\textsubscript{12}, and D; iron, magnesium, and zinc insufficiency states; and thyroid deficiency states, among others. The importance of metabolic and nutritional perpetuating factors is illustrated for vitamin D.

Vitamin D deficiency is commonly observed with chronic, nonspecific musculoskeletal pain.\textsuperscript{258} Nearly 90\% of 150 subjects with musculoskeletal pain had vitamin D levels less than 20 ng/mL and 28\% had less than 8
ng/mL, where levels above 30 ng/mL are considered optimal. Vitamin D deficiency in adults is defined as serum 25(OH)D levels below 20 ng/mL and vitamin D insufficiency as 25(OH)D levels between 20 and 30 ng/mL.\textsuperscript{259,260} Vitamin D deficiencies are endemic in Northern Europe and America and are associated with muscle weakness, myofibrillar protein degradation, reduced muscle mass, osteoporosis, and decreased functional ability.\textsuperscript{261–264} Low levels of magnesium and 25(OH)D have been linked not only to myofascial pain but also to cancer, adenomatous colon polyps, and tendon ruptures.\textsuperscript{265}

Although palpation is truly the gold standard for trigger point identification, meaningful palpation takes time to learn and perfect.\textsuperscript{237} This has driven researchers to seek ways to identify and characterize trigger points using more objective and quantitative techniques. Magnetic resonance and ultrasound elastography are increasingly used in research but are not yet common in clinical practice.\textsuperscript{40,41,266} Piezoelectric and electrohydraulic shockwave emitters are common in Germany for the identification and treatment of trigger points and their specific referred pain patterns.\textsuperscript{267,268} Both types of shockwave emitters are able to reproduce patients’ familiar referred pain patterns. Although endplate noise was found to be characteristic of trigger points, in clinical practice, there is no advantage to using electromyography for the identification of trigger points.\textsuperscript{269}

Recent advances in ultrasound technology have made it an especially appealing tool to try to bring into the clinical assessment of myofascial pain secondary to trigger points. Studies have focused on three modes of ultrasound imaging: two-dimensional (2D) grayscale (B-mode), Doppler, and vibration sonoelastography.\textsuperscript{135,266,270–272} Under 2D grayscale ultrasound, healthy muscle appears uniform in fiber orientation and echotexture. Active and latent trigger points both appear as hypoechoic ellipses or bands, although no significant differences have been noted between them in terms of echogenicity or echotexture.\textsuperscript{266,273} The underlying reason for the hypoechoic appearance is not known at this time. Color Doppler imaging of blood vessels in the vicinity of trigger points shows that although both active and latent trigger points have similar unique waveforms indicative of retrograde diastolic flow relative to
normal muscle, more active than latent trigger points show abnormality (69% of active vs. 16.7% of latent).\textsuperscript{45,273} Spectral Doppler imaging illustrates that both kinds of trigger points also have high pulsatile flow more frequently than normal muscle, further indicating that trigger points are associated with blood flow abnormality.\textsuperscript{44,45,273} Under vibration sonoelastography, trigger points appear as regions of increased tissue stiffness corresponding to the localized hypoechoic regions in the 2D grayscale imaging. Although these results are promising, ultrasound is not a substitute for a comprehensive physical examination including palpation; however, it has the potential to be a useful supplemental clinical tool for the assessment of the heterogeneity and soft tissue properties of muscle and determination of treatment outcomes.\textsuperscript{45}

**TREATMENT OPTIONS**

One of the first decisions to make after the initial examination is whether the patient’s pain complaints have a significant myofascial component. Patients with chronic pain problems may present with a combination of possible contributing factors. If metabolic or nutritional insufficiencies are found, it is unlikely that therapy will be successful until such insufficiencies are adequately addressed. The choice of treatment modalities is partially based on a clinician’s bias, preferences, experience, and skills. A dentist treating a patient with facial pain and trigger points in the masseter muscle may decide to improve the patient’s occlusion assuming that the muscle pain is secondary to the malocclusion. An orthopedic surgeon may manage a patient’s complaint of radiating pain down the leg with epidural injections to reduce radicular pain, whereas a physician familiar with referred pain patterns of myofascial trigger points may decide to treat trigger points in the gluteus medius muscle with trigger point injections or myofascial release techniques. Many patients with chronic myofascial pain may benefit from a comprehensive pharmacologic management strategy, which may include nonsteroidal anti-inflammatory drugs, opioids, antidepressants, and anticonvulsants, although these are not specific for myofascial pain.\textsuperscript{274}

**Patient Education**
Following the initial examination, patients need to be educated about the nature and complexity of their pain. Studies have shown that patients with chronic pain gain understanding and insight when the clinician explains the principles of peripheral and central sensitization rather than focuses on anatomical concepts such as spinal mechanics.275–277 Excellent patient education can reduce disability and assist patients in making appropriate choices, overcoming counterproductive beliefs, and modifying dysfunctional behaviors by increasing physical activity and self-efficacy.278,279 If the patient’s pain complaint could easily be provoked by pressure on certain trigger points, it is likely that trigger point therapy will make significant improvements. However, clinicians should be cautious in promising complete relief, especially for chronic pain conditions with multiple interacting aspects.

Physical Therapy
The role of physical therapy in pain management centers is often limited to instructing patients in proper stretching and strengthening exercises, stabilization programs, and posture corrections as well as providing limited manual therapy interventions. Relatively few physical therapists receive adequate training in pain management, and physical therapists are poorly represented in professional pain management associations.280 Few physical therapy schools have adopted a specific pain science curriculum,281,282 which may explain why as many as 96% of orthopedic physical therapists preferred not to work with patients with chronic pain.283 Patients need to learn self-pacing and setting appropriate and achievable goals, including physical, psychological, functional, and social goals.284 An important variable is the degree of a patient’s belief in their self-efficacy, which is defined as “the belief in one’s capabilities to organize and execute the sources of action required to manage prospective situations.”278,285,286 Patients with a weak belief in their self-efficacy tend to avoid difficult tasks, have low aspirations, maintain a self-diagnostic focus, and emphasize personal deficiencies and adverse outcomes. They are more prone to depression and stress and give up quickly. Patients with a strong belief in their self-efficacy are more likely to set challenging goals, consider difficult tasks as challenges rather than as threats, and
maintain a task-diagnostic focus. They usually are not depressed and increase their effort when faced with difficulties.

**Needling Therapies**

Invasive trigger point therapy usually involves either trigger point injections or dry needling. As Steinbrocker already suggested in 1944, the mechanical stimulation of trigger points is an important mechanism to explain the effects of needling therapies. Trigger point injections are usually performed by medical doctors and their professional support staff. A growing number of physical therapists and physicians around the world utilize trigger point dry needling.

The first comprehensive paper about dry needling was published in 1979 and reported that dry needling of various structures, including trigger points, ligaments, and fascia, caused immediate analgesia in almost 87% of the needle sites. Lewit referred to the immediate reduction of pain as “the needle effect.” In 1980, a prospective dry needling study of injured workers with low back pain showed that dry needling was an effective treatment for low back pain. A Cochrane review supported the use of dry needling as an adjunct for the treatment of patients with chronic low back pain. Trigger point dry needling consists of superficial and deep dry needling based on the depth of needling. The technique used with deep dry needling is similar to the technique of trigger point injections and usually aims to elicit local twitch responses (Fig. 35.8).
The mechanisms and effectiveness of deep dry needling are comparable to trigger point injections.\textsuperscript{191,291–294} Earlier studies suggested that dry needling would cause more post-needling soreness, but there are no differences between injections and dry needling using solid filament needles. Post-needling soreness occurs in most patients and can vary in duration from just a few minutes to several 2 days.\textsuperscript{295} Applying a cold application, using manual compression techniques, applying transcutaneous electrical stimulation, or performing low load exercises following needling procedures does reduce the post-needling soreness in the short term.\textsuperscript{296–299} Psychological factors do impact the degree of post-needling soreness.\textsuperscript{295,300} Vasovagal reactions can occur with any needling procedure, but they are relatively rare. To avoid unnecessary complications from possible vasovagal reactions, patients are needled preferably while lying down on a treatment table.

A local twitch response is an involuntary spinal cord reflex contraction of muscle fibers within a taut band, which can be elicited by manually strumming or needling of a taut band. Local twitch responses can be observed visually, recorded electromyographically, or visualized with diagnostic ultrasound.\textsuperscript{301} When a trigger point is needled with a monopolar Teflon-coated electromyography needle, local twitch responses appear as high-amplitude polyphasic discharges.\textsuperscript{302} Eliciting local twitch responses is helpful when using deep dry needling in clinical practice not only to accomplish optimal treatment results but also to confirm that the needle is placed into a taut band, which is critically important when needling close to peripheral nerves or internal organs, such as the lungs.\textsuperscript{188,291,303,304} In a study of dry needling for low back pain, Koppenhaver et al.\textsuperscript{305} noted that subjects who experienced a local twitch response reported a greater improvement in the function of the lumbar multifidus muscle compared to those who did not experience a twitch response; however, the difference was of short duration. Eliciting a local twitch response had no effect on levels of disability, nociceptive activity, or pain intensity.\textsuperscript{305} Nevertheless, eliciting local twitch responses does normalize the chemical environment of active trigger points.\textsuperscript{138,186,304} In clinical practice, patients commonly
report never having experienced local twitch responses when they were treated with trigger point injections previously.

With superficial dry needling, a solid filament needle is placed into the tissues overlying active trigger points at a depth of approximately 5 to 10 mm for 30 seconds. If there is residual pain, the needle is inserted for another 2 or 3 minutes.\textsuperscript{306,307} Local twitch responses are usually absent with superficial dry needling. The degree of available endogenous opioid peptide antagonists may determine how intensely a patient responds to the therapy. So-called weak responders may have excessive amounts of endogenous opioid peptide antagonists. A rodent model has shown that mice with deficient opioid peptide receptors did not respond well to needle-evoked nerve stimulation.\textsuperscript{308}

The efficacy of dry needling may be monitored visually with ultrasound imaging. A 2015 study sought to characterize changes in ultrasound images taken before and after treatment while also recording changes in trigger point status from active to latent and resolution of pain symptoms.\textsuperscript{45} Participants with at least one active trigger point received a 3-week course of dry needling at their most active trigger point. Grayscale 2D B-mode and color Doppler ultrasound images were taken at the trigger point and palpably normal muscle tissue at baseline and posttreatment. A significant reduction in the heterogeneity of muscle stiffness was observed at those trigger points that responded to treatment.\textsuperscript{45} However, although ultrasound is a promising tool to objectively evaluate trigger points before and after treatment, further research is needed to improve reproducibility and standardize imaging methods and quantitative measures before it can be used reliably for diagnosis.

Trigger point injections are administered with a variety of injectables, including procaine and lidocaine, steroids, and vitamin B\textsubscript{12} (Fig. 35.9). Travell preferred procaine hydrochloride, which is no longer available everywhere.\textsuperscript{16,309} The current recommendation is to use 0.25\% lidocaine, which was found to be more effective than stronger concentrations.\textsuperscript{310,311} Other anesthetics used with trigger point injections include ropivacaine, levobupivacaine, and mepivacaine, among others.\textsuperscript{312,313} Trigger point injections with the 5-HT antagonist tropisetron were found to be more effective than injections with lidocaine solution, but injectable 5-HT
antagonists are not available in all countries.\textsuperscript{314,315} Although widely used, there is no scientific evidence for injections with steroids, vitamin B\textsubscript{12}, nonsteroidal anti-inflammatories, or bee venom. Bee venom has some potential based on its anti-nociceptive and anti-inflammatory effects through activation of brainstem catecholaminergic neurons and activation of the $\alpha_2$ adrenergic and serotonergic pathways of the descending inhibitory system.\textsuperscript{316–318} Melitin, an active ingredient of bee venom, can suppress lipopolysaccharide-induced nitric oxide and the transcription of COX-2 genes and pro-inflammatory cytokines, including TNF-$\alpha$ and IL-1$\beta$ in microglia.\textsuperscript{319,320} Injections of bee venom into specific acupuncture points in several animal and human studies of knee arthritis have been shown to be beneficial and reduced pain levels significantly, but there are no studies that demonstrate the effectiveness of trigger point injections with bee venom.\textsuperscript{317,321,322}

There is a growing body of literature supporting the use of botulinum toxin in the treatment of myofascial trigger points, although this remains a controversial issue. Many botulinum toxin studies fail to demonstrate superiority of botulinum toxin over placebo.\textsuperscript{323} However, clinicians familiar with myofascial trigger points support its use based on the demonstrated mechanisms of botulinum toxin and empirical
Indeed, several studies have shown significant benefit of botulinum toxin injections in the treatment of myofascial trigger points and various pain states including migraine, tension-type headache, low back pain, and phantom pain. Potential problems with these studies relate to the use of different dosages, varying injection sites, and the degree of familiarity with myofascial trigger points. Botulinum toxin prevents the release of ACh from the presynaptic nerve terminal. ACh is released in response to evoked stimulation of the nerve or spontaneously without axonal nerve activation. Botulinum toxin also has an anti-nociceptive effect, which in part may be due to its ability to also block the release of CGRP from the nerve terminal.

Extensive training is required to gain the necessary palpation skills and kinesthetic awareness, without which trigger point needling would become a random process. Anatomical knowledge is required prior to developing the sensory motor skills needed to visualize the tip of the needle and the pathway the needle follows inside patients’ bodies. Clinicians should be able to visualize a three-dimensional image of the exact location and depth of the trigger point and accurately elicit local twitch responses. The needle should not be used as a search tool except in muscles that cannot be palpated directly, such as the subscapularis or lateral pterygoid muscles. Trained clinicians can almost always identify clinically relevant trigger points, except in obese patients where certain muscles may not be accessible to palpation. Myofascial trigger point injections were the second most common procedure after epidural injections in a study of Canadian pain anesthesiologists, although the art of trigger point injections and trigger point palpation is not usually covered in medical schools, and there are no formal postgraduate training programs in Canada.

Dry needling and injections can eliminate or reduce trigger point pain often in just a few sessions with a skilled clinician, allowing the patient to be more successful in the conditioning phase of the rehabilitation program. There are many clinical outcome studies confirming that needling therapies are effective in inactivating trigger points, reducing pain levels, and improving function.

In spite of a rapidly increasing number of clinical outcome studies, the exact mechanisms of trigger point injections and dry needling are still not
known. Deep dry needling and trigger point injections may destroy motor endplates and cause distal axon denervations, which may trigger changes in the endplate cholinesterase and ACh receptors as part of the normal muscle regeneration process. In a rodent study, dry needling caused a significant decrease of spontaneous electrical activity and ACh and AChR levels and a significant increase of AChE.

It is likely that trigger point needling involves central pain mechanisms, including the limbic system, the subcortical gray structures, and the descending inhibitory system. Most deep needling procedures are painful, possibly stretch fibroblasts in connective tissues, and activate the enkephalinergic, serotonergic, and noradrenergic inhibitory systems associated with Aδ fibers through segmental inhibition. Superficial dry needling is often explained in a similar fashion but is a painless procedure that would not activate Aδ fibers unless the needle is rotated after insertion. Aδ nerve fibers are only activated by nociceptive mechanical stimulation for type I high-threshold Aδ fibers or by cold stimuli for type II Aδ fibers. It is conceivable that the light stimulus of superficial dry needling activates mechanoreceptors coupled to slow-conducting unmyelinated C-fiber afferents, stimulating the anterior cingulate cortex with emotional and hormonal reactions representing a sense of progress, reduction of pain, and well-being.

NONINVASIVE TREATMENT OPTIONS

Rickards and Fernández-de-las-Peñas et al. published comprehensive systematic reviews of noninvasive treatment options for myofascial pain. A wide variety of manual therapies are being used in the treatment of myofascial trigger points, such as spray and stretch, trigger point compression, muscle energy techniques, and massage. There is some evidence of the short-term effectiveness of manual therapies, but no conclusions can be made in relation to the medium- and long-term effectiveness. Fernández-de-las-Peñas et al. demonstrated that trigger point compression and transverse friction massage were equally effective in treating trigger points with a significant reduction in visual analogue scores and significant increase in the pressure pain threshold. Hou et al. showed that trigger point compression reduced pain levels within minutes.
Several modalities have been applied to trigger points, such as laser, ultrasound, and electrotherapy. Laser proved to be an effective modality in most trials. Therapeutic ultrasound has mixed reviews. Srbely and Dickey demonstrated a short-term decrease of the sensitivity of trigger points following ultrasound. Another study of high-power static ultrasound was more beneficial than more traditionally applied ultrasound, whereas two other papers did not show any benefit of ultrasound. Transcutaneous electrical stimulation is the most studied electrotherapy modality, but it remains difficult to draw any conclusions beyond short-term effects. A prospective, randomized study of extracorporeal shockwave therapy in the treatment of athletes with acute or chronic shoulder pain showed significantly improved isokinetic force production, a reduction in pain, and overall performance.

Summary

Myofascial trigger points are a very common cause of clinically observed local muscle pain, tenderness, and referred pain in patients with acute and chronic pain. However, they are also a common physical finding in asymptomatic individuals. This dichotomy challenges and behooves pain management practitioners to learn how to palpate the soft tissue and distinguish active from latent myofascial trigger points. Making this distinction is critical in order to adequately identify and treat a myofascial component of pain. Several independent and emerging lines of scientific inquiry, including histologic, neurophysiologic, biochemical, and somatosensory research into the nature of myofascial trigger points have revealed objective abnormalities. These findings suggest that myofascial pain consists of both motor and sensory abnormalities involving the peripheral and central nervous systems. Accordingly, active myofascial trigger points may be viewed as part of a complex series of changes in the peripheral tissue and central nervous system that occur with central sensitization, characteristic of a form of neuromuscular dysfunction. From this perspective, future clinical research studies should focus on identifying the mechanisms responsible for the pathogenesis, amplification, and perpetuation of myofascial pain syndrome. Successful
treatment depends on identifying and targeting these mechanisms and addressing the perpetuating factors that sustain this common pain syndrome.

Clinical practitioners commonly see patients with pain and other somatic symptoms that they cannot adequately explain based on the degree of damage or inflammation noted in peripheral tissues. In fact, this may be among the most common predicament for which patients seek medical attention. Typically, an evaluation is performed looking for a “cause” for the pain. If none is found, these individuals are often given a diagnostic label that merely connotes that the patient has chronic pain in a region of the body, without an underlying mechanistic cause (e.g., chronic low back pain, headache, temporomandibular disorder [TMD]). In other cases, the label given alludes to an underlying mechanism that may or may not be responsible for the individual’s pain (e.g., “knee osteoarthritis”).

Fibromyalgia is merely the current term for individuals with chronic widespread musculoskeletal pain, for which no alternative cause can be identified. Gastroenterologists often see the exact same patients and focus on their gastroenterologic complaints and often use the terms functional gastrointestinal disorder, irritable bowel syndrome (IBS), nonulcer dyspepsia, noncardiac chest pain, or esophageal dysmotility to explain the patient’s symptoms. Neurologists see these patients for their headaches and/or unexplained facial pain; urologists for pelvic pain and urinary symptoms (and use labels such as interstitial cystitis, chronic prostatitis, vulvodynia, and vulvar vestibulitis); dentists for TMD, and so on.

Until recently, these unexplained pain syndromes perplexed researchers, clinicians, and patients. However, it is now clear that

- Individuals will sometimes only have one of these “idiopathic” pain syndromes over the course of their lifetime. But more often, individuals with one of these entities, and their family members, are likely to have several of these conditions. Many terms have been
used to describe these coaggregating syndromes and symptoms, including functional somatic syndromes, somatization disorders, allied spectrum conditions, sensory sensitivity syndromes, chronic multisymptom illnesses, and medically unexplained symptoms. The most recent term coined by the National Institutes of Health in the United States is probably the best accepted at present: “chronic overlapping pain conditions” (COPCs).

- Women are more likely to have these disorders than men, but the sex difference is much more apparent in clinical cohorts (especially tertiary care) when compared to population-based samples.

- Groups of individuals with these conditions (e.g., fibromyalgia, IBS, headache, TMD) typically display diffuse hyperalgesia (increased pain to normally painful stimuli) and/or allodynia (pain to normally nonpainful stimuli) that is identifiable both via quantitative sensory testing and functional neuroimaging. In addition, a number of other central nervous system (CNS) mechanisms are reproducibly seen in these conditions. This suggests that these individuals have a fundamental problem with augmented pain and/or sensory processing rather than simply a nociceptive focus confined to the region of the body where the person is currently experiencing pain.

- Similar types of therapies are efficacious for all of these conditions, including both pharmacologic (e.g., tricyclic compounds, serotonin norepinephrine reuptake inhibitors [SNRIs] and gabapentinoids) and nonpharmacologic treatments (e.g., education, exercise, cognitive-behavioral therapy). Conversely, individuals with these conditions typically do not respond to therapies that are typically more effective when pain is due to damage or inflammation of tissues (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], opioids, injections, surgical procedures).

- Subsets of individuals with any chronic pain condition (e.g., low back pain, osteoarthritis, autoimmune disorders, sickle cell disease) also have the same phenotypic features and underlying mechanisms as those seen in fibromyalgia. These individuals with subthreshold fibromyalgia display the same pathologic features and differential responsiveness to peripherally directed versus centrally directed
therapies. Thus, it is critical that clinicians seeing patients with chronic pain evaluate individuals for the presence of this phenotype as it can dramatically affect which treatments will work, or not work, for a given individual with chronic pain.

Until perhaps a decade ago, these conditions were all on somewhat equal (and tenuous) scientific ground. But within a relatively short period of time, research methods such as experimental pain testing, functional imaging, and genetics have led to tremendous advances in the understanding of several of these conditions, most notably fibromyalgia, IBS, and TMD. Many in the pain field now feel that much chronic pain itself is a neural disease and that many of the underlying mechanisms operative in these heretofore considered “idiopathic” or “functional” pain syndromes may be similar no matter whether that pain is present throughout the body (e.g., in fibromyalgia) or localized to the low back, the bowel, or the bladder. Because of this, the more contemporary terms used to describe conditions such as fibromyalgia, IBS, TMD, vulvodynia, and many other entities include “centralized pain” or “central sensitization” to imply that the CNS is playing a prominent role in amplifying or causing the pain in most individuals with these syndromes.\textsuperscript{3,14} This review of fibromyalgia in the following discussion focuses on our current understanding of this disorder as the prototypical “centralized pain syndromes.”

**Historical Perspective**

Although the term fibromyalgia is relatively new, this condition has been described in the medical literature since the early 1900s. Sir William Gowers coined the term “fibrositis” in 1904. During the next half century, fibrositis (as it was then called) was considered by some to be a common cause of muscular pain, by others to be a manifestation of “tension” or “psychogenic rheumatism,” and by the rheumatology community in general to be a nonentity.

The current concept of fibromyalgia was established by Smythe and Moldofsky\textsuperscript{15} in the mid-1970s. The name change reflected the fact that there was increasing evidence that there was no -itis (inflammation) in the
connective tissues of individuals with this condition but instead -algia (pain). These authors characterized the most common tender points (regions of extreme tenderness in these individuals) and reported that patients with fibromyalgia had disturbances in deep and restorative sleep and that selective stage 4 interruptions induced the symptoms of fibromyalgia. Yunus and colleagues then reported on the major clinical manifestations of patients with fibromyalgia seen in rheumatology clinics.

The next advance in fibromyalgia was the development of the American College of Rheumatology (ACR) criteria for fibromyalgia, which were published in 1990. These classification criteria required that an individual have both a history of chronic widespread pain (CWP) and the finding of ≥11 of a possible 18 tender points on examination. These ACR classification criteria were intended for research use to standardize definitions of fibromyalgia. In this regard, the criteria have been extremely valuable. Unfortunately, many practitioners use these criteria in routine clinical practice to diagnose individual patients, and this unintended use led to many of the current misconceptions regarding fibromyalgia that are discussed in the following text. New criteria that eliminate the need for the tender point exam were developed in 2010 and refined in 2011 and in 2016. These criteria focus on identifying the cardinal symptoms seen in this condition including widespread pain, fatigue, sleep, memory, and mood disturbances.

Once structural damage to tissues or inflammation had been excluded as pathogenic factors in fibromyalgia, many groups of investigators began to explore neural mechanisms to explain the underlying pathogenesis of these disorders. Fortuitously, newer neuroscience research techniques such as functional, chemical, and structural brain imaging were all becoming available tools to examine the CNS, in both healthy individuals and those with chronic pain.

Thus, the conditions we now mechanistically understand best within this spectrum include conditions where these central factors were first studied, including fibromyalgia, IBS (previously termed spastic colitis until the recognition that there was little -itis and that motility changes were not the major pathologic feature), and TMD (previously termed temporomandibular joint syndrome until it was recognized the problem
was not largely within the joint\textsuperscript{24–27} and urinary chronic pelvic pain syndromes (where again, the condition previously called interstitial cystitis is now called bladder pain syndrome\textsuperscript{28–31}). This is not to say peripheral factors, or low-grade inflammation that is not identifiable clinically, do not play some role in these entities. But it is relevant that clinicians who care for individuals with these conditions, and who are quite adept at identifying (with blood tests, imaging, or endoscopy) peripheral damage or inflammation, have generally concluded that these are not inflammatory or peripheral-based disorders.

**Epidemiology**

**CHRONIC WIDESPREAD PAIN**

Epidemiologic studies of the historical component of the ACR criteria for fibromyalgia, CWP, have been extremely instructive. CWP is typically operationalized as pain above and below the waist, involving the left and right sides of the body and also involving the axial skeleton. Population-based studies of CWP suggest that roughly 6% to 12% of the population has these features at any given point in time.\textsuperscript{32,33} Chronic regional pain is found in 20% to 25% of the population. Both chronic widespread and regional pain occur about 1.5 times as commonly in women than men. These findings are very similar in different countries, ethnicities, and cultures, dispelling an early notion that this problem was somewhat unique to more developed countries.

**FIBROMYALGIA**

The original 1990 ACR criteria for fibromyalgia required that an individual has both a history of CWP and the finding of 11 or greater of 18 possible tender points on examination. Tender points represent nine paired predefined regions of the body, often over musculotendinous insertions.\textsuperscript{18} If an individual reports pain when a region is palpated with 4 kg of pressure, this is considered a positive tender point. Between 25% and 50% of individuals who have CWP will also have 11 or greater tender points and thus meet the 1990 criteria for fibromyalgia.\textsuperscript{34} Just as with CWP, the prevalence of fibromyalgia is just as high in rural or nonindustrialized
societies as it is in countries such as the United States.  

**SIGNIFICANCE OF TENDER POINTS**

When the 1990 ACR criteria were published, it was thought that there may be some unique significance to the locations of tender points. In fact, a term “control points” was coined to describe areas of the body that should not be tender in fibromyalgia, and individuals were assumed to have a psychological cause for their pain is they were tender in these regions. Since then, we have learned that the tenderness in fibromyalgia extends throughout the entire body. Thus, relative to the pain threshold that a normal nonfibromyalgia patient would experience at the same points, “control” regions of the body such as the thumbnail and forehead are just as tender as in fibromyalgia tender points.

The tender point requirement in the ACR criteria not only misrepresents the nature of the tenderness in this condition (i.e., local rather than widespread) but also strongly influences the demographic and psychological characteristics of fibromyalgia. Women are only 1.5 times more likely than men to experience CWP but are 11 times more likely than men to have 11 or more tender points. Because of this, women are approximately 10 times as likely to meet the 1990 ACR criteria for fibromyalgia than men. Yet, most of the men in the population who have CWP but are not tender enough to meet criteria for fibromyalgia likely have the same fundamental underlying pathophysiologic problems as the women who meet the ACR criteria for fibromyalgia.

Another unintended consequence of requiring both CWP and at least 11 tender points to be diagnosed with fibromyalgia is that many individuals with fibromyalgia will have high levels of distress. Wolfe has described tender points as a “sedimentation rate for distress” because of population-based studies showing that tender points are more common in distressed individuals. Until recently, many assumed that because tender points were associated with distress, that tenderness (an individual’s sensitivity to mechanical pressure) was associated with distress. However, recent evidence suggests that this latter association is probably due to the standard tender point technique, which consists of applying steadily increasing pressure until reaching 4 kg. In this situation, individuals who
are anxious or “expectant” have a tendency to “bail out” and report tenderness. Recently, more sophisticated measures of tenderness have been developed which give stimuli in a random, unpredictable fashion, and the results of these tests are independent of psychological status.\textsuperscript{39,40} Because tender points are associated with high levels of distress, requiring 11 or greater tender points in order to diagnose someone with CWP with fibromyalgia dramatically increases the likelihood that these individuals will be female and/or and distressed, compared to individuals with CWP and <11 tender points. In fact, population-based studies suggest that the primary symptom of fibromyalgia, CWP, is only modestly associated with distress, and distress is only weakly associated with the subsequent development of CWP.\textsuperscript{41,42} There are far more psychologically “normal” individuals who develop CWP than distressed or depressed people who do, and most individuals with CWP do not have or subsequently develop distress or depression.

In summary, although many clinicians uniquely associate fibromyalgia with women who display high levels of distress, much of this is an artifact of (1) the 1990 ACR criteria that require 11 tender points and (2) the fact that most studies of fibromyalgia have originated from clinical samples from tertiary care centers, where health care seeking behaviors lead to the fact that psychological and psychiatric comorbidities are much higher.\textsuperscript{9} When all these biases are eliminated by examining CWP in population-based studies, a clearer picture of fibromyalgia can be gleamed, and CWP becomes much like chronic pain in any other region of the body.

**OTHER FEATURES OF FIBROMYALGIA GLEANED FROM EPIDEMIOLOGIC OR OBSERVATIONAL STUDIES**

Individuals who develop fibromyalgia nearly always have a lifelong history of chronic pain in various regions of the body as well as other CNS symptoms such as fatigue, sleep, memory, and mood difficulties. Most individuals who eventually develop fibromyalgia begin having pain in multiple body regions beginning earlier in life. The prevalence of any (regional or widespread) chronic musculoskeletal pain in the population is about 30%, so if a single individual has had chronic pain in multiple bodily
regions early in his or her lifetime and he or she does not have an autoimmune or other disorder leading to widespread inflammation or damage, he or she is likely exhibiting a “chronic pain prone phenotype.” Often beginning in childhood or adolescence, individuals who eventually go on to develop fibromyalgia are more likely to experience headaches, dysmenorrhea, TMD, chronic fatigue, IBS and other functional gastrointestinal disorders, interstitial cystitis/painful bladder syndrome, endometriosis, and other regional pain syndromes (especially back and neck pain). In fact, what often looks to one health care provider as a new episode of acute or subacute pain is in fact simply the latest region of the body experiencing pain. Because of this, many experts in the pain field have begun to feel that especially these “centralized” pain states are best thought of as a single lifelong disease that merely tends to manifest in different bodily regions over time.

In addition to fibromyalgia patients having a high personal lifetime history of chronic pain, there is often a strong family history of chronic pain identifiable. The first-degree relatives of fibromyalgia patients are 8 times as likely to have this condition as the family members of controls and also have very high rates of other chronic pain states. These studies also show that family members of individuals with fibromyalgia are much more tender than the family members of controls, regardless of whether they have pain or not. Family members of fibromyalgia patients are also much more likely to have IBS, TMD, headaches, and a host of other regional pain syndromes. This familial and personal coaggregation of conditions which includes fibromyalgia was originally collectively termed affective spectrum disorder and more recently central sensitivity syndromes, chronic multisymptom illnesses, and chronic overlapping pain conditions. In population-based studies, the key symptoms besides pain that typically coaggregate together are fatigue, memory difficulties, and mood disturbances. Twin studies suggest that approximately 50% of the risk of developing fibromyalgia or related pain conditions such as IBS and headache is genetic, and 50% environmental. The strong familial predisposition to fibromyalgia is shared by many chronic pain conditions, and there has been an explosion of knowledge recently regarding the role of specific genetic factors in chronic pain states, which
The environmental factors that are most likely to trigger the development of fibromyalgia are various types of “stressors,” typically that involve acute pain for at least a few weeks. (Table 36.1). Psychological stress, including childhood trauma, is but one such stressor. Fibromyalgia or similar illnesses are found at much higher than expected rates in individuals who have experienced certain types of infections (e.g., Epstein-Barr virus, Lyme disease, Q fever, viral hepatitis), trauma (motor vehicle collisions), and deployment to war. Of note, each of these stressors only leads to CWP or fibromyalgia in approximately 5% to 10% of individuals who are exposed; the overwhelming majority of individuals who experience these same infections or other stressful events regain their baseline state of health. This is a contentious legal issue, and not all would agree that all of these events can seemingly trigger or exacerbate fibromyalgia. Certainly assessing “cause and effect” in any given individual is almost impossible because all individuals experience intermittent stressors of the variety that seemingly can trigger fibromyalgia. It is also likely that part of the reasons these different stressors can seemingly lead to worsening of fibromyalgia or fibromyalgia symptoms is because of how these stressors affect activity level, sleep, or overall distress, any of which then can lead to worsening of pain and other symptoms.

**TABLE 36.1 “Stressors” Capable of Triggering Fibromyalgia and Related Condition**

- Ongoing inflammatory or nociceptive pain (e.g., autoimmune disorders, sickle cell disease, Ehlers-Danlos syndrome)
- Infections (e.g., parvovirus, EBV, Lyme disease, Q fever; not common upper respiratory infections)
- Physical trauma (e.g., automobile accidents)
- Psychological stress/distress (e.g., sexual assault, early childhood trauma)
- Hormonal alterations (e.g., hypothyroidism)
- Drugs
- Vaccines
- Certain catastrophic events (war but not natural disasters)

EBV, Epstein-Barr virus.

Fibromyalgia also is very commonly seen as a comorbidity in other
chronic pain conditions such as osteoarthritis, rheumatoid arthritis (RA), and lupus. The disorder is also associated with other regional pain conditions or autoimmune disorders.\textsuperscript{64–67} This high rate of fibromyalgia in individuals with other chronic rheumatic or autoimmune disorders deserves special attention because of the relevance to practicing clinicians. As many as 25\% of patients correctly diagnosed with generalized inflammatory disorders such as systemic lupus erythematosus (SLE), RA, and ankylosing spondylitis will also fulfill the clinical criteria for fibromyalgia.\textsuperscript{68,69} However, in clinical practice, this coexpression may go unrecognized, especially when the fibromyalgia develops after the autoimmune disorder or regional pain syndrome. In this setting when comorbid fibromyalgia goes unrecognized, patients are often unnecessarily treated more aggressively with toxic immunosuppressive drugs leading to morbidity without the desired therapeutic effects.

This phenomenon had previously been termed secondary fibromyalgia, but because this is so common and might occur in a subset of nearly any chronic pain cohort, a more popular term we prefer to use for this phenomenon is that these individuals have “centralized” their pain. This simply connotes the fact that although peripheral nociceptive input might be responsible some or even much of that individual’s pain, superimposed CNS factors are also likely amplifying pain and leading to other comorbid symptoms such as fatigue, memory problems, and disturbances of sleep and mood.\textsuperscript{70} The term central sensitization is also sometimes used to describe this phenomenon, but many experts feel that this particular term should be reserved for the original spinal mechanism that was identified and called by this name rather than the more general phenomenon we now believe can result via a multitude of different spinal and supraspinal mechanisms.\textsuperscript{14,71} Regardless of what term an individual uses to describe this phenomenon, it is becoming increasingly important to identify it because emerging evidence suggests that therapies that work best for peripheral, nociceptive pain (e.g., NSAIDs, opioids, injections, surgical procedures) are less likely to be effective in these individuals.\textsuperscript{72,73}

Most studies of fibromyalgia to date have excluded individuals with other conditions so nearly all studies to date have examined the pathophysiology of “primary” fibromyalgia. It is not yet clear if there are
any key pathophysiologic differences between primary fibromyalgia (fibromyalgia as a stand-alone disorder, or accompanied by other COPCs, e.g., headache, IBS, TMD) and secondary fibromyalgia (i.e., central sensitization; Fig. 36.1). This latter group might be very responsive to peripherally directed therapies, if nociceptive input is driving central sensitization.

**FIGURE 36.1** There are (at least) two different forms of fibromyalgia, one (top-down) that occurs most commonly in younger individuals who have many other chronic overlapping pain conditions, and may be a primary brain disorder, and the other (bottom-up) that occurs in many individuals with other nociceptive or neuropathic pain conditions, and may be partially driven by ongoing peripheral nociceptive input (i.e., central sensitization).

Fibromyalgia, especially the “primary” form, is also very comorbid with early life and current stress, and many if not most individuals will have a lifetime history of a psychiatric disorder such as depression or anxiety. There is typically more psychiatric and psychological comorbidity seen in tertiary care settings or in individuals who are refractory to treatment. This bidirectional relationship between fibromyalgia and psychiatric conditions is likely due in part to the fact that there are common triggers to both sets of conditions (e.g., early life stress or trauma) as well as shared
pathophysiology (i.e., most of the same neurotransmitters that affect pain transmission also affect mood, memory, fatigue, sleep). Other potentially modifiable risk factors for developing fibromyalgia include poor sleep, obesity, physical inactivity, and poor job or life satisfaction. Similarly, cognitive factors such as catastrophizing (the feeling that pain is very bad and associated with a poor prognosis for recovery) or fear of movement have been shown to be poor prognostic factors in fibromyalgia and other chronic pain states.

Etiology

ANIMAL MODELS OF FIBROMYALGIA

Although few would purport that there is an animal model that mimics all of the key clinical features of fibromyalgia, animal models can nonetheless be very helpful in understanding the pathogenesis of this condition. This topic has been covered in depth in a recent review. For example, arguably the biggest controversy in the field of pain is what is the relative contribution of peripheral versus central factors in leading to chronic pain conditions. Some would argue that there must be some type of ongoing peripheral drive or input to cause chronic pain; however, this is almost certainly not the case. Animals develop the critical features of central sensitization or centralization of pain when exposed to swim stress, neonatal separation from their mothers, and many other nonpainful stimuli. Features of central sensitization and animal pain behaviors consistent with diffuse pain are also seen when CNS neurotransmitters are purposefully altered in the direction found in fibromyalgia. For example, chronic reserpine administration which depletes bioamines leads to features consistent with fibromyalgia, as does directly increasing glutamate levels in the insulae. This latter model of increasing glutamate in the insulae was recently reverse translated to show that the findings of “small fiber neuropathy” could be induced simply by increasing CNS glutamate, as is known to occur in fibromyalgia.

GENETIC FACTORS

The strong familial predisposition to fibromyalgia and other chronic pain
conditions has led many to study specific genetic polymorphisms that may be associated with a higher risk of developing fibromyalgia. First, candidate gene studies showed that genetic findings such as the serotonin 5-HT2A receptor polymorphism T/T phenotype, serotonin transporter, dopamine 4 receptor, and catechol-O-methyl transferase (COMT) polymorphisms all were noted in higher frequency in fibromyalgia patients than controls. Some subsequent studies confirmed some of these associations, whereas others did not\textsuperscript{81,82} Subsequent larger genome-wide linkage and candidate gene studies identified other putative targets.\textsuperscript{83,84} The linkage studies confirmed the strong genetic contribution to fibromyalgia and suggested linkage of fibromyalgia to the chromosome 17p11.2-q11.2 region. The large candidate gene study identified significant differences in allele frequencies between cases and controls were observed for three genes: GABRB3 (rs4906902, \(p = 3.65 \times 10^{-6}\)), TAAR1 (rs8192619, \(p = 1.11 \times 10^{-5}\)) and GBP1 (rs7911, \(p = 1.06 \times 10^{-4}\)). These three genes, and seven other genes with suggestive evidence for association, were examined in a second, independent cohort of fibromyalgia patients and evidence of association in the replication cohort was observed for TAAR1, RGS4, CNR1, and GRIA4 genes. In light of the fact that classic genetic studies have not yet identified strong, reproducible polymorphisms or haplotypes associated with fibromyalgia, and because there is clear evidence of environmental factors such as stress playing a prominent role in the pathogenesis, other groups have postulated that epigenetic findings might be important in fibromyalgia.\textsuperscript{85} This is a promising area that needs further research.

Many of the genes that have been identified to date in leading to increases or decreases in the frequency of chronic pain states, or of pain sensitivity, are involved in regulating the breakdown or binding of neurotransmitters that generally increase pain sensitivity (e.g., glutamate) or decrease pain sensitivity (serotonin, norepinephrine, \(\gamma\)-aminobutyric acid [GABA]). The fact that pain sensitivity is polygenic and that different individuals develop increased pain sensitivity because of imbalances or altered activity of many different neurotransmitters likely partly explains the “U-shaped curve” seen with many analgesics, wherein they either work fairly well or not at all.
EVIDENCE OF CENTRAL NERVOUS SYSTEM DISTURBANCES IN PAIN AND SENSORY PROCESSING

The physiologic hallmark of fibromyalgia, centralized pain, or central sensitization is augmented CNS pain processing. This was originally identified in fibromyalgia (and still can be clinically) by noting that an individual is diffusely tender to palpation. The scientific terms for this phenomenon are diffuse hyperalgesia (increased pain to normally painful stimuli) and/or allodynia (pain in response to normally nonpainful stimuli). In the absence of an identifiable diffuse “peripheral” inflammatory process involving the body tissues, this strongly suggests that the CNS (i.e., spinal cord and brain) is causing augmented pain processing. In 1990, when the original criteria for fibromyalgia were first published, this feature of diffuse tenderness was incorporated into the diagnostic criteria by requiring that an individual had a certain number of tender points (11 or greater) in addition to CWP order to qualify for this diagnosis.18

Subsequent studies using more sophisticated measures of experimental pain testing showed that individuals with fibromyalgia are more tender everywhere in the body, not just in the 18 regions considered to be “tender points.”86,87 Subsequent experimental pain testing studies have identified multiple potential mechanisms that may be responsible for pain amplification in fibromyalgia, including a decrease in the activity of descending analgesic pathways.88,89

EVIDENCE OF A GLOBAL INCREASE IN SENSORY PROCESSING OF NONPAINFUL STIMULI

Individuals with fibromyalgia do not just display disturbances in pain processing, they also as display heightened sensitivity to any type of sensory stimuli (e.g., auditory, visual, olfactory). Gerster and colleagues90 were the first to demonstrate that fibromyalgia patients display a low noxious threshold to auditory tones, and this finding was subsequently replicated.91 However, both of these studies used ascending measures of auditory threshold, so these findings could theoretically be due to expectancy or hypervigilance. A study by Geisser and colleagues92 used an identical random staircase paradigm to test fibromyalgia patients’ threshold to the loudness of auditory tones and to pressure. This study
found that fibromyalgia patients displayed low thresholds to both types of stimuli, and the correlation between the results of auditory and pressure pain threshold testing suggested that some of this was due to shared variance, and some unique to one stimulus or the other. The notion that fibromyalgia and related syndromes might represent biologic amplification of all sensory stimuli has significant support from functional imaging studies that suggest that the insula is the most consistently hyperactive region (see following text). This region has been noted to play a critical role in sensory integration, with the posterior insula serving a purer sensory role, and the anterior insula being associated with the emotional processing of sensations. This finding also strongly supports a crucial role of the CNS in the pathogenesis of fibromyalgia because the changes in pain processing that have been identified could theoretically be due to a diffuse, systemic process involving peripheral nociception. It is difficult to imagine what type of peripheral process could lead to aberrant processing of any type of sensory stimuli.

**BRAIN IMAGING STUDIES**

These initial observations that individuals with fibromyalgia were diffusely tender led to subsequent functional, chemical, and structural brain neuroimaging studies that have been among the best “objective” evidence that the pain in fibromyalgia and related pain amplification syndrome is “real.” These methods such as functional magnetic resonance imaging (fMRI) clearly demonstrate that when individuals with fibromyalgia are given a mild pressure or heat stimuli that most individuals would feel as “touch” rather than “pain,” they experience pain, and similar brain activation patterns in brain areas involved in pain processing (Fig. 36.2). fMRI has also proved useful in determining how comorbid psychological factors influence pain processing in fibromyalgia. For example, in fibromyalgia patients with variable degrees of comorbid depression, the authors found that the anterior insula and amygdala activations were correlated with depressive symptoms, consistent with these “medial” and prefrontal brain regions being involved with affective or motivational aspects of pain processing (and being more closely related to unpleasantness rather than the sensory intensity of
However, the degree of neuronal activation in more lateral structures generally thought to be associated with the “sensory” processing of pain (i.e., where the pain is localized and how intense it is) were not associated with levels of depressive symptoms, or the presence or absence of major depression, consistent with a plethora of evidence in the pain field that pain and depression are largely independent but overlapping physiologic processes.

**FIGURE 36.2** In top left panel, individuals with fibromyalgia (red) given a low-pressure stimulus have similar levels of pain and of neuronal activation in areas of the brain known to be involved in pain processing (ends of arrows) as controls given nearly twice as much pressure. Controls given the same low pressure that causes pain in fibromyalgia rate their pain as 2/20 instead of 12/20 and have no neuronal activation with this amount of pressure. IPL, inferior parietal lobule; SI, primary somatosensory cortex; SII, secondary somatosensory cortex; STG, superior temporal gyri. (Gracely RH, Petzke F, Wolf JM, et al. Functional magnetic resonance imaging evidence of augmented pain processing in fibromyalgia. Arthritis Rheum 2002;46[5]:1333–1343.)

A more recent advance in the use of fMRI is to look at the extent brain regions are “connected” to each other, that is, simultaneously activated (or deactivated). The advantage of resting state analysis is that it is a window into brain changes associated with chronic, ongoing spontaneous pain. Studies have shown that individuals with fibromyalgia have increased connectivity between brain regions involved in increasing pain transmission and neural networks not normally involved in pain such as the default mode network, and the degree of this hyperconnectedness is
related to the severity of ongoing pain. A different group has shown that during a painful stimulus, connectivity is decreased between key antinociceptive regions (e.g., the brainstem—the origin of descending analgesic pathways) and a region they had previously identified to be a potential source of dysfunctional pain inhibition in fibromyalgia. Lopez-Sola et al. have performed imaging studies confirming quantitative sensory testing (QST) studies that these individuals are more sensitive to a number of nonpainful sensory stimuli other than pain (e.g., auditory, visual) and that machine learning paradigms can accurately distinguish fibromyalgia from nonfibromyalgia patients with over 90% accuracy using these results. Similarly, Harte et al. used fMRI to show that an aversive visual stimulus caused greater evoked insula activity in fibromyalgia patients when compared to a control population and that this stimulus (as well as painful stimuli) was significantly attenuated by pregabalin.

Other imaging techniques have been used to identify the neurotransmitter abnormalities that may be driving the pain amplification seen in fibromyalgia and other chronic pain disorders. Wood and colleagues used positron emission tomography (PET) to show that attenuated dopaminergic activity may be playing a role in pain transmission in fibromyalgia, whereas Harris and colleagues showed evidence of decreased µ-opioid receptor availability (possibly due to increased release of endogenous µ-opioids) in fibromyalgia. This latter finding as well as previous studies showing increases in endogenous opioids in the cerebrospinal fluid (CSF) of fibromyalgia patients has been suggested as evidence of why opioid analgesics appear to have poor efficacy in fibromyalgia.

Other groups have used proton magnetic resonance spectroscopy (H-MRS) to probe other neurotransmitters. Several groups have shown there are increases in brain concentrations of the body’s major excitatory neurotransmitter, glutamate, in pain processing regions such as the insula in fibromyalgia. This finding has also been noted in the CSF in fibromyalgia. Drugs such as pregabalin and gabapentin are likely working in part in fibromyalgia by reducing glutamatergic activity. This has been nicely demonstrated by Harris and colleagues who showed that
individuals with fibromyalgia that had the highest pretreatment levels of glutamate in the posterior insula were those most likely to respond to pregabalin. When pregabalin led to improvement in symptoms in these individuals, there was normalization of fMRI and connectivity findings, all suggesting that this neurotransmitter is playing a critical role in the pathogenesis of fibromyalgia in some individuals. An even more important finding from this study was the fact that individuals with fibromyalgia with normal or low baseline levels of glutamate in their posterior insula did not respond to pregabalin, even though this drug further lowered glutamate levels in these individuals as well. This helps us understand why no single class of CNS analgesic is likely to work in every patient with pain of CNS origin.

Conversely, H-MRS has recently been used to demonstrate low levels of one of the body’s major inhibitory neurotransmitters, GABA. This likely accounts for the efficacy of medications such as γ-hydroxybutyrate in fibromyalgia. This finding may also suggest biologic plausibility for the associations between low alcohol consumption (compared to none or high) and improved symptomatology and functionality. Alcohol is known to be a GABA agonist and analgesic, likely showing a U-shaped curve for analgesic effects just as for some beneficial cardiovascular effects. The fact that these imbalances between excitatory and inhibitory neurotransmitters are not diffusely noted in brain structures and seem to be somewhat confined to brain regions such as the insula that are known to be involved in polysensory processing is concordant with the notion that there is a global problem with sensory hyperresponsiveness that is partly responsible for the pathophysiology of fibromyalgia and related conditions. Figure 36.3 illustrates the neurotransmitters that have been demonstrated to influence pain transmission in the CNS.
FIGURE 36.3 Neurotransmitters that are known to play either facilitatory (indicated in red and generally increase pain transmission in the spinal cord) or inhibitory (indicated in blue and decreasing pain transmission) roles in the central nervous system and the respective abnormality found in fibromyalgia (FM).

THE ROLE OF NEUROENDOCRINE OR AUTONOMIC ABNORMALITIES

Because of the link between fibromyalgia and exposure to stress, and because both the neuroendocrine and autonomic nervous systems could cause many of the symptoms of fibromyalgia, these factors have been fairly extensively studied.\textsuperscript{120–122} In fact, for several decades after it was understood that conditions such as fibromyalgia or chronic fatigue syndrome were not due to inflammation or infection, these areas were receiving considerable attention. The problem is that this research has generally yielded inconsistent findings, and treatment studies targeting these systems have failed, so these factors are now generally thought to play some role in some individuals but not central pathogenic factors in all with these conditions.\textsuperscript{122–127} These studies note either hypo- or hyperactivity of both the hypothalamic-pituitary-adrenal (HPA) axis and sympathetic nervous system in individuals with fibromyalgia and related conditions and the precise abnormality varies from study to study. Moreover, these studies only find “abnormal” HPA or autonomic function
in a very small percentage of patients, and there is tremendous overlap between patients and controls in any of these studies.

The inconsistency of these findings should not be surprising because nearly all of these studies were cross-sectional studies that assumed that if HPA and/or autonomic dysfunction was found in fibromyalgia, it must have caused the pain and other symptoms. Data now suggest the opposite. As noted earlier, there are better data suggesting that (especially HPA abnormalities) might represent a diathesis or be due to the pain or early life stress rather than causing it. In fact, in two recent studies examining HPA function in fibromyalgia, McLean showed that salivary cortisol levels covaried with pain levels, and that CSF levels of corticotropin-releasing hormone (CRH) were more closely related to an individual’s pain level or a history of early life trauma than whether he or she were a fibromyalgia patient or control.\textsuperscript{128,129} Because most previous studies of HPA and autonomic function in fibromyalgia failed to control for pain levels, a previous history of trauma, and posttraumatic stress disorder (PTSD) or other comorbid disorders that could affect HPA or autonomic dysfunction, it is not surprising for these inconsistencies.

**THE ROLE OF PERIPHERAL FACTORS IN FIBROMYALGIA**

Although most agree that the core symptoms of fibromyalgia are likely due to changes in the CNS, peripheral factors also play an important role in both the pathogenesis and treatment of fibromyalgia. For example, some elements of the processes of central sensitization can be worsened or driven by ongoing nociceptive input. Thus, it is possible or likely that the many individuals with fibromyalgia who also have comorbid conditions causing ongoing peripheral nociceptive input (e.g., myofascial pain, osteoarthritis, obesity\textsuperscript{130}) would potentially benefit from therapies aimed at reducing peripheral drive of central sensitization. This was suggested in a short-term study by Affaitati\textsuperscript{131} which showed that treating these common comorbid conditions could lead to improvement in the widespread pain and tenderness seen in fibromyalgia. In fact, one of the major areas of study needed into these conditions is to try to differentiate which individuals with these phenomena are being driven from the CNS and
which may be driven by ongoing peripheral nociceptive input and thus still benefit from these types of interventions.

EVIDENCE OF ABNORMAL CYTOKINES OR OF IMMUNE DYSFUNCTION IN FIBROMYALGIA

Although the prevailing view is that fibromyalgia is not an autoimmune disorder and that classic anti-inflammatory agents are not of benefit in this condition, there are some data suggesting that the immune system may be playing a role in the pathogenesis.\textsuperscript{132} Perhaps, the most consistent finding noted to date is a mild elevation in interleukin 8 (IL-8), which is a cytokine associated with sympathetic function.\textsuperscript{133,134} In other conditions closely linked to fibromyalgia such as interstitial cystitis, more sensitive assays of immune system function that can be gleaned by stimulating peripheral immune cells have been shown to be abnormal.\textsuperscript{135} Some have speculated that diet or obesity could contribute to this low-grade inflammation in fibromyalgia and might be a potential target for therapy, whereas others have posited that this may provide evidence of microglia involvement in fibromyalgia. These are areas being actively explored.

THE ROLE OF “SMALL FIBER NEUROPATHY” IN FIBROMYALGIA

There is also a current ongoing controversy regarding the meaning of finding decreased intraepidermal nerve fiber density (i.e., small fiber neuropathy) in fibromyalgia. There is no question that this has been shown by many groups.\textsuperscript{136–138} However, this is a very nonspecific finding that has now been noted in over 50 different pain and nonpain conditions.\textsuperscript{137} Moreover, Harte et al.\textsuperscript{106} recently demonstrated evidence that these findings could be induced in an animal model of central sensitization induced by increasing insular glutamate. We believe that this finding will eventually be shown to be a very nonspecific finding that might simply represent structural and functional reorganization of the peripheral nervous system (not unlike the changes in the CNS noted via voxel-based morphometry of the brain in chronic pain states\textsuperscript{139}) in the context of chronic pain and other neurologic conditions. The hyperexcitable C nociceptors noted in fibromyalgia by Serra and colleagues\textsuperscript{140} could also be
secondary to CNS disinhibition of peripheral systems rather than indicating that there is primary pathology in the periphery. Regardless, the current evidence does not merit routine skin biopsies in suspected fibromyalgia patients and certainly does not yet suggest that this finding is of enough pathophysiologic significance to support the (noninvestigational) use of aggressive cytotoxic and anti-inflammatory regimens that some have proposed. When considering the available data regarding the pathophysiology of fibromyalgia, the data strongly favor CNS factors, and these findings should continue to drive clinical care.

**Diagnosis**

**DIAGNOSIS OF FIBROMYALGIA**

A careful musculoskeletal history and examination remains the most important diagnostic test for individuals with musculoskeletal pain. In other fields of medicine, advances in diagnostic testing have largely rendered a physical examination obsolete. However, in musculoskeletal medicine, technology confuses as much as it helps. For example, a high proportion of the healthy, asymptomatic population has a positive antinuclear antibody (ANA), positive rheumatoid factor, or abnormal results of imaging studies.\(^{141–143}\) Worse yet, these diagnostic tests never tell us how severe the pain is because there is typically a significant discordance between the results of laboratory or imaging studies, and the severity of pain and other symptoms that the individual is experiencing. Therefore, the musculoskeletal history and examination must allow the clinician to arrive at the diagnosis (or at worst a very narrow differential diagnosis), and then if necessary, further diagnostic testing should be used to confirm these findings.

There are a number of diagnostic criteria that can be used for fibromyalgia. For reasons noted in the preceding text, the use of the original 1990 criteria is now being replaced by the more contemporary criteria proposed in 2010 and then modified in 2011 and 2016.\(^{19–21}\) The advantages of these criteria are several-fold. These criteria acknowledge the nonpain symptoms of fibromyalgia and centralized pain and with the elimination of the tender point requirement appropriately diagnose the
many men who have fibromyalgia or centralized pain. These criteria are also entirely symptom-based and thus are more likely to be embraced by primary care or other providers who never learned how to perform a tender point examination. Finally, perhaps the best advantage of these criteria is that instead of using a cut point to either declare that an individual does or does not meet criteria for fibromyalgia, these criteria can also be used to place a patient on a spectrum of central sensitivity, which has been termed “fibromyalgianess.”

Wolfe was the first to note the importance of the concept of fibromyalgianess, by showing the importance of “subs syndromic” or “subthreshold” fibromyalgia. In a series of studies, he showed that in individuals with conditions such as RA, low back pain, or osteoarthritis, an individual’s fibromyalgia score, derived with measures very similar to the 2010/11/16 criteria, was typically more predictive of pain and disability than more objective measures of activity of these diseases, such as measures of inflammation or joint damage.145,146

The survey version of these criteria is entirely patient self-report and can be administered on a single piece of paper. Our group uses the Michigan Body Map to assess the Widespread Pain Index (up to 19 body areas each counted as one point)147 as well as the Symptom Severity Index that asks about the presence and severity of fatigue, sleep disturbances, and memory difficulties (each scored 0 to 3 for the presence and severity) as well as irritable bowel, headaches, and mood problems (1 point each, total Symptom Severity Index Score is 0 to 12) (Fig. 36.4). The Widespread Pain Index and Symptom Severity Index are combined for a total score of 0 to 31. When used as a dichotomous measure with a variety of “cut points” that can be used, this measure will roughly identify most of the same individuals as the old criteria (except many more males).19,20 However, when fibromyalgia is considered more as a physiologic construct to determine where on the continuum of pain sensitivity an individual is, then this can be used as a continuous measure (i.e., degree of fibromyalgianess or the degree to which pain is centralized) that can be useful in the diagnosis and treatment of virtually any patient with a rheumatic disorder that is experiencing pain.144
FIGURE 36.4 The histogram displays the distribution of fibromyalgia scores using the 2011 Fibromyalgia Survey Criteria from a cohort of patients undergoing total knee and hip arthroplasty. Both patient A (fibromyalgia score = 1) and patient B (fibromyalgia score = 11) have a fibromyalgia score below the threshold for being termed fibromyalgia positive. However, when compared to patient A, after adjustment for other covariates, patient B would consume 80 mg oral morphine equivalents more opioid during the postoperative inpatient admission and be five times less likely to achieve the threshold for meaningful pain improvement 6 months after surgery. (Data from Brummett CM, Janda AM, Schueller CM, et al. Survey criteria for fibromyalgia independently predict increased postoperative opioid consumption after lower-extremity joint arthroplasty: a prospective, observational cohort study. Anesthesiology 2013;119[6]:1434–1443.)

In several recent studies, this concept of fibromyalgianess or subsyndromal fibromyalgia has been shown to be very clinically important. In these studies by Brummett and colleagues,\textsuperscript{147,148} individuals who were scheduled for either lower extremity joint replacement or hysterectomy completed a broad battery of validated self-report measures prior to their surgery. The group hypothesized that individuals with higher fibromyalgia scores on the 2011 Fibromyalgia Survey Criteria would predict increased opioid requirements in the inpatient admission following surgery as well as to long-term surgery pain outcomes. Again, this measure is scored from 0 to 31 with a level of 13 is typically used as being diagnostic cut point of fibromyalgia. These studies demonstrated that even after adjustment for each 1-point increase in this measure from 0 to 31, individuals needed an adjusted 7 to 9 mg more oral morphine equivalents...
to control their pain in the first 24 to 48 hours following surgery and were 15% to 20% less likely to improve following arthroplasty, all after adjustment for other patient and clinical care variables.\textsuperscript{72, 73, 148} These findings were independent of a number of preoperative characteristics, including age, sex, anxiety, depression, catastrophizing, and opioid use. More importantly, these findings were linear and the same incremental increase in opioid and surgery nonresponsiveness was seen in individuals well below the threshold used to diagnose fibromyalgia and extending well into the range of individuals exceeding this threshold. Figure 36.5 shows two different individuals with osteoarthritis, neither of whom would meet criteria for fibromyalgia but who are at different points of the fibromyalgia continuum, and shows the marked difference in opioid responsiveness and improvement in pain following arthroplasty that these two individuals would experience. These data suggest that this measure of fibromyalgianess might serve as the degree of pain centralization an individual is experiencing and help identify individuals in perioperative or other settings who are less likely to respond to peripherally directed analgesics such as surgery, or opioids.
FIGURE 36.5 The 2011 Fibromyalgia Survey Criteria is a brief, simple self-report measure. It is made up of two components, the Symptom Severity Index (SSI) and the Widespread Pain Index (WPI). The SSI includes six questions about comorbid central nervous system symptoms with a score ranging from 0 to 12. Our group collects the WPI using the Michigan Body Map, which includes up to 31 body regions to allow patients to better describe their areas of pain. For the purposes of creating the fibromyalgia score, only the 19 body areas originally described are scored (original 19 areas are bolded and underlined). The total fibromyalgia score ranges from 0 to 31. (Reprinted with permission from Dr. Chad Brummet and University of Michigan.

In clinical practice, one should suspect fibromyalgia in individuals with multifocal pain that cannot be explained on the basis of damage or inflammation in those regions of the body. In most cases, musculoskeletal pain is the most prominent feature, but because pain pathways throughout the body are amplified, pain can be perceived more generally. Thus, chronic headaches, sore throats, chest pain, abdominal pain, and pelvic pain are very common in individuals with fibromyalgia, and patients with chronic regional pain in any of these locations are more likely to have fibromyalgia.

Because pain is a defining feature of fibromyalgia, it is helpful to focus
on the features of the pain that can help distinguish it from other disorders. The pain of fibromyalgia is typically diffuse or multifocal, is difficult to localize, often waxes and wanes, and is frequently migratory in nature. These characteristics of centralized pain are quite different from nociceptive pain, where both the location and severity of pain are typically more constant. Patients may complain of discomfort when they are touched or when wearing tight clothing and may experience dysesthesias or paresthesias that accompany the pain.

Another defining characteristic of “centralized” pain is the company it keeps. In addition to pain, individuals typically experience a number of other somatic symptoms. These symptoms can generally be broken into two categories: (1) symptoms of CNS origin that are controlled by the same neurotransmitters that control pain processing and (2) symptoms due to generalized sensory hyperresponsiveness. In the first category, fatigue, memory difficulties, and sleep and mood disturbances are all very common in fibromyalgia and other centralized pain states. The reason it is thought that these symptoms are at least partially due to some of the same neurotransmitter abnormalities that contribute to the pathophysiology of fibromyalgia is that several of these symptoms will typically improve along with pain when an individual is successfully treated with drugs that alter these neurotransmitters. The second type of symptom due to generalized hyperresponsiveness often challenges clinicians to doubt the veracity of a fibromyalgia patient’s complaints. This is often responsible for the “pan-positive review of symptoms” that has often characterized these individuals as “somatizers.” As the biology of somatization is becoming increasingly understood as one of sensory hyperresponsiveness, these sensory symptoms throughout the body can be better understood by clinicians if one realizes that all sensory experiences are interpreted by brain regions, such as the insula, that are known to be hyperactive in fibromyalgia and other centralized pain states.

The most common of these more systemic symptoms are fatigue, sleep difficulties, weakness, problems with attention or memory, unexplainable weight fluctuations, and heat and cold intolerance. “Allergies” are reported much more commonly in fibromyalgia patients, although these excess symptoms are better considered hypersensitivities rather than true IgE-
mediated immunologic reactions. These patients are also more prone to nonallergic rhinitis, sinus and nasal congestion, and lower respiratory symptoms, all of which again may primarily attributable to neural mechanisms. Distortions in hearing, vision, and vestibular symptoms are often reported, as are sicca symptoms (dry eyes or dry mouth) sometimes so prominent that these individuals will overlap with those with Sjögren’s syndrome.

Other COPCs, or sensory disturbances throughout the body, are more common in fibromyalgia. These include noncardiac chest pain, heartburn and palpitations, and the frequent comorbidity of IBS. Syncope and neutrally mediated hypotension also occur more commonly in fibromyalgia, as does postural orthostatic tachycardia syndrome (POTS). Pelvic complaints are common, including not only pain but also urinary frequency and urgency. In females, the frequent comorbid diagnoses are dysmenorrhea, interstitial cystitis, endometriosis, and sensitivity disorders like vulvar vestibulitis and vulvodynia, whereas in males, these same symptoms are sometimes often diagnosed as having chronic or nonbacterial prostatitis.

Laboratory testing is generally not useful, except for the purpose of differential diagnosis. One factor that can help guide the intensity of the diagnostic workup is the length of time the patient has had symptoms. If the patient’s symptoms have persisted for several years, minimal testing is required, whereas a more aggressive strategy should be employed for acute or subacute onset of symptoms. Simple testing should be limited to complete blood count and routine serum chemistries, along with thyroid-stimulating hormone (TSH) and erythrocyte sedimentation rate (ESR). Serologic studies such as ANA and rheumatoid factor assays should generally be avoided unless there are historical features not seen in fibromyalgia or abnormalities on physical examination. This represents a problem in clinical practice because several autoimmune disorders share overlapping symptomatology with fibromyalgia. These include not only fatigue, arthralgias, and myalgias but also such symptoms as morning stiffness and subjective swelling of the hands and feet. Certain dermatologic features commonly seen in fibromyalgia, including malar flushing, livedo reticularis, and Raynaud’s disease–like reddening of the
hands, also mimic symptoms of autoimmune disorders. This sometimes results in patients with fibromyalgia being misdiagnosed as having an autoimmune disorder such as SLE.

Aside from the many comorbid conditions already discussed, fibromyalgia may present similarly to a number of disorders or concurrently with other disorders that may confuse the diagnosis. Table 36.2 shows conditions that often mimic or present concurrently with fibromyalgia. Hypothyroidism and polymyalgia rheumatica can be differentiated from fibromyalgia by results of TSH and ESR. Sleep apnea and hepatitis C also simulate fibromyalgia and tend to present more often in men than women.

SLE, systemic lupus erythematosus.

Although the physical examination is generally unremarkable in individuals with fibromyalgia, it is helpful to assess for diffuse tenderness, and there are many ways that this can be done clinically other than performing a tender point count. For example, individuals with fibromyalgia are more sensitive to the inflation of a blood pressure cuff. Another way to assess overall pain threshold while also getting other valuable diagnostic information is to assess pain thresholds in the hands and arms of all chronic pain patients. A rapid examination by applying firm pressure over several interphalangeal (IP) joints of each hand and also over the adjacent phalanges and then more proximally to include firm palpation of the muscles of the forearm including the lateral epicondyle region. This is one way to assess overall pain threshold as well as get...
additional diagnostic information about the patient. If the individual is tender in many of these areas, or in just the muscles of the forearm, he or she is likely diffusely tender (i.e., have a low central pain threshold). However, if the individual is only tender over the IP joints and not the other regions, and especially if there is any swelling over these joints, one should be more concerned about a systemic autoimmune disorder, whereas if tenderness is confined to just the bones, one might suspect a metabolic bone disease or condition causing periostitis (e.g., hyperparathyroidism).

Once a clinician rules out other potential disorders, an important and at times controversial step in the management of fibromyalgia is asserting the diagnosis. Despite some assumptions that being “labeled” with fibromyalgia may adversely affect patients, all existing studies suggest that this is not the case and that the diagnosis of fibromyalgia is often a tremendous source of relief for the patient and leads to decreased health care utilization because of a reduction in referrals and diagnostic testing “looking for the cause of the pain.”

### Treatment

**GENERAL APPROACH**

All individuals diagnosed with a condition such as fibromyalgia should first receive some basic education regarding this disorder. Clinicians can do this in the context of their practice (e.g., with nurse educators or other allied health professionals) or electronically using Web sites and videos (see the following text). This education should emphasize that it is important that the patient plays an active role in their management and that some of the most effective therapies are nondrug therapies, such as exercising, improving sleep, and reducing stress. Although recent treatment guidelines favor the use of nonpharmacologic versus pharmacologic therapies, there are pragmatic factors in routine practice (lack of availability or reimbursement, patient is unwilling to use or try these therapies until his or her symptoms are somewhat better controlled) that often make this impractical. Thus, most patients need some combination of pharmacologic and nonpharmacologic therapies to have meaningful improvement in symptoms and function. Education will be
critical, however, to getting patients to consider nonpharmacologic options. Table 36.3 outlines all of the evidence-based treatments for individuals with fibromyalgia as well as practical suggestions for dosing and initiating therapy.

NSAIDs
- No evidence of efficacy
- Can be helpful to treat comorbid “peripheral pain generators”

Opioids
- Tramadol with or without acetaminophen, 50–100 mg every 6 h
- No evidence of efficacy for stronger opioids

Gastrointestinal, renal, and cardiac side effects

Sedation, addiction, tolerance, opioid-induced hyperalgesia

CNS, central nervous system; FDA, U.S. Food and Drug Administration; FM, fibromyalgia; HTN, hypertension; NA, not applicable; NSAIDs, nonsteroidal anti-inflammatory drugs; RCT, randomized controlled trial.

PHARMACOLOGIC THERAPY
There are a number of classes of drugs that can be of some benefit in fibromyalgia. Unfortunately, as in other chronic pain conditions, drugs only work well in a subset of patients, and the overall effect size of any of these therapies is modest, at best. However, it is a misconception that the
drugs we use to treat fibromyalgia and centralized pain are less effective than drugs we use to treat other pain conditions, or nociceptive pain. It is also of note that there have been very few negative clinical trials of new therapies in fibromyalgia (essentially all have targeted neurotransmitters in the CNS known to be abnormal in fibromyalgia) over the past two decades since drug development for this condition commenced. The majority of fibromyalgia clinical trials have involved CNS-acting drugs of one class or another. Trials studying the oldest class of agents, tricyclic antidepressants (TCAs), are perhaps most abundant but generally underpowered individually. More recently, larger trials have been performed of many other classes of drugs, especially SNRI and gabapentinoids.

**Tricyclic Agents**
The earliest studied pharmacologic therapy for fibromyalgia was low doses of tricyclic compounds. Most TCAs increase the concentrations of serotonin and/or norepinephrine (noradrenaline) by directly blocking their respective reuptake. The effectiveness of TCAs, particularly amitriptyline and cyclobenzaprine, in treating the symptoms of pain, poor sleep, and fatigue associated with fibromyalgia is supported by several randomized controlled trials. Tolerability can be a problem but can be improved by beginning at very low doses (e.g., 10 mg of amitriptyline or 5 mg of cyclobenzaprine), giving the dose a few hours before bedtime, and very slowly escalating the dose. Very low dose cyclobenzaprine has recently shown to be quite effective in a subset of individuals with fibromyalgia with a specific sleep architecture, seemingly with less side effects than seen in some of the earlier studies of higher doses.

**Serotonin and Norepinephrine Reuptake Inhibitors**
Because of a better side effect profile, newer antidepressants, that is, selective serotonin reuptake inhibitors (SSRIs), are frequently used in fibromyalgia. The SSRIs fluoxetine, citalopram, and paroxetine have each been evaluated in randomized, placebo-controlled trials. In general, the results of studies of SSRIs in fibromyalgia have paralleled the experience in other pain conditions. The newer “highly selective” serotonin reuptake inhibitors, for example, citalopram, seem to be less
efficacious than the older SSRIs, which have some noradrenergic activity at higher doses.\textsuperscript{167}

Because TCAs and high doses of certain “SSRIs” such as fluoxetine and sertraline that have the most balanced reuptake inhibition are the most effective analgesics, many have concluded that dual receptor inhibitors such as SNRIs and norepinephrine serotonin reuptake inhibitors (NSRIs) may be of more benefit than pure serotonergic drugs.\textsuperscript{167} These drugs are pharmacologically similar to some TCAs in their ability to inhibit the reuptake of both serotonin and norepinephrine but differ from TCAs in being generally devoid of significant activity at other receptor systems, including acetylcholine. This selectivity results in diminished side effects and enhanced tolerability. The first available SNRI, venlafaxine, has data to support its use in the management of neuropathic pain, and retrospective trial data demonstrate that this compound is also effective in the prophylaxis of migraine and tension headaches.\textsuperscript{168} Two studies in fibromyalgia have had conflicting results, with the one using a higher dose showing efficacy.\textsuperscript{169}

Two newer SNRIs, duloxetine and milnacipran, have undergone more recent multicenter trials and were shown to be effective in a number of outcome variables and are both now approved in the United States for the treatment of fibromyalgia.\textsuperscript{170,171} These drugs seem roughly comparable in the overall efficacy profile, with studies generally noting modest improvement (although not reaching statistical significance in all studies) in domains such as pain, overall improvement, physical functioning, level of fatigue, and degree of reported physical impairment. For both compounds, these effects seemed to be independent of the drug effect on mood, thus suggesting that the analgesic and other positive effects of this class of drugs in fibromyalgia is not simply due to their antidepressant effects. Both of these drugs are better tolerated if taken with food, and if patients are warned about likely initial nausea, and counseled that this typically resolves in a week or so, and if not then they should discontinue the drug. The maximum approved dose of duloxetine is 60 mg per day, but it was studied in trials at doses up to 120 mg and shown to be safe, and similarly, the initial dose of milnacipran is 100 mg, but some patients will benefit from increasing the dose as high as 200 mg. Hypertension is more
likely to be a problem with milnacipran because it appears to have noradrenergic effects; for these same reasons, it might be slightly more likely to help with symptoms such as fatigue.

Es-reboxetine, a selective norepinephrine reuptake inhibitor, was also tested and shown to be efficacious in fibromyalgia.\textsuperscript{172} This adds to emerging evidence suggesting that norepinephrine reuptake activity may be much more important than serotonergic reuptake for analgesic effects.

**Anticonvulsants**

A few classes of antiepileptic drugs have been shown to be effective in the treatment of various chronic pain conditions, including fibromyalgia, postherpetic neuralgia, and painful diabetic neuropathy.\textsuperscript{173} Pregabalin and gabapentin have the same mechanism of action and bind to the $\alpha_2\delta$ subunit of calcium channels, and both are approved for the treatment of neuropathic pain as well as several other indications. Several studies have shown the efficacy of pregabalin against pain, sleep disturbances, and fatigue as compared to placebo in fibromyalgia, leading to this being the first drug approved in the United States for use in this condition.\textsuperscript{174} Gabapentin has been shown to have very similar efficacy and side effect profile in fibromyalgia.\textsuperscript{175} The tolerability of these drugs can be enhanced by beginning at a low dose and giving either two-thirds of the dose, or the entire dose, at bedtime. The maximally approved dose of pregabalin is 450 mg, but in trials, it was studied at doses as high as 600 mg and shown to be safe and efficacious. For most patients, the dose of gabapentin needed for analgesic is often 1,800 to 2,400 mg per day; however, some patients will derive benefit at lower doses. Another antiepileptic compound, clonazepam, has demonstrated efficacy in treating TMD and associated jaw pain and is useful in the treatment of restless legs syndrome.\textsuperscript{173} Thus, clonazepam may be of value in subsets of fibromyalgia patients with these comorbidities; however, the risks associated with chronic benzodiazepine use likely outweigh the potential benefit. In addition, two other drugs that are likely working by counteracting the effects of increased glutamatergic activity in fibromyalgia are memantine and ketamine, both of which have some evidence of efficacy.\textsuperscript{176,177}
Combination Drug Therapy

Combinations of multiple classes of adjunctive pain medications have been a common practice for many years. A recent study demonstrated that the combination of duloxetine and pregabalin was superior to either drug alone in treating fibromyalgia.\textsuperscript{178} The combination improved pain, as well as Fibromyalgia Impact Questionnaire, 36-Item Short Form Health Survey (SF-36), and Medical Outcomes Study Sleep Scale scores. This is consistent with previous data demonstrating that combinations of therapies with differing mechanisms of action are effective in neuropathic pain.\textsuperscript{179}

Other Central Nervous System–Acting Drugs

Sedative-hypnotic compounds are widely used by fibromyalgia patients. A handful of studies have been published on the use of certain nonbenzodiazepine hypnotics in fibromyalgia, such as zopiclone and zolpidem. These reports have suggested that these agents can improve the sleep and, perhaps, fatigue of fibromyalgia patients, although they had no significant effects upon pain.

On the other hand, γ-hydroxybutyrate (also known as sodium oxybate), a precursor of GABA with powerful sedative properties, was recently shown to be very efficacious in improving fatigue, pain, and sleep architecture in patients with fibromyalgia.\textsuperscript{180} Note, however, that this agent is a scheduled substance due to its abuse potential and was not approved by the U.S. Food and Drug Administration (FDA) because of safety concerns. Nonetheless, these studies along with the H-MRS showing low GABA suggest that other less toxic GABA agonists may have an important role in treating fibromyalgia.

Cannabinoids are another class of drugs where there is renewed interest in chronic pain states. There have been two randomized controlled trials of synthetic cannabinoids in fibromyalgia (both with nabilone), and both studies concluded that the drug was efficacious (in one study for both pain and sleep, in the other study at lower dose for just sleep).\textsuperscript{181,182} This is not surprising as there is increased recognition that this class of drugs may have utility in pain of neural origin.\textsuperscript{159}

Pramipexole is a dopamine agonist indicated for Parkinson disease that has shown utility in the treatment of periodic leg movement disorder.\textsuperscript{183}
One study suggested that this compound may improve both pain and sleep in fibromyalgia patients, but these results have not been replicated with this or other dopamine agonists. Because of this, this class of drug may be best reserved for individuals with other indications, such as comorbid restless legs syndrome.

Tizanidine is a centrally acting $\alpha_2$-adrenergic agonist approved by the FDA for the treatment of muscle spasticity associated with multiple sclerosis and stroke. Literature suggests that this agent is a useful adjunct in treating several chronic pain conditions, including chronic daily headaches and low back pain. A recent trial reported significant improvements in several parameters in fibromyalgia, including sleep, pain, and measures of quality of life.

**Classic Analgesics**

There have been no adequate, randomized controlled clinical trials of opiates in fibromyalgia, and most in the field (including the authors) have not found this class of compounds to be effective in anecdotal experience. Tramadol is a weak $\mu$-agonist combined with serotonin/norepinephrine reuptake inhibition. This compound does appear to be somewhat efficacious in the management of fibromyalgia, as both an isolated compound and as fixed-dose combination with acetaminophen.

In addition to the previously studied and cited mechanistic studies suggesting why opioids might not be effective in fibromyalgia (i.e., PET evidence of decrease opioid receptor availability, and high CSF levels of endorphins), recent functional and chemical imaging studies by this same group suggest an even more important potential problem. In these studies, the native state of fibromyalgia may be akin to that of opioid-induced hyperalgesia, in that the regions with the lowest receptor occupancy are the most hyperalgesic. Thus, it is possible that at least in a subset of individuals, opioids may make these individuals’ hyperalgesia worse rather than better. This notion is also supported by previously noted clinical studies suggesting that opioid antagonists such as naltrexone may be effective in fibromyalgia (although the authors of these studies hypothesize these effects are due to glial cell inhibition). If opioids are used for refractory patients, it is possible that those opioids with mixed...
opioid antagonist effects (e.g., buprenorphine), norepinephrine reuptake inhibition (tapentadol), or NMDA receptor blockade (methadone) might be better than pure µ-agonists, but this is entirely conjecture. Another problem with opioid use in fibromyalgia is that this therapy appears to reduce patient motivation to pursue other approaches, particularly nonpharmacologic approaches.\textsuperscript{187} Despite the fact that opioids are not recommended for the treatment of fibromyalgia, studies demonstrate that many fibromyalgia patients are prescribed opioids.\textsuperscript{188}

A large number of fibromyalgia patients use NSAIDs and acetaminophen. Although numerous studies have failed to confirm their effectiveness as analgesics in fibromyalgia,\textsuperscript{189} a recent study of the combination of celecoxib and acyclovir was shown to be effective in fibromyalgia.\textsuperscript{190} It is not known whether the benefit came from one or both of these drugs, and future studies will be necessary to dissect out these findings. There is also limited evidence that patients may experience enhanced analgesia when treated with combinations of NSAIDs and other agents. This phenomenon may be a result of concurrent “peripheral” pain (i.e., due to damage or inflammation of tissues, e.g., osteoarthritis, RA) conditions that may be present and/or that these comorbid peripheral pain generators might lead to worsening of “central” pain.

**NEUROSTIMULATORY THERAPIES**

A variety of neurostimulatory therapies can be effective in treating musculoskeletal pain. For some time, transcutaneous electrical nerve stimulation (TENS) has been used to treat musculoskeletal pain.\textsuperscript{191,192} Conventional TENS (C-TENS) is given at high stimulation frequency with low intensity. Pain relief is immediate, but short-lived, when it occurs. Acupuncture-like TENS (often abbreviated Al-TENS) is given at a lower frequency and higher intensity (which is sometimes uncomfortable) and when it works generally has a longer lasting effect than C-TENS. These neurostimulatory therapies would be expected to be most helpful for pain of peripheral/nociceptive origin.

A new set of neurostimulatory therapies is emerging that would be expected to be more effective for “centralized” pain because these therapies all aim to stimulate the CNS and, in doing so, modulate CNS
pain transmission. Many such therapies have been developed and tested, with many showing some efficacy in several pain states. These include noninvasive techniques such as repetitive transcranial magnetic stimulation (rTMS), transcranial direct current stimulation (tDCS), and newer ways of noninvasively stimulating brain structures. Although the studies to date with these therapies have yielded somewhat inconsistent results, a trend is emerging suggesting that these treatments might be most effective in centralized rather than purely peripheral pain states and with stimulation parameters that enable signals to travel into deeper cortical tissues than occurs with typical delivery of rTMS and tDCS. Other more invasive techniques have also shown promise in patients with more refractory pain states, such as spinal cord stimulation, deep brain stimulation, and vagal nerve stimulation.

NONPHARMACOLOGIC THERAPIES
The two best studied nonpharmacologic therapies are cognitive-behavioral therapy and exercise. Both of these therapies have been shown to be efficacious in the treatment of fibromyalgia as well as a plethora of other medical conditions. Both of these treatments can lead to sustained (e.g., greater than 1 year) improvements and are very effective when an individual complies with therapy.

For exercise, it is important to “start low, go slow.” Many fibromyalgia and other chronic pain patients are quite sedentary, and in these individuals, it is important to focus on becoming more active rather than classic “exercise.” With respect to exercise, nearly any type (aerobic, stretching, strengthening) can be helpful. It is most important that patients understand that they must become more active and then eventually start very mild exercise (e.g., walking).

There are many elements to cognitive-behavioral therapy, but one that has had increased attention recently has been a focus on using behavioral measures to treat the sleep disorders seen in conditions such as fibromyalgia. This increased focus on improving sleep is concordant with more and preclinical and clinical research showing how important sleep is in pain transmission. There is a free Web site for patients (http://www.fibroguide.com) that allows patients to access these
behavioral interventions over the Internet rather than in person, and this Web site was tested in a randomized controlled trial and was shown to be effective.\textsuperscript{199} “Lighter” options such as this will work well in many patients, whereas in other individuals with more severe psychological or psychiatric comorbidity will benefit from more intensive (i.e., group or one-on-one) treatments. A recent study suggested that adding emotional disclosure to standard cognitive-behavioral therapy may be of benefit to a subset of patients who will receive significant improvement.\textsuperscript{200}

Complementary and alternative therapies have been explored by patients managing their own illness as well as health care providers. As with other diseases, there are few controlled trials to advocate their specific use in fibromyalgia, but there is general agreement that the evidence base for using these therapies across pain conditions is increasing dramatically.\textsuperscript{201} Trigger-point injections, chiropractic manipulation, tai chi, yoga, acupuncture, and myofascial release therapy are among the more commonly used modalities, which achieve varying levels of success. There is some evidence that the use of alternative therapies gives patients a greater sense of control over their illness. In instances where this sense of control is accompanied by an improved clinical state (even in the absence of well-controlled studies showing efficacy), the decision to use these therapies is between physicians and patients themselves.

**Prognosis**

The prognosis of fibromyalgia depends largely on where the individual falls on a continuum. One end of the continuum are individuals in the population with CWP or individuals with fibromyalgia that are seen in primary care, with the prognosis in these individuals being quite good.\textsuperscript{202,203} On the other hand, individuals with fibromyalgia seen in tertiary care settings do quite poorly.\textsuperscript{204} In this latter study, there was little change in symptoms over time, and no significant change in health satisfaction, symptoms, or functional disability. With regard to function in fibromyalgia, studies have reported varying disability rates from 9% to 44%.\textsuperscript{203,205,206} Disability has been most strongly associated with functional and work status, pain, mood disturbances, coping ability,
depression, pending litigation, and educational background.

Conclusion

Fibromyalgia is one of several centralized pain disorders characterized by widespread body pain and comorbid symptoms, such as trouble thinking and headaches. Whereas the diagnosis has been controversial in the medical community for some time, it is now among the best studied chronic pain conditions, with overwhelming evidence demonstrating altered CNS function as a key contributor to symptomatology. Treatment should include patient education as well as a combination of behavioral therapies, lifestyle changes, medications, and complementary treatments, as appropriate.

Key Points

- Fibromyalgia is the prototypical centralized pain condition, which is characterized by widespread body pain and comorbid symptoms, such as fatigue, sleep, and memory problems.
- Fibromyalgia patients have higher levels of CNS neurotransmitters that upregulate pain (e.g., glutamate) and lower levels of those that downregulate pain (e.g., norepinephrine and GABA), with a paradoxical increase in endogenous opioids (which may explain why this condition does not appear to be responsive to opioids).
- Psychological comorbidities are more common in fibromyalgia patients but do not explain the sensory abnormalities or pain complaints.
- Rather than considering fibromyalgia as a binary diagnosis, one can consider the degree of “fibromyalgianess” as a means of placing patients on the continuum of more peripheral confined pain to more centralized or widespread pain. Individuals with higher degrees of fibromyalgianess are going to be less responsive to therapies that work well for acute or nociceptive pain (i.e., surgery, opioids) and more responsive to drug and nondrug therapies that work in the CNS.
- Opioids are not recommended in treating fibromyalgia.
- Medications that address the known CNS pathology are preferred,
such as TCA, SNRIs, and gabapentinoids.

- Nonpharmacologic therapies should be the mainstay of therapy and can be very effective, especially promoting activity/exercise and improving sleep using sleep hygiene or cognitive-behavioral therapy.
- Although pain and comorbid symptoms may persistent, many patients appropriately treated for fibromyalgia can lead normal, functional lives.

Pain is not as distinctive a feature of dermatologic disorders as is the related disorder of itch, which is beyond the scope of this discussion. It is well known that itch appears to be so intolerable that the act of scratching inflicts a transient pain with attendant structural damage to the skin. It is generally considered that the induced pain is subjectively more tolerable than the itching. Nonetheless, pain is a distinctive feature of certain dermatologic disorders and merits attention simply because of the great prevalence of skin disorders.

In 2013, almost 85 million Americans (1 in 4 individuals) were seen by a physician for skin disease, resulting in direct health care costs of $75 billion and indirect lost opportunity costs of $11 billion. Of the 10 most prevalent skin diseases seen, viral diseases and wounds are potentially painful. The prevalence of pain in dermatologic disorders is unknown and may be underreported. In one survey of patients with common skin conditions, pain was reported by 23% of all patients. The effects of pain on the patient are best demonstrated by the impact of the persisting pain that sometimes follows herpes zoster or postherpetic neuralgia, which occasionally leads to suicide. This disease is discussed in Chapter 27, but this chapter focuses attention not only on the impact of pain but also on the need for appropriate diagnosis and on the value of appropriate treatment.

The diseases discussed in this chapter can be grouped into the categories of vasculitis, infections of viral and bacterial origin, inflammatory diseases of the subcutaneous space, and neoplasms. Some neoplasms, although benign, are specifically painful based on their neurovascular components. We discuss the causes and pathogenesis of the selected pain-related skin diseases, paying attention to symptoms and signs, methods of diagnosis, and preferred methods of treatment. For more comprehensive discussions of the individual diseases, refer to selected general textbooks of skin disease. Vasculitides and tumors are described in Tables 37.1 and 37.2.

**Basic Considerations: Anatomy and Physiology of the Skin**
Human skin is a vast, sheet-like interface of the organism with its environment. It is adapted to the dryness of the atmosphere, resisting mechanical shearing and puncturing forces as well as the invasion of chemical and infective agents. This organ, which in aggregate covers an area of more than 2 m², has a mass greater than that of any other organ. It contains an extensive vascular and sweat gland system, essential for thermal regulation, and an even more extensive and finely attuned neuroreceptor network, including the varied transducers of pain and other sensations. It is also a major immune system interface.

The skin is covered by a thin, stratified epithelium, the epidermis, which is only 75 to 100 µm thick except on the palms and soles, where it is 4 to 5 times thicker. The bulk of the skin is fibroelastic dense connective tissue known as the dermis, which supports the extensive network of vessels and nerves as well as the specialized glandular structure of the sweat apparatus and keratinizing appendages, such as hair and nail. The subcutaneous space is a variably fatty connective tissue perforated by collagenous septa, continuous on the outermost aspects with the fibers of the dermis and continuous beneath the skin with fascial or periosteal attachments to the skeleton. The immune system involves all layers of the skin.

It is generally believed that the peripheral pain receptors are the network of finely arborized free nerve endings that innervate the epidermis and superficial dermis and has been referred to as the cutaneous sensory nervous system. These fibers convey information from the skin to the central nervous system (CNS) and thus have a sensory role.

The primary sensory nerve fibers that innervate the skin are categorized based on diameter, conduction velocity, and myelination. The thickly myelinated Aβ fibers conduct tactile sensation. Thinly myelinated, fast-conducting Aδ fibers transmit noxious information and cold. Unmyelinated, slow-conducting C fibers transmit burning-quality pain, heat, and itch.

Pruritoception and nociception are physiologic sensations that prompt avoidance of the sensation-causing stimulus. The labeled line theory proposes the existence of itch-specific neuronal fibers that extend from the skin to the dorsal root ganglion. Nociceptive neurons express molecular pain transducers at their peripheral nerve terminals, such as transient
receptor potential (TRP) ion channels, which sense heat, cold, and reactive chemicals. Pruriceptive neurons express G protein-coupled receptors and cytokine receptors that are activated by inflammatory mediators. Upon neuronal activation, signals are relayed via the dorsal horn of the spinal cord to the brain, where they are processed as pain or itch. Spinal interneurons may also play an important role in determining whether the brain interprets a signal as pain or itch.\textsuperscript{12}

In the selectivity theory, overlapping populations of itch and pain fibers exist; although most fibers respond only to painful stimuli, some respond to both pain and itch. The larger population of pain-sensitive C fibers inhibits the smaller population of itch-related C fibers. If a stimulus activates both itch and pain, then the larger population of pain-sensitive C fibers will mask the itch. If the pain pathway is activated, it inhibits itch sensation.\textsuperscript{12–14}

Sensory neurons also have an effector function in the skin and release molecular mediators from their peripheral nerve terminals, including the neuropeptides substance P, calcitonin gene-related peptide, somatostatin, and vasoactive intestinal peptide. The cutaneous sensory nervous system appears to play an important role in the “communication” between the nervous system and the immune system, the vascular system, and the cells of the epidermis. Neuropeptides appear to participate in vital functions such as neuroinflammation, tissue repair, and immunomodulation.\textsuperscript{8,15,16} They have important biologic effects on a variety of cells in the skin, including keratinocytes, endothelial cells, fibroblasts, Langerhans cells, mast cells, macrophages, and smooth muscle cells.\textsuperscript{11} It is easy to imagine how these effector functions may participate in the perpetuation of chronic skin conditions characterized by pain or itch.

The diagnosis of skin disease depends less on deductive logic than on direct observation. One should distinguish localized nodules resulting from small tumors of the skin from the large plaque-like swellings associated with acute edema and redness that mark inflammatory processes and umbilicated small vesicles occurring in clusters on inflammatory bases that are characteristic of the herpetic viral infections. Subtle or marked defects in the integrity of the protective epidermal sheet should be noted, as manifested by denuded sites of bullae (erosions). Also to be noted are
deeper defects in the integrity of the protective barrier that involve loss of the epidermis as well as of some dermis, leading to ulcer formation. Such lesions are inevitably attended by pain, unless associated with a neuropathy, which can best be explained by exposure of free nerve endings.

Clinical Disorders

LEUKOCYTOCLASTIC VASCULITIS

Leukocytoclastic vasculitis (LCV), also known as cutaneous small vessel vasculitis, is a common form of vasculitis that may be confined to the skin\(^1\) or related to systemic vasculitis, connective tissue diseases, or malignancy\(^18,19\) (Fig. 37.1). LCV typically affects postcapillary venules producing palpable purpura which are the clinical hallmark of the disease.\(^17\) Although palpable purpura occurring in dependent areas (e.g., the legs and ankles in ambulatory patients and the back and sacral area in bedridden patients) is typical, a spectrum of other cutaneous lesions may occur such as papules, nodules, vesicles, bullae, pustules, ulcers, urticarial lesions, and livedo reticularis.\(^20,21\) Purpuric lesions may often be associated with tenderness, burning, stinging, or itch.\(^17\) The presence of painful skin lesions has been reported to be associated with a lower risk of systemic involvement.\(^22\)

FIGURE 37.1 Leukocytoclastic vasculitis. (Courtesy of Fan Liu, MD, University of Washington.)

Histologic changes seen with LCV consist primarily of infiltration of
polymorphonuclear leukocytes within and/or around blood vessels and destruction of the vessel wall with fibrinoid necrosis, whereas hemorrhage, nuclear dust (leukocytoclasis), endothelial changes, ulceration, necrosis, and eccrine gland necrosis are considered secondary changes. The differential diagnosis of LCV includes thrombocytopenia, coagulation, embolic phenomena, pigmented purpuric dermatoses, microvascular occlusion, and others.

**Etiology**
Among the many reported etiologic factors associated with LCV are infectious agents (e.g., Streptococcus, hepatitis B and C, HIV, and influenza), medications (e.g., antibiotics and nonsteroidal anti-inflammatory drugs [NSAIDs]), connective tissue and inflammatory diseases (e.g., systemic lupus erythematosus [SLE], Sjögren’s syndrome, rheumatoid arthritis, inflammatory bowel disease, and Behçet disease), and malignancy (both lymphoproliferative and solid tumors). Up to half of all cases of LCV do not reveal an identifiable cause and are considered to be idiopathic.

**Pathogenesis**
LCV is felt to be caused by deposition of circulating immune complexes within the vessel walls of postcapillary venules, activation of complement, infiltration by neutrophils, and release of lysosomal enzymes. Immunoglobulins and complement can be detected in vessel walls by direct immunofluorescence in early lesions that are less than 24 hours old (preferably less than 4 hours), and the presence of immunoglobulin A (IgA) may support a diagnosis of IgA vasculitis. Patients who present with LCV need to be evaluated for systemic involvement, particularly for involvement of kidneys, joints, gastrointestinal tract, and pulmonary and nervous systems. They may need to be reclassified depending on the type of systemic involvement according to the Chapel Hill Consensus Conference nomenclature. Subsets or variants of LCV include urticarial vasculitis, Henoch-Schönlein purpura, and cryoglobulinemic vasculitis. Hepatitis C is an important cause of mixed cryoglobulinemic vasculitis and is responsible for the majority of cases that have an infectious
etiology.²⁶,²⁷

**Treatment**
Any underlying infections should be treated, suspect medications stopped, and other potential etiologic agents avoided. Any associated connective tissue diseases should be treated, and the patient evaluated for underlying malignancy if another etiology is not found.

Specific treatment for the vasculitis should be tailored to the severity of the disease. For most patients, the condition is self-limited and spontaneously resolves within 2 to 4 weeks. Chronic or recurrent disease occurs in approximately 10% of patients.²⁸ For patients who are asymptomatic or have mild disease, options include conservative treatment with topical steroids, leg elevation, compression stockings, antihistamines, and NSAIDs. Dapsone and colchicine may be beneficial for more chronic disease. A short course of systemic corticosteroids may be useful for an acute exacerbation. For patients with more severe and recalcitrant disease, azathioprine, cyclosporine, mycophenolate mofetil, methotrexate, intravenous immunoglobulin (IVIg), and rituximab are considerations.¹⁷

**POLYARTERITIS NODOSA**
Polyarteritis nodosa (PAN) is an uncommon form of vasculitis affecting small- and medium-sized arteries. Two forms of cutaneous involvement can occur: benign cutaneous and systemic.

**Symptoms and Signs**
Cutaneous PAN characteristically manifests with tender nodules, livedo reticularis, and ulcers. It may also be associated with myalgias, arthralgias, neuropathy, and fever.²⁹,³⁰ Patients may have periodic flares or exacerbations of their disease, but the long-term course of their disease is generally benign. Progression to systemic PAN is rare but has been reported. Patients need long-term follow-up to monitor for this possibility.³¹

Systemic PAN may have cutaneous involvement in up to 60% patients manifested most commonly as palpable purpura, bullae, and ulcerations and less commonly as nodules, livedo reticularis, and gangrene.²⁹,³²,³³
Nodules can sometimes be palpable along the course of an artery.\(^{21}\) In both forms of PAN, there is segmental, transmural inflammation of medium-sized arteries in the deep dermis or subcutaneous tissue\(^ {29,30}\) with immunoglobulin M (IgM), fibrin, or C3 demonstrable on direct immunofluorescence.\(^ {29}\) Although most cases are idiopathic, secondary PAN has been reported most commonly from hepatitis B and less commonly hepatitis C, streptococcal infection, cytomegalovirus, HIV, and others. In children, PAN has similar features as adenosine deaminase 2 (ADA2) deficiency, a newly described autosomal recessively inherited condition characterized by early onset vasculopathy with livedoid rash, strokes, and hematologic abnormalities.\(^ {34}\)

**Treatment**

First-line treatment of the benign cutaneous form of PAN is NSAIDs and systemic corticosteroids. A second, steroid-sparing immunosuppressant such as mycophenolate mofetil, azathioprine, or methotrexate may be added if patients do not respond or relapse. General supportive measures include rest, medications for pain, local wound care for ulcerated lesions, and antibiotics for secondary infection. Severe systemic PAN is treated with prednisone and cyclophosphamide to induce remission and then a safer immunosuppressive agent to maintain remission.\(^ {35}\)

**ANTINEUTROPHILIC CYTOPLASMIC ANTIBODIES-ASSOCIATED VASCULITIDES: GRANULOMATOSIS WITH POLYANGIITIS (FORMERLY KNOWN AS WEGENER’S GRANULOMATOSIS)**

Granulomatosis with polyangiitis (GPA) is an uncommon disease of unknown cause characterized by necrotizing vasculitis and granulomatous inflammation involving the upper and lower respiratory tracts, together with glomerulonephritis, although more limited forms of the disease without renal involvement may occur.\(^ {36,37}\) Approximately 90% of patients, when in the active stage of their disease, have antineutrophilic cytoplasmic antibodies (ANCA) of the cytoplasmic type (c-ANCA) directed at proteinase 3.\(^ {37}\) The pathogenesis of GPA remains poorly understood.
Symptoms and Signs
Cutaneous lesions occur in approximately 45% of patients and include palpable purpura, ulcers, vesicles, papules, nodules, necrotic papules, and pustules. Pyoderma gangrenosum (PG)-like ulcerations may occur. Papules, nodules, and ulcerative lesions may be tender or painful. The upper airway is frequently affected and manifestations include oral ulcerations and gingival hyperplasia with petechiae. Friable gingival hyperplasia with petechiae is said to be pathognomonic of GPA. Saddle nose deformity occurs in some patients but is a rare manifestation. On biopsy of cutaneous lesions, one may see small vessel vasculitis, granulomatous dermatitis, and least commonly granulomatous vasculitis. Not all changes may be seen in the same specimen.

Treatment
Treatment of ANCA vasculitis is composed of two components: remission induction therapy and maintenance therapy. For induction, systemic corticosteroids are combined with cyclophosphamide or rituximab. Plasma exchange can be considered as adjunct therapy for severe vasculitis with active glomerulonephritis or alveolar hemorrhage. After remission is achieved, patients are switched to maintenance with a less toxic immunosuppressant, most commonly azathioprine or methotrexate.

MICROSCOPIC POLYANGIITIS
Microscopic polyangiitis (MPA) is a systemic small vessel vasculitis commonly affecting the kidneys, lungs, and skin. The vasculitis affects arterioles, capillaries, venules, and sometimes small- and medium-sized arteries with few or no immune deposits evident on direct immunofluorescence (pauci-immune). Positive ANCA, usually of the perinuclear type (p-ANCA), also referred to as myeloperoxidase-ANCA, has been reported in 60% to 80% patients. There is experimental evidence to suggest that myeloperoxidase-ANCA may be involved in the pathogenesis of vasculitis. Cutaneous involvement has been reported in 35% to 60% patients with MPA. Purpura is commonly reported, but a variety of other cutaneous manifestations include vesicles, bullae, splinter hemorrhages, nodules,
cutaneous necrosis, digital infarction, gangrene, PG-like ulcerations, livedo reticularis, facial edema, urticaria, orogenital ulceration, and erythema elevatum diutinum. Although not focused on specifically in reports, ischemic pain would be expected as in other forms of vasculitis, particularly with ulcers, infarction, and gangrene.

**Treatment**
Serious major organ involvement, such as pulmonary or renal disease, is treated similarly to GPA.

**EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (FORMERLY KNOWN AS CHURG-STRAUSS SYNDROME)**
Eosinophilic granulomatosis with polyangiitis (EGPA) is a rare syndrome characterized by allergic rhinitis, asthma, eosinophilia, granulomatous inflammation, and systemic vasculitis affecting small- to medium-sized arteries. Pulmonary involvement and cardiac involvement are common with coronary arteritis and myocarditis being the principal cause of death, whereas renal involvement is relatively less common and tends to be mild.32,36 Histologically, one sees a vasculitis affecting small vessels, extravascular granulomas, tissue infiltration with eosinophils, and an absence of vascular immune deposits on direct immunofluorescence.44 Thirty percent to 40% of patients have positive ANCA, usually of the p-ANCA directed at myeloperoxidase.45

**Symptoms and Signs**
Cutaneous lesions occur in up to 50% to 70% of patients. The most common cutaneous findings are palpable purpura on the lower extremities and skin nodules.54 Among the many other reported cutaneous manifestations are papules, plaques, petechiae, ulcers, infarcts, bullae, wheals, and livedo reticularis.55 More recently described variations include severe digital gangrene associated with antiphospholipid antibodies56 and purpura fulminans.57 Pain or tenderness is characteristic of the skin nodules58 and also likely occurs on an ischemic basis in some vasculitic lesions as well.
**Treatment**
The treatment of choice is systemic corticosteroids, which usually controls the disease. Severe EGPA requires aggressive treatment with corticosteroids and cyclophosphamide. More than 50% of patients may become steroid-dependent due to persistent asthma or sinusitis. Mepolizumab, an anti-interleukin (IL)-5 monoclonal antibody, is a potential steroid-sparing agent.\(^45\)

**RHEUMATOID VASCULITIS**
Rheumatoid vasculitis is a systemic vasculitis that may affect vessels of different sizes including capillaries and small- and medium-sized arteries. It tends to occur in patients with more severe rheumatoid arthritis of long-standing duration and high titer rheumatoid factor.\(^59\)\(^–\)\(^61\) The diagnostic criteria as originally proposed by Scott and Bacon\(^62\) included rheumatoid arthritis (meeting American Rheumatism Association [ARA] criteria) plus one or more of the following: (1) mononeuritis multiplex, (2) peripheral gangrene, (3) biopsy evidence of acute necrotizing arteritis plus systemic illness such as fever or weight loss, and (4) deep cutaneous ulcers or active extra-articular disease (e.g., pleurisy, pericarditis, scleritis) if associated with typical digital infarcts or biopsy evidence of vasculitis.\(^62\)

Histologically, one finds a vasculitis that may be leukocytoclastic, granulomatous, or lymphocytic.\(^63\)\(^,\)\(^64\) Cutaneous manifestations are one of the most common features of the disease (up to 90% patients) and include Bywaters lesions (periungual infarctions), petechiae, palpable purpura, deep ulcers along medial or lateral malleoli, and erythema elevatum diutinum.\(^65\) Ulcerations and gangrene may be painful on an ischemic basis.

**Treatment**
Patients with isolated periungual infarcts have a low risk of progressing to systemic vasculitis and do not require treatment. Patients with more severe disease are treated with systemic agents, including systemic corticosteroids, cyclophosphamide, and rituximab.\(^66\)

**LIVEDOID VASCULOPATHY**
Livedoid vasculopathy (livedoid vasculitis, see Fig. 37.2) is a recurrent, chronic disease that predominantly affects women. The distal lower legs, particularly the malleoli, are most commonly affected and may exhibit livedoid changes, painful purpuric papules and plaques on the bilateral lower extremities, porcelain-white stellate atrophic scars, and painful recurrent ulcerations. Approximately half of patients may have an underlying hypercoagulable disorder predisposing to thrombin formation.67

![FIGURE 37.2 Livedoid vasculopathy. (Courtesy of John Olerud, MD, University of Washington.)](image)

The histologic changes seen on biopsy are segmental and depend on the age of the lesion. In early stages, hyaline thrombi form in dermal blood vessels, and fibrinoid material is deposited in the vessel wall or surrounding stroma. Later stages show thickening/hyalinization of vessel walls and features of scarring. There are varying levels of inflammation but no leukocytoclasis. Direct immunofluorescence usually demonstrates fibrin, C3, and IgM in vessel walls.

A question arises as to how extensively to evaluate patients for underlying coagulation disorders. Laboratory evaluation for hypercoagulable states, collagen vascular disorders, fibrinolytic disorders, paraproteinemia, and infectious associations can be pursued.67 Hairston et al.68 recommend the following studies: complete blood count (CBC), cryoglobulins, cryofibrinogens, homocysteine, antinuclear antibody (ANA), antcardiolipin antibody, lupus anticoagulant, protein C and S levels, factor V Leiden gene mutation, prothrombin gene mutation [G20210A], and β2-glycoprotein-1 antibody.
**Treatment**

General supportive measures for livedoid vasculopathy include avoidance of smoking, rest, compression for associated venous insufficiency, local wound care for ulcerations, and pain control.

Any underlying coagulation disorders should be treated. In the absence of any specific defects, antiplatelet and antithrombotic agents may be beneficial. The literature on treatment of livedoid vasculopathy consists of case reports or small series with no controlled studies. The concept of a therapeutic ladder as proposed by Callen\(^69\) with treatments with more potentially serious side effects higher on the ladder is a sound one and starts with low-dose aspirin, pentoxifylline, dipyridamole, folic acid/vitamin B complex in patients with homocysteinemia, hydroxychloroquine in patients with antiphospholipid syndrome (APS), stanozolol/danazol in patients with cryofibrinogenemia, warfarin, low molecular weight heparin, hyperbaric oxygen, and tissue plasminogen activator infusion and ends with IVIg.\(^69\)

**Other Vascular Disorders**

**ANTIPHOSPHOLIPID SYNDROME**

APS is an uncommon syndrome characterized by thrombotic occlusion of arteries or veins, complications of pregnancy (miscarriage, spontaneous abortions, and prematurity), thrombocytopenia, and positive anticardiolipin and/or lupus anticoagulant antibodies.\(^{70–72}\) The anticardiolipin and/or lupus anticoagulant tests should be positive on at least two occasions at least 12 weeks apart to exclude transiently positive tests. APS may occur as a primary disorder, as a secondary disorder in patients with lupus erythematosus, and also may occur in a subset of patients with Sneddon’s syndrome (livedo reticularis and multiple cerebrovascular events). Antiphospholipid antibodies alone are not diagnostic of APS because they occur normally in a small percentage of the normal population and have been associated with multiple other conditions.\(^{70,73}\) Histologically, skin biopsies demonstrate noninflammatory thrombosis of arteries and/or veins.
Symptoms and Signs
Cutaneous manifestations of APS are common, with livedo reticularis, digital necrosis, subungual splinter hemorrhages, and superficial venous thrombosis being the most common.\textsuperscript{71} Other signs include cutaneous necrosis and gangrene, ulcers, painful skin nodules, lesions resembling vasculitis, necrotizing vasculitis, livedoid vasculitis, and anetoderma.\textsuperscript{71,73,74} Livedo reticularis is the most common skin manifestation and reported to have irregular broken circles (livedo racemosa) as opposed to the unbroken circles of physiologic cutis marmorata.\textsuperscript{71} The cutaneous lesions of APS may be painful on an ischemic basis, particularly areas of necrosis, ulcers, and gangrene.

Diagnosis is based on the presence of either a thrombotic vascular occlusive event or a qualifying complication of pregnancy, plus the presence of either anticardiolipin or lupus anticoagulant or anti-β2-glycoprotein-1 antibodies.\textsuperscript{75}

Treatment
The patient should be treated for any risk factors for cardiovascular events including hypertension and hyperlipidemia and advised to avoid smoking and oral contraceptives.

APS patients with thrombosis should be anticoagulated indefinitely with an antithrombotic agent. Typically, heparin is used in the acute setting and then transitioned to warfarin. Low molecular weight heparin may also be used. Asymptomatic patients incidentally found to have antiphospholipid antibodies with no history of thrombosis or pregnancy complications may be offered no treatment or low-dose aspirin.\textsuperscript{76} Multiple clinical studies have shown antimalarials to have an antithrombotic effect in patients with SLE.\textsuperscript{77}

Catastrophic APS, an acute severe variant with widespread microvascular occlusive event, is treated with anticoagulation with heparin, high-dose systemic corticosteroids, plasma exchange, and IVIg. Rituximab and eculizumab has been used in more resistant cases. Careful monitoring to detect, treat, or prevent precipitating factors is also recommended, including infections, surgery, trauma, invasive procedures, underlying malignancy, SLE flares, and obstetric complications.\textsuperscript{78}
WARFARIN (COUMADIN) SKIN NECROSIS
Warfarin-induced skin necrosis is a rare reaction to warfarin that causes painful skin necrosis.\textsuperscript{79–81}

Pathophysiology
Warfarin-induced skin necrosis is believed to be caused by a temporary hypercoagulable state that occurs on initiation of warfarin treatment.\textsuperscript{80} Protein C is a vitamin K–dependent natural anticoagulant, whereas factors II, VII, IX, and X are vitamin K–dependent clotting (procoagulant) factors. Because of shorter half-lives of protein C and factor VII, there is a relatively rapid fall in protein C and factor VII when warfarin is begun compared to factors II, IX, and X, leading to a transient hypercoagulable state.\textsuperscript{82} Patients who have hereditary or acquired protein C deficiency, protein S deficiency, or antithrombin III deficiency are at greater risk.\textsuperscript{80,83} Histologically, thrombi in capillaries and venules are considered to be the primary process, but other changes related to necrosis and hemorrhage can be seen.\textsuperscript{80,84}

Symptoms and Signs
Symptoms usually begin within the first 3 to 6 days of starting warfarin but delayed onset of has been reported.\textsuperscript{85} One or more erythematous edematous plaques appear that develop petechiae on their surface followed by blue-black discoloration, hemorrhage, bullous formation, gangrene or necrosis, and finally eschar formation.\textsuperscript{86} The lesions are very painful and favor the areas of increased subcutaneous fat, such as the abdomen, buttock, thighs, and breasts.

Treatment
Warfarin therapy should be discontinued immediately and heparin substituted. Fresh frozen plasma and vitamin K may be used to restore levels of protein C and S. Avoidance of warfarin in the future is the most prudent approach. Restarting warfarin at low dosage under coverage of IV heparin has been done successfully; however, some patients have been reported to experience recurrences of skin necrosis.\textsuperscript{87} Low molecular weight heparin has been recommended over chronic unfractionated
heparin use if warfarin cannot be restarted because of less risk of osteoporosis, lower risk of thrombocytopenia, and there is no need to monitor partial thromboplastin time (PTT). Meticulous wound care and pain management is necessary. More than 50% of patients require surgical intervention in the form of débridement, grafting, and amputation.

COCAINE LEVAMISOLE TOXICITY
Since 2003, there have been increasing reports of vasculitis and vasculopathy due to levamisole-contaminated cocaine (Fig. 37.3). The Centers for Disease Control and Prevention (CDC) estimates about 70% of cocaine in the United States may be adulterated with levamisole, a veterinary antihelminthic agent used as a cutting agent to expand the volume of the drug and potentiate the effects of cocaine.

FIGURE 37.3 Cocaine levamisole toxicity. (Courtesy of Cait May, MD, University of Washington.)

Levamisole-induced toxicity presents with a painful, purpuric rash that
can be associated with agranulocytosis, neutropenia, arthralgias, fever, and oral pain. The purpura has a predilection for the external ears, nose, and cheeks and progresses to skin necrosis. Retiform or stellate purpura can also affect the trunk and extremities.

As a diagnosis of exclusion, other causes of vasculitis should be investigated, including infection and autoimmune conditions. Many other types of vasculitis have also been described in cocaine abusers, including urticarial vasculitis, EGPA, thromboangiitis obliterans, and pseudovasculitis with nasal destruction mimicking GPA. A positive urine toxicology test is contributory; however, the window of detection for cocaine is only 2 to 3 days. Levamisole testing is difficult, given its short half-life of 5.6 hours. ANCA and antiphospholipid antibodies may be positive. On histology, LCV and fibrin thrombi may be present.

Management is supportive and consists of discontinuing use of contaminated cocaine and appropriate wound care. The lesions typically resolve within 2 to 3 weeks.

**CALCINOSIS CUTIS**

Calcinosis cutis results from the deposition of calcium salts in the skin and can be categorized into four subtypes: dystrophic, metastatic, idiopathic, and iatrogenic. Dystrophic calcinosis cutis occurs when there is calcification in damaged tissue, such as in areas of trauma or inflammatory process, and is most commonly seen in autoimmune conditions such as dermatomyositis, systemic sclerosis, and CREST syndrome. Patients present with painful, firm nodules or plaques predominantly in periarticular areas and on fingertips and bony prominences. The lesions may ulcerate and extrude chalky, granular material through the skin. It is often painful and can be debilitating. In dermatomyositis, children diagnosed at a young age have a higher risk of calcinosis than adults, and anti-NXP2 autoantibodies are associated with a substantially increased risk of calcinosis in all age groups.

The pathogenesis of calcinosis cutis remains poorly understood; chronic inflammation and vascular ischemia in the tissue injury has been implicated as well as macrophages, proinflammatory cytokines, and the impairment of calcium-regulating proteins.
Treatment of calcinosis cutis is challenging and should be individualized depending on the location and size of the deposits and the underlying condition. Surgical excision of localized lesions can help decrease discomfort. Results for medical therapies are mixed and inconsistent. Bisphosphonates, sodium thiosulfate, diltiazem, IVIg, tumor necrosis factor inhibitors, and colchicine have been beneficial in some.\(^9^1\)

**CALCIPHYLAXIS**
Calciphylaxis (Fig. 37.4) is a potentially life-threatening cause of painful ulcerations of the skin that occurs most commonly in patients with chronic end-stage renal disease but also rarely occurs in patients without renal failure.\(^9^2\)–\(^9^4\) It has a reported prevalence rate of 4.1% in patients undergoing hemodialysis.\(^9^5\) Many patients have secondary hyperparathyroidism with elevated parathyroid hormone, increased alkaline phosphatase, increased calcium, phosphorous, or calcium × phosphate ion product.\(^9^5\),\(^9^6\) Other potential risk factors include protein C deficiency, protein S deficiency, and warfarin therapy.\(^9^7\)
Cutaneous manifestations may begin as very painful violaceous discoloration similar to livedo reticularis that evolves to indurated plaques, ulcerations, and eschar formation. Lesions favor adipose-rich areas such as the breast, buttocks, and thighs. The 1-year mortality is 45% to 80%, with ulcerated lesions associated with higher mortality and sepsis the principal cause of death. Gangrene requiring amputation may also occur. Diagnosis requires clinicopathologic correlation. Histologically, there is calcification of small arteries, intimal hyperplasia, and noninflammatory thrombosis of vessels. Small vessel calcification, although nonspecific, can be identified on plain films and computed tomography (CT) scans and may aid in the diagnosis. Preservation of pulses, proximal location of ulcers on extremities, and absence of neuropathy favors calciphylaxis over arteriosclerotic ulcers and diabetic ulcers, although patients may have concomitant disease and calciphylaxis ulcers may occur on acral locations. Warfarin-associated nonuremic calciphylaxis appears to be a distinct entity, predominantly below the knees in females, and associated with better outcomes.

**Treatment**

A multidisciplinary approach is necessary. Measures should be taken to lower the serum calcium, serum phosphate, and calcium × phosphate product when elevated. These measures may include low-calcium dialysate, noncalcium phosphate binders, and low-phosphate diet. Sodium thiosulfate has emerged as a first-line treatment and may be given intravenously or injected intralesionally to isolated wounds. Possible adjunct therapies include pentoxifylline and bisphosphonates. Cinacalcet is preferred over vitamin D and parathyroidectomy to treat hyperparathyroidism. Consideration should be given to switching from warfarin to one of the newer anticoagulants if appropriate. Local wound care, pain management, and antibiotics for secondary infection are also essential. Amputation may be needed in some patients.

**Ulcers**
ISCHEMIC ULCERS
Ischemic (arterial) ulcers are a cause of painful ulcerations on the lower extremities most often seen in patients with arteriosclerotic peripheral vascular disease. The ulcers typically have a dry punched out appearance and are located on the distal lower extremities at sites of trauma or pressure including the toes, feet, lateral malleoli, and pretibial areas. There may be associated atrophic skin, loss of hair, delayed capillary filling pressure, and rubor with dependency (reactive hyperemia). The ulcer pain is worse at night and relieved by dependency. Patients also may have a history of intermittent claudication and rest pain if the obstruction is severe enough.

Histologically, arteriosclerosis affects medium and large arteries where one finds plaques with varying degrees of infiltrations with foam cells, smooth muscle cells, inflammatory cells, hemorrhage, platelets, thrombus formation, collagen deposition, and ulceration. Patients may have ulcers with a mixture of venous and arterial disease. Diabetics may also have small vessel disease complicated by peripheral neuropathy leading to further trauma and injury at the site. Neuritis on an ischemic basis may also occur.

The patient should be examined for absent or diminished pulses and bruits over proximal arteries. The patient should be further evaluated with measurements to determine the ankle brachial index (ABI) (ratio of the systolic blood pressure in the ankle to the systolic blood pressure in the arm). A normal ABI is $\geq 1$, $< 1$ is abnormal, and $\leq 0.5$ is severe disease. Patients with calcification of arteries have a falsely elevated ABI because of noncompressibility of vessels.

Treatment
Measures should be taken to treat underlying causes of arteriosclerosis including cessation of smoking, control of blood pressure, hyperlipidemia, and control of diabetes. Elevation of the extremity, compression, and débridement of ulcers are to be avoided. Protection of the extremities from trauma with sheepskin and foot cradling devices is helpful. Patients with claudication may benefit from an exercise program when the ulcer has healed. Adequate pain relief, local wound care, and treating any secondary
infection are important. When conservative measures fail, there are a variety of nonoperative and operative revascularization procedures that may be used, including percutaneous transluminal angioplasty, stent placement, atherectomy, and bypass procedures depending on the individual patient. Amputation may be necessary.

VENOUS ULCERS
Venous ulcers (Fig. 37.5) are a common cause of painful ulcerations on the ankles, typically over the medial malleoli in patients with chronic venous insufficiency. Associated skin findings may include hyperpigmentation from hemosiderin deposition, varicosities, pitting edema, scars from prior ulcerations, and fibrosis and induration of tissues (lipodermatosclerosis). Lipodermatosclerosis itself may be very painful and resemble cellulitis. There may also be associated stasis dermatitis, contact dermatitis from topical medications, and secondary infection. The ulcer itself is typically shallow with irregular borders and sloping edge.
Venous ulcers occur in the setting of chronic venous hypertension due to incompetent venous semi-lunar valves in superficial veins, communicating veins, or deep venous system or with disease of the calf muscles which act as a pump to empty the deep venous system.\textsuperscript{104,110} The valves may be damaged by prior episodes of thrombophlebitis or be congenitally absent.\textsuperscript{110} Obesity and peripheral edema from other causes such as pulmonary, cardiac, hepatic, or renal disease may be contributory or exacerbating factors. Pain in the ulcers is presumably on an ischemic basis.

**Treatment**
Elevation of the legs and support stockings help control peripheral edema. Unna boots and other compressive wraps speed wound healing.
Compression should be used with care in patients with concomitant arterial disease. Bed rest with leg elevation for 1 to 2 weeks may be necessary for edema control when painful lipodermatosclerosis precludes the use of compression. Short stretch wraps applied before getting out of bed in the morning can prevent further leg swelling without being applied too tightly. They are usually well tolerated after the pain of lipodermatosclerosis subsides with bed rest.

Local wound care may include gauzes, films, hydrogels, hydrocolloid dressings, foams, alginates, hydrofibers, or antimicrobial dressings. Occlusive dressings on the wound may also relieve pain. Surgical débridement may sometimes be needed. Cultures should be taken if secondary infection is present and the patient treated with antibiotics effective for Staphylococcus aureus and Streptococcus pyogenes. Dermatitis from stasis dermatitis or contact dermatitis is treated with topical steroids and avoidance of responsible contactants. Surgical management with grafting may be necessary in refractory cases. Weight reduction and diuretics may be helpful in some obese patients. Optimization of therapy for any associated systemic conditions causing peripheral edema such as congestive heart failure or pulmonary insufficiency may also be helpful.

**PYODERMA GANGRENOSUM**

PG is a rare neutrophilic dermatosis characterized by painful skin ulcers (Fig. 37.6). The complex pathogenesis is multifactorial and incompletely understood, implicating neutrophil dysfunction, aberrant activation of inflammatory mediators, and genetic predisposition. Lesions typically begin as an inflammatory pustule or nodule that enlarges and ulcerates with undermined, dusky violaceous margins. Peak incidence occurs in adults 20 to 30 years old without predilection for either sex; however, any age group can be affected. Pathergy (the appearance of lesions at sites of trauma) is present in 20% to 30% of patients. PG may be a component of autoinflammatory genetic syndromes such as PASH (PG, acne, hidradenitis suppurativa [HS]) and PAPA (pyogenic arthritis, PG, and acne).
PG is a diagnosis of exclusion, as there are no diagnostic laboratory or histologic features, and it is important to exclude other more common etiologies for ulcer formation, including infection, venous, and arterial ulcers. The differential diagnosis also includes necrobiosis lipoidica, vasculitides, cutaneous Crohn’s disease, spider bite, and factitial disease. Clinical variants of PG include pustular, bullous, vegetative, peristomal, postsurgical, and drug-induced.

Up to 75% of patients with PG have an associated underlying condition, most commonly inflammatory bowel disease, hematologic disorders, and inflammatory arthritis. Treatment can be challenging and requires multimodality management. After appropriate workup and treatment of any underlying diseases if present, early control with diligent wound care and anti-inflammatory medications are instituted. For limited disease, potent topical corticosteroids and intralesional steroid injection may be sufficient. For more widespread or progressive disease, systemic corticosteroids and immunosuppressive steroid-sparing agents such as cyclosporine and infliximab may be added. Due to pathergy, trauma including wound débridement should be avoided.\textsuperscript{114}
Painful Infections

Many infections of the skin are painful. Common or selected skin infections are discussed here. For more comprehensive coverage of the topic, the reader is referred to a general textbook of dermatology.

NECROTIZING SOFT TISSUE INFECTION/NECROTIZING FASCIITIS

Necrotizing fasciitis is an acute, life-threatening bacterial infection that spreads quickly along fascial planes and is characterized by high mortality, systemic toxicity, and tissue destruction. The pathogen is initially inoculated into the subcutaneous tissue, which may occur with any epithelial disruption. Risk factors include recent trauma, surgery, immunosuppression, diabetes, and alcohol abuse. Necrotizing infection localized to the perineum is termed Fournier gangrene.

The infection may be mono- or polymicrobial. Group A β-hemolytic streptococci is classically associated with necrotizing fasciitis; however, a wide spectrum of causative organisms have been reported, including Staphylococcus aureus, Vibrio vulnificus, Enterobacteriaceae, Pseudomonas, and Bacteroides spp.

Patients who are developing necrotizing fasciitis present with erythema, pain, and woody-feeling edema. They may initially be diagnosed with cellulitis; however, the infection progresses rapidly despite standard antibiotic therapy. Pain is out of proportion to visible skin signs, as the deeper tissues are affected and cutaneous manifestations may be minimal. The patient appears systemically ill and may meet sepsis criteria. Dusky-blue cyanotic discoloration appears, followed by bullae and frank gangrene. Crepitus, representing gas in the soft tissues, may be present. Pain progresses to anesthesia of the involved skin as superficial nerves are destroyed. The gold standard for diagnosis of necrotizing soft tissue infection (NSTI) is an operative exploration to assess the adherence of the fascia to other soft tissue layers.

Early detection and treatment with broad-spectrum IV antibiotics and surgical débridement is critical. Even with optimal treatment, mortality remains high, with rates of 25% to 35%.115–117
HERPES ZOSTER
Herpes zoster is a painful eruption caused by reactivation of the varicella virus in a dermatomal distribution.\textsuperscript{118,119} The topic is presented and discussed in detail in Chapter 27.

HERPES SIMPLEX
Herpes simplex virus (HSV) infection is a common, often painful, DNA viral infection (Fig. 37.7). HSV presents as grouped vesicular lesions on an erythematous base and may be preceded by a 1- to 2-day prodrome of burning, tingling, or itching.\textsuperscript{120–123} The early clear vesicular lesions progress through stages of clouding, central umbilication, crusting, and then healing.

\hspace{1cm}\textbf{FIGURE 37.7} Herpes simplex virus. (Courtesy of University of Washington Dermatology Division.)

\textbf{Symptoms and Signs}
Primary HSV infection (no antibodies to HSV in acute phase serum) may be painful and protracted. It is often accompanied by fever, malaise, tender regional adenopathy, and a higher rate of complications.\textsuperscript{120} “First episode” HSV may be primary infection or may be recurrent HSV where the primary infection was asymptomatic.\textsuperscript{121} Between episodes, the virus remains latent in sensory nerve ganglia and may periodically reactivate. Recurrent episodes are generally milder than the original episode and tend to become less frequent with time. Fever, stress, ultraviolet light, and certain surgical procedures may trigger reactivation of the virus (e.g.,
dermabrasion or laser resurfacing).

HSV infection may present in multiple clinical forms with orolabial (herpes labialis, typically caused by HSV type 1) and genital HSV (typically caused by HSV type 2) being the most common. Keratoconjunctivitis, herpetic sycosis (beard area), herpetic whitlow, herpes gladiatorum, eczema herpeticum, recurrent lumbosacral HSV, and neonatal HSV are other clinical forms of the disease. HSV may also trigger recurrent episodes of erythema multiforme where HSV DNA can be detected in the lesions of erythema multiforme by polymerase chain reaction (PCR). Immunosuppressed patients tend to have more severe and slower healing HSV infections with atypical clinical appearance, such as persistent crusts, erosions, ulcerative, or vegetative lesions. Less commonly, visceral infection may occur affecting the esophagus, lungs, liver, and other organs. Neonatal HSV may occur in utero, at the time of the delivery or in the immediate few weeks after delivery. Patients may have involvement of the skin, eyes, and mouth, CNS, or disseminated disease. Most patients with neonatal HSV have vesicular skin lesions, but a significant percentage of patients, especially with CNS or disseminated disease, have no skin lesions.

Diagnosis
The diagnosis is most readily established by direct fluorescent antibody (DFA) testing of scrapings from early vesicular lesions. Cultures should also be taken when possible from early vesicular lesions and will usually grow out within 48 to 72 hours. PCR has a higher sensitivity and lower cost compared to DFA and is the preferred diagnostic method in suspected meningitis/encephalitis. Tzanck preparation has the advantage of obtaining immediate results but is dependent on the experience and skill of the interpreter and will not distinguish between HSV and herpes zoster virus. Skin biopsy will show ballooning degeneration of keratinocytes and multinucleate giant cells in the epidermis.

Treatment
The principal antiviral medications for treatment of HSV are acyclovir, valacyclovir, and famciclovir. Valacyclovir and famciclovir have an
advantage of less frequent dosing and greater bioavailability but are more expensive than acyclovir. Severe episodes of HSV are treated with IV acyclovir. The dosages of the medications need to be adjusted in patients with renal failure. Representative treatment schedules are available in the references.\textsuperscript{120–123} In general, dosing schedules differ for primary infection, suppressive therapy, episodic therapy, severity of the infection, and immune status of the patient. Acyclovir resistance is more likely to be encountered in immunosuppressed patients, and treatment with foscarnet or cidofovir as alternative agents may be useful.\textsuperscript{120} Treatment with analgesics for pain, damp compresses with Burow’s solution, and antibiotics for secondary infection are helpful supportive measures.

**ERYSIPELAS AND CELLULITIS**

Both erysipelas and cellulitis (Fig. 37.8) are soft tissue infections that cause erythema, edema, warmth, and pain often on the lower extremities but other areas as well. Erysipelas is distinguished from cellulitis in being more superficial in the dermis and sharply demarcated from the surrounding normal skin, whereas cellulitis typically affects deeper tissues and is more indurated and poorly circumscribed.\textsuperscript{126–129} Both may be associated with fever, chills, lymphangitis, and localized lymphadenopathy. Bullous formation may occur with erysipelas and rarely with cellulitis (e.g., vibrio vulnificus).\textsuperscript{127,129} Group A Streptococcus (S. pyogenes) is the principal cause of erysipelas but may also cause cellulitis. Many other organisms may cause cellulitis as well. A break in the skin or portal of entry may sometimes be found (e.g., trauma or fissuring between the toes from tinea pedis).
The diagnosis is often made clinically before lab tests are available. Distinguishing erysipelas from cellulitis may be difficult at times. Culturing any breaks in the skin or ulcers may be helpful in recovering the organism but is not routinely recommended unless the patient is immunosuppressed or has an animal bite. Culturing aspirates from the rash or skin biopsies are low-yield procedures and rarely performed. Blood cultures when positive provide a definitive diagnosis.

**Treatment**

Erysipelas responds to treatment with oral penicillin or amoxicillin. Because *S. aureus* may be difficult to exclude clinically, treatment with cephalexin or dicloxacillin pending culture results is prudent.

Cellulitis of the skin is often caused by *Staphylococcus aureus* and *Streptococcus pyogenes*, and coverage with oral cephalexin or dicloxacillin for milder cases of infection is usually sufficient. Initial therapy is highly dependent on the history of exposure to any unusual organisms, underlying illnesses of the patient, toxicity of the patient, clinical setting (e.g., diabetic foot ulcer), and likelihood of methicillin-resistant *Staphylococcus aureus* (MRSA), which would dictate other antibiotic coverage. Seriously ill patients may need hospitalization, IV antibiotics, and infectious diseases consult.

Elevation of the extremity if no arterial insufficiency is present, local
wound care for any ulcers, and antifungal cream for tinea pedis are important adjunctive measures.

FURUNCULOSIS AND CARBUNCLE

Furuncles and carbuncles (Fig. 37.9) are painful staphylococcal infections in hair-bearing areas that begin as a folliculitis. A furuncle occurs when infection extends down the hair follicle to the subcutaneous tissue with abscess formation producing an erythematous, painful nodule with a superimposed follicular-centered pustule. A carbuncle occurs when infection spreads to multiple adjacent contiguous follicles by subcutaneous extension resulting in a larger, erythematous, painful mass with superimposed follicular pustules. Culture and sensitivity taken from the pustules should guide antibiotic therapy.¹³⁰

![Carbuncle](image)

**FIGURE 37.9** Carbuncle. (Courtesy of University of Washington Dermatology Division.)

**Treatment**

Fluctuant abscesses should be incised, drained, and cultured. Packing of abscesses less than 5 cm in diameter may be unnecessary.¹³¹ Milder cases may respond to incision and drainage and moist heat alone, but careful follow-up is necessary if oral antibiotics are not given. If antibiotics are needed, dicloxacillin or cephalexin 500 mg four times per day for 7 days should be used to treat methicillin-sensitive Staphylococcus aureus (MSSA). If MRSA is suspected, treat with trimethoprim-sulfamethoxazole
one double-strength tablet twice daily or doxycycline 100 mg twice daily for 7 days, but it should be kept in mind that these agents will not treat group A Streptococcus infection. More seriously ill patients may need hospitalization and treatment with IV antibiotics.

In patients with recurrent furunculosis, elimination of nasal staphylococcal carriage and skin colonization may be helpful, although the information on efficacy is limited. Regimens include intranasal mupirocin ointment twice daily for 5 days per month, chlorhexidine washes (away from eyes and ears), dilute bleach baths, and decontamination of personal items.\textsuperscript{117,132,133}

Good hygienic measures may be helpful for patients in preventing recurrences and spread of infection to others such as frequent hand washing, keeping wounds cleanly bandaged, regular laundering of clothing in contact with the wound, regular bathing with soap, avoiding shared towels and other shared items, and cleansing of equipment and surfaces in contact with wound drainage.\textsuperscript{134,135}

**ERYSIPELOID**

Erysipeloid is an acute painful infection of the skin caused by Erysipelothrix rhusiopathiae, a gram-positive rod. It is an occupational hazard of fishermen and butchers and occurs domestically in those who handle raw fish, poultry, and meat products.\textsuperscript{136,137}

The organism gains entrance through a break in the skin to cause what has been referred to as an erysipeloid rash. A painful violaceous red, warm, raised, lesion develops usually on the hand or finger, spreads peripherally, and clears centrally. There is no ulceration or scaling. Usually, the infection remains localized, but systemic infection may occur.

The treatment of choice is penicillin or amoxicillin for 7 to 10 days. Higher doses are needed if systemic infection occurs.\textsuperscript{117}

**Inflammations**

**PANNICULITIS**

The panniculitides are a heterogeneous group of inflammatory disorders of the subcutaneous fat, and all present as subcutaneous nodules that may be
painful. They are conceptually classified by their histologic pattern into septal and lobular categories and are described well in a review by Requena and Yus.\textsuperscript{138}

**Erythema Nodosum**

Erythema nodosum (EN) is the most common panniculitis (Fig. 37.10). It is a septal panniculitis that typically affects young adults between 20 and 30 years of age with male-to-female ratio of 1:6, although any age may be affected.\textsuperscript{138,139} EN usually presents as bilateral tender, poorly circumscribed erythematous nodules, 1 to 10 cm in diameter, on the anterior tibial areas, but more widespread involvement may occur.\textsuperscript{139} The lesions typically heal over a few weeks without scarring, although new lesions may continue to appear. Some patients have constitutional symptoms such as fever, malaise, arthralgias, headache, cough, abdominal pain, vomiting, or diarrhea.\textsuperscript{138} Associated lab abnormalities may include leukocytosis and elevated erythrocyte sedimentation rate.\textsuperscript{139}

![Erythema nodosum](https://example.com/erythema-nodosum.png)

**FIGURE 37.10** Erythema nodosum. (Courtesy of University of Washington Dermatology Division.)

There have been many reported causes of EN including infections (bacterial, viral, fungal, and protozoan), medications (e.g., penicillin, sulfonamides, oral contraceptives, iodides, and salicylates), malignancy, sarcoidosis, inflammatory bowel disease, and pregnancy.\textsuperscript{138–141} Sarcoidosis and streptococcal infections are among the most frequent causes. Streptococcus infection is an important cause of EN in children, reported in 49% cases in one series.\textsuperscript{142} In 35% to 55% cases, no etiology
may be found. Uncommon but important causes to exclude are Mycobacterium tuberculosis, deep fungal infections (histoplasmosis, coccidiomycosis, and blastomycosis), and malignancy (lymphoma, leukemia, and solid tumors). EN is a feature of monocytopenia and mycobacterial infection (monoMAC) syndrome, caused by heterozygous mutations in GATA2 and characterized by monocytopenia and susceptibility to nontuberculous mycobacterial infections.

The pathogenesis of EN is poorly understood and felt to be a hypersensitivity reaction to etiologic agents. Histologically, there is inflammation of the septae between fat lobules that evolves from acute inflammation to granulomatous change followed by fibrosis. The presence of Miescher’s radial granulomas with aggregates of histiocytes and neutrophils around central clefts is a characteristic feature.

Treatment
EN is typically self-limited and resolves within several weeks. Any underlying diseases or infections should be treated. Medications that are a potential cause should be discontinued. Bed rest and NSAIDs may be sufficient. In patients with more persistent or recalcitrant disease, potassium iodide may be helpful. Potassium iodide is contraindicated in pregnant women, should be avoided in renal insufficiency (risk of hyperkalemia), and used cautiously, if at all, in patients with thyroid disease (risk of hyperthyroidism or hypothyroidism). It should be kept in mind that both aspirin and iodides have been reported as both causing and treating EN. A short course of systemic corticosteroids may be helpful if any underlying infectious diseases have been excluded.

DERCUM DISEASE (ADIPOSA DOLOROSA)
Dercum disease is a rare condition of painful lipomas of the skin on the trunk and extremities. It is seen most commonly in obese women between the ages of 35 and 50 years and may be associated with weakness, fatigue, depression, and anxiety. Most cases are sporadic, but familial cases with autosomal dominant inheritance pattern have also been reported. Histologically, one typically finds a lipoma with no distinguishing features from an ordinary lipoma.
**Treatment**

Treatment is often ineffective and short-lasting. The pain in Dercum disease has been characterized as both nociceptive (localized pain in lipomas aggravated by palpation) and neuropathic with allodynia (light touch perceived as painful) so approaches to management similar to other chronic pain syndromes may be beneficial.\(^{147}\)

Weight reduction and analgesics may be helpful. Excision of individual painful tumors may also be helpful, but new painful tumors may continue to appear.\(^{148}\) Liposuction has also been reported to be of benefit.\(^{149,150}\) IV lidocaine may provide pain relief lasting from hours to months.\(^{151–153}\) Corticosteroids have been reported to both cause\(^{154}\) and treat\(^{155}\) Dercum disease. Other treatments with limited evidence include calcium-channel modulators, interferon α-2b, combined infliximab and methotrexate, and rapid cycling hypobaric pressure.\(^{146}\)

**HIDRADENITIS SUPPURATIVA**

HS is a chronic inflammatory follicular-occlusive disease where recurrent painful nodules, abscesses, and sinus tracts involve the intertriginous skin (axillary, inframammary, inguinal, and gluteal folds) (acne inversa, see Fig. 37.11). The incidence has risen over the past decade and disproportionately affects women, young adults, and African Americans.\(^{156}\) HS is associated with comorbidities, including metabolic syndrome, tobacco abuse, polycystic ovarian syndrome, and inflammatory bowel disease. HS may be part of a syndrome-like presentation, such as PAPASH syndrome (pyogenic arthritis, PG, acne, and suppurative hidradenitis) and PASH syndrome (PG, acne, and suppurative hidradenitis). It is also considered to part of the follicular occlusion tetrad, along with acne conglobata, pilonidal sinus, and dissecting cellulitis of the scalp.
Etiology
The etiology of HS is incompletely understood and is felt to be due in part to follicular hyperkeratosis and occlusion leading to rupture and acute suppurative inflammation. Keratinocyte activation and release of proinflammatory mediators also plays a role. The disease usually first appears at puberty, suggesting hormonal factors are contributory. Other factors include genetic susceptibility, mechanical stress, obesity, and smoking. The role of bacteria in pathogenesis is controversial. Antibiotics can be an effective treatment modality; however, the most commonly isolated organisms are commensal bacteria.

Symptoms and Signs
Early on, patients experience recurrent, painful, erythematous nodules that suppurate and eventually breakdown to form sinus tracts and scarring. The sinus tracts may form an extensive interconnecting network in the subcutaneous tissue with multiple openings. The disease process may be circumscribed or more diffuse. Secondary bacterial infection may occur. In addition to being physically painful, the disease may be psychologically debilitating and profoundly impair quality of life, especially in patients with long-standing disease. Squamous cell cancer and amyloidosis are rare complications in patients with chronic HS.

Diagnosis
Initially, the disease appears similar to furuncles or an inflamed epidermal
cyst. However, when the erythematous nodules are recurrent and lead to sinus tracts and retracted scars, the diagnosis becomes clear.

**Treatment**

Treatment is individualized depending on the severity of the disease. Behavioral changes including weight reduction and smoking cessation is advised. Topical clindamycin and cleansing the affected areas with antibacterial soaps such as chlorhexidine may be useful. The U.S. Food and Drug Administration (FDA) has recently issued a warning about rare, but serious, allergic reactions to chlorhexidine.\(^{161}\)

For more limited nodules without sinus tracts, unroofing or intralesional corticosteroids may be beneficial. Incision and drainage is not an effective management strategy, as lesions tend to recur. Systemic antibiotics, such as doxycycline, are often used as initial treatment. The combination of clindamycin and rifampin may be used in patients who do not respond to other antibiotics. Antiandrogenic agents may provide additional benefit.\(^{162}\)

Diffuse involvement with sinus tracts and extensive scarring may require the addition of a biologic agent, such as adalimumab or infliximab. A weekly adalimumab administration has the most robust efficacy data.\(^{163}\)

Surgical interventions may provide relief for severe HS in a localized area that has failed to respond sufficiently to unroofing and medical therapies. Wide excision followed by a graft or healing by secondary intention can have good functional and cosmetic results, although recurrence of disease is possible.\(^{164,165}\) Hair removal by 1064-nm Nd:YAG or intense pulsed light devices can reduce the disease activity in the affected area. Extensive disease has been removed by carbon dioxide (\(\text{CO}_2\)) laser.\(^{166}\)

Pain management can be challenging. Topical analgesics, acetaminophen, and NSAIDs are first line. Additional agents may be required for the neuropathic component and has been reviewed by Horvath et al.\(^{167}\)

**INFLAMED EPIDERMAL CYST**

Epidermal cysts (Fig. 37.12) are very common and typically present after puberty as whitish, sometimes pigmented, well-defined, partially
compressible, subcutaneous nodules with a semisolid feel and often with a pore opening to the surface.\textsuperscript{168,169} They may extrude a thick whitish material with a foul odor through the pore. The cyst wall is stratified squamous epithelium, and the contents are keratin. Most are asymptomatic, but when they are traumatized and rupture into the surrounding tissue, they incite an acute inflammatory reaction that mimics infection with pain, erythema, edema, warmth, and purulence. Initial management consists of hot compresses and incision and drainage. If secondary infection is suspected, culture and sensitivity should be done, and the patient treated an antibiotic effective for \textit{Staphylococcus aureus} and \textit{Streptococcus pyogenes} such as cephalexin or dicloxacillin pending culture results. Once inflammation subsides the residual cyst is excised. Some cysts are destroyed by the inflammation if severe enough.

\textbf{FIGURE 37.12} Epidermal cyst, noninflamed. (Courtesy of University of Washington Dermatology Division.)

Great care should be taken in excising previously inflamed cysts in certain locations because scar tissue may have entrapped important nerves or other structures, for example, the temporal branch of the facial nerve in the temple areas, the spinal accessory nerve in the posterior cervical triangle of the neck, or the parotid duct overlying the masseter muscle on the cheek. In these locations, it may be more prudent to open the cyst, evacuate the contents, and scrape the wall of the cyst with a curette if treatment is felt to be necessary.
Although epidermal cysts typically develop after puberty, an accurate history regarding a particular cyst may not always be available. Cysts that could possibly have been present since birth should be a cause of greater concern especially in certain locations such as the midline of the face, the midline of the scalp, or the midline of the back because they may communicate with the CNS. Should one of these cysts become inflamed or infected, surgery should not be attempted without prior imaging studies such as CT and magnetic resonance imaging (MRI). If a communication is found with the CNS, the surgery needs to be done by a neurosurgeon. Similarly, cysts present at birth on the lateral neck may be branchial cleft cysts that communicate with the pharynx. They may become infected in adult life simulating an inflamed epidermal cyst. Referral to an otolaryngologist is indicated for definitive treatment. Cysts presenting in childhood may be a sign of Gardner’s syndrome, an autosomal dominant condition, associated with multiple benign tumors of the skin, osteomas, intestinal polyposis, and a high risk of colon cancer. Ordinary epidermal cysts have a lining similar to normal epidermis with a granular layer, but cysts with Gardner’s syndrome often have focal areas of pilomatrical differentiation.

**BULLOUS DERMATOSES WITH EROSIONS**

*Stevens-Johnson*/Toxic Epidermal Necrolysis Syndrome

Adverse drug eruptions constitute a large percentage of inpatient hospital consultations for dermatologists. There are numerous types of drug eruptions beyond the scope of this chapter. When evaluating a drug eruption, a complete and thorough history of drug exposure is essential. Over-the-counter medications and dose adjustments should not be missed.

Stevens-Johnson/toxic epidermal necrolysis (SJS/TEN) is a severe, life-threatening mucocutaneous drug eruption that results in painful skin detachment (*Fig. 37.13*). The overall incidence is 1 to 2 cases per million, and mortality has been reported to be up to 30%. Clinically, SJS is defined as less than 10% body surface area (BSA) skin detachment; 10% to 30% BSA skin detachment is SJS/TEN overlap, and greater than 30% BSA is TEN.
Over 100 medications have been reported to cause SJS/TEN. The most common inciting medications are TMP-SMX, allopurinol, nevirapine, lamotrigine, and carbamazepine. SJS/TEN is a delayed-type drug hypersensitivity reaction, with a latency of 4 to 28 days after exposure to the offending medication.

The eruption is preceded by fever and flu-like symptoms. Lesions are initially dusky, irregular, atypical targetoid with necrotic centers that form bullae and desquamate over the ensuing few days. Involvement of at least two mucous membrane sites is present in up to 90% of cases, most frequently the oral mucosa and conjunctiva, and can be very painful. Other mucosal surfaces that may be affected include the esophagus, respiratory tract, and genitourinary. Nikolsky sign (epidermal detachment with lateral pressure on an erythematous zone) may be positive but can be also present in other conditions such as pemphigus vulgaris and staphylococcal scalded skin syndrome. Pain is a distinctive feature of SJS/TEN due to the skin detachment and may not be seen in other uncomplicated, exanthematous drug eruptions. The mean duration from the onset of symptoms to
maximum detachment is 8 days.

The differential includes other blistering skin conditions, including bullous pemphigoid, pemphigus vulgaris, linear IgA bullous dermatosis, bullous erythema multiforme, and graft-versus-host disease. Histologically, there is a lymphocytic infiltrate at the dermoepidermal junction with epidermal necrosis that may be full thickness.

**Pathogenesis:** Keratinocyte necrosis occurs through multiple mechanisms. The culprit drug may act as a foreign antigen, recognized by T cell receptors to activate adaptive immune responses. Activated cytotoxic T cells and natural killer cells produce factors that induce keratinocyte death, including granulysin, perforin, and granzyme B. Apoptosis is induced by the soluble Fas ligand binding to the death receptor Fas/CD95. There is a strong association between HLA-B*1502 and the development of carbamazepine-induced SJS/TEN in the Han Chinese population but not in other races, and the FDA has recommended genotyping all Asian patients prior to initiation of carbamazepine therapy.\textsuperscript{172}

**Treatment:** After prompt withdrawal of the offending drug, supportive care is paramount and management is similar to care for an extensive burn. Patients require burn critical care unit care, and coordination across multiple specialty services including ophthalmology, gynecology, and urology. Due to extensive cutaneous disruption, patients are at risk for fluid and electrolyte loss, increased caloric needs, and secondary bacterial infection. SCORTEN is a severity-of-illness score composed of seven variables that predict outcome, and its utility has been confirmed by several studies.\textsuperscript{171}

The use of systemic medications is controversial, and the evidence is mixed. IVIg and systemic corticosteroids have been used; however, systematic reviews do not show a mortality benefit,\textsuperscript{172} and use of systemic steroids can increase risk of sepsis. Re-epithelialization occurs over 3 weeks. The most common sequelae are visual impairment due to ocular scarring and skin dyspigmentation. Bronchiolitis obliterans, urogenital adhesions, and posttraumatic stress disorder are also reported.\textsuperscript{173}

**Pemphigus Vulgaris**
Pemphigus vulgaris is a rare, autoimmune disorder and the most frequent member of a group of disorders referred to as pemphigus. Other members of the group include pemphigus foliaceous, pemphigus vegetans, pemphigus erythematous, and paraneoplastic pemphigus.

Pemphigus vulgaris usually presents with painful blisters and nonhealing erosions in the mouth that eventually spread to the skin producing flaccid blisters and bullae followed by oozing, crusted, painful erosions.\textsuperscript{174,175} Lateral pressure on the skin adjacent to a bullous lesion causes the epidermis to shear and detach (Nikolsky sign). Uncommonly, patients may have an associated thymoma or myasthenia gravis. Drug-induced pemphigus has been reported with a variety of medications including penicillamine, rifampicin, captopril, enalapril, penicillin, and other drugs.\textsuperscript{174,176} The bullae and blisters are caused by autoantibodies to desmosomal cadherin adhesion molecules, either desmoglein 3 with isolated mucosal pemphigus vulgaris, or desmoglein 3 plus desmoglein 1 with mucocutaneous pemphigus vulgaris, whereas patients with pemphigus foliaceous have antibodies to desmoglein 1 only.\textsuperscript{175} This leads to detachment of cells from one another (acantholysis) that is seen histologically as a suprabasilar split in the epidermis (suprabasilar acantholysis) in pemphigus vulgaris and subcorneal acantholysis in pemphigus foliaceous. The autoantibodies can be detected by direct immunofluorescence of perilesional skin producing a netlike pattern on the surface of keratinocytes. Circulating autoantibodies are commonly present and detected by indirect immunofluorescence or enzyme-linked immunosorbent assay (ELISA) for antibodies to desmoglein 3 and desmoglein 1. Titers of circulating autoantibodies may correlate with disease activity, and declining levels may predict progression from the active phase of disease to early remission.\textsuperscript{177}

**Treatment:** The mainstay of treatment of pemphigus vulgaris are systemic corticosteroids.\textsuperscript{174} A steroid-sparing agent is then typically added, usually azathioprine or mycophenolate mofetil. Pulse steroids and plasmapheresis with and without cyclophosphamide are other treatments that have been used. Rituximab has emerged as a treatment for recalcitrant cases and as a potential first-line adjuvant treatment. A combination of systemic corticosteroids and rituximab as first-line treatment was more
effective than steroids alone in recent studies.\textsuperscript{178,179} Patients need close monitoring for complications of therapy and preventive measures when possible (e.g., measures to prevent osteoporosis related to chronic corticosteroid use). Topical therapy and supportive measures for mucous membrane and cutaneous involvement are also needed.

\textbf{Paraneoplastic Pemphigus}

Paraneoplastic pemphigus is associated with benign and malignant neoplasms, most commonly lymphoproliferative disorders. It causes a painful stomatitis similar to pemphigus vulgaris but a more polymorphic eruption on the skin.\textsuperscript{180} The skin eruption may have features resembling pemphigus vulgaris, bullous pemphigoid, erythema multiforme, or a lichen planus-like (lichenoid) appearance. The polymorphic clinical pattern is reflected in the histology where one sees suprabasilar acantholysis, keratinocyte necrosis, and interface dermatitis. Direct immunofluorescence demonstrates IgG and C3 in a netlike pattern on keratinocytes similar to pemphigus vulgaris and less frequently a linear pattern along the basement membrane. Circulating autoantibodies detected by immunoprecipitation recognize desmoplakins, most commonly envoplakin and periplakin.\textsuperscript{181} Paraneoplastic pemphigus is most frequently associated with non-Hodgkin lymphoma, followed by chronic lymphocytic leukemia, Castleman’s disease, thymoma, Waldenström’s macroglobulinemia, Hodgkin lymphoma, and monoclonal gammopathy. Mortality ranges from 51\% to 90\%, with most patients dying from sepsis, respiratory failure, or the underlying malignancy.\textsuperscript{182,183}

\textbf{Treatment:} Treatment of paraneoplastic pemphigus involves treating the underlying tumor, which in some cases may clear the eruption but is less likely to if the tumor is malignant.\textsuperscript{180} Variable response has been reported with prednisone alone or combined with other immunosuppressive agents.\textsuperscript{182}

\textbf{Bullous Pemphigoid}

Bullous pemphigoid (Fig. 37.14) is the most common autoimmune subepidermal bullous disease and typically affects elderly patients. Other pemphigoids, including mucous membrane pemphigoid, pemphigoid
gestationis, and anti-p200 pemphigoid, are beyond the scope of this chapter. Tense bullae develop on normal or erythematous skin, commonly distributed on the lower abdomen, axillae, groin, and flexor extremities. Transient oral lesions may also appear. Itch is common and may be severe, and erosions can be painful after of bullae. Peripheral blood eosinophilia is often an associated finding. Most cases of bullous pemphigoid are idiopathic, but exposure to certain systemic medications may play a role in the development of BP, including diuretics, antibiotics, analgesics, and others.

Histologically, one finds a subepidermal bullous lesion with varying degrees of cellular infiltrate, often with eosinophils. Direct immunofluorescence demonstrates IgG and C3 in a smooth linear pattern at the epidermal basement membrane. Two bullous pemphigoid antigens have been identified associated with the hemidesmosomal plaques at the dermal–epidermal junction. Bullous pemphigoid antigen 1 (230 kD) is an intracellular antigen, and bullous pemphigoid antigen 2 (180 kD) is a transmembrane protein. ELISA detects BP180 autoantibodies in 72% to 93% of cases.

**Treatment:** Milder cases of bullous pemphigoid or localized bullous disease may respond to high-potency topical steroids alone. Tetracycline or erythromycin 500 mg four times per day plus nicotinamide or dapsone
may also be considered in patients with more severe disease who are not good candidates for treatment with systemic corticosteroids or as adjunctive treatment with systemic steroids.

Most patients with moderate to severe, generalized bullous pemphigoid are treated with prednisone, and a steroid-sparing agent is added if needed. Azathioprine or mycophenolate mofetil are used most commonly. For patient with severe or extensive disease, total body applications of clobetasol 0.05% cream twice daily was shown to be superior to prednisone 1 mg/kg/day in terms of effectiveness and survival in one study. IVIg and rituximab has been used in refractory disease.

Epidermolysis Bullosa

Epidermolysis bullosa refers to a group of rare disorders that may be inherited or acquired. They all exhibit abnormal skin and sometimes mucous membrane fragility with minor trauma leading to blister formation, painful erosions, and, in some cases, scarring. Scarring may manifest as milia or dystrophic nails or, in more severe cases, as pseudosyndactyly, esophageal strictures, and conjunctival scarring.

The different types of epidermolysis bullosa are differentiated from one another on the basis of whether they are inherited or acquired; the inheritance pattern; level of split within, below, or at the junction of the epidermis and dermis; distribution and severity of skin and mucous membrane involvement; scarring or nonscarring; and the affected protein and mutated gene. Determining the level of the split within, below, or at the junction of the epidermis and dermis is an important part of the initial evaluation of the patient. This may be done with electron microscopy or immunofluorescent mapping with antibodies such as those to type VII collagen, laminin, or bullous pemphigoid antigen. The inherited forms of epidermolysis bullosa demonstrate little if any inflammation on biopsy, whereas the acquired form, epidermolysis bullosa acquisita (EBA), may have an intense inflammatory infiltrate. In EBA, autoantibodies are bound in the basement membrane zone that is localized to the floor of the blister when detected by immunofluorescence on salt split skin. EBA can be associated with other diseases, such as malignancies, amyloidosis, diabetes, inflammatory bowel disease, SLE, and other autoimmune
disorders; thus, workup of the patient for an underlying disease is indicated.\textsuperscript{188,190,193}

**Pathogenesis:** Ultrastructural, immunohistochemical, and molecular biologic techniques have enabled the identification of affected proteins, point mutations, and corresponding ultrastructural findings in the inherited forms of epidermolysis bullosa.\textsuperscript{192} For example, mutations in the keratins 5 and 14 are responsible for epidermolysis bullosa simplex, mutations in laminin 5 occur in junctional epidermolysis bullosa, and mutations in type VII collagen occur in dystrophic epidermolysis bullosa.\textsuperscript{191} EBA is an autoimmune disease with autoantibodies against type VII collagen leading to loss of or diminution of anchoring fibrils in the papillary dermis similar to the dystrophic epidermolysis bullosa phenotype.\textsuperscript{189}

**Treatment:** Avoidance of friction, pressure, trauma, and heat to skin and mucous membranes are important in the management of epidermolysis bullosa. Pain control, emollients, nutritional support, drainage of larger bullae, topical antibiotics, and nonadherent skin dressings are also important.\textsuperscript{194} Some patients with the severest forms of the disease may need surgical correction of pseudosyndactyly, esophageal dilation for stricture, ophthalmologic care for scarring, dental care, and monitoring for renal complications and complicating squamous cell cancer of the skin.\textsuperscript{194} Genetic counseling is also needed with the inherited forms of the disease. Novel molecular and pharmacologic approaches are being investigated, such as cell-based therapies, bone marrow transplantation, and gene therapy.\textsuperscript{195}

EBA is difficult to treat with no controlled studies and poor or variable response to a variety of agents. Dapsone and colchicine are usually first line, followed by systemic corticosteroids and steroid-sparing agents (azathioprine and mycophenolate mofetil). IVIg and rituximab have been used in refractory cases.\textsuperscript{196,197}

**Disorders of Connective Tissue Structure (Cartilage Disorders)**

**RELAPSING POLYCHONDHRITIS**

Relapsing polychondritis (RP) is a rare, potentially life-threatening,
episodic systemic autoimmune inflammatory disease affecting cartilage containing structures (e.g., ears, nose, joints and respiratory tract) and proteoglycan-rich tissues (e.g., eyes, inner ear, cardiovascular system and kidneys). Recurrent episodes of pain, erythema, and swelling of the ears are the most common feature of the disease. The earlobe is spared, and eventually, the ears may become “floppy” or have a “cauliflower-like” appearance as the cartilage is destroyed. Nasal chondritis may lead to a saddle nose deformity over time, sometimes without clinically apparent inflammation. Ocular inflammation is common and may simulate cellulitis. Other features of the disease include nonerosive polyarthritis, laryngotracheal and bronchial chondritis, cardiovascular disease, and renal disease. The most common cause of death is infection, usually pneumonia, in which airway collapse or steroid therapy may play a role. Associated diseases are not uncommon in RP, including myelodysplasia, Sweet’s syndrome, and an underlying malignancy. Autoantibodies to type II collagen, matrilin-I, and circulating immune complexes have been found in RP, suggesting an autoimmune pathogenesis. Trauma and the HLA-DR4 haplotype may also play a role.

Cutaneous manifestations have been reported in up to 37% of patients. Purpura, aphthosis, and EN-like nodules of the lower extremities were the most common manifestations. Other reported cutaneous features of RP include urticaria, livedo reticularis, superficial thrombophlebitis, ulcers, pustules, and distal necrosis. Cutaneous manifestations were noted in 91% of patients with associated myelodysplasia. Different sets of revised diagnostic criteria are available in the references.

**Treatment**
Milder cases of RP may respond to dapsone, colchicine, or NSAIDs. Acute flares and more serious involvement of vital structures are usually treated with systemic corticosteroids and sometimes cyclophosphamide. Adjunctive steroid-sparing agents are added if needed, including azathioprine, methotrexate, or cyclosporine. Methotrexate was found to be the most effective in the series reported by Trentham and Le. Other agents that have been used include tumor necrosis factor-α antagonists, tocilizumab, and abatacept.
Surgery and other intervention may be needed for complications of the disease including tracheostomy, cardiac valve replacement, aortic aneurysm repair, and placement of a cardiac pacemaker for conduction disturbances.\textsuperscript{198,199} Survival has improved over time with a 94\% survival in patients who have had their disease on average 8 years.\textsuperscript{204}

**CHONDRODERMATITIS NODULARIS HELICIS**

Chondrodermatitis nodularis helicis (CNH) is a common painful disorder where tender papules occur on the rim of the helix or the antihelix of the external ear. The papules may have scaling, crusting, or ulceration suggesting the diagnosis of squamous cell cancer or basal cell cancer. Biopsy should be performed if the diagnosis is in doubt. Histopathologic features may include ulceration with exudate, epidermal hyperplasia, fibrinoid dermal necrosis, mixed inflammatory cell infiltrate, thickening of the perichondrium, and degeneration of cartilage.\textsuperscript{206} Neural hyperplasia has also been observed on occasion which has been suggested might explain the induction of pain by light pressure.\textsuperscript{207} The pathogenesis remains unclear, but chronic pressure may lead to ischemia of the underlying cartilage.

Various treatments have been used employed with different degrees of success and recurrence rates. Pressure relief, surgical excision techniques, and topical nitroglycerin are among the most effective. If the patient sleeps habitually on one side, a pillow with a hole in it or self-adherent foam padding behind the ear may be helpful in relieving symptoms.\textsuperscript{208}

**Neurovascular Cutaneous Disease**

**SENSORY MONONEUROPATHIES**

Further information on painful neuropathies can be found in Chapter 24. Sensory mononeuropathies are not uncommon and may affect the head, trunk, and extremities. They may manifest themselves as numbness, burning, itching, hyperesthesias, and frequently pain.\textsuperscript{209} Among the more common are cheiralgia paresthetica (superficial branch of the radial nerve), meralgia paresthetica (lateral femoral cutaneous nerve), notalgia paresthetica (dorsal rami of T2–T6), and gonyalgia paresthetica
(infrapatellar branch of the saphenous nerve). A less common but important neuropathy to be aware of is mental nerve neuropathy, which presents as unilateral numbness of the chin and lower lip (numb chin syndrome).\textsuperscript{209-211} It is usually associated with malignancy, most commonly breast cancer or lymphoma, so thorough evaluation is needed.\textsuperscript{210}

Notalgia paresthetica is a sensory neuropathy affecting the posterior rami of T2–T6. Patients usually complain of itch and less commonly pain, paresthesias, and hyperesthesia in a unilateral localized area on the upper back medial to the scapula.\textsuperscript{212} Findings on examination may include hyperpigmentation and hypoesthesia.\textsuperscript{209,213} Electromyographic evaluation may show evidence of paraspinal denervation in some cases.\textsuperscript{214} In a study of 43 patients, 60.7% were found to have radiographic abnormalities of the spine corresponding to the nerves involved suggesting impingement of spinal nerves.\textsuperscript{212} Massey\textsuperscript{209} postulated the posterior rami of T2–T6 are subject to trauma because they traverse the multifidus spinal muscle at a right-angle course. A hereditary variant of notalgia paresthetica has been described and has also been reported in multiple endocrine neoplasia type 2 (MEN2A) syndrome.\textsuperscript{213} Histologically, one may find postinflammatory hyperpigmentation, lichenification, and, in some cases, macular amyloidosis possibly related to excoriation.\textsuperscript{215}

**Treatment**

Treatment of notalgia paresthetica and other sensory neuropathies has met with variable success with such agents as topical anesthetics, capsaicin, gabapentin, and amitriptyline.\textsuperscript{216}

Oxcarbazepine (a derivative of the anticonvulsant carbamazepine with a better side effect profile) was reported to be partially effective in 3 of 5 patients treated with the medication.\textsuperscript{217} A paravertebral block using a combination of bupivacaine and methylprednisolone led to complete resolution of symptoms for at least 1 year in one patient.\textsuperscript{213} Gabapentin in a dose of 600 mg per day provided complete relief of symptoms in one patient with notalgia paresthetica.\textsuperscript{218}

**ERYTHROMELALGIA**
Erythromelalgia is a rare acquired or hereditary (primary) condition characterized by hyperthermia, redness, and burning pain, usually of the extremities. The primary form is inherited in an autosomal dominant manner and is caused by a mutation in SCN9A, which encodes a sodium channel protein subunit in sympathetic and nociceptive sensory neurons of the dorsal root ganglion.

The feet are most frequently affected, followed by the upper extremities and face. The symptoms are usually symmetric, intermittent, and exacerbated by heat exposure and dependency and relieved by cold exposure and elevation. The pain can be debilitating and significantly impair quality of life. Erythromelalgia may be associated with an underlying myeloproliferative or autoimmune disorder. Acrocyanosis, ulcers, and even gangrene can develop, which is secondary to injury from excessive exposure to cold water in efforts to obtain relief.

The differential diagnosis includes reflex sympathetic dystrophy (also termed complex regional pain syndrome type 1, covered in Chapter 25), peripheral vascular disease, neuropathy, cellulitis, Fabry’s disease (FD), Raynaud’s phenomenon, and lipodermatosclerosis. Evaluation should include a CBC to exclude a myeloproliferative disorder.

Treatment is challenging, as erythromelalgia can often be refractory. Patients are advised to avoid excessive ambient heat, prolonged standing, and strenuous exercise. Cooling the affected area, such as with short, intermittent exposure to cool water, may be helpful; however, careful attention must be paid to avoiding prolonged exposure and subsequent cold injury. Topical therapy with compounded amitriptyline and ketamine cream has been reported to improve pain. Systemic medications that have been used include aspirin (particularly for patients with underlying myeloproliferative disease), NSAIDs, gabapentin, β-blockers, sodium nitroprusside, misoprostol, topical or IV analgesics, carbamazepine, and antidepressants.

**FABRY’S DISEASE**

FD (also known as Anderson-Fabry disease) is a rare X-linked recessive lysosomal storage disease caused by deficiency of the enzyme α-galactosidase A, leading to accumulation of globotriaosylceramide in
lysosomes in the endothelium, vascular smooth muscle cells, autonomic and dorsal root ganglia, renal cells, cardiac conduction fibers, and other cell types. Deposition within these cells leads to its various symptoms, including vascular occlusions that lead to ischemia, infarction, and pain.

**Symptoms and Signs**

Angiokeratomas are the characteristic skin lesion of FD that occurs in a pattern referred to as angiokeratoma corporis diffusum (ACD) to distinguish them from other variants of angiokeratomas not associated with FD such as isolated angiokeratomas. Individual angiokeratomas are reddish-blue to black, 3- to 4-mm papules that may be scaly, hyperkeratotic, or verrucous. In ACD, they are usually distributed between the umbilicus and the knees but may be widespread and affect mucous membranes as well.

Hypohidrosis with heat intolerance, peripheral edema, and asymptomatic eye findings are other features of the disease. Female carriers in general may be asymptomatic, have mild disease, or rarely severe disease manifestations. Episodic painful acroparesthesias, due to small fiber neuropathy of the hands and feet, may be the first manifestation of the disease. Acute attacks of abdominal pain may occur, simulating an acute abdomen. The most serious complications of the disease relate to involvement of the kidneys, heart, and CNS. Untreated patients typically develop end-stage renal disease by the fifth decade.

Histologically, ACD demonstrates dilated vessels in the papillary dermis with epidermal hyperplasia or acanthosis. The abnormal lipid in the endothelial cells may be detected with a lipid stain or periodic acid-Schiff stain. Examination of the urine with polarized light may show birefringent glycosphingolipids in cells with a Maltese cross appearance.

Molecular genetic testing confirms the diagnosis, and genetic counseling should be offered to potentially affected family members.

**Treatment**

Enzyme replacement therapy (ERT) with recombinant α-galactosidase A (agalsidase β, Fabrazyme, Genzyme Corp., Cambridge, MA) should be initiated as soon as possible in males with low levels of alpha-Gal-A, even
if they are asymptomatic, and female carriers with clinical manifestations. ERT has been associated with improvement of neuropathic pain, relief of gastrointestinal symptoms, and stabilization of renal function and cardiomyopathy. Benefits are more limited in patients who already have advanced renal disease.\textsuperscript{225,226}

There is no need to treat the angiokeratomas unless they are symptomatic, which can be done with a variety of local destructive methods such as laser or liquid nitrogen. The angiokeratomas have not been found to be a useful surrogate marker to follow disease activity with ERT.\textsuperscript{227} There is some evidence for the efficacy of carbamazepine, phenytoin, and gabapentin for the treatment of neuropathic pain associated with FD.\textsuperscript{228}

Other Painful Dermatologic Disorders

**CUTANEOUS ENDOMETRIOSIS**

Cutaneous endometriosis is a rare condition that may cause tender nodules in the skin.\textsuperscript{229,230} They occur most frequently within surgical scars (e.g., cesarean section, episiotomy scars, or appendectomy scars) but also may occur as primary cutaneous endometriosis in which case they usually affect the umbilical area. Tenderness and bleeding may occur at times of menstruation. The histologic appearance may correspond to different stages in the menstrual cycle, but in general, there is a poor correlation between histologic appearance and the menstrual stage.\textsuperscript{231} The range of histologic findings in cutaneous endometriosis has been reviewed.\textsuperscript{232} Wide local excision usually suffices for treatment and recurrence is rare, but referral for gynecologic evaluation is also appropriate.\textsuperscript{230,233}

**PAINFUL NEOPLASMS**

Both benign and malignant neoplasms may sometimes be painful because of ulceration, location on the body where they are repeatedly traumatized, or on pressure-bearing surfaces such as the soles of the feet. Certain benign neoplasms are characteristically painful and bring to mind a differential diagnosis that has been reported under the mnemonic acronym “ANGEL” for angiolipoma (also angioleiomyoma), neurilemmoma,
glomus tumor (Fig. 37.15), eccrine spiradenoma, and leiomyoma (Fig. 37.16). These tumors are all true neoplasms where pain is a characteristic feature. They are listed in Table 37.2 with their comparative features. Treatment when needed consists of complete excision, which is usually curative.

**FIGURE 37.15** Subungual glomus tumor. (Courtesy of University of Washington Dermatology Division.)
Leiomyomas are deserving of further discussion because of their association with Reed’s syndrome, characterized by hereditary leiomyomatosis and renal cell cancer.\textsuperscript{234,235} This is an autosomal dominant condition due to mutations in the enzyme fumarate hydratase that is associated with cutaneous leiomyomas, leiomyosarcoma (rarely), uterine fibroids (leiomyomas), and renal cell cancer. Most patients have multiple cutaneous leiomyomas, but even a single leiomyoma may be a marker for the syndrome. When a patient with a cutaneous leiomyoma is encountered, a history should be taken for any personal or family history of cutaneous leiomyomas, uterine fibroids, early hysterectomy, and renal cell cancer.\textsuperscript{235} If the history is suggestive, imaging studies of the kidneys and testing for fumarate hydratase mutations is indicated, along with lifetime surveillance and examination of relatives if studies confirm the diagnosis.

**ACKNOWLEDGMENTS**

The authors wish to acknowledge the contributions of Dr. George F. Odland to this chapter. He was the original primary author, and many of his touches and words remain part of the fabric of the chapter.

Pain in one form or another is a frequent manifestation of arterial, venous, or lymphatic problems. The nature and location of pain complaints may be virtually diagnostic of the underlying vascular condition. On the other hand, pain arising from nonvascular conditions may mimic that associated with various vascular conditions, thereby delaying or complicating diagnosis and therapy. This chapter explores the mechanisms and pathophysiology of vascular pain and its relief; it emphasizes basic neuroanatomy and neurophysiology relevant to vascular pain and includes a compilation of different vascular pain syndromes.

Because pain is a frequent presenting feature of vascular disease and its therapy, topics covered herein necessarily share an interface with numerous other chapters in this text. Information provided in this chapter is, however, intended to be supplementary or expansive on material elsewhere rather than duplicative. For more detailed discussions of vascular pain, the reader is referred to comprehensive sources on this subject.¹⁻⁴

**Basic Neuroanatomic and Neurophysiologic Considerations**

A review of the neuroanatomy and neurophysiology of vascular structures and the organs and parts they serve helps inform an understanding of the way vascular disease results in pain. This is further clarified by an understanding of how pain is stimulated peripherally and transmitted and experienced centrally.

The International Association for the Study of Pain defines pain as “an unpleasant sensory and emotional experience associated with actual or
potential tissue damage, or described in terms of such damage.”

The perception of pain is a consequence of many variables including past and current pain experiences, level of consciousness, and the patient’s emotional state.

Nociceptive pain is an uncomfortable sensation associated with injurious stimulation, whereas neuropathic pain arises in the absence of such injury. From a teleologic perspective, pain’s “purpose” is to signal the presence of (and presumably prevent) tissue damage and, thus, exists as one aspect of homeostasis. Only when it becomes chronic, or is a manifestation of the postoperative state, is pain unhelpful.

Pain can be characterized by its location, duration, quality, and severity or intensity. Qualities of pain include the descriptive terms “aching,” “burning,” “cramping,” “radiating,” “sharp,” or “dull.” Focal pain is noted at the site of injury, whereas diffuse pain is more characteristic of deep structures.

Radicular pain radiates along peripheral nerve pathways, not uncommonly in concert with motor or sensory neurologic deficits. Referred pain is perceived at a site remote from where the noxious stimulation is actually occurring and results from a misplaced cortical appreciation of pain. Referred pain generally follows spinal segmental innervation and must be differentiated from radicular pain, which generally follows specific dermatomal distributions. Visceral pain is dull, aching, and has an agonizing, “sickening” component.

Pain can result from numerous physical stimuli including pressure, puncture, squeeze, tension, and extreme heat or cold. Pain can also result from chemical effects such as those resulting from a marked change in pH or the presence of various mediators—histamine-like materials, serotonin, bradykinin, and other similar polypeptides. Endogenous prostanoids can lower the pain threshold as a consequence of certain stimuli; local acidosis can enhance perception of pain. Local mediators such as substance P are released at sites of injury and the neural stimulation which results can be interpreted as pain.

Nociceptive receptors are usually free nerve endings, and pain is transmitted from them in the small unmyelinated A-delta and C nerve fibers. These afferent nerves’ cell bodies are located in the dorsal root
ganglia, and their axons enter the spinal cord through the dorsal roots. These axons synapse in the dorsal grey of the cord with second-order neurons. Most pain is transmitted centrally via the crossed lateral spinothalamic tract up the cord to third-order neurons in the thalamus. The spinothalamic tract, including the periaqueductal grey region of the brainstem, is relevant to more diffuse, longer lasting pain and, probably, neuropathic pain. Interestingly, the precise central nervous system (CNS) location for pain perception remains obscure.

Large- and medium-sized arteries have two types of innervation: afferent (sensory) nerves and autonomic (sympathetic) nerves. Pain is the primary sensation transmitted via nociceptive afferents in arteries and veins; position, temperature, and other such sensations do not appear to be transmitted via the innervation of blood vessels. In large- and medium-sized arteries, these receptors appear to be stimulated by direct trauma (e.g., an arteriography needle), stretch (as noted with balloon dilatation or stent placement), or shear (as in arterial dissection).

Nociception in large- and medium-sized veins is due to pain receptors in the venous adventitia which appear to respond primarily to stretch (as in venous distention or engorgement, perhaps the consequence of downstream thrombosis or other obstruction).

Classic neuroanatomic investigations by Pick demonstrated that sympathetic and sensory fibers enter the arterial (and venous) adventitia to form an intrinsic neural network (“adventitial plexus”), mostly composed of sensory afferents. From this plexus, bundles of nonmyelinated fibers (mostly sympathetic) approach the media (“border plexus”), and extensions of this network ramify within the media (“muscular plexus”).

The basis for neuropathic pain, and how it is sustained, remain obscure. Neuropathic pain also appears to be transmitted by sensory afferents, but, unlike nociceptive pain, it has autonomic (sympathetic nerve) components as well. This results in the well-established (although poorly understood) role of sympathetic modulation for neuropathic pain by pharmacologic or anesthetic blockade or by sympathectomy. Recognition, diagnosis, and management of various forms of sympathetically mediated or sympathetically sustained pain (formerly termed causalgia or reflex sympathetic dystrophy [RSD] but now subsumed, by fiat of expert panels,
under the umbrella term complex regional pain syndrome (CRPS)) is discussed in detail in Chapter 25.

Most nociceptive pain is relieved when the underlying noxious stimulus is resolved. On occasion, the presence or severity of nociceptive pain warrants consideration of more invasive procedures to effect pain relief. Analysis of these procedures’ results, both in the near term and chronically, has provided substantial insight into the way peripheral pain is transmitted and appreciated.

**Vascular Pain Syndromes**

Pain in one form or another is a common manifestation of various vascular disorders, and the location, quality, and natural history of such pain may be crucial to the diagnosis or treatment of the condition. For example, sudden tearing interscapular pain is virtually diagnostic of an acute type B thoracic aortic dissection; mitigation of this pain is a hallmark of satisfactory “medical” management of this condition by means of antihypertensive therapy with β-blockers. A compendium of the types of pain associated with various arterial, venous, and lymphatic conditions follows.

**INTERMITTENT CLAUDICATION**

Claudication is one of the most common pain complaints seen by vascular specialists. The pathophysiology of arterial claudication is based on a reduction of arterial perfusion to a degree that is inadequate to meet the needs of working muscles. The most common cause is arterial occlusive disease due to generalized atherosclerosis, and the most common sites are shown in Figure 38.1. The clinical phenomenon is not only seen most commonly in the gastrocnemius/soleus muscle group distal to atherosclerotic occlusion of the superficial femoral artery but can also be seen in more proximal thigh muscle groups with aortoiliac occlusive disease or in the upper extremities with chronic brachiocephalic arterial stenoses or occlusion (Fig. 38.2). Rarely, patients may note claudication of the gluteal or lumbar paraspinal muscles in association with pelvic arterial insufficiency. Claudication of the muscles of mastication is almost diagnostic of involvement of the external carotid artery by giant cell
FIGURE 38.1 The most common sites for atherosclerotic occlusive arterial disease in peripheral arteries. The extent, degree, and pattern of the obstructive lesion vary considerably at each site.
FIGURE 38.2 Sites of pain (radiating lines) caused by atherosclerotic occlusive arterial disease in different parts of the arteries of the lower limbs. A: Obstruction in the right common iliac artery, which produces pain in the right hip, buttock, thigh, and calf. B: Obstruction in both common iliac arteries and the lower aorta, which produces pain in both hips, buttocks, thighs, and calves—the so-called “Leriche syndrome.” C: Obstruction of the superficial femoral artery, which produces severe and incapacitating intermittent pain in the calf. D: Obstruction of the popliteal and tibial arteries (and dorsal pedal arterial arch) produces pain in the foot. This foot pain can occur at rest in the distal part of the foot when the patient lies in bed (E) and the rest pain is often relieved when the limb is dependent (F).

The quality and pattern of the pain associated with intermittent claudication is stereotypical. It is absent at rest but appears following muscle exertion of a specific amount, disappearing quickly following
cessation of exercise. That the phenomenon is a consequence of inadequate perfusion to working muscles is demonstrated by the parallel course of the development of symptoms and the decline in skeletal muscle perfusion as measured by Doppler arterial pressure ankle/arm indices (AAIs—or ankle/brachial indices, ABIs) during treadmill walking and by symmetrical improvement in symptoms and AAI when treadmill walking is halted (Fig. 38.3).

**FIGURE 38.3** A: Mean ankle–arm indices (ankle systolic blood pressure divided by arm [brachial] systolic blood pressure) at rest and after exercise in normal subjects and subjects with atherosclerotic occlusive disease. The location of the occlusion is indicated by the letters: P, popliteal artery below the knee; SF, superficial femoral artery; AI, aorta and iliac arteries; ML, multilevel. B: Ankle pressure and calf blood flow before and after exercise in a patient with occlusion of the iliac, common femoral, and superficial femoral arteries. This patient had severe claudication and moderate rest pain. BP, blood pressure. (Modified from Sumner DS. Practical approach to vascular laboratory testing in occlusive arterial disease. In: Rutherford RB, ed. Vascular Surgery. 2nd ed. Philadelphia: WB Saunders; 1984:45–56. Copyright © 1984 Elsevier. With permission.)

The pain associated with the claudication of arterial insufficiency is localized to the working muscles and is characterized as “burning,” “cramping,” or “aching.” The muscles are not particularly tender, and because basal blood supply is adequate, no distal trophic lesions occur. At the cellular level, claudication pain likely results from a combination of ischemic neuropathy (particularly of small unmyelinated Aδ and C sensory fibers) and a localized lactic acidosis resulting from the anaerobic metabolism of ischemia, perhaps heightened by elaboration of substance P.

Several types of intermittent pseudoclaudication exist and contribute to an important differential diagnosis among patients presenting with walking-related extremity pain. The most important and commonly seen of
these alternative diagnoses is that of neurogenic claudication, resulting from one form or another of lumbosacral neuropsopinal compression syndrome—spinal stenosis, herniated disk, arachnoiditis, spondylolisthesis, and the like. Initially, such patients’ complaints may appear to be very similar to those of subjects with arterial insufficiency, to the extent that they are occasionally subjected to surgical revascularization when they actually need a laminectomy (or vice versa).

Fortunately, a careful history will frequently solve this diagnostic conundrum. Because the basis for neurogenic claudication involves compression of nerve roots by a diffuse fibrotic or inflammatory process in the region of the lower spinal cord or the cauda equina, neurogenic claudication is more commonly bilateral than that associated with arterial insufficiency. Furthermore, the pain of neurogenic claudication is more diffuse, frequently extending from buttocks to feet, and often has a deeper, more aching or burning quality, not infrequently associated with distal paresthesias or numbness.

The subject with neurogenic claudication frequently finds relief from his or her steadily worsening symptoms by bending over while walking; when hip and leg pain forces the subject to halt, symptom relief commonly results only with sitting. Unlike the individual with arterial claudication who can walk the same distance on the level or on the treadmill over and over again with equal interspersed rest periods, the individual with neurogenic claudication who attempts to walk very far achieves shorter and shorter walking distances at the expense of longer and longer periods of sitting. Neurospinal compression may result in pain or numbness just with standing, once again and relieved by sitting.

The pain of neurogenic claudication is felt to result from both ischemia and reactive swelling of nerve roots at their site of compression, an impression confirmed by studies utilizing intrathecal fiber optic endoscopy during treadmill walking in patients with neurogenic claudication. Temporary relief of the pain of neurogenic claudication by various postural changes such as sitting appears to result from the fact that flexion of the hip and back relieves lumbosacral nerve root “stretch” and allows decongestion of the epidural veins in the region.

Substantial diagnostic confusion can result from the fact that older
patients with lower extremity claudication may have both atherosclerotic arterial occlusive disease and degenerative lumbosacral spine disease. Minimal or no change in Doppler AAI in the presence of development of lower extremity symptoms during treadmill exercise excludes arterial occlusive disease as a cause of the patient’s lower extremity symptoms. Other much less common causes of intermittent claudication include the following: proximal venous occlusive disease of the lower extremities, resulting in a characteristic sense of “bursting” discomfort and engorgement of the exercising extremity (“venous claudication”)\(^\text{10}\) as well as various forms of myositis, the most common of which is an iatrogenic muscle inflammation and necrosis which results from the administration of various statin medications to treat hyperlipidemia.\(^\text{11}\)

Lower extremity claudication in younger individuals should bring to mind two diagnoses—popliteal entrapment syndrome and (when exercise-induced pain is localized to the anterolateral aspect of the leg) chronic compartment syndrome. The intermittent claudication seen in young people (often athletes or military recruits) associated with popliteal artery entrapment syndrome (Fig. 38.4) has the same pathophysiologic mechanism as that associated with atherosclerotic lower extremity arterial occlusive disease.\(^\text{12}\) The cellular basis for the anterior muscle compartment pain associated with chronic compartment syndrome is ischemia resulting from diminution of the intramuscular arteriovenous pressure differential due to venous congestion and compartment tissue hypertension.\(^\text{13}\)

**FIGURE 38.4**  
A: The normal relationship of the popliteal artery and the two heads of the gastrocnemius muscle. B: The most common anomaly, which causes popliteal artery entrapment syndrome. The popliteal artery is looped medially around and then under the medial head of the
gastrocnemius. The medial hamstring muscles have been retracted for clarity. During strenuous exercise of the leg, the muscle compresses the artery, with consequent ischemia and intermittent claudication.

AORTIC AND OTHER LARGE ARTERY PAIN
A substantial number of pain receptors populate the media of large- and medium-sized arteries. As noted previously, these receptors can respond to direct stimulation, for example by a needle or other penetrating instrument; they also may respond to stretch or shear. Sensory nerve fibers do not appear in or near the arterial intima, perhaps explaining why atherosclerosis, even when it is “inflammatory,” is not painful. Chronic slow dilatation of arteries, such as occurs with abdominal aortic aneurysm (AAA), does not appear to stimulate intra-arterial pain fibers; although palpation of an AAA occasionally results in a diffuse deep sickening ache, in the author’s experience, this occurs with equivalent frequency following deep palpation of normal nonaneurysmal aortas. Stimulation of periaortic autonomic fibers by such palpation may contribute to this characteristic sensation.

The pain associated with aortic aneurysmal rupture, usually into the peritoneal cavity, the retroperitoneum, or (rarely) the pleural space, is generally described as sudden, steady, burning, and penetrating in nature. Such pain likely arises as a consequence of nociception at several levels, including stimulation of pain fibers in the torn aorta, in the stretched or torn peritoneum or pleura and as a consequence of extravasation and hematoma expansion in an enclosed pleura or retroperitoneum (tellingly, free rupture of an AAA into the abdominal cavity is commonly characterized by transient pain only, followed by rapid loss of consciousness as the patient expires from hypovolemic shock).

Pain—characteristically “tearing,” “ripping,” or “boring” and located in a substernal or interscapular location—is a hallmark of aortic dissection. Similar burning pain in the lateral neck characterizes extracranial carotid arterial dissection. Shearing of nociceptive receptors in the aortic or carotid media by progression of the pulsatile hematoma within the media is the likely explanation for this pain. Except for patients with Marfan or Ehlers-Danlos syndromes, whose aortic or arterial dissections may occur asymptotically, pain is a constant consequence of arterial dissection. As
previously intimated, relief of such pain with hypotensive therapy is felt to indicate satisfactory control of an aortic dissection, whereas persistent pain suggests that such therapy is inadequate, obligating either that such therapy be augmented or be replaced by a more invasive intervention (operation or endovascular repair).

Vasculitic inflammatory involvement of large- and medium-sized arteries is uncommon but not rare. The most common such involvement of the aorta is the development of an inflammatory aneurysm, usually of the abdominal aorta. Although the pathophysiology of this process remains obscure, its presentation is stereotypically as a thickened “rind” of chronically inflamed fibrofatty perianeurysmal tissues, frequently with an adhesive involvement of the ureters or the duodenum which can significantly complicate open aneurysmal repair. Patients with inflammatory AAAs commonly complain of diffuse aching midback discomfort, and their aneurysms are dully tender to palpation.

Besides the jaw claudication often associated with giant cell arteritis, such patients’ inflammatory vasculitis can be associated with diffuse pain and tenderness over the affected arteries—especially the superficial temporal artery, biopsy (or duplex scanning) of which may be diagnostic of the underlying condition. As for inflammatory AAA and other large- and medium-sized vessel arteritis, the diffuse and poorly localized pain seen in this condition is likely due to inflammatory involvement of nociceptors found both in the arterial media and adventitia as well as in periarterial connective tissue. That the pain associated with this condition is inflammatory is borne out by its resolution following administration of anti-inflammatory agents (particularly corticosteroids).

REST PAIN, ULCERS, AND GANGRENE
Advanced or critical arterial insufficiency—usually in the lower extremities—displays characteristic symptoms and signs which signal impending limb loss. Indeed, all patients with rest pain, ischemic ulcers, or gangrene will require an operative intervention—either a procedure to reestablish vascular supply to the affected area or an amputation. Such patients’ arterial occlusive disease is severe and multilevel (“tandem”), and their mortality rate exceeds 50% over the next 5 years as a consequence of
premature, aggressive coronary artery disease.

Rest pain is characterized by a diffuse, ill-localized aching or burning pain in the distal foot (occasionally the heel). It is generally initially present at night when the patient is recumbent or the leg and foot are elevated. Symptoms dissipate if the leg is hung over the edge of the bed or the subject arises and walks around. The pathophysiology of rest pain is likely that of an ischemic neuropathy, with positional malperfusion of small sensory nerves in the distal foot. The symptoms of rest pain (or other advanced arterial insufficiency) necessarily develop in the most distal small arteries, those farthest away from the heart. Thus, pain at rest does not occur proximal to the foot (with one cardinal exception: rest pain may develop with severe ischemia in the stump of a patient with a below- or above-knee amputation).

Arterial ulceration in the nondiabetic patient is characterized by a shallow, pallid, nonhealing erosion of the skin in the distal foot, in a similar location as that for rest pain. The pain of such ulcerations is unremitting and severe, occasionally refractory even to high-dose oral narcotic analgesic agents, and is treated only by urgent revascularization or by amputation. The pain of such ulcerations is described as aching or burning and arises not only from the same severe ischemic neuropathy, which gives rise to ischemic rest pain, but also to actual necrosis of sensory nerves in the skin at the site of the arterial ulcer.

Gangrenous changes of the toes or heel are indications that tissue death has occurred. Associated pain complaints are thus a summation not only of ischemic neuropathy but also of actual necrosis of sensory nerves as well as the consequences of skin and subcutaneous tissue infarction, osteomyelitis, and ascending infection. As for patients with arterial ulceration, such patients’ pain may be severe and unremitting; on the other hand, in certain such patients, necrosis of sensory nerves may actually make such gangrenous distal feet insensate and anesthetic, paradoxically resulting in less pain than would be anticipated from the degree of tissue destruction present.

Atheroembolism, usually to the toes or distal foot ("blue toe syndrome") occurs because of digital or distal branch artery occlusion from debris (clot, atheroma), which has embolized into the distal
circulation from a proximal source (e.g., an aortoiliac or popliteal aneurysm or an ulcerated atherosclerotic plaque). The syndrome occurs only with patent proximal arteries, and the distal limb is usually not ischemic. Pain is therefore uncommon until digital ischemia is severe enough to result in sensory nerve damage.

The diabetic foot is a special circumstance in which chronic nonhealing lower extremity and foot ulceration and toe gangrene may occur; yet, the underlying pathogenesis revolves around not only ischemia but also diabetic neuropathy, foot structural changes, and diabetics’ inability to combat bacterial infection. Indeed, most diabetic foot lesions are not ischemic, and revascularization is not necessarily required as part of their management. Widespread loss of distal foot and even lower leg sensation in diabetics consequent to diabetic neuropathy makes pain due to ulceration, gangrene, or infection relatively uncommon. On the other hand, neuropathic pain is frequent (see later text).

**PAIN SYNDROMES FOLLOWING STROKE**

Pain is uncommon in association with cerebrovascular accident (CVA), except for patients whose cerebrovascular ischemia results from intracranial hemorrhage or tumor. Stroke survivors sometimes experience what appears to be a centrally mediated pain ipsilateral to the neurologic deficit. Dejerine and Roussy first described excruciating pain involving the contralateral half of the body in a patient who had suffered a thalamic stroke and termed the condition thalamic syndrome. Similar symptoms can arise following injury anywhere along the course of the spinothalamic tracts, and this syndrome has been termed central poststroke pain (CPSP).

CPSP occurs after ischemic or hemorrhagic stroke. Patients report burning or lancinating pain associated with sensory abnormalities in the painful region. Sensory abnormalities include decreased perception of sharpness and temperature, often accompanied by allodynia and hyperalgesia. The pain is often constant but may occur in paroxysms, and it is usually limited to an area that is smaller than the area affected by sensory deficits. The pain is often worsened by stress and relieved by relaxation, and the pain can present an enormous burden to the patient,
causing severe depression. Following thalamic stroke, CPSP is not uncommon. In a series of 100 patients with thalamic hemorrhage, 9% developed CPSP. In a prospective study of 267 consecutively admitted stroke patients, CPSP occurred in 8% of the patients during the first year, with more than half of those with pain reporting moderate to severe pain. In 63% of the patients, pain onset was within 1 month after stroke.

CPSP is a difficult condition to treat, and pain reduction rather than pain relief has to be the goal of the treatment. Conventional analgesics and opioids have been noted to be ineffective. Numerous other types of drugs have been tried in the treatment of CPSP, but large controlled trials are lacking, and the treatment is far from being standardized. Treatment of CPSP has been reviewed in detail elsewhere.

**PAIN ASSOCIATED WITH DISEASES INVOLVING SMALL ARTERIES**

Numerous regional or systemic disorders include involvement of small arteries. In the extremities, such conditions commonly manifest coolness, pallor, numbness, cyanosis, and pain—manifestations of Raynaud’s syndrome. Often, such symptoms and signs result simply from abnormal arterial reactivity, such as occurs in its benign form, termed Raynaud’s disease (seen primarily in young and middle-aged women or as a consequence of chronic vibratory tool use, primarily in young male laborers). Dull aching digit pain is noted by such patients during periods of extreme vasoconstriction; with the hyperemia of digital reperfusion, when vasoconstriction is replaced by vasodilatation, this dull aching pain is commonly replaced by a burning “fiery” pain as the digits are suffused via vasodilated digital arteries.

A more ominous form of small artery involvement associated with Raynaud’s syndrome (termed Raynaud phenomenon in this setting) results from digital arterial occlusions resulting from one or another form of various rheumatoid conditions—especially scleroderma. To these individuals’ diffuse pain syndrome, resulting from digital vasoconstriction and then vasodilatation, is added intractably painful fingertip ulceration or necrosis. Such patients’ distal digital pain is frequently severe and
unremitting, not uncommonly refractory even to large doses of opiate analgesic medications, and may require amputation for relief. Pathophysiologically, these lesions are similar to those of advanced chronic lower extremity arterial insufficiency.

A rare form of small artery involvement resulting in severe pain is that associated with Buerger’s disease (thromboangiitis obliterans [TAO]), a condition most commonly seen in young male tobacco addicts. TAO is a nonatherosclerotic necrotizing condition of smaller distal arteries, veins, and nerves, primarily in the extremities. Because only the tibial arteries in the lower extremity, or the distal radial and ulnar arteries of the upper extremity, are commonly involved in Buerger’s disease, these patients have excellent arterial inflow but inadequate collateralization (Fig. 38.5), and their ability to heal refractory ulcerations or areas of gangrene is poor. These patients’ foot or hand pain is described as severe, unremitting, aching, burning, and agonizing; amputation is commonly the best management.

PAIN ASSOCIATED WITH VENOUS DISORDERS

Venous disease is common and is frequently undiagnosed. This occurs in part because one major component of venous disease—deep venous thrombosis (DVT)—commonly occurs in a relatively vegetative, bland fashion associated with only minimal inflammation. Such patients’ first symptom may be painless lower extremity edema or, on occasion, chest pain and cardiorespiratory collapse associated with pulmonary embolus. Pain is only inconsistently associated with superficial venous disease. Patients with primary or secondary venous varicosities may note diffuse aching or burning pain associated with their venous varicosities, a discomfort likely secondary to stretch stimulation of nociceptors in and around the venous adventitia and media or in the surrounding soft tissue.

Patients who have suffered a prior lower extremity DVT often display symptoms and signs of the postphlebitic (postthrombotic) syndrome. This condition is characterized by chronic lower extremity edema, secondary venous varicosities, and characteristic skin changes including stasis pigmentation and eczema, subcutaneous atrophy, and, in advanced stages, skin breakdown and chronic nonhealing ulcerations around the medial and lateral malleoli. These stasis ulcerations, usually relatively small and shallow but occasionally circumferential and extending from ankle to midleg, are, in the author’s experience, notably nonpainful, often manifesting only mild itching or burning. When significant pain occurs in a stasis ulcer, a secondary diagnosis should be entertained—invasive infection (usually streptococcal) or (rarely) malignant transformation, ischemia, or osteomyelitis.

Superficial phlebitis generally results from chemical irritation of the intima of peripheral veins as a consequence of intravenous infusions of various medications or agents of abuse, may be a manifestation of sterile
inflammation secondary to indwelling catheters or other foreign bodies, or bacterial infection. Such phlebitis is characterized by marked localized tenderness with overlying cellulitis, demonstration of a palpable “cord” along the course of the vein and, rarely, systemic toxicity. Pain is characteristically well localized along the vein and is burning in nature, resulting from stimulation of vein-wall nociceptive receptors. In addition, perivenous inflammation results in elaboration of acidic inflammatory or infectious mediators which stimulates perivenous nociceptors.

PAIN ASSOCIATED WITH LYMPHATIC DISEASES
The most common lymphatic disorder is lymphedema praecox—idiopathic, bland nonvenous swelling, usually of a lower extremity. Other forms of lymphedema are either iatrogenic (consequent to lymphadenectomy or irradiation) or result from infections of various sorts. The lymphatics are not innervated so most forms of lymphedema are painful only when cellulitis or lymphangitis—an unfortunately common complication of lymphedema—supervenes.

PAIN ASSOCIATED WITH AMPUTATION
Commonly performed because of intractable pain in a nonsalvageable limb, amputation itself sometimes results in pain of various types. These can be classified as being either acute—at the time of the amputation—or chronic—occurring weeks, months, or even (on occasion) years following the initial procedure.

Acute postamputation pain may be related to the surgical procedure itself or to incompletely understood central or neuraxial phenomena arising from the patient’s preoperative pain status. Acute postamputation pain may result from the obligatory section of major nerves during limb amputation. The incisional and wound pain that results from transtibial or transfemoral amputation commonly resolves within a week or so following amputation—sooner in many surgeons’ experience if a rigid dressing is applied to the residual limb.30

Other relatively straightforward amputation pain issues occurring early in the postoperative period include those related to stump hematoma or ischemia or actual muscle necrosis because the amputation was performed
too far distally, resulting in thrombosis of the stump’s residual arterial blood supply. The latter complication generally requires reamputation at a higher level.

Early postamputation pain problems unrelated to the wound itself include the development of diverse neuropathic phenomena, including phantom limb sensation or pain. Virtually all amputees experience the sense that the amputated limb is still present, for example, that it itches and needs to be scratched. Phantom limb sensation is generally considered to be benign and self-limited. Phantom limb pain, on the other hand, can frequently be severe and, on occasion, even incapacitating, although patients can be reassured that the phenomenon generally diminishes or disappears within months to a year following amputation. Treatment with antiseizure medications, tricyclic antidepressants, regional sympathetic blockade with long-acting local anesthetic agents, cutaneous electrical stimulation units, sympathectomy, spinal cord stimulation (SCS), or even rhizotomy or distal reentry zone sectioning has been attempted for persistent or severe phantom limb pain.

Late postamputation pain most commonly results from a poorly fitted artificial limb, and an experienced prosthetist’s opinion is invaluable in this setting. Other less common but important causes of late postamputation stump pain can include progressive stump ischemia, DVT, progressive autonomic dysfunction (e.g., CRPS), or neuroma formation—the last problem best prevented by assuring that large nerves sectioned at the time of the original amputation are buried in muscle, well away from cut bone ends and the skin flap.

**Differentiating Vascular from Nonvascular Pain**

It is clinically self-evident that a large overlap occurs between the pain syndromes arising from vascular and nonvascular diseases. The not infrequent misdiagnosis of a ruptured AAA as ureteral or biliary colic, of an aortic dissection as a myocardial infarction or gastroesophageal reflux, or of lower extremity ischemic pain as lumbar spinal stenosis all point to the importance of considering the entire constellation of diagnostic possibilities present in patients presenting with various forms of pain.
The scope of this chapter precludes an exhaustive discussion of those disease states in which the misdiagnosis of vascular for nonvascular disease (or, as important, the converse) can occur; the reader is referred to seminal general and vascular surgical texts for further details.\textsuperscript{33–35} Those intent on formalizing the divergence of vascular surgery from general surgery,\textsuperscript{36,37} both in the context of resident training and as a separate specialty, must make every effort to ensure that future vascular surgeons and their general surgery colleagues experience a shared body of clinical knowledge and judgment in this context.

**The Relief of Vascular Pain**

The relief (or at least the mitigation) of pain is the sine qua non of the rationale for many vascular interventions to the extent that an inability to achieve pain relief may be tantamount to failure—either of the original diagnosis or of the intervention itself. The patient who continues to experience calf claudication after a technically successful femoral–popliteal bypass may well have needed more preoperative attention paid to the status of his lumbosacral nerve roots. The return of claudication after a period of pain-free walking suggests the progressive deterioration of the original revascularization.

As in other areas of medicine and surgery, minimally invasive techniques and nanotechnology have grown increasingly to dominate therapeutic maneuvers. In industrialized countries more than 90\% of aortic aneurysm patients are managed by percutaneous catheter-based stent graft means (Fig. 38.6). The initial approach to the management of lower extremity arterial occlusive disease is by means of similar transcatheter balloon angioplasty or stenting.
Relief of several types of aortic pain can take both “medical” and surgical forms. As previously intimated, the presence of tearing central truncal pain is a hallmark of aortic dissection. All type A aortic dissections require immediate referral to a cardiothoracic surgeon for urgent intervention. However, type B aortic dissections’ natural history as well as their indications for operative or endovascular intervention are heavily dependent on the relief of this lesion’s characteristic pain by pharmacologic therapy—specifically, the administration of β-blocker agents, whose effect is to halt the medial hematoma’s dissection by lowering systolic and mean blood pressure as well as left ventricular dV/dt.\textsuperscript{38}

The pain associated with an expanding, leaking, or ruptured abdominal or thoracic aortic or iliac aneurysm is relieved by successful graft interposition, either by open or stent-graft means. Graft repair of aneurysms eroding into the spine commonly relieves the pain from such bony erosion. Similarly, and for obscure reasons, graft repair of inflammatory AAAs tends to resolve the characteristic inflammatory “rind” around the aorta and, with it, the diffuse, poorly localized, boring...
mid-abdominal-to-mid-back ache these patients commonly note. Interestingly, the use of corticosteroids, administered systemically or by injection, can also diminish the pain associated with an inflammatory aneurysm, although such therapy theoretically increases the risk of aneurysm expansion and rupture.

A preponderance of pain resulting from vascular disease arises from inadequate tissue oxygenation, most commonly with exertion or other increased nutritive blood flow demands but also in basal blood flow states in which tissue viability itself is threatened. Many vascular interventions focus on restoring tissue perfusion to (or toward) normal—not only various revascularization procedures, either by open or endovascular means, but also pharmacologic or hygienic measures as simple as the encouragement of smoking cessation or aerobic exercise or the administration of hemorheologic medications. Although such interventions are most commonly carried out for the symptomatic consequences of lower extremity atherosclerotic occlusive disease, the principle of relieving vascular pain by improving tissue nutrition can be relevant for nonatherosclerotic diseases of the upper extremities as well—for example, the salubrious effects seen with the administration of cilostazol in patients with various small artery occlusive phenomena of the digits or the relief of dialysis access-associated rest pain of the hand by the performance of distal revascularization/interval ligation.

In unusual circumstances, revascularization by conventional operative or pharmacologic means may not be feasible or may not provide tissue reperfusion adequate to relieve pain or other ischemic manifestations. In certain limited circumstances, the observation, initially popularized by Leriche, that sympathectomy can increase skin perfusion may offer a therapeutic alternative. Ipsilateral lumbar sympathectomy (most effectively by operative excision, although a therapeutic effect can result from phenol or absolute alcohol ablation) can heal shallow ischemic skin lesions and relieve associated ischemic rest pain, probably by the combined effects of increased skin blood flow and interruption of afferent pain fibers traveling within the lumbar sympathetic chain. Patients subjected to such therapy have a 10% risk of developing a sometimes debilitating although transient burning pain termed postsympathectomy
neuralgia.  

Revascularization to treat severe ischemia may not be possible or, even if technically feasible, may not be successful in relieving pain. When tissue loss—advanced ischemic ulceration or gangrene—supervenes, amputation is indicated. However, in that subset of patients with far-advanced, refractory ischemia in which significant tissue loss has not yet developed but in which pain is severe and unremitting, Jacobs and colleagues have extensively investigated the possibility that SCS might relieve pain and forestall the need for amputation as a pain-relief measure. Initial enthusiasm for this approach, based on nonrandomized studies demonstrating improved microcirculatory blood flow in subjects with advanced nonreconstructible lower extremity arterial disease, has waned with publication of less favorable results of more recent prospective trials of SCS. At the current time, the role of SCS in the management of subjects with advanced chronic limb ischemia appears to be restricted to those with relatively preserved microcirculatory skin perfusion.

Pain associated with venous disease of various sorts is ubiquitous although rarely severe or incapacitating. The central role of vein wall distention as the proximate cause of lower extremity venous symptoms associated with saphenous or deep venous insufficiency is perhaps best demonstrated by the almost universal symptomatic improvement associated with such “low-tech” maneuvers as limb elevation or the donning of elastic support stockings. The “swollen” or “bursting” sensations associated with significant large-vessel lower extremity venous obstruction (“venous claudication”) may only be effectively treated by venous bypass or by endovascular relief of proximal venous occlusions. The pain associated with acute venous thrombosis, either deep or superficial, is both congestive and inflammatory and is optimally treated with limb elevation and/or compression plus anti-inflammatory medications.

The management of acute pain is central to the cultural identity of most medical specialties. Unfortunately, published research has repeatedly documented that most medical professionals have inadequate training, experience, or understanding of the proper management of acute or chronic pain. Aronoff has recently discussed this problem as well as
recent research findings which could inform a more coherent approach to the medical management of pain. Pharmacologic (or other) management of chronic or severe pain of any origin is increasingly the domain of pain specialists, frequently with an anesthesiology background, in a multidisciplinary pain clinic setting.

**Conclusion**

How best to manage the manifold types of vascular pain is a vast and incompletely illuminated topic. Vascular pain’s multifactorial nature confounds simple or stereotypical prescriptions for its relief. In a large majority of cases, restoration to (or toward) normalcy of the underlying arterial or venous condition will resolve or improve associated vascular pain. Chronic vascular pain is closely allied with neuritic or neuropathic abnormalities, the management of which warrants involvement of specialist consultants in chronic pain.51

An important and incompletely understood cause of upper extremity pain is subsumed under the rubric of “thoracic outlet syndrome” (TOS). This condition arises from compression of neurovascular structures as they enter/exit the neuraxis and the mediastinum at the base of the neck. Particularly in cases involving chronic compression of the brachial plexus, TOS can be a complicated and frustrating condition to manage due to ongoing controversy about the underlying pathophysiology, how the diagnosis is best made, and differing views about proper and effective treatment. Many of the problems regarding TOS revolve around the uncertain natural history of the condition with and without intervention. In this chapter, we discuss the various types of TOS with a particular emphasis on the neurogenic type—by far the most common, the most disputed, and also the most likely to result in pain.

**Anatomy and Pathophysiology**

The thoracic outlet is the aperture through which the subclavian artery and trunks of the brachial plexus pass as they exit the neuraxis and the upper mediastinum at the base of the neck. In normal anatomic circumstances, the thoracic outlet is bound by several musculotendinous and bony structures including the anterior and middle scalene muscles and, inferiorly, the first rib (Fig. 39.1). In pathologic circumstances, compression of the neurovascular bundle at the thoracic outlet is most commonly the consequence of abnormalities of the scalene muscles and/or the first rib. However, neurovascular compression can also result from the
presence of a cervical rib, abnormal fibrous bands, callus from a clavicular fracture, scarring from prior trauma or radiation therapy, or (rarely) a superior sulcus (Pancoast) tumor of the lung.

FIGURE 39.1 The anatomy of the normal thoracic outlet and abnormalities leading to thoracic outlet syndrome. A: Normal anatomy of the thoracic outlet. B: The presence of a first cervical rib can lead to compression of the subclavian artery and/or the brachial plexus (red shaded region) between the cervical rib and the clavicle. C: Hypertrophy of the anterior and middle scalene muscles following trauma can lead to compression (arrows) of the subclavian artery and/or the brachial plexus.

Because the subclavian vein lies anterior to the anterior scalene muscles, it does not actually pass through the thoracic outlet. It is, however, located between the clavicle and the first rib in its course toward the mediastinum.

In normal circumstances, arm elevation or abduction results in a functional reduction in the caliber of the thoracic outlet aperture because of posterior rotation of the clavicle and contraction of the scalene muscles. The space between the clavicle and the first rib narrows, and below the shoulder, the pectoralis minor muscle contracts.

Trauma, particularly cervical hyperextension (“whiplash”), or chronic repetitive use of the upper extremities (particularly in an out-front or overhead position), may, over time, result in chronic spasm, inflammation, and contracture of the scalene muscles, producing both the thickening of the anterior and middle scalene muscles as well as microstructural changes in muscle fiber type.\textsuperscript{1,2}
Provocative maneuvers of the arm may result in compression of the subclavian artery and vein in up to 30% of normal individuals. Reduction in the caliber of the thoracic outlet by pathophysiologic circumstances can result in extrinsic compression of the subclavian artery or vein in more than 90% of patients with TOS.

A cervical rib, abnormal bands, or residua from a clavicular fracture can result in subclavian artery dilation or even aneurysm or mural thrombus formation, from which embolization into the arterial circulation of the wrist or hand may occur.

Extrinsic compression of the subclavian vein in the costoclavicular space, perhaps involving the tendon of the subclavius muscle, can, in concert with repetitive use of the upper extremity, result in axillosubclavian venous thrombosis, likely due to intimal damage and venous stasis.

**Clinical Presentation: Symptoms and Signs**

Arterial TOS is extremely uncommon, comprising less than 1% of the totality of any TOS practice, and almost always presents as forearm or hand “claudication” (or other upper extremity ischemic symptoms) or evidence for distal upper extremity embolization. Physical examination demonstrates diminished or absent wrist pulses; vascular laboratory examination may show occlusion of the radial and/or ulnar arteries or their palmar or digital branches. On occasion, patients may present with rest pain or gangrene of the fingers due to far-advanced ischemia from repetitive distal arterial embolic occlusion.

Physical findings in patients with arterial TOS are primarily those of absent or diminished pulses and/or manifestations of distal upper extremity ischemia.

Involvement of the upper extremity venous circulation by compression of the subclavian vein at the thoracic outlet comprises approximately 5% of a TOS practice. Patients with such venous TOS (also termed Paget-Schroetter syndrome or “effort” thrombosis of the axillosubclavian vein) may present with aching pain distributed diffusely throughout a swollen, ruborous upper extremity. In more chronic circumstances, pain and
swelling may be less prominent.

On exam, patients with acute venous TOS manifest arm swelling and discoloration; in later stages, prominent veins can be seen over the upper arm and around the shoulder.

By far the most common presentation—the overwhelming majority of the patients seen in a TOS practice—results from compression of elements of the brachial plexus, that is, neurogenic TOS. Patients with neurogenic TOS almost always have a prior traumatic event—a cervical hyperextension ("whiplash") injury, a fall on an outstretched arm, an object falling on the head or the shoulder—or alternatively have a history for a repetitive stress injury, usually due to exigencies of their occupation. Workplace risk factors for neurogenic TOS include sustained effort with the upper extremity or extremities out-front or overhead and may be seen in drywall hangers, dental hygienists, beauticians or hairdressers, grocery checkers, shelf stockers, or clerical workers engaged in prolonged keyboarding.

Such injury or workplace-related postures and stresses have been demonstrated to result in chronic contracture and spasm of the suspensory muscles in and around the shoulder girdle—among them the anterior and middle scalene muscles. Obesity, sedentary lifestyles, and maladaptive postures—in neurogenic TOS, characterized by the head flexed on the neck and the shoulders down and forward—exacerbate chronic scalene muscle spasm.

Patients with neurogenic TOS may have few or no symptoms with the arms in a neutral position. However, they will quickly note the onset of pain and paresthesias with the arms placed in an out-front, overhead, or abducted posture. Indeed, this presentation is so stereotypic that we do not seriously entertain the diagnosis of neurogenic TOS in the absence of a subject’s observation of worsened symptoms with the arms in such provocative postures.

Symptoms characteristically evoked in neurogenic TOS patients include elevational arm aching, particularly proximally around the shoulder, the axilla, and the upper arm, associated variably with numbness and tingling out the arm, distal weakness, and a limitation in range of motion of the affected upper extremity. Paresthesias are found predominately in a lower
trunk (C8–T1) distribution, appropriate to impingement on the lower aspects of the brachial plexus. Indeed, 80% of patients with neurogenic TOS demonstrate pain and paresthesias radiating along an ulnar nerve distribution, often into the small and ring finger as a consequence. This presumably results from upward traction on the first rib by the scalene muscles, thus selectively impacting the inferior aspects of the brachial plexus.

A significant proportion of patients with neurogenic TOS have significant headaches, primarily occipital. They also may note symptoms of facial or jaw pain or pain around ear. Muscle pain is commonplace in neurogenic TOS, particularly around the neck and the shoulder, the scapula, and the upper arm. It is frequently difficult to discern whether such symptoms arose from neurogenic TOS itself or from concurrent soft-tissue injuries (e.g., the paraspinal or periscapular muscles: the rotator cuff in the shoulder) suffered at the same time as the injury causing the neurogenic TOS.

Patients with neurogenic TOS frequently display a series of symptoms associated with activities of daily living which, in the aggregate, strongly indicate the presence of neurogenic TOS. Elements of our clinical template are shown in Table 39.1.

**TABLE 39.1 Clinical Elements that Suggest Neurogenic Thoracic Outlet Syndrome**

| Inability to drive with the hands elevated in the normal 10 o’clock/2 o’clock position on the steering wheel |
| Problems with grooming (shampooing the hair or use of a hairdryer) |
| Awakening at night with pain or numbness in the affected arm(s) |
| “Drop attacks”: the tendency to drop things, often without recognizing that grip strength has diminished |
| Inability to carry out sustained overhead activities, for example, changing multiple light bulbs in the ceiling |
| Loss of handwriting legibility (with involvement of the dominant upper extremity) |
| Inability to remove a tight jar lid |

In neurogenic TOS, objective physical examination findings are sparse. Such individuals have limited range of motion of the affected upper extremity and manifest diminished spontaneous (adventitial) movements of the extremity as well as an unwillingness to place or maintain the
affected limb in various provocative postures. Muscle tenderness over the anterior and lateral neck is commonplace, as is neck muscle tightness or contracture. In the supraclavicular fossa, tenderness can be elicited with palpation over the brachial plexus at the scalene triangle, often resulting in radiation of neuritic sensations into the axilla or out the arm (a positive Tinel sign). Occasionally, a cervical rib can be palpated. Tenderness over the pectoralis minor tendon attachment at the coracoid process below the shoulder is commonplace.

More peripherally in the upper extremity, tenderness may be elicited with palpation deep in the axilla. Tenderness of the arm or forearm muscles or tendons, or evidence for peripheral nerve compression at the carpal or cubital tunnels, may be present but is not, however, a primary manifestation of neurogenic TOS. Instead, this may represent the concurrent upper extremity injury that may accompany neurogenic TOS ("double crush" syndrome).§ Rarely, intrinsic hand muscle atrophy may be observed, a so-called Gilliatt-Sumner hand.¶

A series of provocative tests are commonly performed which, individually or in the aggregate, are thought by many to demonstrate the presence of neurogenic TOS. The Adson test is carried out with the affected arm held downward and backward: The ipsilateral wrist pulse is palpated as the head is turned toward this arm while the subject undertakes a sustained inspiration. A positive test, suggesting the presence of neurogenic TOS, results when the wrist pulse is obliterated.

The military or shoulder brace position involves retraction of the shoulders backward and downward, which may result in pulse obliteration at the wrist.

The Roos or abduction/external rotation (AER) ("hands-up") test involves, as described, the arms held at 90 degrees at the shoulders, the elbows flexed 90 degrees, and the hands then contracted repeatedly. A positive test involves rapid fatiguing and pain in the affected upper extremity.

Sanders and colleagues⁷ have reported the high positive and negative predictive value of the brachial plexus tension test. Here, the arms are held horizontally with the elbows and wrists straight and the neck is laterally flexed away from the affected arm: Both wrists are then extended. A
positive test is characterized by a sense of tightness and pain in the ipsilateral neck as well as neuritic symptoms radiating out the affected arm.

Although not a provocative test for neurogenic TOS, the Spurling test is important in the evaluation of this condition. Because an important alternative diagnosis in these patients may be cervical radiculopathy, development of characteristic symptoms with lateral flexion of the neck toward the affected extremity makes neuroforaminal compression due to herniated disk, scar, or arthritis more probable and neurogenic TOS less likely.

The aforementioned provocative tests are commonly performed as part of an evaluation for neurogenic TOS. Skeptics point out that, although the sensitivity of each of these tests may be high, their specificity is very low (e.g., more than 30% of the asymptomatic population may have a positive Adson test). Similar results hold for the military (shoulder brace) position. The AER (“hands-up”) test has a high sensitivity and much better specificity for neurogenic TOS. Experienced clinicians’ view is that patients ultimately demonstrated to have neurogenic TOS will be strongly positive for many or most of these tests, individually or in the aggregate.

**Diagnostic Tests**

In patients with arterial TOS, chest roentgenography will frequently confirm the presence of a cervical rib or callus from a clavicular fracture. A noninvasive vascular laboratory examination of the upper extremity will confirm the absence of (or reduction in) arterial flow at the hand and wrist level, not uncommonly in a pattern consistent with thromboembolic occlusion. Duplex scanning of the subclavian artery may demonstrate stenosis with poststenotic dilation or aneurysm formation with mural thrombus within. Computed tomography (CT) scan or catheter-directed arteriography may demonstrate sharp angulation of the subclavian artery over a cervical rib or around a clavicular fracture callus (Fig. 39.2); such imaging studies may also document the specific distribution of distal forearm, wrist, or hand arterial occlusions.
In venous TOS, noninvasive vascular laboratory examination will demonstrate partial or complete axillosubclavian venous thrombosis.\textsuperscript{8} Enlarged venous collaterals around the shoulder may be displayed. Not uncommonly, upstream venous tributaries of the arm such as the basilic vein may demonstrate partial or complete thrombosis as well.

In neurogenic TOS, chest roentgenography may demonstrate a cervical rib. We commonly perform an apical lordotic view because, with a standard chest roentgenogram, on occasion, a cervical rib may be hidden as it underlies the first rib (Fig. 39.3). A chest roentgenogram may also, as
for arterial TOS, demonstrate a clavicular fracture; it may also document the presence of a superior sulcus tumor causing the patient’s symptoms.

![Image](image_url)

**FIGURE 39.3** Chest x-ray demonstrating presence of cervical rib (arrows) in a patient with symptoms of thoracic outlet syndrome. (Image courtesy of Dean Donahue, MD, Division of Thoracic Surgery, Massachusetts General Hospital, Boston, MA.)

Arteriography may demonstrate extrinsic narrowing or occlusion of the subclavian artery by the aforementioned anatomic stricture, particularly when the affected arm is maintained in an abducted/externally rotated posture. Imaging studies such as magnetic resonance imaging (MRI) or CT may demonstrate hypertrophied or inflamed scalene muscles or edema or inflammation of the brachial plexus.  

Electrodiagnostic testing is commonly performed in patients thought to have neurogenic TOS. For patient with “true” neurogenic TOS (a rarely seen condition which results from direct brachial plexus trauma, e.g., a stab or gunshot wound), specific electrodiagnostic criteria have been established—primarily, reduction in median motor and ulnar sensory nerve amplitude. In patients with the much more common “nonspecific” or “disputed” neurogenic TOS, standard electromyography (EMG) or nerve conduction velocity testing is almost always normal. This is not because nerve compression is not present but, rather, as demonstrated by Tender et
it is because such compression occurs much more centrally, at the
level of the cervical nerve roots and proximal brachial plexus trunks—an
area that is difficult to assess via nerve conduction testing.

More recent data have suggested the possibility that electrodiagnostic
evaluation of the median antebraclial cutaneous nerve may provide useful
diagnostic information in neurogenic TOS.\textsuperscript{14}

Most significant in the diagnostic evaluation of neurogenic TOS in our
practice has been the use of temporary scalene muscle inactivation, carried
out by EMG-guided intrascalenene injection of either bupivacaine\textsuperscript{15} or
botulinum toxin A (Botox).\textsuperscript{16} Scalene muscle block has been demonstrated
to have a sensitivity and specificity exceeding 90\% for the presence of
neurogenic TOS.\textsuperscript{15} After administration of one of these agents into the
scalene muscle, the patient with neurogenic TOS commonly notes a
reduction in pain and paresthesias as well as an improvement in flexibility
and range of motion in the affected arm. Headache is frequently relieved
and the dysautonomic symptoms (bluish discoloration, constant aching
pain, moist skin) that accompany neurogenic TOS in up to 10\% of patients
are relieved.

On occasion, after a positive block, patients become emotional and burst
into tears with such novel and unanticipated relief of their symptoms
(sometimes having been told by prior examiners that they are delusional or
are malingerers). The effects start within a few minutes with bupivacaine
injection and last from 15 minutes to several hours; with botulinum toxin
A administration (which we utilize both diagnostically and as a treatment
maneuver), the onset of relief of symptoms, which occurs in more than
95\% of patients who have had a positive bupivacaine block, occurs within
48 to 72 hours and last for 1 to 4 months.\textsuperscript{16,17}

\section*{Differential Diagnosis}

A number of alternative conditions present with symptoms and signs
similar to those of various forms of TOS, thus complicating the diagnosis.
This is most particularly true for neurogenic TOS, although on occasion,
arterial TOS may be written off for a time as Raynaud syndrome (or
phenomenon) or some sort of dysautonomic disorder such as complex
regional pain syndrome (CRPS). Venous TOS may uncommonly be misdiagnosed as lymphedema or, again, some variety of sympathetic dystrophy.

In neurogenic TOS, a wide range of conditions in the central nervous system or the neuraxis, most particularly multiple sclerosis but also such exotic disorders as syringomyelia, have masqueraded for a time as neurogenic TOS. Impingement on the cervical spinal cord or its nerve roots by herniated disk, arthritis, or cervical spinal stenosis can commonly present with neck, supraclavicular, shoulder, axillary, or upper extremity symptoms. Involvement of the shoulder joint or the scapula is a common concomitant of the injury which may initially have led to the neurogenic TOS itself. Cubital tunnel compression of the ulnar nerve in the elbow, or even carpal tunnel compression of the median nerve at the wrist, may manifest upper extremity symptoms which, on occasion, may be difficult to distinguish from those of neurogenic TOS.

Migraineurs may sometimes experience facial, jaw, or neck pain. Generalized shoulder girdle pain is a commonplace manifestation of fibromyalgia. Polymyositis, temporal (cranial) arteritis, and polymyalgia rheumatic are connective tissue disorders which variably present with pain and tenderness of the muscles of the head, neck, and shoulder girdle.

The initial trauma (e.g., the “whiplash” injury suffered in a motor vehicle crash) commonly results in aches and pains and tenderness in the neck and out one or both upper extremities; it may even result in radicular symptoms which worsen with provocative postures of the arm. Such symptoms are not, however, those of neurogenic TOS, which we consider to be the consequence of chronic scarring and contracture of the scalene muscles. Indeed, we assert that the diagnosis of neurogenic TOS should not be invoked until at least 3 to 6 months after the initial traumatic event.

**Management**

In patients with arterial TOS, two separate treatment goals must be met: relief of distal limb ischemia and eradication of the more proximal embolic source that resulted in the distal extremity ischemia. Although repair of the proximal subclavian arterial lesion is relatively straightforward (usually
aneurysmorrhaphy with a short segment of prosthetic graft material or of reversed saphenous vein), restoration of distal arterial flow is often difficult because the embolization that has occurred is chronic. The fact that the occlusion is long-standing often stymies efforts at catheter-directed thrombolysis or open arterial thrombectomy. Fortunately, if pulsatile flow can be restored to the level of the palmar arch, then more distal digital tissue loss is generally avoided.

Conventional management of venous TOS should include systemic anticoagulation (this is, after all, a form of deep venous thrombosis and pulmonary emboli have certainly occurred as a consequence) and, particularly if the onset of symptoms is recent, an attempt at catheter-directed axillosubclavian vein thrombolysis. If venous thrombus is thus relieved, a stricture is often identified within the subclavian vein at the costoclavicular junction. Balloon angioplasty may frequently be carried out; however, it is generally agreed that venous stenting should not be performed at this site because of the high likelihood of stent fracture between the “hammer” and “anvil” formed by the clavicle and first rib.

Because of concerns about recurrent axillosubclavian venous thrombosis and chronic upper extremity postthrombotic symptoms, conventional management of venous TOS has also commonly included not only thrombolysis and anticoagulation but also staged operative thoracic outlet decompression. Such an approach is designed to resolve the structural mechanism which led to the initial venous damage (also, by removing the costoclavicular “anvil,” later stenting of the stenotic subclavian vein can be carried out if this is deemed necessary).

However, several recent natural history studies have suggested that recurrent axillosubclavian venous thrombosis is quite uncommon and that the natural history of this condition is benign—enough so that thoracic outlet decompression may only rarely be warranted. These authors argue that, far from preventing further complications, the magnitude of the dissection required for first rib resection is such that collateral vein disruption around the damaged axillosubclavian vein might paradoxically lead to worsening of the patient’s venous congestive symptoms.

Early and mild-to-moderate neurogenic TOS should be treated by aggressive physiotherapy emphasizing postural training, abdominal
breathing, and emphasis on stretching and relaxing the scalene muscles. Unfortunately, physiotherapy attempted in the early stages of neurogenic TOS is frequently misdirected, emphasizing resistance exercises; these, of course, tend only to exacerbate further scalene muscle contracture. Soon, the scalene muscles are hypertrophied and scarred, such that it is difficult to imagine much benefit from physiotherapy. Histologic studies of scalene muscle removed at this stage further support this conclusion: The muscle fibers are found to have changed from type II to type I and are interwoven with abundant fibroblasts.¹,²

For these and other reasons, we believe that, once established, neurogenic TOS is effectively managed only by thoracic outlet decompression. Two means—chemodenervation with botulinum toxin A¹⁶,¹⁷ or open surgical decompression of the thoracic outlet—are practiced: Each has advantages and disadvantages.

Botulinum toxin, administered intramuscularly under EMG- or ultrasound-guided control, relieves symptoms of neurogenic TOS in the vast majority of subjects who have previously responded positively to a diagnostic scalene muscle block with local anesthetic. Such patients’ symptoms are relieved for 1 to 4 months (mean 3 months).¹⁷ A substantial proportion of such individuals can undergo repeat intrascalene botulinum toxin administration with attainment of another equivalent period of symptom relief.

However, scalene muscle chemodenervation, although temporarily affective at relieving symptoms of neurogenic TOS, does not appear to alter the underlying natural history of neurogenic TOS. Even when vigorous physiotherapy has been pursued during the period of time of scalene muscle denervation, durable improvement in the underlying condition is uncommon. Tachyphylaxis to botulinum toxin is demonstrable in a substantial number of patients. The use of botulinum toxin for the treatment of TOS is not approved by the U.S. Food and Drug Administration; thus, there is limited availability of this treatment. Insurance authorization is difficult to achieve, and botulinum toxin is costly. Although a few of our surgery-averse patients have continued to undertake repeat botulinum toxin chemodenervation, a majority have ultimately opted for operation.
Surgical decompression of the thoracic outlet has historically been based on partial or complete excision of the first rib. The operative rationale is transparent—because the first rib is located at the bottom of the anatomic “triangle” forming the thoracic outlet and serves as the site of insertion of the anterior and middle scalene muscles which comprise the remaining two sides of the “triangle,” first rib removal should effectively open this orifice. Because the short, wide first rib plays no significant role in chest wall dynamics and the scalene muscles (developmentally archaic accessory muscles of respiration) serve no significant functional role, dismantling of the musculoskeletal bounds of the thoracic outlet should have minimal functional impact. Numerous patients undergoing first rib resection by transaxillary, supraclavicular, or posterior approaches have demonstrated significant improvements in their prior neurocompressive symptoms 75% to 90% of the time.

Patients with symptoms of neurogenic TOS who have cervical ribs have generally done well simply with resection of the cervical rib as well as the tight adhesions (“bands of Roos”) commonly associated with these extrathoracic ribs.

However, based in part on neurogenic TOS patients’ stereotypic response to intrascalenine bupivacaine or botulinum-mediated chemodenervation, we have rethought our operative strategy for neurogenic TOS. Because a positive response to scalene muscle block is an obligatory part of our indications for operative intervention for neurogenic TOS (a positive block has a >90% positive predictive value for a favorable outcome of operative intervention\textsuperscript{15}), we have concluded that the pathophysiology of this condition resides in the scalene muscles and not the first rib. We now consider the rib a victim of the condition rather than its cause. Others\textsuperscript{30,31} have reasoned similarly.

We have thus ceased performing resection of the first rib and now focus our operative efforts on radical excision of the anterior and middle scalene muscles. We have carried out more than 850 consecutive thoracic outlet decompression procedures without excising the first rib: Our results (90% “excellent” or “good” outcomes) are equivalent to those we recorded with rib excision plus total scalenectomy, but patients in whom rib preservation has been carried out appear to rehabilitate substantially more rapidly than
those in whom subtotal first rib resection had taken place.

We have come to believe that a separate site of brachial plexus compression, in addition to the well-accepted interscalene and costoclavicular locations, occurs beneath the pectoralis minor tendon attachment to the coracoid process, a site where tendinous impingement on the upper aspect of the axillary nerve can occur. It has long been our practice to decompress this area by dividing the pectoralis minor tendon via a small vertical infraclavicular incision separate from the supraclavicular approach through which we decompress the brachial plexus. Sanders and Rao\textsuperscript{32} had likewise recently adopted this approach.

### Outcomes

Patients with arterial TOS are generally diagnosed and managed in timely fashion due to the importance of finger, hand, and upper extremity neurovascular function. Even when chronic thrombotic occlusion of distal vessels is present, upper extremity arterial collateralization is generally robust enough to maintain distal hand and finger tissue viability and function.

For venous TOS, the long-term outcome following first rib resection appears to be good.\textsuperscript{21,22} However, the natural history of this condition without first rib resection also appears to be excellent,\textsuperscript{23,24} leading to recent skepticism regarding whether excision of the first rib in such patients really is in fact an obligatory part of management of this condition.

Published data suggest that, although thoracic outlet decompression rarely completely resolves symptoms of neurogenic TOS, the vast majority of patients undergoing surgical thoracic outlet decompression appear to improve and to do well. Even among a high-risk group of workmen’s compensation patients undergoing surgery for neurogenic TOS following prolonged administrative delays, the vast majority felt themselves to be improved and indicated they would undergo operation again if confronted by the problem.\textsuperscript{33}

Approximately 5% to 10% of patients who have initially undergone decompressive surgery for neurogenic TOS will display persistent or
recurrent neurogenic TOS symptoms. Such individuals may be found to have a missed cervical rib, a residual stub of first rib impinging on the brachial plexus, or, most frequently in our experience, adherence of scar and unresected residual scalene muscle to the brachial plexus. In such circumstances, reoperative surgery, although associated with increased risk of peripheral nerve or brachial plexus damage, may be helpful in relieving symptoms. EMG-guided scalene muscle block may be highly useful in demonstrating the presence of adherent residual scalene muscle as the inciting problem in such patients.

Recently, a 496-page, 70-author compendium on various forms of TOS has been published, and reporting standards for TOS have been proposed by the Society for Vascular Surgery.

Pain following spinal cord injury (SCI) is common and includes a spectrum of pain types which can impact function across the physical, psychological, and social domains. This chapter provides an overview of SCI-related pain, including the extent and impact, assessment and classification, psychosocial aspects, and treatment.

**Extent and Impact of the Problem**

Four out of five individuals with SCI report pain, defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage\(^1\) as an ongoing problem.\(^2\) Many individuals with SCI and pain do not have just one pain but experience at least two different distinct types of pain with many reporting three or more.\(^3,4\) In the same person, this might, for example, include shoulder pain from overuse and neuropathic pain related to SCI or spinal cord disease.

In more than half of individuals who report ongoing pain, the ongoing pain interferes with activities of daily living and work,\(^2\) whereas one out of every five individuals with SCI who is unemployed reports that it is pain rather than loss of function that prevents them from working.\(^5\) One out of every four people with SCI and significant pain note they would be willing to trade a chance of recovery of bowel, bladder, or sexual function for relief from the pain.\(^6\)

Pain prevalence does not differ among those with different levels of injury nor degree of completeness of injury.\(^7\) The same holds for men and women with SCI with neither group being more likely to report pain.\(^7\)
Assessment and Classification of Pain Following Spinal Cord Injury

Most pains after SCI are either nociceptive or neuropathic. Nociceptive pain occurs when intact peripheral nerve sensory receptors capable of transducing and encoding noxious stimuli (also known as nociceptors) are activated within an intact somatosensory nervous system, whereas neuropathic pain occurs when a lesion or disease of the somatosensory nervous system activates the somatosensory nervous system.\textsuperscript{1,8}

The International Spinal Cord Injury Pain (ISCIP) Classification was developed to organize the different types of pain seen after SCI in to an easily understandable framework (Table 40.1).\textsuperscript{9,10} Within this framework, in addition to the nociceptive and neuropathic pain types, there is a third type of pain, labeled as “other” pain, for which no identifiable noxious stimulus nor any inflammation or damage to the nervous system responsible for the pain can be identified. Pain syndromes of unknown etiology such as fibromyalgia and complex regional pain syndrome type I fall into this category.

1904
In determining where a particular pain that a person describes fits within the ISCIP Classification, it is helpful for clinicians to elicit the seven cardinal pain attributes described in Table 40.3 through the completion of a thorough history and physical examination. This physical examination should include a neurologic examination which incorporates the International Standards for the Neurological Classification of SCI as a correct neurologic classification of the SCI and is essential in order to correctly differentiate between at-level and below-level SCI pain and to provide insight into the likelihood of nociceptive pains being perceived in relation to retained sensation.\(^\text{13}\)

</tr>
</tbody>
</table>
| Temporal pattern    | • Differentiates between subtypes, as nociceptive pain often is present only when there is stimulation of offending nociceptors, whereas neuropathic pain often may be more persistent due
to damage related neuronal ectopy

Pain quality
- Indicates subtype, especially if a few specific descriptors such as “burning,” “electric shock-like,” or “tender” are specified, as the first two descriptors are more commonly seen in neuropathic types, whereas the latter is commonly described for nociceptive pain.

Ameliorating and exacerbating factors
- Differentiates nociceptive and neuropathic subtypes, especially if movement is involved, as a pain generator can often be localized by replicating exacerbating factors.

Associated sensory disturbances
- Allodynia or hyperpathia, either noted on history or on physical examination, are highly suggestive of neuropathic subtypes.

Pain intensity
- Intensity is an accepted proxy for severity of pain and is the most commonly used measure of the effectiveness of treatment.

SCI, spinal cord injury.

As it is clear that that there can be an enormous emotional, physical, and social impact of pain on a person’s daily life, any assessment of pain is not complete without an assessment of the numerous psychosocial factors and conditions that have been associated with pain-related distress and pain-related functional disability after SCI. It is important to obtain a psychosocial history that includes an assessment of present and past mental health history, as well as a more general understanding of the patient’s perception of pain, with specific focus on important coping strategies, such as pain catastrophizing. Furthermore, the assessment should seek to understand how environmental factors, such as the impact of the workplace or home environment, or social factors, such as interactions with family, friends, and coworkers when a person is in pain, contribute to the chronic pain experience. To aid in this assessment, clinicians may find it useful to use questionnaires to routinely screen for common difficulties, such as mood disorders. Measures like the Patient Health Questionnaire-9 (PHQ-9) or its 2-item form, the PHQ-2, are validated in SCI and can be quickly scored and interpreted. All of these psychosocial factors and conditions also referred to as yellow flags (Table 40.4) must be addressed if the treatment of pain is to be successful if they are contributing to ongoing or worsening pain. At an absolute minimum, pain interference with sleep, mood, and activities should always
be evaluated and therefore are included in the ISCIPBDS (see Table 40.2).^{11}

**MUSCULOSKELETAL PAIN**

Musculoskeletal pain is nociceptive pain resulting from activation of nociceptors within musculoskeletal structures including muscles, tendons, ligaments, and bones within areas of at least partially retained sensation. In areas of apparent complete loss of sensation, nociceptors may be activated and can exacerbate at-level and below-level neuropathic pain as well as trigger autonomic dysreflexia (AD) and AD headache (see “Other Nociceptive Pain” section). Musculoskeletal pain typically changes in intensity with movement or palpation of the responsible musculoskeletal structures in which the nociceptors are activated. Appropriate imaging (x-ray, magnetic resonance imaging [MRI], ultrasound) often shows musculoskeletal pathology consistent with the pain presentation. As might be expected after a traumatic SCI, musculoskeletal pain is common in the acute period related to acute fractures of the spine and other musculoskeletal trauma.^{16,17} Subsequently, this acute injury–related pain resolves, and other pains then begin to appear as individuals begin to function in new ways which predispose them to develop overuse injuries.

If it is unclear if a particular pain is nociceptive or neuropathic, as musculoskeletal pain typically responds better than other types of pain to rest, joint protection, anti-inflammatory medications, and physical
measures such as stretching and massage, treatment of the pain using these specific interventions may be diagnostic. The converse may also be true in that many of the adjuvant medications recommended for the treatment of neuropathic pain such as those within the gabapentinoid and antidepressant classes may also be effective in ameliorating nociceptive pain.

**Shoulder Pain**

Approximately one-half of individuals with SCI, including people with either paraplegia or tetraplegia and complete or incomplete injuries who use all types of mobility devices ranging from wheelchairs to ambulatory assist devices, experience shoulder pain.\(^{18}\) In the acute period after SCI, shoulder pain is thought to develop due to the high demand on unconditioned muscles, whereas in the chronic phase, shoulder pain is thought to be related to overuse from repetitive motions and secondary degeneration of affected musculoskeletal structures.

Either global shoulder muscle weakness related to a high level cervical SCI or an imbalance of specific stabilizing muscles of the shoulder and scapula can be a factor in the development of pain in both acute and chronic phases for individuals with paraplegia or tetraplegia. This imbalance can develop insidiously through relative strengthening of certain muscles (e.g., shoulder abductors and flexors) with everyday activities such as transfers and wheelchair propulsion or through substitution of different muscles in those with cervical SCI if some of the usual shoulder stabilizers are not fully innervated and are therefore weak. Different activities stress different muscles; for example, in propelling a wheelchair up a ramp, the greatest activation is found in the shoulder flexors followed by the external rotators. This is in contrast to the greatest activation in the sternal pectoralis major muscle followed by the infraspinatus and supraspinatus muscles during push-up lift maneuvers.\(^{19,20}\) It has been shown that many individuals who develop shoulder pain have decreased muscle strength, particularly in the shoulder adductors, and lower levels of physical activity even before the onset of pain.\(^{21}\)

Acquired tightness of the shoulder capsule and contracture of the scapular thoracic articulation caused by a lack of passive or active range of
motion and underlying spasticity are also commonly associated with shoulder pain in individuals with tetraplegia, much less so in individuals with paraplegia. Individuals with tetraplegia are also more likely to have pain related to shoulder instability resulting from weakness of the muscles that stabilize the shoulder joint.

Specific etiologies of shoulder pain related to all of the mentioned mechanisms include the rotator cuff impingement syndrome, subacromial bursitis, bicipital tendonitis, adhesive capsulitis, and osteoarthritis.\textsuperscript{22–24}

**Elbow and Wrist Pain**

Musculoskeletal causes of elbow pain in persons with SCI include medial and lateral epicondylitis, triceps tendonitis, osteoarthritis, and olecranon bursitis. The latter often occurs in individuals who lean on their elbows for balance support or in those who push off with their elbows to assist with positioning and bed mobility.

Common musculoskeletal causes of wrist pain in adults include de Quervain tenosynovitis, inflammation/arthritis of the carpometacarpophalangeal joint of the thumb, and arthritis of the wrist. These typically are overuse injuries caused, for example, by repetitive grasping of a wheelchair push rim during wheelchair propulsion.

**Back Pain**

Musculoskeletal back pain in persons with SCI is common for a number of reasons, including a high prevalence of spinal surgeries, trunk muscle imbalances owing to spasticity and/or trunk weakness, kyphoscoliosis, and frequent dependence on wheelchairs. Structures in which nociceptors may be activated in and near the spine include muscles, tendons, and ligaments; the facet joint; the intervertebral disk; and the sacroiliac joint. Pain caused by spinal instability or spinal hardware failure is typically primarily nociceptive. After a portion of the spine is fused, the spinal segments adjacent to (above or below) the fusion often compensate for the lost motion of the fused segments and, over time, develop secondary degeneration and often pain. Sitting in a wheelchair, especially sitting in a kyphotic posture, can induce back pain in individuals with or without SCI.\textsuperscript{25}
When an individual with limited hip flexion range (usually less than 90 degrees) is positioned for an extended period in a wheelchair with a seatback angle of 90 degrees, he or she is at increased risk of acquiring back pain depending on the degree of at least partially preserved sensation. If the lack of hip flexion is unilateral, the individual will accommodate to leaning to the side opposite whenever sitting. If the lack of hip flexion is bilateral, the only way the individual will be able to “fit” within the chair is to have his or her ischial tuberosities (and sacrum) contact the seat more anteriorly than is optimal causing the lumbar spine to be unsupported and the thoracic spine to assume an exaggerated kyphotic posture.

**Muscle Pain Related to Spasticity**

Spasticity is a syndrome of different components, including a velocity-dependent increased resistance to passive motion, involuntary muscle contractions or spasms, and hyperreflexia. The involuntary muscle contractions result from different muscles acting synergistically, typically in a specific flexion or extension pattern. In someone with retained sensation, continuous or paroxysmal muscle spasms are often painful. Spasticity when significant and present to a greater degree on one side of the trunk as compared to the other often causes a coronal imbalance in spinal alignment (or a functional scoliosis) which can lead to musculoskeletal back pain especially in those with retained sensation in the spinal region of imbalance. Nociceptors activated through this coronal imbalance may arise not only from spastic muscles such as for instance the quadratus lumborum and thoracolumbar paraspinals but also from within the sacroiliac joint and lumbar facet joints on the side with more significant spasticity through the greater forces transmitted through these joints.

**VISCERAL PAIN**

Visceral pain refers to pain located in the thorax, abdomen, or pelvis, which is believed to be primarily generated in visceral structures. Visceral pain of gastrointestinal system origin often is temporally related to food intake or bowel function and can be associated with symptoms of AD, anorexia, nausea, or vomiting as well, any of which can be more
prominent than the pain itself. Tenderness to palpation of the abdomen is a common physical sign (in persons with some retained trunk sensation) as are the pain descriptors of “cramping,” “dull,” or “tender.” The characteristics of chronic abdominal pain in SCI are very similar to those of chronic constipation, and appropriate imaging often shows visceral pathology consistent with the pain presentation (e.g., colonic distension by stool). Abdominal visceral pain has a late onset being relatively uncommon during the first 5 years after SCI and increasing in prevalence afterward with approximately one-fifth of those at 10 years and one-third of those at 20 years reporting it; the prevalence does not seem to increase after 20 years, however.

Other less common causes of visceral pain include bowel obstruction, bowel infarction, bowel perforation, cholecystitis, choledocholithiasis, pancreatitis, appendicitis, splenic rupture, bladder perforation, pyelonephritis, urinary tract infection, or superior mesenteric syndrome. As individuals with limited somatic sensation in the abdominal wall may experience only dull or aching pain, even with serious intra-abdominal emergencies such as acute appendicitis, cholecystitis, peritonitis, bowel obstruction, or mesenteric artery thrombosis, a degree of suspicion for these other causes should always be maintained.

**OTHER NOCICEPTIVE PAIN**

Other (nociceptive) pain refers to a nociceptive pain that does not fall into either the musculoskeletal or visceral categories. These pains may be indirectly related to the SCI (e.g., pain from nociceptor activation within the disrupted integument due to pressure injury) or may be unrelated to SCI (e.g., migraine headache).

One particular other nociceptive pain worthy of special mention is headache pain due to AD. It can be severe and usually is described as “pounding.” It is most common in a person with a neurologic level of injury (NLI) at or above T6. AD headache is associated with an elevated blood pressure and often with diaphoresis, piloerection, cutaneous vasodilatation above the level of injury, bradycardia or tachycardia, nasal stuffiness, conjunctival congestion, and mydriasis. AD is usually triggered by a noxious stimulus caudal to the NLI, usually related to the bowel or...
bladder (e.g., bowel impaction or urinary tract infection).

An algorithm for the assessment of nociceptive pain developed by Siddall and Middleton\(^{29}\) is outlined in Figure 40.1.

**FIGURE 40.1** Algorithm for assessing and treating nociceptive pain after spinal cord injury. (From Chhabra HS. ISCoS Text Book on Comprehensive Management of Spinal Cord Injuries. 1st ed. New Delhi: Wolters Kluwer; 2015. Figure 55.3.)

**AT- AND BELOW-LEVEL SPINAL CORD INJURY PAIN**

At-level SCI pain is neuropathic pain perceived within the dermatome of the NLI and/or a maximum of three dermatomes below this level. It must
be attributed to damage to the spinal cord or nerve roots. Pain thought
to injury to the cauda equina is always classified as at-level SCI pain.
One-third of individuals with SCI report at-level SCI pain soon after
injury, and its prevalence over time does not seem to change. At-level
SCI pain is suggested by altered sensation within the painful area,
especially allodynia or hyperalgesia, and the descriptors of “hot,”
“burning,” “tingling,” “pricking,” “pins and needles,” “sharp,” “shooting,”
“squeezing,” “painful cold,” or “electric shock-like.” It is usually
difficult to distinguish between the two subcategories of at-level SCI pain,
spinal cord pain and radicular pain, because both are typically involved in
any traumatic SCI and may have the exact same clinical presentation.
However, radicular pain is generally, although not always, unilateral and
radiating in a dermatomal pattern. When at-level SCI pain is associated
with spinal instability where spinal movement exacerbates the pain
especially if there is evidence of nerve root traction or compression, the
pain is presumably more likely to be radicular in etiology. Neuropathic
pain in this location at or inferiorly adjacent to the NLI that is not
attributed to either spinal cord or nerve root damage should be classified as
other neuropathic pain and not as at-level SCI pain. One example of other
neuropathic pain is focal peripheral nerve compression (e.g., symptomatic
carpal tunnel syndrome in a person with a lower cervical SCI).

Below-level SCI pain refers to neuropathic pain perceived more than
three dermatomes below the NLI, with or without extension up to the NLI,
that is attributed to damage to the spinal cord. If a pain that occurs within
the NLI and the three dermatomes immediately below the NLI is
considered by the individual experiencing it to be the same pain that is
experienced distal to those three dermatomes adjacent to the NLI, this pain
should be classified as a single below-level pain and not as at-level and
below-level pain.

The pain distribution of below-level spinal cord pain should be thought
of, not as dermatomal, but regional, enveloping large areas such as the anal
region, the bladder, the genitals, the legs, or commonly the entire body
below the NLI. It is usually continuous in presence, although the intensity
of the pain can fluctuate in response to yellow flag factors and conditions
(see Table 40.4), fatigue, smoking, noxious stimuli below the level of
injury, and weather changes.

Less than one-fifth of individuals report below-level SCI pain in the first year after injury, but its prevalence increases to approximately one-third after the first year and beyond.\textsuperscript{16,17,30} Below-level SCI pain can occur in persons with complete or incomplete SCI, and its descriptors are the same as those listed for at-level SCI pain.\textsuperscript{10} Allodynia or hyperalgesia can be present within the pain distribution for persons with incomplete injuries. In fact, sensory hypersensitivity (particularly cold-evoked dysesthesia) at 1 month postinjury seems to be a predictor for the development of below-level SCI pain at 1 year.\textsuperscript{16} Similar to at-level SCI pain, neuropathic pain that occurs in this distribution that cannot be attributed to spinal cord damage should be classified as other neuropathic pain and not as below-level SCI pain.

An evaluation including search for potentially treatable causes of neuropathic pain, such as nerve root or spinal cord compression, tethering, or posttraumatic syringomyelia (PTS), should be initiated when the cause is not clearly apparent.

There are three scenarios where worsening of already established neuropathic pain can be seen (Fig. 40.2). In the first, the worsening is due to the natural history of the pain related to ongoing neuroplastic changes occurring within the nervous system during that first year after SCI. In the second, there is progression of the neurologic injury (nerve root or spinal cord) due to changes in degree of nerve root or spinal cord compression, tethering, or PTS. In the third and probably most common scenario, there is the development of a red flag condition (Table 40.5) that may aggravate neuropathic pain.\textsuperscript{15} A thorough history and physical exam is the first step needed to determine to which of the three scenarios the worsening of pain can be attributed. For evidence of the first, which we can call natural pain evolution, improvements in other neurologic findings such as improved sensation and motor strength on examination (or at least no signs of neurologic deterioration) can be reassuring. In contrast, concurrent worsening of other neurologic findings such as loss of sensation, strength, and deep tendon reflexes indicates that the neurologic decline is likely due to changes in or development of nerve root or cord compression, tethering, or PTS or other structural change, and a diagnostic workup in most cases
should be begun.

FIGURE 40.2 Algorithm for evaluating an exacerbation of at-level or below-level spinal cord injury pain.

Evidence for the third scenario, aggravation of existing neuropathic pain by a red flag condition, is bolstered by a stable neurologic exam and the presence of signs and symptoms pointing to changes in other organ systems. It is not uncommon that associated changes in severity of at-level or below-level neuropathic pain can even be more prominent than those other signs and symptoms of a potential red flag condition. These red flag conditions presumably cause ascending noxious stimuli which provide feedback onto existing pain pathways (not necessarily perceived as such in a person with impaired or absent sensation), although the exact pathophysiologic mechanisms for the worsening pain are not clear. Red flag conditions typically require additional diagnostic evaluation and medical intervention.

One specific cause of late-onset spinal cord pain worthy of further mention is PTS. Although it is common to find evidence of a cyst within the spinal cord at the level of the injury using appropriate imaging (MRI or computed tomography [CT] myelogram), only 2% to 5% of all people with SCI develop PTS. The hallmark of PTS is the new onset of signs and symptoms of neurologic decline which may include pain, sensory loss, weakness, altered muscle tone, and various autonomic symptoms presumably caused by expansion of the cyst and compression of the residual spinal cord at the level of the cyst leading to these signs and symptoms.

A delayed onset of pain after SCI, especially beginning after 1 year, should strongly raise the suspicion of PTS as the cause of pain. Bulbar signs and symptoms, especially facial pain, associated with at-level pain of late onset, are rare but virtually diagnostic of PTS. The most commonly reported initial symptom of PTS is pain, either unilateral or bilateral, whereas pain presenting only with cough is not an uncommon initial presentation historically. “Burning,” “dull,” and “aching” are the most commonly reported descriptors reported in several large series, although “sharp,” “electrical,” and “stabbing” have been reported as well.

MRI is the diagnostic study of choice in the evaluation of PTS, although a CT myelogram with up to 24-hour delayed imaging often will show contrast dye within a syrinx cavity in those for whom an MRI is unobtainable.
Another late cause of neuropathic pain is spinal cord or nerve root tethering. Tethering of the spinal cord is a result of meningeal or arachnoid scar formations that can occur after SCI and prevent normal rostrocaudal sliding of the cord within the spinal canal. Tethering of the cord in the cervical spine can generate enough cord traction with flexion of the neck to cause cord or brainstem displacement and neurologic symptoms, including pain, weakness, and sensory deficits. Tethering of the thoracic and lumbar spine often also includes changes in bowel and bladder function. MRI is the diagnostic study of choice for the evaluation of tethering.

At-level spinal cord and nerve root and below-level SCI can result from late compression of the spinal cord or nerve roots by progressive spondylosis, progressive spinal deformity caused by posttraumatic or surgical destabilization, intervertebral disk herniation, or hardware failure. Nociceptive musculoskeletal pain is typically experienced concurrently. X-rays, CTs, and MRIs are the diagnostic studies of choice.

An algorithm for the assessment of neuropathic pain developed by Siddall and Middleton is outlined in Figure 40.3.
OTHER NEUROPATHIC PAIN

Other neuropathic pain refers to neuropathic pain that is present above, at, or below the NLI but is not directly related to the SCI. Compressive neuropathy pain fits within this category and occurs in a specific peripheral nerve distribution distal to the root level and is attributed to compression of a specific peripheral nerve or plexus of nerves, most commonly affecting not only the median nerve at the wrist but also the ulnar, radial, and axillary nerves. The signs and symptoms of carpal tunnel syndrome include numbness or tingling of thumb, index, or middle fingers; abnormal sensation on testing; or numbness or tingling with provocative tests. This syndrome is thought to result from a combination of repetitive trauma, as occurs with propulsion of manual wheelchairs, and ischemia.
from repetitive marked increases in carpal canal pressures, as occurs with push-up pressure reliefs or transfers from one seating surface to another.\textsuperscript{38} A higher risk for developing pain has been shown in those who are overweight or use improper wheelchair propulsion biomechanics.\textsuperscript{39}

**PSYCHOSOCIAL ASPECTS OF PAIN AFTER SPINAL CORD INJURY**

Psychosocial factors are understood to play a significant role in the chronic pain experience. In contrast to past generations of medicine where the mind–body dualistic perspective resulted in medically unexplained pain being labeled psychogenic, the modern biopsychosocial approach suggests that few patients—if any—should be classified in such a manner. In addition to being inaccurate, the diagnosis is also often counterproductive to successful pain management.\textsuperscript{40} However, one must always be attentive to the psychosocial factors that may have a significant impact on pain intensity, function, and quality of life.

**Psychological Factors**

A growing body of research suggests a strong relationship between pain and psychological factors. Indeed, some have suggested that psychosocial rather than biologic factors are more closely associated with the presence and severity of pain.\textsuperscript{4,6} Broadly, research on psychology and pain can be summarized in two areas.

The first explores the association between pain (primarily pain intensity) and psychological factors (primarily mood), through cross-sectional research. These studies have consistently identified strong relationships between psychological symptoms (depression, anxiety, and/or posttraumatic stress disorder [PTSD]) and pain intensity.\textsuperscript{41–47} The few longitudinal studies have highlighted potential causal relationships, with one study supporting a likely bidirectional relationship, such that the presence of either pain or mood difficulties may make higher levels of the other more likely.\textsuperscript{48}; in contrast, another study more specifically highlighted the ways in which chronic pain contributes to depressed mood.\textsuperscript{49} Furthermore, a longitudinal study assessing mood trajectories in people with SCI suggested that having greater pain intensity is associated
with a moderate to severe depression trajectory. As with much of the chronic pain experience, though, it is important to note that stronger relationships may be present between pain interference and mood rather than pain intensity and mood.

The second broad area of pain psychology research refers to the ways in which a person copes with pain, including his or her thoughts, beliefs, and pain-related behaviors. Although these are generally factors that emerge once a person already has pain, it is important to recognize that how individuals approach their pain at onset may influence the evolution of their pain and function over time. The most commonly studied pain coping construct is pain catastrophizing, a maladaptive and disproportionate worry about chronic pain, which has consistently been associated with greater pain intensity and pain interference in persons with SCI. Important implications also exist for other coping strategies, with task persistence repeatedly demonstrated as an adaptive approach, but guarding (e.g., tensing muscles for self-protection or avoiding engaging affected muscles) and resting (e.g., avoiding activity) have been found to be maladaptive approaches. More generally, active coping strategies (e.g., those that promote engagement with the world) have more positive impacts on outcomes relative to passive coping strategies (e.g., those that cause an individual to withdraw from the world around them). Finally, more recent research has emphasized the relationship of pain acceptance with pain-related outcomes, such that being willing to experience pain and/or engaging with valued life activities despite pain is associated with greater function and quality of life.

Social and Environmental Factors
Research also suggests a strong association of social and environmental factors with the pain experience. In general, greater social support is associated with greater function in persons with chronic pain and disabilities, including SCI. However, functioning is greater in individuals who receive social support without solicitous responses relative to those who receive solicitous support. Furthermore, perceived negative responses from friends, caregivers, and relatives may have a negative effect. For example, punishing responses have been shown to have a
negative impact on pain severity.\textsuperscript{58}

\section*{Management of Pain in People with Spinal Cord Injury}

Effective management of chronic pain after SCI remains a clinical challenge. Although some types of nociceptive pain may respond to commonly used interventions, neuropathic SCI pain has been a poorly understood entity that is largely resistant to a variety of interventions.\textsuperscript{59,60} Treatment approaches attempt to address the growing but incomplete body of knowledge regarding the multiple potential mechanisms underlying the development of neuropathic pain. Variable responses are common, and many interventions found to be successful in the treatment of non-SCI neuropathic pain have had disappointing results when applied to SCI neuropathic pain. The experience of pain must be considered and treated in the context of psychosocial factors. This section reviews existing literature for available interventions for chronic SCI pain.

\section*{NOCICEPTIVE PAIN}

\subsection*{Musculoskeletal Pain}

The principles of care used in the general population to treat degenerative and inflammatory musculoskeletal conditions may be applied to people with SCI, although there are specific therapeutic considerations.\textsuperscript{61} For example, complete or even relative rest of a painful overused upper extremity can be difficult to implement in a person who is reliant on the upper extremities for all mobility. Activity restrictions may result in the need for additional caregiver or transportation services, new equipment such as power mobility, or modifications to transfer techniques. Surgery may not always result in good functional long-term outcomes due to the overuse of the repaired structures necessitated by the intrinsic limitations in functional mobility caused by SCI. Because of this impact, knowledgeable and timely treatment of such pain is critical to preserving independence. Physical and occupational therapy play a key role in appropriately adapting musculoskeletal care principles to those with impaired mobility, or utilizing SCI-specific protocols for addressing
common musculoskeletal problems, such as shoulder impingement and dysfunction.\textsuperscript{62,63}

The primary treatment strategy to address chronic nociceptive musculoskeletal pain after SCI is focused on addressing the established or probable etiologic condition and its root cause. Short-term and occasional long-term pharmacologic management may be required if nonpharmacologic interventions fail to sufficiently improve function and quality of life.

Nonpharmacologic Management
Factors that may lead to chronic inflammatory musculoskeletal pain include abnormal posture, altered gait or upper limb biomechanics, and the cumulative effects of repeated transfers and wheelchair or assistive device use. Correcting or reducing excessive mechanical stresses is a fundamental and key principle in the treatment of musculoskeletal SCI pain and can be addressed by appropriate education, retraining, and equipment modifications. Seating in wheelchair users influences not only trunk position but also shoulder position and biomechanical forces during wheelchair propulsion, transfer activities, and activities of daily living. Optimizing seated position is the foundation for long-term protection of upper limbs in wheelchair users. Comprehensive guidelines to address the highly prevalent problem of upper limb musculoskeletal SCI pain are available.\textsuperscript{62}

Pharmacologic Management
Pharmacologic interventions for inflammatory musculoskeletal pain are often indicated. Options include the use of simple analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), local corticosteroid injections, and antispasticity medications.

Acetaminophen is preferable over NSAIDs as the first-line analgesic for musculoskeletal pain, due to the risk for NSAID-related gastric erosion and the potential for poor clinical detection of gastrointestinal bleeding in people with high SCI levels. However, cautious use of NSAIDs may be considered as the next option, in the absence of other contraindications, and preferably outside the acute period following SCI when the risk for gastritis is at its peak. If NSAIDs and acetaminophen are not appropriate
or effective, opioids with relatively weak opioid activity, such as tramadol, would be reasonable. Rarely, “stronger” opioids may be necessary for short-term management of severely limiting pain such as might occur after surgery. However, the use of “stronger” opioids, as a treatment in chronic, noncancer pain is discouraged due to inconclusive or weak evidence in support of this practice and high rates of adverse effects including tolerance, dependence (both physical and psychological), and opioid-induced hyperalgesia. Specific considerations for long-term use of opioids in people with SCI, if they are used at all, include the potential for these drugs to exacerbate bowel or bladder dysfunction, contribute to cardiovascular and respiratory compromise, osteoporosis, and hypogonadism. Case-by-case consideration for long-term opioid therapy should strictly follow published clinical and regulatory guidelines.

Extended-release venlafaxine is a serotonin-norepinephrine reuptake inhibitor that has been used effectively to manage non-SCI nociceptive pain and neuropathic pain from peripheral sources. Research of individuals with SCI and major depressive disorder suggests that extended-release venlafaxine may be superior to placebo in reducing nociceptive pain intensity and interference, with half of the subjects in one study experiencing >50% improvement in nociceptive pain intensity, whereas the same effect was not present for neuropathic pain. Interestingly, in the same study, treatment with a minimally effective dose of 150 mg daily resulted in improved benefit profiles for subjects with mixed SCI pain.

Surgical Management
Stabilization is the most effective treatment for pain arising from spinal instability. Charcot spine, or traumatic spinal arthropathy, is a potential late complication after traumatic SCI that leads to instability. The affected segments typically involve the thoracolumbar spine. Patients with Charcot spine can present with back pain, a change in spasticity or bladder function, audible noises with trunk motion, or otherwise unexplained AD. Timely diagnosis and stabilization is critical to prevent further progression of pain, deformity, or possible neurologic decline. Concurrent
infection should be excluded and appropriately addressed if present.

**Management of Spasticity-Related Pain**

Spasticity is a common neuromuscular complication of SCI, affecting the majority of individuals with chronic SCI.\(^81,82\) Spasticity can interfere with safe mobility, seating, or sleep and may cause varying levels of pain in some individuals. It is important to note that spasticity may also be beneficial when individuals use it to aid function such as to facilitate transfers. Therefore, the decision to treat spasticity should include weighing the beneficial effects of treatment such as pain relief with potential adverse effects of treatment such as sedation or functional loss.

Because the features and mechanisms underlying muscle hypertonia associated with SCI spasticity are distinct from muscle spasms that occur in people who are neurologically intact, a different treatment approach is warranted. SCI disrupts descending inhibitory neural control pathways, resulting in hyperreflexia and spasticity in muscle groups below the NLI. People with chronic SCI will frequently develop a baseline level of spasticity and may also have exacerbations due to noxious triggers that maintain a heightened reflex arc, such as urinary tract infections or skin breakdown. In the latter, appropriate treatment would eliminate the induced nociceptor activation allowing the spasticity to return to a baseline level.

The current collective quality of evidence for antispasticity treatment is varied due in part to the multifaceted nature of spasticity and small studied subject populations. Common nonpharmacologic management options include stretching, positioning, heat or cold modalities, static and dynamic orthotic treatment, vibratory, and electrical stimulation. These are frequently used in conjunction with pharmacologic management. More comprehensive reviews are available on this topic.\(^83–85\) However, conventional practice and the strongest level of evidence support the use of oral baclofen, a γ-aminobutyric acid (GABA) B spinal receptor agonist, as the first-line agent for SCI-related spasticity.\(^82\) The primary limiting side effect is somnolence, and slow and cautious uptitration is critical. Cautious use in people with seizure disorder is indicated, as baclofen use can lower the seizure threshold. Tizanidine is an imidazoline derivative with affinity
for spinal and supraspinal $\alpha_2$ receptors and has reasonably strong evidence for efficacy in reducing polysynaptic reflexes contributing to spasticity in SCI. The drug enhances presynaptic inhibition.\textsuperscript{86} When combined with CYP1A2 inhibitors, including ciprofloxacin, tizanidine may lead to heightened tizanidine adverse effects. Common side effects may include sedation, dry mouth, dizziness, and hypotension. Aminotransferase level monitoring is recommended due to the risk for hepatotoxicity.\textsuperscript{87}

Benzodiazepines used for spasticity treatment include the GABAergic medications diazepam, clonazepam, and clorazepate. Diazepam was historically a mainstay in the treatment of SCI spasticity but is currently considered as a second- or third-line agent, after baclofen or tizanidine, and is primarily used to control nocturnal spasms that interfere with sleep quality, or if a parenteral antispasticity medication is needed. Consideration must be given to the potential for developing drug tolerance, as well as side effects such as sedation that are associated with benzodiazepine use, particularly if used in combination with other sedating agents. Dantrolene, a peripherally acting muscle relaxant, decreases calcium release from the sarcoplasmic reticulum, resulting in a reduction in the strength of muscle contractions. Although dantrolene is an appealing and reasonable adjunct antispasticity treatment that would theoretically limit cognitive adverse effects, evidence specifically addressing the treatment of SCI-related spasticity is scarce, and concerns regarding potential hepatotoxicity have led to its infrequent use in persons with spasticity related to SCI.

Chemodenervation via injection of botulinum toxin is widely used as an effective treatment for focal muscle spasticity for 3 months or longer, although the body of evidence for its efficacy in SCI spasticity is limited.\textsuperscript{84,88,89} Direct neurolysis with alcohol or phenol disrupts the reflex arc that mediates spasticity and effectively creates lower motor neuron dysfunction in a selected distribution to reduce focal muscle spasticity. Effects typically last for at least 3 months, possibly longer.\textsuperscript{89} Because of the risk for dysesthesias, alcohol or phenol nerve blocks are conventionally used to target peripheral nerves innervating larger muscle groups with limited sensory innervation, such as the obturator nerve to decrease adductor spasticity. Targeted motor point blocks to individual muscle
branches may also be considered. However, there is a paucity of SCI-specific controlled studies that assess efficacy and safety of alcohol or phenol neurolytic and motor point blocks for spasticity treatment. Factors currently limiting widespread use include the greater time intensity with motor point localization compared to botulinum toxin chemodenervation, and fewer practitioners with experience in the injection technique. Given the potential to manage spasticity with fewer limiting adverse side effects, it is very reasonable to consider chemodenervation and neurolytic blocks to address localized muscle spasticity, either alone or in combination with other agents.

If these interventions fail to provide sufficient pain relief or result in unacceptable side effects, there are some evidence to support consideration of intrathecal baclofen administration via an implantable, programmable drug delivery device or pump. As with other treatment interventions for SCI-related spasticity, higher quality evidence for use of intrathecal baclofen in SCI is limited, although there is widespread and anecdotally successful use of this intervention.90–92

There are many proposed nonpharmacologic strategies for managing spasticity.84 Stretching results in short-term spasticity reduction. Transcutaneous electrical nerve stimulation (TENS) has evidence from a small randomized controlled trial (RCT) to support spasticity reduction in SCI, whereas variable benefit has been documented in studies using functional and spinal cord electrical stimulation.93–95

In general, the treatment of SCI spasticity is complex and multidimensional and often involves a range of pharmacologic and nonpharmacologic interventions used in combination. As such, a physiatric consultation for spasticity assessment and management can be helpful in navigating all the options.

VISCERAL PAIN

The primary treatment approach for visceral SCI pain is the identification and appropriate treatment of the underlying painful condition, with specific consideration given to medical conditions frequently associated with SCI, such as complications of neurogenic bowel and bladder, or an atypical presentation of visceral disease, such as acute abdomen in those
with high neurologic levels of injury.

OTHER NOCICEPTIVE PAIN
Treatment should be targeted for the specific condition, such as incisional pain or headache due to AD or migraine headache.

OTHER NEUROPATHIC PAIN AND OTHER PAIN
Pain attributed to compression or disease involving nerve roots, plexus, or peripheral nerves may be treated with therapy, orthotics, local or systemic medications, interventional procedures, or surgical decompression following similar indications and principles as the general population. However, special consideration should be given to the impact of activity or postoperative restrictions on the function of people with SCI. Treatment of complex regional pain syndrome often requires a comprehensive treatment plan and is discussed elsewhere.96,97

AT- AND BELOW-LEVEL NEUROPATHIC PAIN
Anticonvulsants
The ability of anticonvulsant or antiepileptic drugs to modulate excessive neuronal discharge by decreasing excitability or augmenting inhibition has led to its widespread adoption as the preferred treatment for various neuropathic pain conditions, including SCI. Drugs in this category modulate neuronal firing through a wide variety of cellular-level mechanisms, including decreasing sodium channel conductance, binding to the $\alpha_2\delta$ subunit of dorsal horn voltage-gated calcium channels or NMDA receptors, attenuation of excitatory glutamate release, or facilitation of GABAergic inhibition.

Gabapentinoids: Gabapentin and pregabalin are distinguished by an apparent dichotomy of structure and action. Although they are structurally related to GABA, they do not seem to significantly bind to GABA receptors or affect sodium conductance. Instead, these drugs purportedly interact primarily with the $\alpha_2\delta$ ligand of voltage-gated calcium ion channels, and secondarily with NMDA receptors. A meta-analysis concluded that both gabapentin and pregabalin are effective at reducing SCI neuropathic pain intensity as well as improving sleep interference,
anxiety, and depression.\textsuperscript{98}

Pregabalin currently has the highest quality of evidence supporting its tolerability and efficacy in reducing SCI neuropathic pain. This body of evidence includes two large, multisite RCTs of subjects with SCI\textsuperscript{99,100} and one RCT of subjects with central neuropathic pain, including a subpopulation with SCI.\textsuperscript{101} The studies reported significant improvement in pain intensity among subjects with at- or below-level SCI neuropathic pain treated with a flexible regimen of 150 to 600 mg pregabalin daily. A significantly greater percentage of subjects who received pregabalin as compared to placebo reported at least 30\% or 50\% reduction in pain intensity and the studies showed improvement in secondary outcome measures such as sleep-related pain interference and health status. Therapeutic benefit was usually seen within 1 week.\textsuperscript{99,102} The average effective daily dose in the studies was generally more than 350 mg per day, and in one study, two-thirds of participants received a maximum daily dose ranging between 450 and 600 mg daily.\textsuperscript{100} The primary adverse effects were noted to be mild to moderate somnolence, dizziness, lower limb edema, dry mouth, and fatigue.\textsuperscript{99,100}

Gabapentin has long been the mainstay in the treatment of various neuropathic pain conditions, albeit with conflicting and less robust evidence than pregabalin to support its use in SCI. An unequivocal determination of efficacy in previous studies may have been limited by the small sample sizes, dosing regimens with low maximal doses, or withdrawal due to adverse effects from rapid dose escalation. A significant reduction in neuropathic pain and improvement in most neuropathic pain subtypes (but not “itching,” “dull,” “sensitive,” and “cold” characterized pains) has been reported in various studies.\textsuperscript{103–106} Statistically significant pain relief has been achieved by the second week of gabapentin administration when subjects receive 1,800 mg daily. Gabapentin doses of 3,600 mg per day are tolerated by most people, although a significantly higher rate of adverse side effects in one study was seen in the active treatment group as compared to placebo (65\% vs. 25\%) that was both reversible with dose adjustment and did not result in withdrawal from the study. Primary adverse side effects noted with gabapentin treatment include somnolence, dizziness, weakness, edema, and vertigo.\textsuperscript{103,107,108}
Two RCTs, however, failed to demonstrate significant difference in pain intensity between gabapentin and placebo.\textsuperscript{107,108} One of these studies showed a significant reduction in “unpleasant feeling” and a trend toward improved pain intensity and decreased burning pain.\textsuperscript{107} A small sample size may have limited achieving significance. Despite the conflicting evidence, a meta-analysis of gabapentinoid treatment studies suggest that gabapentin is effective at reducing neuropathic pain intensity.\textsuperscript{98}

Lamotrigine which is primarily used to treat peripheral neuropathic pain is purported to inhibit voltage-gated sodium channels to decrease neuronal excitability and inhibit excitatory glutamine release.\textsuperscript{109,110} Although a single RCT did not show significant reduction in overall pain from SCI, a subgroup analysis supported the effective use of 200 to 400 mg of lamotrigine daily to reduce at- and below-level neuropathic pain among subjects with incomplete SCI.\textsuperscript{111} One randomized longitudinal comparative study demonstrated that lamotrigine was effective in reducing neuropathic pain intensity in participants with SCI.\textsuperscript{112} Adverse side effects noted include dizziness, somnolence, headache, and rash. There is an U.S. Food and Drug Administration (FDA) black box warning regarding possible Stevens-Johnson syndrome with lamotrigine use.

Valproic acid has wide-ranging neuromodulation mechanisms which make this drug an appealing candidate for the treatment of neuropathic SCI pain. A single RCT evaluated the use of valproic acid in a small population of subjects with SCI-related central pain. Compared to placebo, use of valproic acid resulted in a nonsignificant trend toward SCI pain reduction.\textsuperscript{113}

Levetiracetam may have several analgesic mechanisms, including binding to voltage-gated calcium channels and thru its GABAergic properties. One crossover RCT showed levetiracetam did not significantly reduce pain intensity versus placebo.\textsuperscript{114}

Carbamazepine acts primarily on voltage-dependent sodium channels to dampen neuronal firing.\textsuperscript{115} Oxcarbazepine, a structural analog, may share a similar mechanism of action. One RCT demonstrated limited protective benefit from early carbamazepine use on SCI neuropathic pain severity at 1 month but not at 3 or 6 months.\textsuperscript{116}

Topiramate targets sodium and calcium channels, potentiates
GABAergic inhibition, and inhibits glutamate receptors. There is currently scant evidence to support its efficacy in managing neuropathic SCI pain. One small RCT in people with neuropathic SCI pain showed positive results with topiramate at the highest doses tested, 800 mg, only after the subjects were treated with this dose for 4 weeks.\textsuperscript{117}

**Conclusion: anticonvulsants for management of neuropathic spinal cord injury pain:** Gabapentinoid anticonvulsants are considered first-line treatment for neuropathic pain following an SCI. Gabapentin and pregabalin monotherapy are both effective at reducing SCI neuropathic pain intensity as well as potentially improving sleep interference, anxiety, and depression. However, the relatively increased risk for adverse side effects such as dizziness, edema, and somnolence warrants close monitoring for dose titration. Lamotrigine may be of benefit to reduce neuropathic pain in individuals with incomplete SCI, especially those with evoked pain, but has a risk of significant potential serious adverse effects that must be carefully weighed against the potential benefit before initiating treatment.

**Antidepressants**

Although the neuromodulatory actions of antidepressants are conventionally attributed to norepinephrine and serotonin reuptake inhibition, other actions including NMDA-receptor antagonism and sodium channel blockade may also play a role in analgesia. A meta-analysis of four antidepressant RCTs for neuropathic pain control after SCI (two studying amitriptyline, one studying trazodone, and one studying duloxetine) showed a small, but significant, benefit over placebo. The effect was greatest for amitriptyline, followed by duloxetine. Those treated with antidepressants experienced a higher rate of complications such as constipation and dry mouth, with side effects limiting adherence rates and potentially underestimating treatment effect.\textsuperscript{118}

**Tricyclic antidepressants:** Amitriptyline is a tricyclic antidepressant found to be effective in treating other pain conditions such as diabetic and postherpetic neuropathy and headaches. Effective doses range from 25 to 150 mg daily.\textsuperscript{108} As with many other pharmacologic interventions for SCI pain, there is scarce and conflicting direct evidence for the effectiveness of
tricyclic antidepressants in the treatment of neuropathic SCI pain. For example, relative to controls, amitriptyline was found to be efficacious in treating neuropathic pain in patients with SCI and major depressive disorder, but no significant differences were found in a study that excluded individuals with major depressive disorder.\textsuperscript{108,119} Furthermore, no significant differences were found when amitriptyline was compared to gabapentin\textsuperscript{108} or lamotrigine.\textsuperscript{112} The most common adverse effects of amitriptyline cited are dry mouth, dizziness, constipation, increased spasticity, and urinary retention.\textsuperscript{119} Secondary and tertiary amine tricyclic antidepressants such as nortriptyline and desipramine have not been adequately studied in the treatment of neuropathic pain after SCI but are purported to have less intense anticholinergic effects which may improve tolerability. Some studies indicate benefit from combined therapy with amitriptyline and other pharmacologic and nonpharmacologic treatments.\textsuperscript{120,121}

**Trazodone:** The selective serotonin reuptake inhibitor trazodone, at doses of 150 mg daily, has not been shown to be more effective than placebo in managing neuropathic pain in subjects with traumatic SCI.\textsuperscript{122}

**Duloxetine:** Duloxetine, a dual serotonin and norepinephrine reuptake inhibitor, has been demonstrated to be safe and effective in the treatment of painful conditions such as diabetic peripheral polyneuropathy at doses of 60 to 120 mg daily\textsuperscript{123–125} and with lower quality of evidence of effectiveness for fibromyalgia.\textsuperscript{125,126} However, in neuropathic central pain due to SCI and stroke, one RCT noted only a nonsignificant trend toward pain intensity reduction. Duloxetine did appear to be superior to placebo in reducing cold-induced allodynia in this mixed patient population and in improving Patient Global Impression of Change scale scores.\textsuperscript{127} Duloxetine merits further study in the treatment of pain conditions in SCI given the emerging broad applications for pain treatment. Although generally well tolerated, side effects are dose-dependent and most commonly include nausea, dry mouth, dizziness, fatigue, and constipation. Hypertension and serotonin syndrome is possible and due diligence is needed due to potential drug interactions.\textsuperscript{128}

**Venlafaxine:** As previously addressed under treatment of nociceptive musculoskeletal pain, the serotonin-norepinephrine reuptake inhibitor
venlafaxine XR did not significantly improve neuropathic SCI pain in the presence of major depressive disorder in one study. However, some benefit was noted with higher doses in subjects with mixed SCI pain.\textsuperscript{76}

**Conclusion: antidepressants for the management of chronic neuropathic spinal cord injury pain:** A trial of tricyclic antidepressants appears to be reasonable in clinical practice given supportive evidence from other neuropathic pain conditions, particularly in the presence of concurrent depression. It may be beneficial as an adjunct treatment intervention. However, tricyclic antidepressants may have a number of side effects that should be considered in the population with SCI including sedation, constipation, dry mouth, orthostasis, headache, nausea, and urinary retention. Additional considerations include the potential for cardiac side effects and potential drug interactions.\textsuperscript{118,129,130}

### Local Anesthetics
Lidocaine, a sodium channel blocker, has been the most frequently studied local anesthetic for neuropathic pain conditions. Intravenous lidocaine infusion in a small population that included individuals with SCI neuropathic pain demonstrated reduction of spontaneous ongoing pain, brush-evoked allodynia, and static mechanical hyperalgesia but had no effect on thermal allodynia.\textsuperscript{131–133} One RCT of intravenous lidocaine failed to demonstrate significant improvement in SCI neuropathic pain intensity.\textsuperscript{134} Nevertheless, ongoing outpatient treatment with parenteral lidocaine administration is not practical. Several case reports for the use of topical lidocaine for at-level neuropathic pain after SCI exist, but no RCTs have been performed.\textsuperscript{135–137} Mexiletine, an oral lidocaine analog, was not shown to be effective for neuropathic SCI pain at a dose of 450 mg per day in an RCT of 11 subjects.\textsuperscript{138}

### N-Methyl-D-Aspartate Receptor Antagonists
In support of the hypothesis that NMDA receptor activation is one mechanism for neuropathic pain, parenterally administered NMDA receptor antagonist ketamine was found to be more effective than placebo at managing below-level neuropathic SCI pain in three RCTs.\textsuperscript{134,139,140} Ketamine was shown to have similar analgesic efficacy as fentanyl and
was particularly beneficial for evoked, wind-up pain more than chronic ongoing pain. In general, the effective doses for treating mixed-diagnosis neuropathic pain were subanesthetic doses. Ketamine has typically been administered as a bolus or short-term infusion, with a similarly limited analgesic period.\textsuperscript{141,142} In one study,\textsuperscript{140} a multiday low-dose ketamine infusion combined with oral gabapentin was more effective at reducing neuropathic SCI pain intensity than intravenous placebo + gabapentin, and the effect was noted up to 2 weeks after cessation of the infusion. As with lidocaine, long-term and outpatient administration of ketamine remains problematic. Although there are reported extemporaneously formulated oral compounds, there are currently no effective commercially available oral alternatives. There are significant risks associated with its use, including hallucinations, panic attacks, cognitive impairment, somnolence, abuse potential, cardiovascular, and gastrointestinal side effects with rare hepatotoxicity. One uncontrolled, open-label study explored treatment of acute allodynia in 13 subjects with highly motor incomplete SCI using parenteral ketamine followed by variable periods of oral ketamine. All subjects had successful pretreatment single-dose ketamine challenges with dramatic neuropathic pain reduction. Pain improvement with ketamine treatment was seen in three quarters of participants at the study conclusion and in 97\% at follow-up. Those treated acutely were reported not to experience recurrence, and five of the subjects experienced mild side effects that included a sensation of floating while receiving the infusion.\textsuperscript{143} Parenteral ketamine may prove to be an option in treating severe, refractory neuropathic pain with in-hospital monitoring. Although the preliminary studies suggest ketamine has potent analgesic properties for neuropathic pain, further studies are needed to determine therapeutic indications and methods of administration and to better understand its toxicity profile.

**Opioids**

In general, the evidence to support opioid use across various chronic neuropathic pain conditions is limited or of low quality.\textsuperscript{144,145} Although RCTs evaluating intravenous morphine\textsuperscript{146} and alfentanil\textsuperscript{139} in decreasing neuropathic SCI pain have shown statistically significant short-term
benefit, there is very limited evidence for the use of oral or transdermal opioids for SCI neuropathic pain.

Tramadol, a low-affinity µ-receptor agonist and monoamine reuptake inhibitor, is a scheduled drug in the United States. One RCT demonstrated effective reduction in pain intensity and anxiety versus placebo and improved sleep quality and global satisfaction with life. However, nearly half of the subjects in the active treatment group withdrew from the study primarily due to the adverse effects experienced by over 90% of subjects in this group. The most frequently cited adverse effects were fatigue, dry mouth, and dizziness. There is a risk for serotonin syndrome when tramadol is taken concurrently with tricyclic antidepressants and tramadol lowers the seizure threshold for those at risk for seizure activity.

A multisite observational study of oxycodone in subjects with SCI showed significant reduction in neuropathic pain intensity at 3 months, with improvements in quality of life and impact on physical activity and sleep. The study did not exclude concurrent treatment with anticonvulsants, and the majority of subjects received such treatment.

All opioid medications carry the risk for dependence and withdrawal, with additional considerations in the SCI population for sedation, constipation, cardiorespiratory, and endocrine suppression. The decision to use opioids in the treatment of chronic SCI pain is rarely indicated and the decision to initiate treatment should include a careful analysis of the risks and benefits and should comply with any state or federal regulatory requirements and available clinical practice guidelines as previously referenced.

**Cannabinoids**

Tetrahydrocannabinol (δ9-THC) is the active component in cannabis that binds to cannabinoid receptors to modulate pain, mood, and memory. The current direct evidence for use of cannabinoids for SCI pain is limited and conflicting, but increasingly widespread access and use has resulted in anecdotal reports of benefit and a strong expert panel recommendation for prioritization of targeted research in this area. Common adverse effects included dry mouth, constipation, and drowsiness.

One small pilot study comparing dronabinol and diphenhydramine
placebo showed no significant reduction in chronic below-level neuropathic pain.\textsuperscript{150} Another open-label prospective study of chronic neuropathic pain in a mixed population, including four of eight participants who had SCI, failed to demonstrate reduction in pain, quality of life, and functional impact.\textsuperscript{151} The majority of the participants exhibited adverse side effects, necessitating drug cessation. Of concern is the noted hyperalgesia in one quarter of participants in one study of δ9-THC in patients with SCI-related spasticity versus one-fifth who noted pain improvement.\textsuperscript{152}

**Drug Combinations**

Combined drug therapy or concurrent drug and nonpharmacologic interventions may be beneficial when a single agent is ineffective. For example, combinations of anticonvulsants and tricyclic antidepressants may be more effective than either administered alone.\textsuperscript{120,121} This approach requires cautious exploration of possible side effects of drug combinations, such as the potential for serotonin syndrome with the concurrent use of tramadol or duloxetine and a tricyclic antidepressant.

**Spinal Drug Administration**

Intrathecal (IT) drug administration has emerged as an alternative to systemic or parenteral drug delivery when the latter is ineffective or associated with unacceptable side effects. However, the body of evidence for its efficacy in reducing SCI pain is limited to case series and a small number of controlled trials, and the strength of evidence varies depending on the drug(s) infused.

In one case series, spinal administration of morphine and clonidine was found to be effective in some individuals.\textsuperscript{153} IT clonidine or morphine alone was not found to be more effective than placebo in reducing the intensity of SCI-related pain. However, combined intrathecal morphine and clonidine administration was found to be superior to monotherapy with either drug. Although the combination was effective in the population with chronic at- and below-level neuropathic SCI pain, greater pain reduction was noted in the group with at-level neuropathic pain.\textsuperscript{154} Intrathecal ziconotide has been used to treat neuropathic pain.
conditions, but the evidence for its successful use to manage SCI-related at- and below-level neuropathic pain is currently limited to one case report of combination therapy with intrathecal hydromorphone. Beneficial combinations of IT morphine, clonidine, or ziconotide with baclofen in those with neuropathic pain and spasticity from SCI have been described. Although intrathecal baclofen can reduce pain related to spasticity in people with SCI, it has not been shown to significantly improve neuropathic pain.

Any combination IT drug regimen requires very knowledgeable and cautious titration of each drug to prevent overdose or underdose. Use of nonapproved drugs in an intrathecal drug delivery system may lead to premature device failure. The risks associated with surgical implantation and management of an implanted drug delivery system requires careful and often multidisciplinary assessment and screening for physical and cognitive candidacy, a drug trial, and a detailed discussion to ensure the candidate has full understanding of the potential risks and benefits and maintenance requirements and to manage expectations from the therapy. Sufficient cerebrospinal fluid flow through areas of potential scarring or blockage is also necessary for the drug to reach its local target.

PSYCHOLOGICAL AND ENVIRONMENTAL MANAGEMENT
There are multiple roles for psychological intervention in pain management. In terms of direct intervention, there are now numerous psychotherapeutic approaches focused directly on improving how individuals cope with chronic pain. Cognitive-behavioral therapy (CBT) represents a variety of therapeutic approaches targeting the improvement of cognitive content and behavioral engagement, including modules such as cognitive restructuring and relaxation therapy. Preliminary research supports the use of CBT for the treatment of pain after SCI. Acceptance and commitment therapy (ACT) is a newer therapeutic technique that focuses on psychological flexibility, being present-focused despite the presence of challenges, and focusing behavior on engagement with valued activities. Although there are no studies evaluating the technique for the treatment of pain after SCI, a growing body of literature
suggests that the intervention is effective for persons with chronic pain and there are no apparent reasons that the intervention would function differently for persons with SCI.\textsuperscript{166–168} Furthermore, ACT targets the acceptance-based coping strategies that have been shown to be highly correlated with pain outcomes in persons with SCI, such as activity engagement and willingness.\textsuperscript{55,56} Finally, hypnotic approaches have been effective in facilitating pre- to posttreatment improvements in pain intensity that are maintained at 3-month follow-up in persons with SCI.\textsuperscript{169} Hypnotic analgesia involves an induction of a hypnotic (or suggestible) state, followed by the therapist giving suggestions of alternative interpretations of painful sensations, alternative responses in the setting of pain, and other similar opportunities for improving the way one experiences pain.

Given the association of mood and psychiatric disorders with pain outcomes, it is also important to consider whether psychological intervention is warranted focused more on the presence of those factors. Whereas pain management would be primary in the previously described interventions, here, pain management might be secondary to more traditional psychotherapies that focus on depression, anxiety, PTSD, or other mental health conditions. Moreover, given the significant adjustment inherent to experiencing SCI, therapy focused on adjustment to SCI may also be warranted. A myriad of interventions may be useful, but the majority of existing evidence again focuses on the use of CBT.\textsuperscript{170}

Although psychological interventions can be delivered in a standalone format, such interventions may be best delivered in concert with other interventions. Psychologists routinely play a critical role within multidisciplinary teams that together address the totality of the biopsychosocial spectrum.\textsuperscript{171}

**OTHER NONPHARMACOLOGIC MANAGEMENT OF PAIN IN PEOPLE WITH SPINAL CORD INJURY**

The impact and treatment challenge presented by chronic SCI pain, along with the desire to minimize drug adverse side effects, has engendered interest in exploring nonpharmacologic strategies for pain management.\textsuperscript{60,172}
A Cochrane review of studies on nonpharmacologic treatment strategies for SCI pain found the body of evidence generally insufficient to support the efficacy of these interventions, underscoring the need for more high-quality studies of such treatments.\textsuperscript{173}

**Neurostimulation**

The effect of TENS was evaluated in two studies, with one RCT that found significant reduction in SCI neuropathic pain with low-frequency stimulation.\textsuperscript{174,175} One study of subjects with longer duration of SCI did not show benefit in reducing pain with either high- or low-frequency stimulation protocols.\textsuperscript{176} The recommended electrode application site is a region with sensory preservation.\textsuperscript{131}

Surgical neuromodulation strategies via spinal cord, deep brain, and motor cortex stimulation have also been studied. Spinal cord.\textsuperscript{177,178} However, diminished pain relief is noted over time.\textsuperscript{179} Sufficient dorsal column function is presumed necessary for effective treatment.\textsuperscript{130} In general, response rates from spinal cord stimulation are felt to be less robust than seen in other pain populations.\textsuperscript{180} These factors may limit its clinical utility in SCI, particularly in the setting of complete SCI.

The evidence for effectiveness of deep brain stimulation (DBS) in reducing SCI pain is conflicting and limited, and DBS is considered investigational for the treatment of pain.\textsuperscript{180} Multiple targets have been reported, including the thalamic nuclei, periaqueductal grey, and internal capsule. One systematic review noted less than one-fifth of subjects had long-term improvement in subjects with SCI pain.\textsuperscript{181} The surgical risks, investigational status for pain treatment, and lack of sufficient evidence currently limit the justification for the clinical use of DBS for SCI pain.

Motor cortex stimulation has primarily been studied to provide relief from central poststroke and facial pain. There are very few reports of its use to treat SCI pain, primarily case reports and series. These modalities had varying but generally inferior results in SCI when compared to other populations.\textsuperscript{180,182,183}

The mechanism underlying pain relief from transcranial direct current stimulation (tDCS) is uncertain, although it is postulated to modulate central pathways.\textsuperscript{184} The use of tDCS resulted in greater short-term
reduction in pain intensity over sham control in three RCTs\textsuperscript{185–188} but was not effective versus sham treatment in another trial.\textsuperscript{189} A meta-analysis of the data suggests tDCS produces moderate effect in reducing neuropathic SCI pain, but the relief is not sustained at follow-up.\textsuperscript{190} However, combination therapy using tDCS and visual illusion has been shown in one study to be highly effective at reducing pain intensity and the benefits are sustained for at least 12 weeks.\textsuperscript{187} No serious adverse effects have been noted with conventional tDCS use.\textsuperscript{191} tDCS is favored for neuromodulation because of ease of use, cost, and duration of benefit.\textsuperscript{185} Preliminary results support the need for further investigation of tDCS, alone or in combination with other modalities.

**Massage**

Massage therapy was identified as one of the most frequently explored nonpharmacologic interventions among people with chronic SCI pain.\textsuperscript{172} A recent RCT of 40 individuals with SCI who received 30 minutes of weekly massage therapy or guided imagery showed statistically significant reduction in both pain and fatigue from both interventions at 5 weeks. Massage therapy twice weekly for 6 weeks reduced pain interference measures at 6 weeks, but the result was not sustained at 2 months.\textsuperscript{192}

**Acupuncture**

At present, the body of evidence for the use of acupuncture to treat neuropathic SCI pain is conflicting and varied, yielding overall inconclusive findings. However, a few small pilot trials showed promise in the treatment of SCI pain, including short-term significant reduction in neuropathic\textsuperscript{192,193} and mixed SCI pain types.\textsuperscript{194} One RCT showed a moderate but nonsignificant trend in the treatment of shoulder pain in SCI, but a large placebo effect may have blunted the treatment effect.\textsuperscript{195} Potential practical limitations cited include finding a qualified provider and selecting stimulation sites.\textsuperscript{130} Larger, randomized controlled studies of acupuncture for SCI pain are warranted.

**Physical Therapy and Exercise**

Physical therapy addresses factors contributing to chronic musculoskeletal
pain in people with SCI as previously described, whereas regular physical activity and exercise routines have been shown to improve pain and mood.\textsuperscript{196,197} Evolving knowledge about neuroplasticity mechanisms for pain development, sensory pathway activation by exercise, and activity-dependent neuroplasticity has intensified research interest in the effects of exercise interventions on neuropathic pain.\textsuperscript{198} Despite this, large, randomized studies in humans of the effects of exercise on neuropathic SCI pain are currently lacking. Two studies on small populations of people with SCI have shown beneficial effects of exercise on pain. One study of seated double-poling ergometry showed that four of seven subjects with neuropathic pain showed clinically meaningful reduction in pain intensity with over half noting improvement on patient global impression of change. More significant improvement was noted in nociceptive musculoskeletal pain.\textsuperscript{199} Both neuropathic pain intensity and mood were significantly improved by a single 15-minute wheelchair propulsion exercise in 10 individuals with SCI. Electroencephalogram correlates showed exercise-related effects on peak $\alpha$ activity, felt to be a biomarker for neuropathic pain. Preexercise baseline peak $\alpha$ activity in the parietal and occipital lobes was lower in subjects with SCI than in healthy controls, and the central peak $\alpha$ activity increased after exercise.\textsuperscript{200} Exercise intervention may address SCI pain by not only mitigating existing pain but also potentially as an intervention that seeks to modify the underlying mechanisms of pain evolution after SCI. Given the potential health and analgesic benefits of exercise for both neuropathic and musculoskeletal SCI pain, and relative safety of the intervention, further research into this area is encouraged.

**SURGICAL INTERVENTIONS**

Surgical care to address a neurologically significant structural lesion, such as decompression of a nerve root or peripheral nerve, detethering of roots, and treatment of progressive, symptomatic syrinx formation, may be performed to improve pain or prevent neurologic decline. However, the surgical correction may not always result in pain reduction and may at times exacerbate pain, highlighting the need for individualized surgical assessment and thorough discussion of potential and expected risks and
benefits.

Surgical ablative approaches, including microsurgical techniques, address pain by abolishing or severing pathways to the site of abnormal neuronal activity. As with other interventions, variable outcomes have been described in SCI and only several uncontrolled studies are available due to the invasive nature of the interventions. Cordotomy or cordomyelotomy is rarely used due to the risk for neurologic loss and with variable reports of effectiveness and is not currently recommended.\textsuperscript{201–203} Dorsal root entry zone (DREZ) lesioning aims to selectively deafferent hyperactive dorsal horn neurons close to the level of injury and may provide relief of neuropathic pain, particularly at-level neuropathic pain.\textsuperscript{204,205} Extension of the DREZ lesion may improve outcomes in more diffuse SCI pain.\textsuperscript{203} Use of intramedullary recordings of spontaneous and C fiber evoked electrical hyperactivity to guide DREZ lesioning also seems to boost effectiveness at relieving both at- and below-level neuropathic pain. One study reported 100% pain relief of pain in more than three quarters of subjects who received DREZ with intramedullary guidance.\textsuperscript{206,207} Although additional study is warranted, DREZ shows promise as a valuable treatment option for refractory neuropathic SCI pain.

**Conclusion**

Pain represents a common and impactful challenge for individuals living with SCI. Consistent with chronic pain at large, individuals living with SCI and pain are understood to have poorer function, more physical and psychological comorbidities, and lower quality of life than their peers who live without pain. As described in this chapter, there is significant diversity in the types, causes, and treatments for SCI-related pain. The limited evidence and varied quality of literature to address the problem of pain in people with SCI speaks to the value of systematic reviews,\textsuperscript{129,208} updated evidence-based expert panel consensus on management,\textsuperscript{130,209} as well as further targeted and high-quality research to explore promising individual and combination regimens. To facilitate this inquiry, use of standardized systems of assessment and classification, such as the ISCIP Classification and the ISCIPBDS, as well as the selection of appropriate outcome...
measures are vital. Optimal management attends to not only the intensity of the pain but also, more importantly, improving patient function despite the challenge of pain. When effectively utilized, clinical intervention can aid patients in improving the function and quality of life that has been negatively impacted by this challenge.

Cancer is a highly prevalent and serious public health issue. It most commonly affects the elderly—the average cancer patient in the Western world is aged 65 at first diagnosis—and cancer is more likely to occur in particular clinical settings, such as life-long smokers, in obesity, and with certain environmental and heritable risks. Specifically, the World Health Organization reports that about one-third of cancer deaths are attributed to the increased risk associated with five major behavioral and dietary risk factors: tobacco use, high body mass index, low fruit and vegetable intake, lack of physical activity, and alcohol use. Tobacco use itself is responsible for about 22% of cancer deaths around the world. However, there is no one who is immune from the disease regardless of age. In North America, about 1 in 3 adults will develop cancer in their lifetime, with about a 50% fatality rate. Cancer is sufficiently prevalent that some individuals will develop more than one type of malignancy, either sequentially or concurrently. Cancer is often painful, and pain is a common heralding manifestation of the disease. For example, about two-thirds of women have pain at the onset or recurrence of ovarian cancer. As cancer progresses, it is more likely to be associated with pain, and the pain is more likely to be severe. A range of epidemiologic studies in several countries and practice settings suggests that pain from a wide variety of cancers is present in about one-third of patients receiving cancer treatment and in 60% to 90% of patients with advanced illness.

Cancer treatment can also cause pain, and cancer pain is commonly classified as being either due to the underlying disease or due to its treatment. In pediatric malignancies, pain due to treatment is more
common than pain from the underlying disease. Cancer patients can also have pain from non–cancer-related conditions, and the causes and prevalence are similar to pain in patients without a cancer diagnosis. Clinicians should be especially wary about missing a treatable cause of pain in cancer patients, whether the pain is due to cancer, cancer treatment, or due to a noncancer mechanism.

There is an array of factors that contribute to the likelihood of pain being present, its severity, and the best approach to its management. Thus, in order to understand the wisest approach to assessing and managing the cancer patient who presents with cancer pain, the situation is best appreciated within the perspective of where the patient is in the disease trajectory and what other clinical factors are likely to be at play.

The intention of this introductory chapter is to provide a clinical context of the individual patient and to bring into focus the extensive information that follows in subsequent chapters where more detailed approaches to assessment and management will be elaborated. This chapter is divided into six sections:

- Summary of the epidemiology of cancer pain
- How to perform a cancer pain history
- How to perform a physical examination of a cancer pain patient, including bedside provocative maneuvers to help identify potential underlying pain-sensitive structures
- Problem formulation
- Constructing an analgesic strategy
- Managing pain in specific clinical situations

**Epidemiology of Cancer Pain**

Epidemiology is “the study of disease as it affects groups of people. . . . [It] contributes to the control not only of infectious diseases but also of conditions such as heart disease and cancer. Their distributions in populations can provide important insight to possible causes. The relation between the environment and disease is an essential part of epidemiology.” The epidemiology of cancer pain refers to cancer pain within the overall population, and its characterization suggests plausible
factors at play within an individual patient.

**PAIN RELATED TO EXTENT OF DISEASE: THE CANCER DISEASE TRAJECTORY**

Commonly, patients with solid tumor malignancies present with an asymptomatic mass; less than 15% of patients with nonmetastatic disease describe pain from their cancer. Cancer can present clinically in a wide variety of ways, including dyspnea, nausea, urinary symptoms, weakness, numbness, weight loss, and other signs and symptoms. When pain is the first symptom of cancer, there is a tendency for the cancer to be more advanced, and perhaps for this reason, pain can be an independent predictor for poorer survival.

The clinician can use this information to suspect the underlying cause of pain. For example, imagine a patient with a diagnosis of melanoma who presents with a 3-day history of new onset of headache. Headache could be due to a benign cause (e.g., migraine) or due to malignancy (e.g., brain metastasis). Stage of cancer strongly predicts the risk of brain metastases from a solid tumor. In this example, the likelihood of central nervous system metastasis is much lower in a patient who has recently undergone resection of a primary melanoma in the leg, with regional lymph nodes negative, compared to the patient who has known liver and lung metastases from melanoma. About 90% of patients with advanced melanoma have central nervous system metastases at the time of autopsy, and the report of any headache in a patient with known metastatic melanoma is ominous. If imaging studies of the brain are negative in a patient with metastatic melanoma and a new headache, the possibility of meningeal disease should be considered, along with a diagnostic dural puncture for cerebrospinal fluid analysis.

**SPECIAL NEEDS OF PARTICULAR AGE GROUPS: PEDIATRIC, YOUNG ADULT, ADULT, GERIATRIC**

Pain is a subjective experience, and the pain of cancer can be foreign and puzzling for the patient. Pediatric patients can lack the language and the sophistication of adults in communicating their inner world. Although cancer can result in an overwhelming sense of threat at any age, the
pediatric age group requires special skills and support. For instance, pediatric patients and their families become the “unit of care,” far more so than with adult oncology, and specialized assessment tools must be used for this population (see Chapter 49).

Cancer pain is prevalent at all ages. However, there are several remarkable features of cancer pain within the pediatric population. Pain from cancer treatment is highly prevalent, in part related to the high prevalence of procedures to manage hematologic malignancies and other malignancies which are prevalent in this age group. Particular attention needs to be taken to diminish the fear of pain from procedures and treatment. Painful procedures include placement of intravenous catheters, repeated spinal taps, bone marrow biopsies, extensive cancer surgery, and others. Importantly, young patients are often proficient at managing their pain once taught an appropriate technique. Patients as young as 5 years can safely and effectively use a patient-controlled analgesia device, with the overall outcome of good pain control and potentially less risk of nausea or respiratory depression compared to continuous opioid infusions.

Sarcoma and hematologic malignancies are more common in the 16- to 21-year-old age group. Rarely, young adults can present with what looks clinically to be depression, but in fact, the patient has uncontrolled pain. Particular attention needs to be placed on supporting the patient to be as active and have as normal a life as possible despite the potentially disfiguring effects of cancer treatment, difficulty with cancer pain, and the many challenges of cancer treatment.

Working-age adults with cancer pain face their own challenges. A need to generate income or fulfill parenting roles despite illness, financial obligations, fear of addiction, and the difficulties of managing emotional distress are all issues that need to be directly addressed in order to provide comprehensive symptom control. Young adults often choose or have indications for more aggressive or prolonged cancer treatments. For example, aromatase inhibitors are commonly used in the adjuvant treatment of breast cancer over the course of several years; almost half of these patients describe joint pain or stiffness. Usually, symptoms are mild or moderate, but nearly one quarter of patients rate their symptoms from aromatase inhibitors as severe.
The geriatric population often has medical comorbidity, such as underlying heart, lung, renal, or cognitive impairment, and may be on a variety of medications that interact with analgesic medications. Dosages of medications such as opioids may need to be lowered because the metabolism of medication can be much slower with advanced age or underlying organ impairment. An important, emerging concept within the geriatric population is that of frailty. Factors that promote return to health or maintenance of good health—resilience—are powerful in the pediatric and young adult population; with advancing years, the ability to maintain homeostasis becomes less. Frailty is a term that describes what has become an area of intense research in the geriatric health care community and is a key factor in analgesic care in the older cancer population. Changes in medications in the geriatric population should generally be made more slowly and with smaller dosing increments. Attention needs to be paid to drug–drug interactions, and the clinician should be vigilant for the appearance of early signs of cognitive impairment. Because of the high prevalence of delirium in the medically ill geriatric oncology population and the difficulty in making an early diagnosis, some clinicians have advocated for the routine use of delirium screening tools.

SPECIAL NEEDS OF PARTICULAR ETHNIC GROUPS: COMMUNICATION STYLES, COMMON PREFERENCES, AND MANAGING TABOOS

Some countries and certain ethnic groups are particularly vulnerable to specific health issues. Ineffective cervical cancer prevention programs, low rates of cervical cancer screening, and difficulty accessing cancer treatment services are associated with higher rates of cervical cancer and higher rates of cancer death. About 90% of cervical cancer deaths occur in low- to middle-income countries. Nasopharyngeal cancers are highly prevalent in patients who originate from Pacific Rim countries, and the higher risk persists for decades after moving to a Western country. There are some First Nations communities in North America where diabetes mellitus has reached epidemic proportions, with half or more of all adults being afflicted; cancer care can be greatly complicated by underlying diabetes. Every culture and ethnic group has a unique set of medical issues
that are of particular concern.

Some countries, or parts of countries, have a lengthy history of violence and social upheaval in association with the licit or illicit drug trade, and the medical use of opioids is greatly frowned on. Some religious cultures are believed to hold the experience of suffering to be of spiritual value. Others are commonly believed to place a taboo on disclosure of a cancer diagnosis to the patient, relegating the burden of that knowledge and the decision making about cancer care to the eldest son.

There are approximately 6,900 discrete languages spoken in the world and uncountable distinct ethnic, religious, and other cultures. How is the clinician to be alert to all possible areas where culture can have a major influence on patient preferences and on patient assessment?

Basic knowledge of common beliefs within certain cultures is inarguably important, such as the prevalence of modesty as a dominant value in the Muslim faith community. Beliefs common to many cultures are complicated by the tendency in Western society for a shift to occur within immigrant families, with increasing orientation toward secular values from one generation to the next. So when the patient who is thought to belong to a particular culture is in the physician’s office along with his or her spouse and his or her adult children, which is likely to be the dominant culture? The clinician is wise to not make assumptions about what are the beliefs, values, and preferences of the patient or his or her family. Instead, it is far better to ask because these issues will all have an impact on the patient’s pain experience and treatment. There are many variations of beliefs within broad cultural groups, and it has been recommended in the clinical realm to instead focus on the patient and the family unit as having their own culture. It is the task of the clinician to understand and respect that culture.

If there is a taboo against disclosing a life-threatening diagnosis to the patient, the family will almost invariably make this wish abundantly clear to the clinician at an early stage. This traditional practice can conflict with a patient’s right to information. There is an emerging ethical construct that supports the clinician to respect a family’s request, if it is the explicit wish of the patient. If the patient indicates that another family member is to be the receiver of medical information and is to make all treatment and
other decisions on the care of the patient, the patient has duly exercised his or her autonomy. The family, or a specific individual within the family, becomes the unit to which the authority of informed consent is conferred. It is legitimate for the clinician to periodically confirm what is the preferred communication style and to whom the patient has conferred decision-making authority. Fortunately, taboos in disclosure of diagnostic information rarely interfere with obtaining information directly from the patient regarding his or her experience of pain and the effect of analgesic interventions.

**COMORBIDITIES ASSOCIATED WITH SPECIFIC CANCERS: LUNG DISEASE, LIVER DISEASE, RENAL DISEASE, AND NEUROLOGIC DISEASE**

Lung cancer is about 30 times as prevalent in life-long smokers as life-long nonsmokers. Patients with lung cancer commonly have clinically significant chronic obstructive lung disease, ischemic heart disease, or symptomatic peripheral vascular disease. If patients have preexisting carbon dioxide retention, there is a risk the carbon dioxide retention will worsen with the use of opioids, especially if benzodiazepines are taken concurrently for anxiolysis, for example. Other than in the situation of life-threatening carbon dioxide retention, where very careful titration under monitored conditions may be indicated, opioids are generally not contraindicated by the presence of lung disease and should be carefully titrated to effect while monitoring for toxicity.

Premorbid liver disease is also prevalent in patients with specific cancer types, such as hepatoma and esophageal cancer. The major clinical features of liver disease relate to portal hypertension, with an elevated risk of episodes of gastrointestinal (GI) bleeding, ascites, and malnutrition. The capacity of the liver to metabolize medications is often less affected than other aspects of liver function, and the dose of medications commonly used in cancer pain such as opioids should not routinely be reduced. Instead, medications should be titrated to effect. Acetaminophen should be used with caution, however, particularly in the setting of cirrhosis. The clinical presentation of liver metastases is often pain and jaundice; it is rare to encounter metabolic liver failure until almost all of the liver is replaced.
Renal disease is becoming much more prevalent in Western society, and many cancer treatments, such as platinum-based chemotherapy, are nephrotoxic. Cancer patients are at risk to accumulate medications or their active metabolites in the presence of even mild underlying renal impairment. This has led to recommendations of some opioids over others, although the evidence for this approach is still emerging. Some authorities recommend morphine be used with caution in the presence of known renal impairment. Doses of some medications used for neuropathic pain, such as gabapentin, are routinely reduced in the setting of renal impairment, but opioids are not. Instead, opioids should be titrated to effect, recognizing that a reduction in dose or increase in dosing interval may be required. In the face of end-stage disease with near-complete or total kidney failure, renally cleared opioids (or those with clinically active renally excreted metabolites such as morphine) should be avoided or administered on an as-needed basis rather than around-the-clock.

About half of cancer patients are aged 65 years and older, an age group that has a particularly high prevalence of comorbid neurologic illness. Also, cancer and its treatments are associated with neurologic illness, such as stroke, meningitis, and other conditions. Concurrent cancer and neurologic disease affects pain management in several ways, but two deserve particular mention. First, pain assessment largely depends on an intact cognition. The widespread use of pain assessment tools such as the numeric rating scale has helped to bring some quantification to what is otherwise a subjective and often silent experience. But what if the patient is confused and provides the wrong numbers? There is then a risk of overmedication or undermedication. The Brief Pain Inventory documents several discrete domains of the pain experience: average pain in the past 24 hours, worst pain in the past 24 hours, least pain in the past 24 hours, and others. Study of the psychometrics of pain tools has revealed that the present pain intensity is the most reliable domain in the setting of cognitive impairment and is the measure that should be used if there is any question of cognitive impairment. Also, the information should be confirmed by other direct questions by the clinician, such as “Is the pain bad, or not bad right now?” Furthermore, cognitive impairment in cancer patients
generally arises because of many contributing factors. Families are often quick to blame the pain medications. Only uncommonly are analgesics the sole or the major cause. However, in the absence of other obvious causes for delirium, rotating to a different pain medication, along with hydration and other general supportive measures, can reverse an episode of delirium even when other contributing factors are not correctable.

**CANCER PAIN AND SUBSTANCE ABUSE**

“Abuse” is a somewhat pejorative word, but its use has been widely accepted. Substance abuse has been defined in a variety of ways but is generally taken to mean use of a recreational drug despite harm to self or others. “Addiction” is taken to be a far extreme in the spectrum of abuse, where there is an overwhelming focus on obtaining a supply, craving, and social disintegration. About 15% of adult men in Western societies abuse alcohol, and only about half that proportion of adult women. A smaller proportion of the population abuses other substances, such as cocaine, methamphetamine, or cannabinoids. Some cancer patients are actively abusing psychoactive substances, and others have a past but not current history of abuse. Some active abusers are open about their lifestyle choices, and others keep it a secret.

Pain management is challenging in patients who have a prior history of substance abuse; they have more symptoms, have more interference of function from pain, have more distress, and have more problematic drug-related behaviors than cancer pain patients who do not have a history of substance abuse. Pain is common in the street-connected opioid-abusing population, with about a third of patients in methadone maintenance programs describing moderate to severe, chronic noncancer pain. Pain can be difficult to reliably assess in cancer patients who have preexisting chronic pain, a history of abuse of pain medications or other psychoactive compounds, or a coping strategy that has included the use of chemicals ostensibly to help them cope. There is a clash of cultures when the clinician, who believes that the pain is what the patient describes it to be, becomes aware that there may be reasons to not fully trust the patient’s description. In the setting of possible or definite past or present substance abuse, the clinician should carefully document the patient’s description of
his or her pain experience and obtain collateral information from family, friends, or other members of the health care team, whenever possible. There is a role for greater reliance on diagnostic imaging to confirm clinical assessment. Furthermore, there is an emerging appreciation of the use of routine risk stratification tools to assess the potential for opioid misuse in all cancer pain patients.¹⁹

All patients deserve adequate pain control and to be treated with respect. However, the situation of a cancer patient with active substance abuse requires a distinct approach that will protect the patient and his or her environment from things that can get in the way of successful pain management. An overall strategy for managing cancer pain in the addict is described at the end of this chapter, along with a summary of safe prescribing practices and universal precautions that should be used when prescribing opioids whether or not there is a history of substance abuse.

**CANCER PAIN IN INMATES**

The incarcerated population has unique cancer risks, in part related to underlying demographics.²⁰ Most inmates are men, are from ethnic minorities, and are less likely to be in the geriatric age group compared to the general population. Certain cancer risk factors are known to be highly prevalent in inmates, including smoking, drug and alcohol use, and AIDS-related illnesses. Rates of infection of inmates are higher for hepatitis C, and HIV infection rates are much higher than the national average.²¹ High rates of human papillomavirus infection have been found in women inmates. The incidence of lung cancer, head and neck cancers, liver cancer, and cervical cancer are much higher in inmates than expected compared to age-matched controls. Survival from cancer is poorer in incarcerated cancer patients compared to controls: In one study, the standardized mortality ratio was 1.6 (95% confidence interval [CI], 1.4 to 1.7) in men and 1.4 (95% CI, 1.0 to 1.9) in women.²⁰ In brief, compared to the general population, inmates are more likely to be affected by certain cancers, more likely to have cancers that are characterized by difficult-to-manage symptoms, and more likely to have a past history of substance abuse or viral infection that can complicate pain management.

Not surprisingly, inmates with cancer have been found to have a high
prevalence of pain and to be undermedicated for cancer pain.\textsuperscript{22} Drug misuse, actual drug diversion, fears held by prescribers of potential drug diversion, and lack of patient credibility have been identified as barriers to cancer pain management.

**Components of the Comprehensive Medical Evaluation of a Patient with Chronic Cancer Pain**

An enormous amount of information is available to guide the clinician in assessing a patient with chronic cancer pain. Pain assessment tools have been extensively validated in a range of clinical settings, languages, and in different ages and disease states (see Chapter 20 referencing pain assessment).

However, cancer patients are often systemically ill. In addition to pain, they may have low energy and may have a range of other symptoms. Clinicians need to find a balance between the wish to complete a comprehensive assessment and yet respect the constraints of patients’ abilities to tolerate such a comprehensive evaluation. Cancer patients and their families are not always able to endure lengthy clinic visits with use of extensive bedside assessment tools, detailed psychosocial evaluations, and evaluation of other important domains.

Furthermore, cancer patients and their families have many needs that compete for their time and attention. In addition to symptom control, they also are keen to learn about cancer treatment options, meet the needs of their family members such as children, and fulfill other social obligations related to their employment, completing required insurance forms and managing competing financial imperatives, such as purchasing food and prescriptions. Likewise, clinicians need to attend to their many professional roles despite the constraints of competing demands for their time: They must not only assess patients but also discuss treatment options and facilitate decision making, coordinate care, provide treatment, communicate with other team members, and attend to many other patients and other professional responsibilities. Time itself can be scarce: Health care professionals involved in symptom control can be predicted to have many calls on their time, which can have effects on patient care such as
pushing palliative and supportive care issues into the background and also
can result in professional stress and burnout.

How does a clinician decide on the most appropriate level of assessment
of the cancer pain patient? Pragmatically, it is wisest to comprehensibly
evaluate the patient at the first encounter, to the extent the patient is able to
tolerate it. If necessary, the evaluation can be completed with more than
one encounter to respect patient or family limitations. After that point, it
should only be necessary to comprehensively reevaluate if there is a major
change in the clinical presentation.

The complete bedside evaluation of the patient with cancer pain
includes five major components: history, physical examination, bedside
provocative maneuvers, diagnosis formulation, and construction of an
overall analgesic strategy.

Pain History

DEFINITION OF PAIN

Pain is defined as “an unpleasant sensory and emotional experience
associated with actual or potential tissue damage, or described in terms of
such damage.” Pain is always a subjective experience. Most nociception
is mediated by nociceptors (pain receptors) found within visceral and
somatic tissues. Nociceptors are present in most tissues in the body. There
are some striking exceptions including most parts of the parenchyma of the
central nervous system. Also, certain modalities of nociception cannot be
sensed in certain parts of the body; for example, the stomach can sense
stretch as an unpleasant sensation, whereas when cauterized, there is no
pain sensation that results.

Presumably, all receptors within more vulnerable body parts will have
been activated many times during a person’s lifetime, such as nociceptors
found in the nondominant thumb: Pretty much everyone has hit their
thumb with a hammer or some other blunt object many times. In contrast,
the majority of nociceptors throughout the body will rarely or never
actually be activated during the entire lifetime of the individual. It should
come as no surprise that patients describe their pain experience in a way
that reflects their own uniqueness as a person and often, reflects their
unfamiliarity with the new pain experience.

Imagine, for example, the situation of a patient who has metastasis involving the left C3 facet. Most people will never experience left C3 facet pain in their entire life. The experience of nociceptors being discharged for the first time in a person’s life can be puzzling, unpleasant, and difficult to describe. When experiencing a new, unfamiliar pain, patients may want to not use the word pain but instead use alternative descriptive words such as discomfort, unpleasant, hurt, and others. The clinician should recognize that any unpleasant sensation may in fact be pain and should at all times support and legitimize the patient’s experience.

Furthermore, the pattern of pain referral may have gone unnoticed by the patient, particularly if the referred pain is less severe than the primary site of pain. If recognized, however, patterns of referral can greatly assist the identification of the underlying pain-sensitive structure. Studies have evaluated the referral pattern of pain in a range of tissues in many parts of the body, particularly nerves, connective tissues, ligaments, and muscles; mapping out the distribution of the resultant pain has resulted in construction of somatotopic maps. Clinicians are generally most familiar with the distribution of referred neuropathic pain along the corresponding dermatomes. Sclerotomal pain refers to the pattern of referred pain when the pain-sensitive structure arises in connective tissues and ligaments. Stimulation of various muscles has resulted in similar, although distinct, patterns of referred pain, known as myotomal pain. Going back to the previous example of left C3 facet pain, this is a kind of sclerotomal pain and has a characteristic pattern of referral, with pain felt draped laterally across the ipsilateral neck and projected rostrally toward the occipitonuchal junction.

**DEFINITION OF SUFFERING**

Suffering, as a human experience, needs to be distinguished from pain, per se, although the two are often interdependent: Suffering is commonly present with pain and often increases as pain increases. There have been many insightful approaches to understanding suffering within the medical domain. One of the most widely accepted approaches describes suffering as a perceived threat to an individual’s sense of intactness as a complete
If suffering is in part caused by pain, this definition speaks to the meaning that the person attributes to their pain. For example, at childbirth, intensity of labor pains commonly reaches 8 out of 10 or greater and is often described as “horrible” on the McGill categorical scale. The sense of threat to a person’s intactness as a human being during labor, however, is generally believed to be less than the situation of pain of a similarly high intensity caused by a life-threatening illness such as advanced cancer.

In Western countries, patients often conceptually link “pain” and “suffering” and may use the words interchangeably. In the comprehensive assessment of a patient with cancer pain, it is incumbent on the clinician to have an approach that is respectful of the patient’s current circumstance. The clinician should not make assumptions about how much of the patient’s distress is due to pain and how much is due to suffering. Remaining curious and empathic, the clinician works within the limitations of the comprehensive assessment in order to discover along with the patient as to how much of each of pain and suffering is present, and how they might be related. There may be early clues about exigent pain as a major component of suffering: Pain descriptors with a high affective component, such as “suffocating pain,” have been found to predict the presence of suffering.25

Clinicians will encounter cancer patients with severe pain who are suffering enormously, particularly toward the end of life. This often results in clinicians being drawn into a strong awareness of their own sense of compassion. But what does “compassion” mean, within the health care setting? The nature of compassion within health care providers has been studied, as have cancer patients’ preferences about compassionate care delivered by their health care providers.26,27

VALIDATED ASSESSMENT TOOLS
Many clinicians routinely use validated tools to support assessment of cancer patients, particularly to distinguish pain and suffering. There are several outstanding and widely used tools which are available. Some selected examples of the most largely used are as follows:

The Edmonton Symptom Assessment Scale—Revised Version (i.e., the ESAS-R, commonly referred to as “the ESAS”), includes 10 items: pain,
tiredness, nausea, depression, anxiety, drowsiness, appetite, well-being, shortness of breath, and “other problem” (Fig. 41.1). Like many successfully applied clinical tools, it is short and has been extensively validated in a variety of countries and practice settings. The ESAS has several strengths: It is not overly burdensome to fill out, it is an effective screening tool to identify distress due to symptoms, and it identifies symptom clusters (see the following text) which, if present, can make pain more difficult to manage.

![Edmonton Symptom Assessment Scale—Revised Version](image)

**FIGURE 41.1** Edmonton Symptom Assessment Scale—Revised Version. The Edmonton

The Edmonton Classification System for Cancer Pain (ECS-CP) is a 5-item bedside tool that helps characterize prognosis for control of pain (Fig. 41.2).

**Edmonton Classification System for Cancer Pain (ECS-CP)**

Patient Name: ____________________________

Patient ID No: ____________________________

For each of the following features, circle the response that is most appropriate, based on your clinical assessment of the patient.

1. **Mechanism of Pain**
   - No pain syndrome
   - Nc Any nociceptive combination of visceral and/or bone or soft tissue pain
   - Ne Neuropathic pain syndrome with or without any combination of nociceptive pain
   - Nx Insufficient information to classify

2. **Incident Pain**
   - Ib No incident pain
   - Ii Incident pain present
   - IX Insufficient information to classify

3. **Psychological Distress**
   - Po No psychological distress
   - Pp Psychological distress present
   - Px Insufficient information to classify

4. **Addictive Behavior**
   - Ao No addictive behavior
   - Aa Addictive behavior present
   - Ax Insufficient information to classify

5. **Cognitive Function**
   - Co No impairment. Patient able to provide accurate present and past pain history unimpaired
   - Ci Partial impairment. Sufficient impairment to affect patient’s ability to provide accurate present and/or past pain history
   - Cu Total impairment. Patient unresponsive, delirious or demented to the stage of being unable to provide any present and past pain history
   - Cx Insufficient information to classify.

**ECS-CP profile: N__ I__ P__ A__ C__** (combination of the five responses, one for each category)

The Brief Pain Inventory—Short Form (widely referred to as the BPI), delineates several aspects of the pain experience, including worst pain in the past 24 hours, average pain in the past 24 hours, least pain in the past 24 hours, physical functioning, and emotional functioning. The BPI holds several advantages: It has been extensively validated, it assesses several specific dimensions of the pain experience, and it has been used for both research outcomes and for clinical care (Fig. 41.3).
Brief Pain Inventory (Short Form)

Date: ______/_____/______    Time: ___________
Name: ______________________  ______________________  ______________________
                   Last          First          Middle Initial

1. Throughout our lives, most of us have had pain from time to time (such as minor headaches, sprains, and toothaches). Have you had pain other than these everyday kinds of pain today?
   1. Yes
   2. No

2. On the diagram, shade in the areas where you feel pain. Put an X on the area that hurts the most.

3. Please rate your pain by circling the one number that best describes your pain at its worst in the last 24 hours.
   - 0: No Pain
   - 10: Pain as bad as you can imagine

4. Please rate your pain by circling the one number that best describes your pain at its least in the last 24 hours.
   - 0: No Pain
   - 10: Pain as bad as you can imagine

5. Please rate your pain by circling the one number that best describes your pain on the average.
   - 0: No Pain
   - 10: Pain as bad as you can imagine

6. Please rate your pain by circling the one number that tells how much pain you have right now.
   - 0: No Pain
   - 10: Pain as bad as you can imagine

There are several other widely used screening tools to support assessment of cancer pain patients (see Chapter 20).

**TYPES OF PAIN**
Throughout the pain history, the clinician is looking for clues as to the
underlying mechanism of pain. Because pain can be a foreign experience, it can be difficult to characterize in words. Patients sometimes appreciate being offered choices of words that might help describe their pain, such as burning, achy, dull, sharp, deep, and so on. Broadly, pain can be thought of as somatic, visceral, or neuropathic. The words the patient uses to describe their pain experience can guide the clinician to make inferences regarding the underlying mechanism.

Somatic pain arises from bone, muscle, ligament, subcutaneous tissue, or skin. It is often experienced as sharp or dull and is typically well localized by the patient. Less commonly, it can be referred to cutaneous sites characteristic of the tissue of origin, such as sclerotomal (connective tissue in origin) or myotomal (muscle) referred pain, as described earlier.

Visceral pain arises from organs such as lung, liver, or bowel and is broadly understood to arise from tissue that is embryologically mesodermal in origin (see Chapters 47 and 61–65). It is characteristically described as dull and achy and is usually poorly localized; typically, the patients will use their entire hand to describe the location of the pain. Visceral pain is often also referred to distant sites, such as liver pain being experienced in the ipsilateral shoulder. Examination of the shoulder does not reproduce this pain.

Neuropathic pain is generally described as dull, achy, itchy, or burning. The skin can be sensitive to light touch (“allodynia”: pain due to a stimulus that does not normally provoke pain—see Chapters 24–28), and there may be brief stabbing episodes of neuralgic pain. The burning may be superficial as in the experience of scalded skin or can be deep, as if there is a feeling of having been burned deep inside. The spontaneous use of the word burning by the patient predicts the presence of neuropathic pain. However, the clinician should be cautious: Several other pains can also be experienced as an unpleasant, burning sensation, such as muscle spasm pain—a kind of somatic pain. Combinations of words, such as burning numbness, and clinical findings such as hypesthesia, anesthesia, hyperalgesia, or allodynia in a segmental pattern within an area of pain, are of greater value in making the clinical diagnosis of neuropathic pain. For example, neuropathic pain should be diagnosed if there is significant clinical evidence such as a description of burning numbness along with
tingling experienced in a distribution consistent with damage to a particular part of the nervous system; there may also be signs of motor dysfunction such as the loss of deep tendon reflexes (e.g., ankle or knee jerks) or muscle weakness; there may be bedside provocative maneuvers that reproduce the pain, such as the presence of a Tinel sign or a positive straight-leg raise maneuver. The clinician should be wary of making a diagnosis of neuropathic pain based solely on the patient’s description of “burning pain,” although this is an important clue to initiate further investigations.

Mixed pain is the clinical situation where there is both nociceptive (i.e., somatic and/or visceral) and neuropathic pain. A common example is chest wall pain from lung cancer; there may be poorly localized deep ache consistent with visceral (pleural) pain, sharp and well-localized somatic pain from contiguous rib invasion, and burning numbness of the overlying skin due to invasion of intercostal nerves. The term mixed pain has less commonly been applied to the situation of multiple mechanisms of somatic pain in the same patient—for example, painful metastasis to the humerus with contiguous muscle spasm and shoulder joint articular changes because of immobility of the painful limb. Mixed pain may benefit greatly from applying several modalities of analgesic intervention concurrently, such as simple analgesics (acetaminophen or anti-inflammatories); opioids; adjuvant analgesics in specific pain syndromes; nondrug interventions such as heat, cold, stretch, and massage; or orthotic interventions such as a joint-immobilizing splint.

Teasing out the many components of pain in the region of the body where the patient is experiencing pain will help the clinician to develop a more comprehensive approach to managing the pain and is therefore an essential part of the comprehensive pain assessment in a cancer patient.

PRESENTING COMPLAINT
The presenting complaint of the pain should contain four elements: onset, progression, focality, and accompaniments. Once the patient assessment has been completed, these four elements can be summarized in a single sentence and often represent a thumbprint of the underlying mechanism of pain.
Pain Onset

Patients are understandably often keen to tell you how long the pain has been severe. In order to characterize the nature of the underlying process, however, it is critical to also delineate the onset of pain: the time from when the pain first ever began until it became as bad as it was going to get (Table 41.1). Broadly, cancer pain unfolds in three different ways: It may have an onset of less than a day, days to weeks, or months in duration. Be wary of the tendency of pain to fluctuate, with good days and bad days, or good weeks or bad weeks; behind this background noise is the true onset of how the pain developed over time. As a guideline, pain that takes less than 1 day to become as bad as it is going to get is often vascular in origin. An example of this is an acute thigh hematoma from trauma to the leg or pain from hemorrhage into a site of metastasis. Pain that takes between a day and a month to reach its peak often has an inflammatory mechanism, such as a subcutaneous abscess, with each day being worse than the previous. Pain that is worse month after month, pain that is chronic, progressive, and focal, is most consistent with a diagnosis of cancer. These are only general guidelines, and there are many exceptions. However, delineating the onset of the pain, the time from when it first began until it reaches its peak, can be an important clue regarding the nature of the underlying diagnosis.

Typically an inflammatory process
- Infected cancer wound
- Shingles pain
- More than 1 month
- Chronic, progressive and focal: likely cancer.
  Example: progressive neck pain due to bone metastasis
- Chronic, progressive and diffuse: likely toxic or degenerative.
  Example: peripheral neuropathy pain
- Course of a painful area successfully treated, such as following radiation therapy
- Relapsing and remitting
  - A relapsing and remitting condition such as multiple sclerosis or change in lymphoma pain with steroids
  - Spells
    - Neuralgic pains are brief, electrical stabs of pain lasting seconds
    - Seizures
  - Pulmonary
  - Small or large bowel diarrhea or constipation
  - Urinary (hematuria)
  - Neurologic (confusion)
  - Endocrine (hypoglycemia)

Pain Progression
There are only a few common patterns of how cancer pain progresses over time. Once it has commenced, cancer pain is typically progressive, and usually, this progression occurs over months. A second pattern of cancer pain is fluctuating, such as pain that is worse with standing because of metastasis to weight-bearing bone, pain worse with bladder emptying due to cancer invading the detrusor muscle, and pain that is worse at night and relieved by pacing, a classical description of pain experienced with epidural spinal cord compression. Back pain that gets worse with lying down is especially concerning for the presence of neuraxial tumor. A third pattern of pain progression is pain that is improving: It began, peaked, and is now getting better or has resolved. This temporal profile is consistent with an underlying mechanism of pain that has been effectively treated, such as successful radiation treatment of an area of metastasis. A fourth temporal profile is intermittent episodes of pain. This temporal profile of
pain can be incapacitating and can often be effectively managed with specific interventions. One example is a patient with neuropathic pain who has constant, deep, achy pain in the affected dermatome and also has superimposed spells of brief stabbing neuralgic pain. This pain is characteristically electrical in character, peaks instantly, and lasts seconds. Neuralgic pain commonly improves dramatically with anticonvulsant agents such as gabapentin, pregabalin, or carbamazepine. Another example of intermittent episodes of pain is the patient with baseline achy neuropathic pain with superimposed brief episodes of burning pain in the skin precipitated by light touch: allodynia. Allodynia is a strong predictor of the presence of underlying neuropathic pain, and once the diagnosis is made, there are several analgesic interventions that can be effective.

**Focality**

In what region of the body is the pain being experienced? The medical approach to the cancer patient involves a systems approach, such as the respiratory system, the cardiac system, and so on, but it is also important to assess where pain is experienced because of referral sites remote from the organ involved or due to the presence of painful distant metastases. There are several ways to classify regional pains. A simple approach is to describe seven regions of the body: head and neck, chest, shoulder and arm, abdomen, pelvis, back, and the buttock and leg region. There is commonly overlap, such as the patient who has back pain, buttock pain, and leg pain. In considering the patient who has pain in a certain region of the body, it encourages the clinician to be mindful of all potential pain-sensitive structures that could result in the experience of pain in that part of the body. The following pain history exemplifies this phenomenon.

A 47-year-old premenopausal woman presented to her oncologist with a 3-month history of progressive back pain. Two months ago, the pain progressed down the right leg into the foot, in association with tingling and loss of sensation in a distribution similar to the pain. She had a prior history of breast cancer with 3 of 12 nodes positive, treated with surgery followed by radiation therapy, chemotherapy, and was currently on aromatase inhibitors.
The regional pain exam revealed marked local spine tenderness including paraspinal muscle spasm that reproduced her back pain. Also, there were signs of active right L5 radiculopathy, including an unequivocally positive ipsilateral straight-leg raise maneuver (neuropathic pain in the right leg below the knee). An MRI of the spine revealed evidence of a large right lateral herniated L4–L5 disk and no evidence of cancer.

The presenting complaint of this cancer patient helped focus the rest of the history and the regional pain examination toward diagnoses, both cancer and noncancer, that can potentially cause chronic, progressive back pain and unilateral neurologic trouble in a leg.

**Symptoms That Accompany Pain**

Are there other symptoms that accompany the pain? They can be a strong indicator of the underlying disease process. Consider a patient suspected of having cancer who presents with chest pain. Accompanying symptoms can provide helpful guidance about the underlying disease. Typical examples could be chest pain with breathlessness and cough from lung cancer; episodes of chest pain associated with palpitations from angina; or deep achy chest pain associated with nausea after eating, a 30-lb weight loss, and dysphagia over 3 months from esophageal cancer (see Table 41.1). The symptoms that accompany the pain are a clue as to the underlying system that is involved in the disease process. Often, these other symptoms will unfold in a similar temporal profile of the underlying pain.

**Formulating the Presenting Complaint**

Integrating these four elements of the pain presenting complaint together within a single sentence—pain onset, progression, focality, and accompaniments—can bring clarity to an otherwise complex clinical presentation, even if the clinician has never encountered the situation previously. Here is an example of such a presenting complaint, described by a patient who was encountered by the author:

A 68-year-old man presented with a 1-year history (onset) of progressive (progression) left lateral abdominal wall and flank (focality) deep ache, burning numbness of overlying skin, and a 30-lb
weight loss (accompaniments).

This pain syndrome is neuropathic and potentially also visceral. This perplexing presenting complaint suggests cancer of the left flank area, as the pain is chronic, progressive, and focal. The differential diagnosis includes diabetic abdominal wall neuropathy, a rare diabetic neuropathy typically encountered in adults with early-onset, mild diabetes. There are other possible causes of this presenting complaint, but postherpetic neuralgia is not likely if the presenting complaint is accurate: Being inflammatory, shingles pain typically has a subacute onset, becoming maximal within days of its first appearance. This particular patient was not known to have active cancer (although there was a past cancer diagnosis), and all investigations at the time of presentation were negative. Pain was controlled with opioids and adjuvant analgesics, and he was given appointments for follow-up computed tomography (CT) scans of the abdomen every 3 months for a year. At 9 months, the patient developed CT findings consistent with a left adrenal metastasis and retroperitoneal lymphadenopathy, and after a biopsy demonstrated metastatic adenocarcinoma, palliative radiation therapy was effective to relieve pain. This is an example of a presenting complaint that was strongly suggestive of the underlying mechanism of pain.

DETAILS OF THE PAIN HISTORY
Because pain is a subjective experience, it is essential to obtain from the patient a description of the experience of pain, including the amount of pain. There is evidence that estimates of a patient’s pain by others are commonly inaccurate; health care providers tend to underestimate pain, and family caregivers often overestimate pain. The input of surrogates should take second place to direct input of the patient’s own experience. Estimating how much pain a patient is in, based on their facial expression or other indicators, should be approached with great caution, although behavioral cues may be the only way to assess pain in a non–self-reporting patient.

Extensive research has found that there are ways to inquire of a patient which are more likely than others to get a response from the patient that is valid, reliable, and reproducible. A widely used approach is to ask the
patient how much pain he or she is experiencing on a scale of 0 to 10, if 0 is “no pain” and 10 is the “worst pain possible.” This approach has been broadly adopted as clinical policy within health care institutions. The clinician needs to be wary of the uncommon circumstance where the numeric rating scale turns out to be less reliable. One such situation is delirium, a syndrome of fluctuating encephalopathy commonly encountered in cancer patients before death or in association with concurrent acute illness. When delirium is known to be present, it is still appropriate to ask the patient how much pain he or she is experiencing using the 10-point numeric scale and to record his or her answer but also one should record that he or she have delirium. In this setting and any other settings where there is doubt about the reliability of the patient’s description, an additional method to quantify pain intensity should be used to confirm their description. A highly reliable, valid, and reproducible scale is the McGill categorical scale. One asks the patient if he or she would describe his or her pain as none, mild, discomforting, distressing, horrible, or excruciating. If there is any question to the reliability of the patient’s description, it is best to keep the questions simple and dichotomous, for example, “Is your pain bad, or not bad?” The more ways one poses the question, the more confident the clinician can be about the interpretation of the patient’s response.

A detailed description of the many facets of the pain experience is described in detail in Chapter 20. In cancer pain, clinicians often ask the patient about his or her present pain intensity (on a scale of 0 to 10), the worst pain experienced in the past 24 hours, the least pain experienced in the past 24 hours, and the average pain. If the patient is struggling to find words to describe his or her pain, the clinician should be supportive and encouraging, offering words to the patient such as burning, sharp, or crushing. If the patient spontaneously offers a word with a strong affective component, such as “suffocating” pain, the clinician should not only inquire about comorbidities such as concurrent dyspnea but also recognize the possibility that such affectively loaded words may signal a more global sense of suffering. This requires further inquiry and evaluation.

After delineating the intensity of the pain and the description of the
pain, the clinician should find out, in detail, what part(s) of the body are affected and what the characteristics of the pain are throughout these locations. A differential description of discrete pains within the same region of the body can give a clue as to the underlying mechanism. For example, patients with malignant brachial plexopathy often describe several different pains. There is often a deep, achy, poorly localized discomfort draped over the ipsilateral shoulder, with burning pain and tingling in the ipsilateral lateral hand. There can also be pain with light touching of the area of numbness in the affected arm (allodynia), and superimposed spontaneous episodes of brief stabbing electrical pain in the arm, experienced as single neuralgic jabs or brief trains (volleys) of pain. If present for several months, patients can develop pain from frozen shoulder or other articular or myofascial complications of immobility of the affected shoulder girdle region. All of these discrete pains can be elicited and described by the patient during the pain history.

The clinician then focuses on the experience of pain over time: what makes it better and what makes it worse. In particular, one seeks a description of the change of pain over time with medication (i.e., pharmacodynamics). Typically, one would expect there would be relief of pain beginning about one half hour after swallowing a short-acting opioid, peaking at approximately 60 to 90 minutes, and then it would wear out sometime thereafter. If the duration of analgesia is too brief (in this case, less than 4 hours after taking a short-acting opioid), the patient probably has end-of-dose failure. Identifying this phenomenon can guide the clinician to estimate the extent to which the patient is undermedicated.

Next, construct a detailed list of all prescription and nonprescription medications the patient has taken; the patient or family should be encouraged to look through the medication cabinet for all pills. The list should include the names of medications, the maximum dose that was taken, and the duration that the maximum dose was taken, with what effect and what toxicity (Table 41.2). The goal is to be as confident as possible that the patient has completed an adequate trial of each of these medications, and if they did not have an adequate trial, one then can consider reembarking on a trial of that medication in a more thorough manner. By the end of this description, the clinician should have a clear
understanding what sequential trials of analgesics and combinations of analgesics the patient has had over time.

Depending on the patient’s past history and current social circumstances, it may be appropriate to apply certain chemical misuse/abuse/dependency risk tools, such as the CAGE (Table 41.3) or the Opioid Risk Tool (ORT). Stratifying risk allows for a structured approach to pharmacotherapy that is tailored to each patient’s particular circumstances.

**TABLE 41.3 Cage Test to Screen for Alcoholism**

Please check the one response to each item that best describes how you have felt and behaved over your whole life.
1. Have you ever felt you should cut down on your drinking?
2. Have people annoyed you by criticizing your drinking?
3. Have you ever felt bad or guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (eye-opener)?

The clinician should also seek information about other risk factors for poor pain prognosis. This includes any history of psychiatric disorder, the presence of breakthrough pain, neuropathic pain, other psychosocial stressors, use of high-dose opioids without satisfactory pain control or excessive adverse effects, and the presence of significant interference of
function by pain. Interference of function refers to pain interfering with physical functions, such as sleep, activities of daily living, and work; social functioning, such as a parenting role and sexual relations; and emotional functioning, such as ability to engage meaningfully with those around them and ability to cope.

The clinician then embarks on a detailed medical and psychosocial history. The medical history involves a review of systems such as respiratory, cardiovascular, GI, genitourinary, musculoskeletal, dermatologic, neurologic, and endocrine. There is a high risk of comorbidity with particular patterns of systems dysfunction in specific cancers. An example is the high prevalence of underlying respiratory disease in a patient who has a tobacco-related malignancy or a lengthy history of tobacco use.

The elements of a psychosocial history have been described elsewhere in this book (Chapter 21).

Physical Examination

The pain physical exam includes a general physical exam, more specific neurologic examination guided by history, a regional pain exam, and bedside provocative maneuvers.

GENERAL PHYSICAL EXAMINATION

The general examination of the cancer patient includes a brief screening physical exam including vital signs, head and neck, respiratory system, cardiovascular system, the abdominal exam, genitourinary exam including rectal exam (as appropriate to the clinical circumstance), musculoskeletal exam, peripheral vascular exam, neurologic exam and in particular detail as informed by the history, and dermatologic exam. Attention is paid to document the extent of underlying malignancy; patients presenting with cancer pain may have a greater extent of disease than was previously suspected, so the clinician needs to examine the patient with a view toward stigmata of underlying organ disease.

THE REGIONAL PAIN PHYSICAL EXAMINATION

The clinician approaches the regional pain examination as guided by the
pain history. This approach complements but does not replace the more traditional systems approach to the physical examination described earlier. Seven regions of the body are head and neck, chest, shoulder girdle and arm, abdomen, back, pelvis, and buttock and leg (Table 41.4). For example, if the patient describes pain in the head and neck, a regional pain exam is done of that part of the body. The clinician pays particular attention to look for evidence of underlying disease in that region, which may be vascular, infectious, or neoplastic in origin. The clinician looks for evidence of degenerative neck disease, with reduced range of motion of the neck, neurologic disease with ptosis suggesting ipsilateral cancer in the low cervical spine, vascular disease such as carotid artery or vertebral artery bruit, palpable muscle spasm, and other signs of an underlying pathologic process.

**BEDSIDE PROVOCATIVE MANEUVERS**

The bedside provocative maneuvers are an important part of the pain physical exam. The goal is to gently reproduce the patient’s pain complaint(s). If the clinician successfully reproduces the pain, the patient may be relieved, having their subjective complaints validated. As described earlier, because pain is a subjective experience, often, patients have the sense that others might not appreciate how serious their pain is. If the clinician is able to reproduce the pain, the patient may believe that the clinician has confirmed that it exists. Furthermore, if the clinician is able to localize, or “touch,” the pain, the patient may have greater confidence the pain can be relieved. For the clinician, being able to reproduce the pain provides insight into the underlying mechanisms or pain-sensitive structures.

For each of the seven regions of the body, there is a list of regional bedside provocative maneuvers (Table 41.5). For example, in the situation of a patient who presents with head and neck pain, the clinician would first do a general physical exam and then a regional pain exam in order to look for underlying disease processes. After this time, the clinician would
systematically embark on bedside provocative maneuvers. This would include neck range of motion in six directions, including an evaluation for meningismus, palpation of the skin, assessing for allodynia, and deep palpation of underlying tissues. One continues to palpate more deeply trying to identify areas of myofascial pain or muscle spasm. One looks at typical tender points\textsuperscript{31,32} and also areas that commonly develop muscle spasm in response to disease, such as the paraspinal muscles. Muscle tenderness can be sought throughout the neck, the face, the jaw, and other areas. The clinician should put on a glove and palpate the masseter musculature as well as posterior pharyngeal examination of the pterygoid muscles. Following this, bone structures should be systematically examined by palpation and percussion, including the orbit, the skull, the occipital condyle, and then down the cervical spine. Next, palpate the carotid arteries (gently), the orbits, and the sinuses. Additional bedside provocative maneuvers can be performed based on the clinical situation. The clinician should approach bedside provocative maneuvers as a sleuth, looking for evidence that will rule in or rule out various pain-sensitive structures as being the source of the pain. Further detail on pain caused by cancer of the head and neck and oral mucositis is covered in Chapter 45.

**SPECIFIC BEDSIDE PROVOCATIVE MANEUVERS AND THEIR ROLE IN PAIN DIAGNOSIS**

**Spurling’s Test**

Spurling’s test of the cervical spine (also known as Spurling’s maneuver) is performed if there is concern the patient might have active cervical nerve root compression.\(^{33}\) It is analogous to the straight-leg raise maneuver that detects active lumbosacral radiculopathy (see the following text).\(^{34}\)
Spurling’s test consists of gentle lateral flexion of the neck for about 1 minute toward the side of the pain, followed by lateral flexion of the neck for about 1 minute away from the side of the pain. A variation is lateral flexion plus lateral rotation of the neck (“throw your ear over your shoulder”) for 1 minute to one side and then to the other. The test is positive if it results in neuropathic pain, tingling, or numbness below the elbow or loss of a previously present arm reflex such as a triceps reflex. The side and nerve root distribution of the arm pain or other neurologic impairment localizes the site of the mass that is pushing on the thecal space. Some reports have recommended axial loading be undertaken at the same time as lateral flexion and rotation (the examiner pushes down on the top of the head). We do not recommend that approach for cancer patients as there may be bone destruction and the test could be dangerous. Spurling’s test can be particularly helpful to distinguish malignant brachial plexopathy (in which case the maneuver is almost invariably negative) from spinal cord compression in the cervical spine (in which case the maneuver is often but not always positive) (Fig. 41.4). The procedure should not be undertaken if baseline pain is severe, until radiographs or other imaging studies confirm that the neck is mechanically stable. Positive and negative predictive values for Spurling’s test along with other bedside provocative maneuvers have been described for active cervical radiculopathy due to underlying benign disease but has not been well studied when due to cancer.

**FIGURE 41.4** Spurling’s test.

**Dermatomal Pain**

At some point, the clinician is likely to encounter an area of primary tenderness with pain apparently referred to a distant site. Clinicians are familiar with dermatomal pain or radicular pain, such as L5 nerve root pain caused by a herniation of the L5–S1 disk. The radicular pain can be
provoked by a straight-leg raise maneuver. The straight-leg raise maneuver is a validated bedside provocative maneuver that has been carefully tested in a range of clinical situations, disease types, and ages and with a range of specific techniques to perform the test.\textsuperscript{34} L5 radicular pain is felt down the ipsilateral buttck into the posterior part of the thigh and down the posterolateral leg into the dorsal or dorsolateral foot.

**Sclerotomal Pain**
There are other mechanisms for pain that may appear strikingly similar to dermatomal pain, including sclerotomal pain. A common example of sclerotomai referred pain is pain referred from the sacroiliac joint. The bedside provocative maneuver is to gently place the thumb in the sacroiliac joint and press with a few kilograms of pressure (see “Myofascial Pain: How Hard Should You Press?” section). The positive maneuver reproduces the ipsilateral paraspinal and low back pain the patient has been having. Referred sclerotomal pain goes down the ipsilateral posterior buttck and lateral leg into the lateral aspect of the ipsilateral ankle. L5 radicular pain and ipsilateral sacroiliac pain can occur in the same patient. This confusing clinical scenario may arise in a patient with active lumbosacral radiculopathy due to disk protrusion. Presumably, the sacroiliac pain is a consequence of biomechanical changes that occur in a patient who is limping because of pain from the active radiculopathy. Eventually, the stress on the ipsilateral sacroiliac joint is such that it too starts to hurt. The patient may ultimately have a surgical procedure to remove herniated disk material. However, the sacroiliac pain can persist, leaving the patient with a wrong impression that the surgery was a failure. This clinical situation raises the complexity of regional pain in cancer patients, whereby there can be several distinct but interdependent mechanisms of pain in the same region of the body. Teasing out the various components of that regional pain will allow the clinician to direct therapeutic interventions at each.

**Myotomai Pain**
A third kind of referred pain is myotomai pain: pain that arises from muscles. Referred myotomai pain does not generally extend far from the
irritated muscle. In cancer patients, myotomal pain is generally not a major cause of referred pain, but it can occur in a manner similar to sclerotomal pain resulting from secondary mechanical dysfunction.

**Myofascial Pain: How Hard Should You Press?**

Myofascial pain is a term that can be used to describe specific myofascial tender point sites or can be used as a more generic term for regional pain of muscular origin that is not due to primary pathology in the muscle. Myofascial pain is common in cancer pain patients, and it can mimic other types of pathology. Identifying its presence can lead to specific therapeutic interventions, such as heat, stretch, cold and massage, trigger point injections, or regional blockade, and it is therefore important to make the diagnosis when possible. Separate from regional myofascial pain, rheumatologists have characterized the systemic condition fibromyalgia (in part) by a series of bedside provocative maneuvers palpating for tenderness in specific areas, applying an amount of pressure that would not normally be uncomfortable. Whether in health or disease, muscle tenderness will result if the examiner presses hard enough. Research in muscle tenderness has identified that most commonly, muscles do not normally hurt when the examiner presses with up to 4 kg of pressure per square centimeter using the thumb. The clinician can use a baby weigh scale to become familiar with what represents 4 kg or can use a bedside dolorimeter, which is a bedside tool meant to gauge how hard one is pressing. Fibromyalgia can be diagnosed through the patient’s history without performing a tender point exam. However, the condition is usually associated with myofascial tenderness using a standardized methodology, with the finding of at least 11 of 18 typical tender point sites. The tender point exam in fibromyalgia has a diagnostic sensitivity of 88.4% and a specificity of 81.1%. The bedside exam of the cancer patient, looking for regional myofascial pain unrelated to fibromyalgia, is best undertaken with a similar technique.

**Back Pain**

In approaching the bedside examination of the patient with back pain, the clinician needs to pay particular attention to be gentle. In examining the
spine, one would first palpate in the area where the patient describes the worst pain. Push very gently, with less than a kilogram of pressure per square centimeter on the palpating finger on the area of the worst pain and then the broad area around it, looking for paraspinal muscle spasm. If negative, one can palpate with more pressure. There are some situations where a patient appears to have severe back pain and yet the regional pain exam demonstrates that the spine is completely aligned and there is neither spinal tenderness nor palpable paraspinal muscle spasm. How can there be severe back pain but not back tenderness? Retroperitoneal tumor can cause lumbar or thoracic regional pain where there is no tenderness with even deep percussion. There may be a suggestion that the patient has a retroperitoneal cause of back pain based on the patient’s posture as you enter the examination room: The patient may have adopted a so-called pain-relieving posture, such as sitting on the bed with the knees folded up into the chest. This posture results in lumbar kyphosis and, therein, relief of pain from a retroperitoneal pain-sensitive structure.

**Retroperitoneal Pain Stretch Maneuver**

In order to diagnose a retroperitoneal source of back pain, once the spine and paraspinal areas have been examined and have been found to not be tender, have the patient sit upright in the bed with the legs stretched out. This is best done in a bed in which the back of the bed can be elevated. Place a pillow into the small of the back so there is moderate thoracolumbar lordosis and have the patient lay back down in the bed. Gently lower the back of the bed so the patient goes toward a supine direction (Fig. 41.5). Retroperitoneal tumor can cause severe back pain and is reproduced with this maneuver. Oddly, it can take a few minutes for the pain to become fully apparent as the bed is lowered and the spine is extended. The history will commonly give a suggestion that this sign will be positive because the patient may describe back pain upon laying flat, with the patient having thereafter sought sleep in a recliner.
Abdominal Wall Pain

The abdominal wall is frequently a source of pain, and how to examine it has been less clearly defined than examination of underlying abdominal structures. Abdominal wall pain is a common mechanism of severe idiopathic abdominal pain. It also can be a long-term sequela of abdominal surgery such as hernia repair, open cholecystectomy, etc. The distinction between an underlying and medically serious intra-abdominal source of pain from a benign abdominal wall source of pain is made through a bedside provocative test, Carnett’s maneuver.

Carnett’s maneuver: The patient is found to be tender on gentle palpation, typically in the left or right lower quadrant (Fig. 41.6). If the patient tenses the abdominal wall, such as by lifting both legs a few centimeters in the air or lifting the shoulders off the bed, an inflamed visceral organ is protected from the palpating hand. Alternatively, if the pain-sensitive structure is within the abdominal wall, such as caused by a
myofascial trigger point, a neuroma, a hematoma, or some other cause, pain becomes markedly worse with tensing of the abdominal wall during palpation.

Another cryptic cause of abdominal wall pain can be neuropathic pain. This can be caused by cancer invading intercostal muscles, by retroperitoneal tumor, by diabetic abdominal wall neuropathy, shingles, and by other mechanisms. There are several bedside provocative maneuvers that can diagnose abdominal wall neuropathic pain. First, gently touch the normal side and then the abnormal side with a cold object, then a piece of cotton, then a pin (see Table 41.5). If any of these normally nonnoxious stimuli results in pain, the patient likely has abdominal neuropathic wall pain. Sensitivity to temperature, touch, or pinprick can be one of the most dramatic bedside signs in the pain physical examination and is strong evidence of the presence of underlying neuropathic pain. The abnormal sensation can linger for up to a minute or longer, so called “after sensation.” Abdominal wall neuropathic pain can be accompanied by numbness or loss of abdominal wall muscle tone.38

Formulating a Cancer Pain Diagnosis
SYNDROME DIAGNOSIS

Although it can be tempting for the clinician to make a specific diagnosis as to the underlying cause of the pain, it may be wiser to begin with a more general syndrome diagnosis. Broadly, pain can be classified into somatic, visceral, neuropathic, or mixed syndromes. Diagnosing the pain syndrome based on the characteristics, the pattern of referral, the accompaniment, and the provocative maneuvers can make it more likely that the clinician will consider a broad differential diagnosis.

The use of the taxonomy of somatic, visceral, and neuropathic pain syndromes can be challenged by closer scrutiny of their pathophysiologic basis. For example, some peripheral nerves are themselves pain-sensitive structures, being innervated by nociceptors. In addition, other aspects of neuropathic pain can be nonnociceptive, that is, pain generated by a damaged nervous system. Thus, when the peripheral nervous system is invaded by cancer, there can be both nociceptive and nonnociceptive pain. A common clinical scenario is malignant brachial plexopathy. The nociceptive component generated by nociceptors within the brachial plexus is pain draped over the ipsilateral shoulder; the nonnociceptive component of the pain is commonly burning pain in the ipsilateral, numb hand. An example of a central generator of neuropathic pain is poststroke thalamic pain. Central pain caused by brain metastases is extraordinarily uncommon and may relate to the long period of time it takes for central pain to develop. However, the taxonomy remains of clinical value, and a more complex version is described in Table 41.6.

</tbody>
</table>
There are other causes of pain which appear nociceptive in characteristic but have a nonnociceptive mechanism. Pain purely or mostly of psychological origin (often inappropriately termed psychogenic pain) is extraordinarily rare in the cancer population and must be used cautiously as it can either take the focus away from other equally or more important causes of pain or might stigmatize the patient as being less than genuine, truthful, or trustworthy. For this reason, the term psychogenic pain is usually avoided. An example of pain of psychological origin would be a patient who feels pain as part of a psychotic sensory hallucination. Likewise, factitious pain is uncommon and is due to a compulsive need for unwarranted health care (different than malingering). Idiopathic pain is pain for which the cause is not evident after a detailed history, physical exam including bedside provocative maneuvers, and referral for appropriate diagnostic imaging, laboratory tests, and consultation as needed. The pain clinician should be wary about the situation of idiopathic pain in a patient with known cancer. Commonly, idiopathic pain in a cancer patient turns out to be due to metastatic disease that was not evident despite extensive investigations. A wise approach to the cancer patient with idiopathic pain is to complete investigations and then see the patient in follow-up on a regularly scheduled basis such as every 3 months. Diagnostic imaging can be repeated at that time along with a repeat clinical assessment.

The role of bedside provocative maneuvers in formulating a cancer pain diagnosis has been described. In this prospective study of 50 patients, all or much of the pain that brought the patient to the clinical venue was reproduced by a positive maneuver in 47 of 50 patients. Most commonly, pain was somatic, but it could also be visceral or neuropathic, and about half the time, it was mixed pain. Myopathic pain or muscle spasm pain was present in about half of all patients and allowed a broader approach to overall pain control strategies.

**PATHOPHYSIOLOGIC DIAGNOSIS**

The temporal profile of how the pain progressed over time will commonly reveal the underlying mechanism of pain (see Table 41.1). Vascular events are usually as bad as they are going to get within less than a day. An
example of a vascular event is a spontaneous bleed within a tumor bed, exemplified by a patient with a vascular neoplasm, such as choriocarcinoma or melanoma, who develops a headache and accompanying neurologic symptoms that become fully established in less than a day. An inflammatory process typically takes between 1 and 30 days to be as bad as it is going to get. An example could be a tumor-related skin or deep tissue abscess. When pain takes more than a month to become as severe as it is going to get, is focal, and is progressive, it is usually due to a growing mass. Needless to say, in a patient with known cancer, severe pain should be considered to be progression of malignancy in that region of the body until proven otherwise.

Complementary Clinical Perspectives in the Care of Cancer Patients

Pain is a symptom and not a diagnosis. Chronic pain can be a symptom of ongoing tissue injury or a disease process in and of itself as previously discussed. The overall approach to a pain management strategy, therefore, is greatly shaped by the underlying pain mechanisms involved and the overall goals of care. The medical approach focuses on disease diagnosis and disease cure; the palliative approach aims to relieve, suppress, or mask pain to the greatest extent possible; the rehabilitative approach (an approach widely employed by chronic noncancer pain clinics) focuses on improved function and adaptive coping; and the anesthetic approach has the objective to diagnose and block, such as a combination of “medical” and “palliative” approaches. With each of these perspectives, however, the goal is to relieve pain as quickly as possible, with the least toxicity possible. These various, but not mutually exclusive, approaches can be exemplified in a clinical case.

A 53-year-old man, who was previously healthy, developed a gradual onset of epigastric pain. He began to develop nausea and heartburn; symptoms worsened after eating. He developed weight loss. He seeks care from his physician 4 months after the onset of these symptoms.

THE MEDICAL MODEL: PAIN IS A MANIFESTATION

1995
OF DISEASE
In the medical model, pain is seen as a manifestation of an underlying illness. The general orientation is that of a systems approach, whereby the clinician focuses on the affected system. Using a rule in/rule out method, the clinician considers GI disease such as erosive esophagitis, gastritis, duodenal ulcer, and upper GI malignancy; cardiovascular disease such as a descending aortic aneurysm and ischemic heart disease; and other neoplastic disease such as an intrathoracic malignancy with referred pain. Diagnostic tests are ordered to rule in or rule out each of these conditions. In this situation, pain is helpful in that it alerts the patient that something is wrong and needs to be investigated. This is discussed in Chapter 43.

PALLIATIVE MODEL: PAIN IS BOTH USELESS AND HARMFUL
In this model, the underlying mechanism for pain is almost always known. The extent of underlying disease is also known and pain is both physiologically useless and potentially harmful to patient health. Today, there is intense research and clinical interest whether better control of cancer symptoms, such as pain, results in prolonged survival.40,41 “Palliative” is an invented word based on the Latin for mask or cloak. The approach of the palliative model is to comprehensively assess the whole patient, including his or her underlying disease, his or her social situation, his or her emotional state, and his or her spirituality, and then to mask or suppress the pain as much as possible. Other symptoms, such as anorexia, low energy, or nausea, should also be assessed and suppressed with medications or other approaches. Another closely related term commonly used to describe a whole-person approach to care of the cancer patient is “supportive care.” An example of a palliative approach to cancer treatment is palliative chemotherapy or radiation therapy and is discussed more fully in Chapter 48.

REHABILITATIVE (“CHRONIC NONMALIGNANT PAIN”) MODEL: FOCUS ON DYSFUNCTIONAL PAIN BEHAVIOR AND PAIN-RELATED DECONDITIONING
A third model for pain diagnosis and treatment is the rehabilitation model
for the management of the chronic pain syndrome and is applied in the setting of dysfunctional pain behaviors. In this scenario, pain has been investigated with findings of no underlying somatic, visceral, or neuropathic process to account for the pain or the underlying disease (e.g., arthritis) cannot be eradicated, so pain must be minimized in order to optimize quality of life. Either way, therapy is directed at reversing any chronic dysfunctional pain behaviors, and the client undergoes some form of behavior modification and functional restoration therapy. This is discussed in Chapter 88.

ANESTHETIC MODEL: DIAGNOSTIC AND THERAPEUTIC BLOCKS

A fourth approach is the anesthetic model. In this approach, the patient undergoes a diagnostic procedure whereby local anesthetic is injected into or around suspected pain generator sites or regional blockade of sensory or autonomic nerves is performed. If the pain goes away, the patient may also undergo a series of such interventions or, in selected cases, a more definitive therapeutic block with a neurolytic agent such as phenol or alcohol. A detailed description of interventional pain therapies is presented in Chapter 44.

All of the aforementioned are perspectives, and none should be adopted as the sole correct approach but applied and integrated, depending on clinical context. In the case history of the patient with epigastric pain in the earlier discussion, the patient may present to his or her physician for assessment and, through the medical model, will have several conditions ruled out until a definitive diagnosis, such as pancreatic cancer, is made, during which time analgesics should be used to treat pain. He or she may undergo cancer treatment, but at the same time, he or she may be started on long-acting opioids, with the plan of masking or suppressing the pain, or he or she may be referred for a celiac plexus block. If this patient is having difficulty coping, or if he or she develops dysfunctional pain behaviors or aberrant medication use, a rehabilitative approach that focuses on behavior modification should be employed. Thus, the sage clinician can fluently move between different models of pain treatment and care depending on the clinical context and may in fact consider more than
one model at the same time (Fig. 41.7).

**FIGURE 41.7** Complementary clinical perspectives in the care of cancer patients.

### Management of Pain in Specific Clinical Presentations

#### BONE PAIN
Cancer-related bone pain is common. About 80% of patients who die from breast cancer will have bone metastases at the time of autopsy, and a similar prevalence has been observed in other kinds of cancer. Bone scintigraphy studies have revealed the surprising findings that bone metastases are far more numerous in any given patient than what would be expected by the pain history; about two-thirds of bone metastases are painless. Although the risk of pain correlates to an extent with the degree of bone destruction and whether or not the metastasis is in a weight-bearing bone, it can be difficult to predict based on imaging studies as to whether a metastatic lesion is painful or not. Oddly, bone pain can be transient and migratory, that is, very painful for several days and then appears to not be painful but other bone metastases become painful.

Typically, pain from bone metastases become worse over the course of months. However, at a point in time, the pain may start to increase more quickly in a crescendo pattern, becoming worse each day. There is often
severe muscle spasm in the contiguous muscles. This pattern of crescendo pain in bone metastasis predicts fracture. Crescendo back pain predicts collapse of a vertebral body; one should urgently investigate such patients for exigent or impending epidural cord compression to offer definitive treatment prior to developing their neurologic symptoms. Bone pain is described in more detail in Chapters 46 and 47.

PAIN AND DELIRIUM
Delirium is a transient and potentially reversible neuropsychiatric syndrome characterized by global cognitive dysfunction.\(^{42}\) Tools have been developed to assist the clinician to make the diagnosis as it has been found that while delirium is common in cancer patients, the diagnosis is often delayed or missed. Because pain is a subjective symptom, there is a risk that the presence or severity of pain will be misunderstood if the diagnosis of delirium is not made.

Delirium can be caused by severe pain, pain medications, or can occur in a patient with advanced illness and organ failure who also happens to have pain. It can be challenging to distinguish between these different clinical scenarios. Almost invariably, delirium in the palliative setting is multifactorial in origin. In order to quantitate the pain, the patient’s numeric rating of the pain should be dutifully recorded, if possible, using tools that are intended for cognitively impaired individuals. Behaviors suggestive of pain should be sought, such as the patient grabbing the painful part of the body, the patient using other words to describe the pain, or the presence of a known destructive process in that region of the body.

Pain patients who develop delirium commonly describe a worsening of their pain, but the pain is often generalized to the whole body. In this situation, if all other potential causes of delirium have been ruled out or treated and opioids are being used, a trial of opioid dose reduction or rotation to a different opioid may be employed. Potentially reversible causes of delirium should be identified and treated, including a very wide array of possibilities such as hypercalcemia, along with hydration and other supportive measures to manage the delirium.\(^{43}\) If there is clinical suspicion that the delirium may be caused by uncontrolled pain, a short-acting opioid should be considered as a test dose.
PAIN AND NAUSEA
Chronic nausea is a prevalent symptom in cancer patients, and opioids themselves can be emetogenic. Complicating this situation is the experience of patients who have both pain and nausea and are unable to take oral medications.

A wise approach to the presence of both pain and nausea is to assess each of them individually and treat any underlying cause. If there is any possibility that the opioid is causing or contributing to the nausea, this symptom should be treated aggressively and/or the patient should be rotated to a different opioid or to a nonopioid pain treatment strategy. As common as opioid-related nausea is, it is fortunate that this symptom is usually self-limiting, only uncommonly necessitating discontinuation from opioid therapy. Alternative routes of administration, such as transdermal or injectable opioids, may need to be considered if the opioids are effective for pain but the patient cannot manage to take them by the oral route until habituation to this symptom occurs.

PAIN AND ANOREXIA/CACHEXIA/ASTHENIA
Anorexia/cachexia/asthenia is a common triad that accompanies many types of cancer, and when pain is also present, symptoms can be particularly difficult to manage. Although fatigue is the most common symptom in cancer patients, affecting about 70% of patients, a large minority fulfill diagnostic criteria of anorexia with cachexia. Such patients may have difficulty tolerating opioids, may have concurrent nausea, or may not be able to tolerate oral opioids because of upper GI malignancy. Such patients require alternative routes of drug administration or other pain treatment strategies. Furthermore, many interventions are available to support comprehensive assessment and management of anorexia, cachexia, and asthenia.

PAIN AND BOWEL DISEASE
Slow-release opioids are about 50% absorbed in the large colon. Patients who have had a partial or complete colectomy may malabsorb slow-release opioids, as a function of the more rapid transit time. The clinician may be suspicious of this by the presence of end-of-dose failure of the opioid,
occurring several hours before the medication would be expected to wear off. Patients may report seeing the “ghost” of slow-release tablets in their stool. Most patients who have a low colostomy (in the left lower quadrant on abdominal exam) only uncommonly malabsorb slow-release opioids, whereas patients with a right-sided colostomy or ileostomy are at much higher risk. These patients should be considered for transdermal opioids or some other route of opioid administration.

Patients who have upper GI malignancy and pain are also at risk to develop concurrent nausea, obstruction, or other GI symptoms. At an early stage in their disease, they should be considered for another route of administration of analgesic medication.

MANAGING CANCER PAIN IN THE ADDICT
The overall strategy for pain management in the patient who carries an addiction diagnosis should be tempered according to whether the history is that of remote addiction, recent addiction, or active addiction. It must be stated that use of controlled substances for any legitimate medical purpose requires vigilance and a risk management approach that considers diversion and abuse, irrespective of the patient’s diagnosis or history. However, medical judgment must be used to determine the extent of such programs relative to the patient’s individual circumstances. In all situations, the clinician will want to understand if the patient is in active recovery and/or maintenance therapy, communicate with the patient’s addiction counselor/therapist, and look carefully for evidence of aberrant or problematic drug-taking behavior. The patient with a remote history of substance abuse and who currently has a stable social situation and a spouse or other close family member should be managed as any other cancer pain patient. However, these patients and their family members are oftentimes very concerned about rekindling addiction and may be highly opioid phobic. Long-acting oral opioids, transdermal opioids, or opioid preparations with abuse-deterrent technologies are the preference. The dose should be titrated upward to effect, with a structured management program (e.g., frequent follow-up visits, small or modest supplies of medicine dispensed at any given time, urine drug screens) to provide sufficient support for the patient and family. There should in most
circumstances be only one prescribing physician, and once stable analgesia is achieved, there should be sufficient confidence and evidence of compliance and increasingly longer periods of time between prescribing visits. To the patient who is a recent user and in recovery, the discussion needs to be more frank and the plan of care more structured. The clinician should not only outline the goals of care (improved comfort and improved function) but also inquire the patient about his or her level of concern regarding opioids. The physician should warn the patient to not take the opioids for any reason other than relief of pain. Together, they should agree as to how often the medication prescriptions should be refilled and by whom. Comanagement with an addiction specialist is advised if the prescribing clinician is not well versed in addiction medicine. Unsanctioned dose escalation is not allowed, and if necessary, the medications may need to be controlled by the spouse or other family member.

Cancer patients who are actively abusing pose particular challenges. The patient and the clinician hope that the patient can achieve relief of pain, but the prescribing physician will be particularly wary of causing harm. Harm includes the risk of drug diversion or overdosing because the patient is accustomed to a less potent source of drug. Also, there is the risk that the pain medication may be stolen by those around the patient because of the social circumstances that often accompany addiction. There needs to be a firm, concrete framework to support clinical care. In these situations, daily dispensing of pain medication is often required, along with observed ingestion. If transdermal fentanyl patches are prescribed, which may be useful in these circumstances, the patch should be replaced under observation and then either disposed of properly or the used patch may be brought to the next prescribing visit and disposed under observation of clinicians. Liquid methadone may also be preferable over other analgesics or formulations in this circumstance.

A written agreement delineates expected behavior and the consequences of nonadherence. The agreement (sometimes referred to as an opioid contract) should include periodic unscheduled drug screening if the patient has committed to not use other drugs. In certain jurisdictions, the prescribing physician can benefit from a state or provincial computerized

2002
prescription network whereby it can be determined if the patient is obtaining prescription medications from another legitimate source. One should avoid high doses of opioids and should also consider nonpharmacologic interventions at an earlier stage (such as palliative radiotherapy or neural blockage).

SAFE PRESCRIBING PRACTICES: UNIVERSAL PRECAUTIONS

Beyond strategies applicable for the situation of cancer pain in a patient with a history of addiction is an emerging approach to safe prescribing opioid practice which is designed to guide care for all patients who are potentially candidates for opioids, whether or not there is a history of substance abuse. Recent years have seen heightened awareness of risk of misuse of opioids acquired through the health care system—awareness by the health care community, by patients and their families, by the public, and by regulatory bodies. Extensive guidance is available regarding safe prescribing practices44 and universal precautions.45 Although much attention has been paid to safe practices in noncancer pain management, increasingly, there is awareness that cancer pain, palliative care, and end-of-life care are situations which warrant similar high levels of caution.

Accurate use of words helps to delineate the landscape of substance abuse and the clinician’s role in risk reduction. As described elsewhere in this book (see Chapter 32), addiction is on the far end of a spectrum of substance use disorders. Addiction is characterized by continued substance use despite demonstrable harm, craving, loss of control, and compulsive drug use such as gorging. Drug abuse is defined as drug use in a manner different than social norms. Evidence of drug abuse in the clinical setting can include aberrant drug behavior or nonadherence behavior.

A universal precautions strategy to prescribe opioids for cancer pain should be applied to all pain patients; it should include a specific focus on clinical assessment to stratify for risk, and a focus on elements of ongoing care:

Clinical assessment to stratify for risk
• Personal history of alcohol consumption
• Personal history of drug abuse
• Current heavy smoking/chronic unemployment
• Poor psychosocial support
• Family history of alcohol or drug abuse
• Establish treatment goals such as targets for pain reduction or improved function

Ongoing care
• Only one physician prescribes scheduled medications.
• Regularly review a patient’s scheduled prescriptions using a state, provincial, or national prescription drug monitoring program.
• Monitor for and respond to aberrant behavior such as unsanctioned dose escalation, lost prescriptions, seeking medications from other physicians, or other aberrant activity.
• Continue opioid therapy only if meaningful benefits are present that outweigh the risks to patients.

Clinicians working in a cancer pain practice are often surprised at advice that they should consider instituting safe prescribing practices which are more commonly encountered in the chronic noncancer population. However, drug abuse touches almost all parts of society. Having a prospective, structured approach to safe prescribing equips the clinician to continue to have a prescribing relationship with a patient who subsequently develops what appears to be aberrant behavior.

Commensurate with risk, the clinician should consider a range of approaches to respond to problematic behavior. These can include weekly, semiweekly, or daily carries of prescription refills for scheduled medications; random urine drug screens; blood levels of analgesics or of acetaminophen if it is present in breakthrough medications (record carefully when the last dose was taken in relation to timing of phlebotomy); home visits by physician or nurse, including medication reconciliation and direct interview of family members to explore their perspectives; or switch to opioid preparations considered to have a lower risk of diversion or abuse.

If drug diversion has occurred, stop prescribing or switch to a highly structured regimen such as witnessed ingestion of methadone.

SYMPTOM CLUSTERS
Cancer patients commonly have more than one symptom. A large survey of medical oncology inpatients and outpatients from a US Veterans Affairs medical center revealed that most had several symptoms, including low energy (62%), pain (59%), dry mouth (54%), shortness of breath (50%), and sleeping difficulty (45%). Patients with “moderate” intensity pain had a median number of 11 symptoms, and as the performance status fell, the number of intense symptoms increased. Other studies have confirmed that cancer patients commonly have many distressing symptoms, and as the severity of disease increases, so does the number and severity of symptoms.

The concept of symptom clusters has emerged as an area of intense research. Symptom clusters have been defined as three or more concurrent symptoms that are related to each other but do not necessarily share the same etiology. There is evidence that the coexistence of several symptoms in the same patient is associated with worse quality of life and potentially will benefit from specific, targeted therapeutic approaches. For example, it has been suggested that release of cytokines may result in a range of symptoms related to cancer and its treatment. A wide array of specific clusters has been reported. Examples posited to date include fatigue-anorexia-cachexia cluster (easy fatigue, weakness, anorexia, lack of energy, dry mouth, early satiety, weight loss, and taste changes), upper GI cluster (dizzy spells, dyspepsia, belching, bloating), neuropsychological cluster (sleep problems, depression, and anxiety), and others.

Further research is needed to confirm their existence as discrete nosologic entities, to delineate their underlying pathogenesis and connectedness, and to explore mechanism-based approaches to their management. Cancer pain can be difficult to manage in the presence of other cancer-related symptoms, in part because opioids, nonopioids, and nondrug analgesic interventions can be more difficult for the patient to tolerate. Furthermore, even if pain is effectively managed, the patient may continue to have other severe symptoms and poor quality of life.

**PAIN AT THE END OF LIFE**

In the final hours of life, it may not be appropriate or there may not be sufficient time to obtain a detailed history, physical examination, and
diagnostic studies in order to quickly obtain relief of distressing symptoms. The actual mechanism of pain becomes increasingly less relevant as death approaches. In the instance of severe pain, one would consider subcutaneous or intravenous opioids with rapid titration to effect. Severe regional pain such as abdominal, pelvic, or lower extremity pain can be managed with neuraxial (epidural, intrathecal) local anesthetics or opioids. In a pain crisis at the end of life, the patient may be a candidate for palliative sedation. Palliative sedation is appropriate when the patient is aware that they are at the end of life, other interventions are not expected to relieve pain quickly enough, and the patient or family has requested this approach and given their informed consent. Assessment tools have been developed to guide the depth of sedation and must be used. These issues are discussed further in Chapter 109.

CANCER PAIN EMERGENCIES

Occasionally, patients will present to their physician with persistent, horrible cancer pain. A cancer pain emergency has been defined as pain that is severe or excruciating (8 out of 10 on a 0 to 10 scale), for more than 6 hours. Such patients typically come to an emergency room in great distress. The patient may already be on large doses of opioids and may be dehydrated due to limited oral intake during the previous days. Often, the patient will not have slept at all during that time. In such cases, the patient assessment is greatly truncated. The physician examines the patient quickly to determine whether there is evidence of a ruptured viscous, subarachnoid hemorrhage, ischemic crisis, pathologic fracture, spinal cord compression, or other catastrophe. Vital signs and cognitive status are monitored, and an intravenous access is secured. Opioid is administered with rapid upward titration using a mini-bolus technique until there is relief of pain. Intravenous protocols for cancer pain emergencies have been described for morphine and fentanyl; oral transmucosal and other routes of administration of opioids have also been described. Unlike conscious sedation, rapid upward titration of opioid in the setting of unrelieved cancer pain almost never results in serious toxicity. After relief of pain is obtained, the physician reassesses the patient in detail for the underlying cause of the pain crisis. Some patients appear to be able to
leave the emergency room an hour or few hours after obtaining relief of pain. Only uncommonly will the cause of the cancer pain emergency be apparent, such as a pathologic fracture. Typically, the flare of pain arises in a place of known metastatic disease, and the pain goes away as mysteriously as it came. Pain crises can occur in the palliative setting, and interventional approaches may be needed to obtain control of pain in a timely manner.\textsuperscript{58}

**OPIOID DIVERSION AT THE END OF LIFE**

Cancer pain often increases as disease progresses and death approaches. As a result, opioid dose often also increases. Clinicians who have undertaken home visits in patients with advanced cancer have seen literally stacks of pill containers which have accumulated over time, covering bedroom furniture, filling bathroom cabinets, and overflowing onto the floor or stuffed into suit cases. After death, families often have custody of very large amounts of analgesic pills, injectable medications, and other drug preparations. What happens to these prescription medications? Little is actually known. It is suspected, however, that some of this medication is diverted by family or friends and much of this may happen without it ever being discovered.

To prevent drug diversion at this most vulnerable of times, safe prescribing practice in end-of-life care should include identification of a medication custodian at an early time in this journey, usually the spouse or main caregiver. That individual should be asked to create an ongoing medication inventory and assure that scheduled medications are always secure. There should be a discussion about a formal plan for drug disposal after death, such as agreement with the dispensing pharmacy to dispose of this medication.

**Conclusion**

Cancer pain is common and, when present, is often severe. Fortunately, a great deal is known about its epidemiology, assessment, and management. An individualized approach to each patient offers the best opportunity to provide relief of pain and improve the quality of life at all stages of
oncologic disease.

References
Cancer is a major health problem in the United States and other countries and is the second leading cause of death in the United States and the most prominent cause of death in terms of years of potential life lost (Fig. 42.1).\(^1,2\) In the United States, there was a total of 1,688,780 new cancer cases (or 4,600 new cancer diagnoses per day) and 600,920 deaths for cancers in 2017.\(^3\) For all sites combined, the cancer incidence rate is 20% higher in men than in women, whereas the cancer death rate is 40% higher in men. From 1991 to 2014, the overall cancer death rate dropped 25%. Prostate, lung and bronchus, and colorectum account for 42% of cases in men, whereas in women, breast, lung and bronchus, and colorectum account for 50% (Fig. 42.2). Prostate cancer accounts for 1:5 new diagnoses in men, and breast cancer almost 1:3 of new diagnoses in women. Lung and bronchus cancers present approximately 1:4 cancer-related deaths in men and women (see Fig. 42.1). Cancer incidence patterns reflect trends in behaviors associated with cancer risk and changes in medical practice, such as the introduction of screening. Over the past decade of data, the overall cancer incidence rate in men declined by about 2% per year overall, whereas the incidence rate in women has remained generally stable since 1987 (Fig. 42.3).
Over the past three decades, the 5-year relative survival rate for all cancers combined has increased 20 percentage points among whites and 24 percentage points among blacks. The decline in cancer mortality over the past two decades is the result of steady reductions in smoking and advances in early detection and treatment, reflected in considerable decreases for the four major cancers (lung, breast, prostate, and colorectum) (Fig. 42.4). In contrast to declining trends for the four major cancers, death rates rose from 2010 to 2014 by almost 3% per year for liver cancer and by about 2% per year for uterine cancer. Cancer survival, particularly for advanced-stage diseases, will likely improve because of advances in precision medicine and immunotherapy for late-stage cancers (e.g., melanoma, lung cancer).\(^4\)\(^5\) Cancer incidence and death rates vary considerably between racial and ethnic groups, with rates generally highest among blacks and lowest among Asian/Pacific Islanders.\(^3\) The major behavioral determinants of cancer, such as smoking, diet, alcohol use, obesity, physical inactivity, reproductive behavior, occupational and environmental exposures, and cancer screening, are substantially influenced by individual and area-level socioeconomic factors.\(^6\) Health care inequalities have also risen in both absolute and relative terms and socioeconomic and racial/ethnic disparities in stage at diagnosis and survival from major cancers have persisted.\(^1\)

Figures 42.2, 42.3, and 42.4 show estimated new cancer cases and...
deaths, trends in cancer incidence (1975 to 2013) and death rates (1975 to 2014) by sex and trends in death rates by sex overall and for select cancers, United States (1930 to 2014).

The number of cancer survivors has steadily increased since the 1970s with an estimated 13.7 million people in the United States in 2012 who had been diagnosed with cancer representing approximately a threefold
increase compared to 1975 (Fig. 42.5). The number of cancer survivors is projected to increase by 31% to almost 18 million in 2018, which indicates an increase of more than 4 million survivors in 10 years\(^7\) or more than 20 million in 2026\(^8\) with 60% of cancer survivors aged 65 years or older by the year 2020.\(^9\) Improvements in survival for the most common cancers have been similar by sex but are much more pronounced among patients aged 50 to 64 years than among those aged older than 65 years likely reflecting lower efficacy or use of new therapies in the elderly population.\(^10\) Progress has been more rapid for the hematopoietic and lymphoid malignancies and less so for lung and pancreatic cancers for which the 5-year relative survival is 18% and 8%, respectively.\(^3\) As the number of cancer survivors continue to grow, the need to address the effect of symptoms of cancer, including pain, on individuals’ lives will become increasingly critical to efforts to reduce the burden of cancer and its treatment.

Despite advances in early detection and effective treatments, cancer is one of the medical conditions patients fear most.\(^11\) The diagnosis often
results in complex decisions at a time when patients may feel particularly vulnerable and distressed. Although clinical decisions previously followed one standard, many guidelines now outline several options and include explicit recognition of the need to incorporate patients’ preferences to determine the most appropriate treatment. Consequently, the demands and stresses imposed on patients during treatment may be considerable. In addition to anxiety about cancer as a potentially lethal disease, patient and family expectations that pain is an inevitable and untreatable consequence are additional major sources of distress. Cancer pain elevates psychological distress, alters social life, disturbs sleep, affects enjoyment of life, and potentially compromises survival. Fatigue, insomnia, neuropathy, and pain are among the most common troublesome symptoms experienced by cancer survivors suggesting that pain rarely occurs in isolation. Furthermore, survivorship from cancer imposes its own issues including physical, psychosocial, and financial burdens with its associated impact on quality of life (QOL).

Differences exist between cancer pain patients and those that experience acute pain and/or chronic nonmalignant pain. The possibility of multiple complex and potentially painful oncology treatments (surgery, radiation therapy, chemotherapy, bone marrow transplantation, or other new treatments such as endocrine therapy for breast cancer) may result in a constant changing environment resulting in new pain complaints separate from the original tumor-related pain. For example, breast cancer is a major health burden and endocrine therapy with aromatase inhibitors (AIs) may be prescribed for up to 10 years in patients with hormone receptor-positive tumors. Unfortunately, AI-associated arthralgia is an adverse event associated with low compliance with treatment. Cancer patients also tend to have a higher symptom burden (especially psychological) compared to noncancer patients. Patients may experience moderate-to-severe symptom distress (particularly pain, fatigue, and insomnia) after cancer treatment initiation. End-of-life considerations and palliative care are rarely major issues for acute and chronic nonmalignant pain conditions, but these concerns become extremely important for the cancer pain patient with advanced disease (see Chapter 109). The complexities that emerge from the medical and psychosocial aspects of the situation necessitate a
multi- and/or interdisciplinary approach for care. The changing nature of
cancer pain, either in response to treatments directed at the tumor and/or
progression of the tumor, mandates vigilance and potential frequent
alteration of treatment strategies for pain. In addition, cancer survivors
face ongoing surveillance for the possibility of disease recurrence, and
new pain complaints in these patients require careful assessment. As
cancer treatments continue to improve survival, many oncology patients
face long-term pain management issues from aggressive treatment of their
disease. As such, different treatment strategies may need to be considered.
The effects of cancer diagnosis and subsequent treatment represent a
continuum with an initial focus in early disease on health in survivorship
and with advanced disease on QOL. Comprehensive cancer care usually
requires that many health care professionals become involved with the
cancer pain patient at any one time. Successful pain management requires
that the person or persons responsible for pain management adopt, or at
least become familiar, an interdisciplinary approach. In addition, the
humanitarian nature of cancer pain management, the focus on suffering
and comfort, and the associated effects on patients’ relatives all contribute
to the uniqueness of this form of pain control.

Issues in Assessment and Diagnosis of Cancer Pain

Controlling pain associated with cancer is a major health care problem.
Multiple studies from the 1990s documented inadequate treatment of pain
in patients with cancer. Despite the subsequent availability of
effective pain treatments and various pain management guidelines, these
deficiencies continued both in the United States and in other countries into
the new millennium. In 2008, approximately 1:2 patients with cancer
pain was considered undertreated with geographic and economic trends in
favor of the wealthiest countries. A 2009 study suggested that 1:4
patients were untreated. In a follow-up 2014 study from the 2008 study
using similar methodology, 25% of patients were still considered
untreated. Ineffective pain management can have significant
consequences. QOL for cancer patients and their families is profoundly
affected by the presence of severe pain and other symptoms.
related QOL parameters (physical functioning, appetite loss, and pain) provide significant prognostic value in addition to the sociodemographic variables (age and sex) and clinical variables (World Health Organization [WHO] performance status and distant metastases) and increase the predictive accuracy of the survival prognoses in patients with cancer.\textsuperscript{40} Individual studies or those focusing on a particular cancer site generally reported a higher hazard ratio for pain,\textsuperscript{41,42} appetite loss,\textsuperscript{43} and physical functioning,\textsuperscript{44} suggesting that the prognostic value of health-related QOL parameters scales might vary between different cancer sites.

Barriers to adequate pain management in cancer patients differ in low-versus high-resource environments.\textsuperscript{45} Trainee physicians in the high resource group identified inadequate knowledge of cancer pain, assessment of pain etiology, concerns about opioid dependence, and drug-seeking behaviors as well as physicians’ reluctance to prescribe opioids, as the major barriers. Trainee physicians in the low resource group reported less competence in cancer pain management despite having more cancer patients with advanced disease were less inclined to think that patients benefited from cancer pain management and less likely to consult another physician for cancer pain management and felt that patients poorly characterized their pain. Experienced physicians have also recognized a need for significant improvement in cancer pain assessment and treatment in their practice.\textsuperscript{46,47} Lack of expertise by clinicians in assessing and managing cancer pain is an important cause of poor pain control.\textsuperscript{30,48,49}

Pain management requires a variety of assessment skills and the integration of knowledge about pharmacology, pharmacokinetics and pharmacodynamics, patient characteristics like individual variability and compliance with medications, side effects and QOL determinants, and disease specifics. These skills must contribute to clinical judgment and decision making, often requiring substantial individual experience. Most studies concerning pain education of undergraduate medical students focus on knowledge, but relatively little is known about the interviewing skills and pain evaluation. Leila et al.\textsuperscript{50} suggested that formative assessment of both knowledge and communication skills is essential for the development of a functional pain curriculum for training medical students in pain management of chronic pain patients. Core competencies in pain

2019
management include domains that define the multidimensional nature of pain, pain assessment and measurement, management of pain, and the context of pain management. These serve as a foundation for developing, defining, and revising curricula and as a resource for the creation of learning activities across health care professions. Introducing pain education early in the training of health professionals offers the opportunity to reverse the disparity between what students are taught and what they confront in practice. Continuing education is needed across many disciplines but, in order to ensure the provision of quality pain management care, it is especially important to reach the following providers: oncologists, hematologists, urologists, surgeons, and radiation therapists who initially treat cancer patients; primary care physicians; nurses; and social workers and other providers of psychosocial services.

Pain and the Cancer Patient

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage. The sensory features and subjective qualities of pain vary, depending on its origin. Activity induced in the nociceptor and nociceptive pathways by a noxious stimulus is not pain, which is always a psychological state, even though one may well appreciate that pain most often has a proximate physical cause. Its emotional features depend in part on the social and physical context in which pain occurs, associated cognition, and the meaning of tissue trauma for the individual, but they are almost always negative.

It is important to recognize that the source of pain in the cancer patient is usually not a single entity but often has multiple sources that are dependent on different issues such as tumor staging, treatment phase, preexisting conditions that may cause chronic pain, and posttreatment complications. As such, it is more accurate to use the term pain in the cancer patient than the more confusing term cancer pain. Many clinical trials in cancer pain do not differentiate the two and tend to use the latter descriptor resulting in difficulty in interpreting results.

Tumor-related pain may be classified as nociceptive or neuropathic.
Patients may present with different sources of tumor pain. Figure 42.6 shows a patient with extensive locally recurrent sacral chordoma presenting with tumor infiltration of somatic (sacrum, left sacroiliac [SI] joint, left iliac wing, left gluteal muscles) and neuropathic sources of pain (left S1 foramen with nerve root involvement, encasement of the left lumbosacral plexus). Pain is labeled nociceptive if the noxious stimulus is related to ongoing tissue injury and is subdivided into somatic and visceral types. Pain is neuropathic if there is evidence that the pain is associated with injury to neural tissues and is sustained by aberrant somatosensory processing in the peripheral or in the central nervous system (CNS). The International Association for the Study of Pain (IASP) defines neuropathic pain as pain caused by a lesion or disease of the somatosensory nervous system. The restriction to the somatosensory nervous system is important because conditions such as musculoskeletal pain (e.g., due to spasticity) arising indirectly from disorders of the motor system should not be confused with neuropathic pain. Caraceni and Portenoy defined tumor pain characteristics and syndromes and was nociceptive due to somatic injury in 71.6% of patients, nociceptive visceral in 34.7%, and neuropathic in 39.7%. Prevalence rates for tumor-related neuropathic pain are difficult to determine. Often, studies reporting on neuropathic pain in cancer patients tend to have mixed sources (Table 42.1).

**FIGURE 42.6** Magnetic resonance imaging image (axial T1 gadolinium-enhanced) of pelvis. Patient has extensive locally recurrent chordoma. A: A mass within the left sacrum and iliac wing spanning the left sacroiliac joint with large extralossous soft tissue component extending into the left gluteal muscles (green arrow heads) and left iliopsoas muscle in addition to the left piriformis. The sacroiliac mass approaches the left S1 neural foramen (red arrow). B: The anterior margin of the left sacroiliac mass abuts and partly encases the left lumbosacral plexus at the level of S1 (red arrow heads).
The major pain syndromes comprised bone or joint lesions in 41.7% of patients, visceral lesions in 28.1%, soft tissue infiltration in 28.3%, and peripheral nerve injuries in 27.8%. Somatic nociceptive pain may be grouped into superficial (cutaneous) and deep. Most cutaneous pain is well localized, sharp, pricking, or burning. Deep tissue pain usually seems diffuse and dull or aching in quality. Visceral pain is very diffuse, often referred to the body surface, perseverating, and frequently associated with a queasy quality that patients describe as “sickening.”

The mechanisms of tumor involvement of the nervous system are heterogeneous and include lesions within the cerebrospinal fluid (CSF) space, local invasion, compression, direct infiltration, perineural spread, and rarely intraneural metastasis. Tumor involvement of the CNS occurs intracranially or within the spinal cord. Direct mechanisms for tumor involvement of the spinal cord occur in one of three anatomic compartments: parenchymal (intradural intramedullary), subarachnoid or CSF (intradural extramedullary), or epidural (extradural). Parenchymal (intradural intramedullary) spinal cord disease may be metastatic (intramedullary metastases from systemic cancer) or the consequence of a primary spinal cord tumor. Direct spinal cord disease may also result from
disease of the subarachnoid/CSF compartment as in leptomeningeal metastasis (LM) or by extramedullary intradural primary spinal cord tumors. Direct spinal cord disease may also occur due to epidural metastases resulting in epidural spinal cord compression. Peripheral nerves consist of all the spinal nerves as well as the cranial nerves, with the exception of the optic nerve (cranial nerve II), which is a tract of the diencephalon rather than a peripheral nerve. Lymphoma, as well as breast, lung, prostate, colorectal, gynecologic, skin, and head and neck cancers, invade peripheral nerves through direct extrinsic involvement or perineural spread. Once the dense connective tissue of the epineurium is disrupted, malignant cells can travel both proximally and distally along the perineural and endoneural planes while remaining encased by the epineurium.\textsuperscript{64} Compression and invasion of nerves by tumor results in the destruction of myelinated and unmyelinated fibers and of supporting tissue. Because peripheral nerves can usually evade pressure from a tumor on one side, infiltration by tumor tissue is the quintessential tissue trauma stimulus. In addition, indirect damage of unknown pathogenesis might also occur to peripheral nerves in the context of tumor conditions (e.g., paraneoplastic syndromes). Infiltration of tumor tissue into the perineural cleft is seen relatively often, and perineural tumor spread is more frequently associated with carcinoma arising in head and neck tumors with sources from minor or major salivary glands (more often adenoid cystic carcinoma), mucosal or cutaneous squamous cell carcinoma, basal cell carcinoma, melanoma, lymphoma, and sarcoma.\textsuperscript{65} Neurolymphoma is a rare extranodal manifestation of lymphoma that reflects intraneural infiltration of malignant lymphocytes. Neurolymphoma has been encountered with both B-cell and T-cell lymphoma, yet it appears to occur most frequently in the context of large B-cell non-Hodgkin lymphoma (NHL).\textsuperscript{66} A massive and subsequent painful entrapment of a nerve plexus or individual nerves may occur, especially in extensive breast carcinomas and their recurrences or in chest wall metastases of lung tumors.

**MOLECULAR MECHANISM OF TUMOR PAIN**

In addition to cancer cells, tumors consist of different cell types including inflammatory cells and blood vessels that are often adjacent to primary
afferent nociceptors. These cells include immune system cells such as macrophages, neutrophils, and T cells. These secrete various factors that sensitize or directly excite primary afferent neurons and include prostaglandins (PGs), tumor necrosis factor (TNF), endothelin, interleukin (IL)-1 and IL-6, epidermal growth factor, transforming growth factor (TGF), and platelet-derived growth factor (PDGF). Receptors for many of these factors are expressed by primary afferent neurons. Endothelin (endothelin-1, endothelin-2, and endothelin-3) is a family of vasoactive peptides that are expressed at high levels by several types of tumor, including prostate cancer. Endothelin could contribute to cancer pain by directly sensitizing or exciting nociceptors, as a subset of small, unmyelinated primary afferent neurons expresses endothelin-A receptors. Like PGs, endothelins that are produced by cancer cells are also thought to be involved in regulating angiogenesis and tumor growth. Consequentially, these factors and others from cancer and inflammatory cells, such as adenosine triphosphate (ATP), bradykinin (BK), H+, nerve growth factor (NGF), PGs, and vascular endothelial growth factor (VEGF) excite or sensitize adjacent nociceptors. Tumor growth, spreading, and metastasis require the development of a local vasculature. One of the key signaling processes in the development of the tumor vasculature is the hypoxia-induced stimulation of VEGFs production, and the development of anti-VEGF therapy (e.g., bevacizumab) provides options for limiting tumor growth by targeting angiogenesis. Adjacent nociceptors such as vanilloid receptor-1 (VR1) detect extracellular H+ and endothelin-A receptors detect endothelins released by cancer cells. NGF increases angiogenesis through its tropomyosin receptor kinase A (TrkA) on endothelial cells and by indirectly inducing VEGF expression. Nociceptor activation results in the release of neurotransmitters, such as calcitonin gene-related peptide (CGRP), endothelin, histamine, glutamate, and substance P (SP). Nociceptor activation also causes the release of PGs from the peripheral terminals of sensory fibers, which can induce plasma extravasation, recruitment and activation of immune cells, and vasodilatation.

Other mechanisms, particularly tissue acidosis, may be involved in tumor-related pain. Tumors could cause a decrease in pH by several
mechanisms. As inflammatory cells invade neoplastic tissue, they release protons that generate local acidosis. The large amount of apoptosis that occurs in the tumor environment also contributes to acidosis, as apoptotic cells release intracellular ions to create an acidic environment. This decrease in pH can activate signaling by acid-sensing channels (including VR1) that are expressed by nociceptors. Tumor-induced release of protons and acidosis might be particularly important in the generation of bone cancer pain. Finally, tumor-induced distention of sensory fibers may also be involved in tumor-associated nociceptive processes.

**SOMATIC PAIN**

Somatic cancer pain can be caused by tumor invasion of bone, joint, muscle, or connective tissue. Somatic pain is the most common type of tumor pain with the most prevalent being tumor bone involvement. Nociceptive afferents are most concentrated in the periosteum. Some of the mechanisms contributing to neoplastic bone pain include stretching of the periosteum by tumor expansion, local microfractures that cause bony distortion, nerve compression due to either collapsed vertebrae or direct tumor encroachment, and local release of algesic substances from the bone marrow. Because inactivity and deconditioning predisposes to muscle pain, the debilitated cancer patient may experience muscle pain that is likely to contribute to complaints of localized or generalized pain. Skeletal muscle accounts for approximately 50% of body weight and is a major cause of morbidity. Myofascial pain is often underdiagnosed and inappropriately treated. Myofascial pain should be considered separately from fibromyalgia. In 2010, the American College of Rheumatology abandoned the use of a tender point count in the diagnostic criteria of fibromyalgia with the definition now based on the number of painful body regions and the presence and severity of fatigue, unrefreshed sleep, cognitive difficulty, and the extent of somatic symptoms. Myofascial pain syndrome (MPS) is a local or regional pain problem with tender areas that reproduce symptoms on palpation and may be primary or secondary to another condition. There may be associated muscle stiffness and decreased range of motion with palpable taut bands or nodules. Trigger points may be defined as the presence of defined “exquisitely” painful
trigger in a taut band of muscle that produce characteristic patterns of referred pain on palpation and a local twitch response to mechanical stimulation or needling. Proposed criteria for diagnosis of MPS are listed in Table 42.2. Sustained contractile activity leading to increased metabolic stress and reduced blood flow likely contributes to the persistence of a myofascial trigger point. In addition to the sustained contractile activity, metabolic alterations and cell stress trigger release of myokines, inflammatory cytokines, and neurotransmitters that contribute to myofascial trigger points and MPS.\textsuperscript{76,77} Muscle pain is generally described as aching and cramp-like. It can be difficult to localize and may be referred to other deep somatic structures.

Muscle nociceptors are free nerve endings connected to the CNS by thin myelinated (group III) or unmyelinated (group IV) afferent fibers.\textsuperscript{78} Muscle nociceptors can be sensitized to chemical and mechanical stimuli. Muscle nociceptors can be activated by BK, prostaglandin E\textsubscript{2} (PGE\textsubscript{2}), serotonin (5-HT), and other endogenous substances.\textsuperscript{79} SP, CGRP, and somatostatin are neuropeptides present in primary afferent fibers from muscle.\textsuperscript{80} In muscle-free nerve endings, SP, CGRP, vasoactive intestinal polypeptide, NGF, and growth-associated protein 43 are present.\textsuperscript{81} These neuropeptides are synthesized in the soma of the primary afferent neuron in the dorsal root ganglion and transported via axonal transport to the receptive ending in muscle and to the central terminals in the spinal cord.
Molecular receptors for many algesic substances (BK, 5-HT, PGE$_2$, and ATP) are present in muscle tissue and are released during painful stimulation or pathologic conditions. Some of these receptors control ion channels that cause an ion flux across the membrane that can depolarize the ending. Purinergic receptors may be of particular importance for muscle pain because ATP, which is present in large amounts in muscle tissue and is released during muscle damage, could excite the nociceptor directly. Muscle nociceptors do not respond to everyday stimuli, such as normal contractions or weak deformation of muscle tissue. Two chemical stimuli are particularly relevant as causes of muscle pain. The first is a drop in tissue pH, and a large number of painful alterations of muscle tissue are associated with an acidic interstitial pH. The second important cause of muscle pain is a release of ATP.

**VISCERAL PAIN**

Visceral pain refers to pain resulting from noxious stimuli such as painful swelling, ischemia, and inflammation that act on visceral organs via peripheral and central pathways. Visceral pain is typically correlated with the excitation of spinal (thoracolumbar, sacral) visceral afferents. Spinal visceral afferents are polymodal and activated by adequate mechanical and chemical stimuli. All groups of spinal visceral afferents can be sensitized (e.g., by inflammation). Spinal visceral afferent neurons project into the laminae I, II (outer part IIo), and V of the spinal dorsal horn over several segments; mediolateral over the whole width of the dorsal horn; and contralateral. Typically, patients complain of a vague sensation with an unclear location that may be referred to other nonvisceral somatic areas and associated with autonomic changes. The majority of thoracic and abdominal visceral organs, except the pancreas, are dually innervated by parasympathetic (craniosacral) and sympathetic (thoracolumbar) outflows. Thoracic viscera and upper abdominal viscera are primarily innervated by the vagus (cranial nerve X) and spinal thoracolumbar outflows. The lower abdominal viscera, including the small and the large intestine and the urogenital organs, are innervated by thoracolumbar (i.e., lumbar splanchnic nerve and hypogastric nerve) and sacral (i.e., pelvic nerve) outflows. Sensory afferents innervating the visceral organs are not just a
homogeneous group of afferents signaling visceral pain to the CNS. Pain is primarily signaled by spinal afferents, whereas vagal afferents signal nonpainful sensations such as hunger, satiety, fullness, and nausea.\textsuperscript{85} Transient receptor potential (TRP) channels are predominantly distributed in both somatic and visceral sensory nervous systems and play a crucial role in sensory transduction.\textsuperscript{86} The majority of spinal afferents projecting to the gastrointestinal tract or pelvic organs are TRPV1, TRPA1, and/or TRPM8 positive and respond to mechanical stimulation\textsuperscript{87–89} and are also sensitive to noxious stimuli from pungent compounds, temperature, acid, and inflammation.\textsuperscript{90} Visceral nociceptive messages are conveyed to the spinal cord by relatively few visceral afferent fibers that activate many central neurons by extensive functional divergence through polysynaptic pathways.\textsuperscript{84}

Pancreatic pain is perceived as a severe discomfort in the upper abdomen frequently radiating through to the back. Malignant pancreatic tumors, acute and chronic inflammation of the pancreas, and obstruction of the pancreatic duct can produce severe pain. Hepatic, biliary, and pancreatic pain appear to be mediated by afferent fibers in sympathetic nerves, and vagal innervation does not appear to contribute to nociceptive transmission.\textsuperscript{91} Pain related to pancreatic cancer may occur in 50\% to 70\% of patients,\textsuperscript{92} but only 30\% of patients with early stage pancreatic cancer complain of abdominal pain, compared to 60\% of patients with limited and 80\% of patients with advanced pancreatic cancer.\textsuperscript{93,94} Abdominal pain tends to occur regardless of tumor location, although it was reported by more patients with cancer in the body and tail of the pancreas (90\%) compared with those with cancer in the head of the pancreas (70\%).\textsuperscript{95} Histopathologic and molecular changes have been observed in pancreatic cancer specimens which are associated with pain which include increased nerve density and nerve hypertrophy, peri- and endo-neural cancer cell invasion, altered expression of nociceptors, parenchymal immune cell infiltration in the pancreas, and release of neurotrophic growth factors which are undetectable in the normal pancreas.\textsuperscript{96} Others have proposed perineural spread or invasion by the tumor, capsular stretching, and pancreatic cancer ductal obstruction as mechanisms of pain.\textsuperscript{97} Afferent signaling of pancreatic nociceptive processes is likely via the celiac plexus
and thoracic splanchnic nerves as suggested by the efficacy of celiac plexus block in managing associated pain.\textsuperscript{92}

**NEUROPATHIC PAIN**

Pain usually results from activation of nociceptive afferents by actual or potential tissue-damaging stimuli. Pain may also arise by activity generated within the nervous system without adequate stimulation of its peripheral sensory endings. Neuropathic pain arises as a direct consequence of a lesion or disease affecting the somatosensory system. The presence of symptoms or signs (e.g., touch-evoked pain) alone does not justify the use of the term neuropathic and as such neuropathic pain is a clinical description (and not a diagnosis) which requires a demonstrable lesion or a disease that satisfies established neurologic diagnostic criteria. As such, neuropathic pain should not be diagnosed by pain descriptors only. The process of tumor compression and invasion of nerves entails several degenerative, regenerative, and other pathophysiologic processes.\textsuperscript{98} The whole afferent neuron is affected and goes through reactive, presumably reparative, biochemical changes. The neuron loses its neuropeptides,\textsuperscript{99} atrophies, and may finally degenerate. Animal models indicate that axonal degeneration following peripheral nerve injury causes neuropathic pain,\textsuperscript{100} and these effects are related to the production of proinflammatory cytokines such as TNF-\(\alpha\) with upregulation in endoneurial macrophages and Schwann cells\textsuperscript{101} with other cytokines such as IL-1\(\beta\) and IL-6 and of the anti-inflammatory cytokine IL-10 both in the peripheral (sciatic nerve, dorsal root ganglia [DRG]) and the central (spinal cord) nervous system.\textsuperscript{102} Nerve injuries both proximal and distal to the DRG induce mechanical allodynia, which are likely related to DRG TNF-\(\alpha\) expression and apoptosis.\textsuperscript{103} Microglia and astrocytes within the CNS play a pivotal role in the development and maintenance of neuropathic pain. Microglia propagate neuroinflammation by recruiting other microglia and eventually activating nearby astrocytes, thus prolonging the inflammatory state and leading to chronic neuropathic pain.\textsuperscript{104}

**AFFECTIVE PROCESSING AND SUFFERING**
Fear of pain in patients has cognitive and emotional variables in the experience of pain in patients with advanced cancer. The aversive nature of pain elicits a powerful emotional reaction that feeds back to modulate pain perception. Negative emotions are associated with increased activation in the amygdala, anterior cingulate cortex, and anterior insula, brain structures that not only mediate the processing of emotions but also are important nodes of the pain neuromatrix that tune attention toward pain, intensify pain unpleasantness, and amplify interoception. Anger, sadness, and fear may result from pain and affect biobehavioral processes that influence pain perception to exacerbate anguish and suffering. The emotional mechanisms of cancer pain are the reasons that it generates suffering. Brain processing of pain in humans is based on multiple ascending pathways and brain regions that are involved in several pain components, such as sensory, immediate affective, and secondary affective dimensions. Brain mechanisms supporting discrimination of sensory features of pain extend far beyond the somatosensory cortices and involve frontal regions traditionally associated with affective processing and the medial pain system. The level of psychological and emotional distress associated with a cancer diagnosis contributes to increased rates of comorbidities and mortality while reducing QOL and compliance to care. Transient mood disturbances occur frequently among cancer patients during the disease trajectory, and depression often persists in these patients. Lower QOL scores may be associated with variables related to a patient’s premorbid psychological characteristics and with coping skills for the cancer than to cancer-related variables (e.g., treatment types and cancer severity). Of course, most cancer patients suffer from a complex array of problems and not only pain. Nonetheless, sustained nociception in and of itself can produce suffering because of its ability to create negative emotional arousal and elicit associated stress responses.

Suffering is a complex, negative emotional and cognitive state characterized by perceived threat to the integrity of the self, perceived helplessness in the face of that threat, and exhaustion of psychosocial and personal resources for coping with that threat. The perceived threat to the self may encompass the body, the psychosocial self, or both. Suffering related to cancer is inherently emotional, unpleasant, complex, and
enduring. The clinician should recognize that, although suffering may be a consequence of pain, it is separate from pain and not a synonym for it. It differs from pain in that it entails additional cognitive affective states. For example, perceived helplessness (inability to cope; bankruptcy of physical, psychological, or social resources) is a key element in the suffering of most patients with incurable disease. Similarly, grief can ensue when a cancer patient perceives the loss of a psychological or social resource, a body part or desired personal appearance, a prized employment status, or a physical capability for a treasured activity. Loss often equates with perceived threat to self. In addition, suffering in the cancer patient sometimes involves a sense of separation from social support or alienation. These factors, combined with the emotional distress, fatigue, and stress associated with prolonged pain produce a complex state that differs from pain itself. Wilson et al.\(^\text{114}\) in a study of 381 patients with advanced cancer found that 25% of patients were suffering at a moderate to extreme level and that suffering is a multidimensional experience related most strongly to physical symptoms but with contributions from psychological distress, existential concerns, and social-relational worries.

**PSYCHOLOGICAL FACTORS AND THE COMPLEXITIES OF CANCER PAIN**

Somatic symptoms are a feature of anxiety, depressive, somatoform, and other psychiatric disorders. Somatization refers to patients who transform distress and global suffering into pain and symptom expression, and health care providers frequently view pain reported by cancer patients as primarily somatogenic, whereas chronic nonmalignant pain in patients who lack adequate objective physical pathology is viewed as psychogenic.\(^\text{115}\) Consequently, providers tend to treat cancer pain with pharmacologic, medical, or surgical modalities. Psychological factors tend to be considered of secondary importance.\(^\text{116}\) Pain is a complex experience entailing physiologic, sensory, affective, cognitive, and behavioral components. The final individual perception of pain is dependent on nociceptive input and psychological modifiers such as fear, anxiety, anger, and depression (\textit{Fig. 42.7}).
FIGURE 42.7 Individual perception of pain. Noxious stimuli are modified at supraspinal level by emotions such as anxiety, fear, and anger.

Turk et al.\textsuperscript{115} classified the multidimensional nature of cancer pain and compared the adaptation of cancer patients and chronic noncancer patients to persisting pain. The majority of the cancer patients, both with (81\%) and without (84\%) metastatic disease as well as the noncancer chronic pain patients (85\%) fit one of three psychosocial subgroups: dysfunctional (high levels of pain, perceived interference, affective distress, and low levels of perceived control and activity), interpersonally distressed (high levels of affective distress, negative responses from significant others, and low levels of perceived support), and adaptive copers (low levels of interference and affective distress, high levels of perceived control and activity).

Substantial evidence suggests that psychological factors play an important role in exacerbating pain with clear origins of disease (see Chapters 29 to 33). For example, the belief that pain signifies disease, a commonly held belief among cancer patients,\textsuperscript{117} is associated with elevated pain intensity.\textsuperscript{118,119} Although pain is frequently associated with metastatic disease, it is by no means universal.\textsuperscript{120,121} Spiegel and Bloom\textsuperscript{119} reported on the affective states of cancer patients and the belief that pain is an indicator for disease progression and that medication use predicts pain severity. Patients who attribute their pain to a warning of underlying disease report greater pain intensity than patients with more non–tumor-associated interpretations, despite comparable levels of disease...
progression. In this study, the predictors of pain were use of analgesics, emotional distress, and pain beliefs, and that treatment of metastatic pain should include attention to the patient’s mood and adjustment to illness.

Because of psychological factors, the relationship between pain severity and the extent of disease is rarely as linear as one might assume, and there is a nonlinear relationship between cancer pain severity and interference with function. Research investigating the relationships between physical pathology and pain in cancer has shown conflicting results. First, not all patients with advanced cancer report pain. Twycross and Fairfield reported that only 41 of 100 terminal-stage cancer patients reported pain due to disease. Front et al. demonstrated that for many cancer patients, pain reports did not correspond to the presence or location of bone metastases. Turk et al. found that patients with cancer-related pain reported a significantly higher level of perceived disability and inactivity due to pain than did those with pain of nonmalignant origin. Because the level of pain severity was comparable for the two patient groups, elevated disability may have been a consequence of the meanings patients attributed to their pain. The progression of disease means further deterioration of health and impending death. Indeed, the patients with cancer-related pain appeared to be more fearful of pain and reported significantly higher levels of cognitive and behavioral fear responses than did the patients with chronic pain not associated with cancer. These patients appeared to think and worry more about pain, avoid activities in order to prevent initiation of pain, and they generally felt more hopeless than the patients with non–cancer-related pain.

**Depression in Cancer Patients**

The prevalence of major depressive episodes is increased with most chronic conditions but especially those characterized by inflammation and pain. The prevalence of depression among cancer patients increases with disease severity and symptoms such as pain and fatigue. Adjustment disorder, major depression, delirium, and anxiety disorders occur between 10% and 34% of cancer patients. Major depression has been found to occur in approximately 16% of patients with cancer,
with minor depression and dysthymia combined reported in almost 22% of patients. Mood disturbance, sleep disturbance, fatigue, and pain either alone or in combination is also highly prevalent in patients receiving cancer therapy. The overlap of physical illness and symptoms of major depression is widely recognized in physically healthy adults based on the presence of neurovegetative complaints, including insomnia, anorexia, fatigue, and weight loss in addition to depressed mood, hopelessness, guilt or worthlessness, and suicidal ideation. Major depressive disorder is a debilitating disease that is characterized by depressed mood, diminished interests, impaired cognitive function, and vegetative symptoms, such as disturbed sleep or appetite. Similarly, vegetative symptoms such as appetite loss, insomnia, and fatigue are not uncommon in the cancer patient particularly with advanced disease or cancer treatment, and the diagnosis of depression in cancer patients can be difficult because of this overlap. Levels of physical impairment, age (particularly younger patients), advanced stages of illness, inadequately controlled pain, prior history of depression, and the presence of other significant life stresses or losses are associated with a higher prevalence of depression in cancer patients. In addition, patients with certain cancer types such as pancreatic, head and neck, gastric, and lung cancers have higher rates of depression, with the highest rates in lung, gynecologic, breast, colorectal, and genitourinary patients. Within these disease states, a diagnosis of major depression was more likely in patients who were younger, had worse social deprivation scores, and, for lung cancer and colorectal cancer (CRC), female patients. Seventy three percent of 1,538 patients with depression were not receiving potentially effective treatment. Various chemotherapy agents including alkylating agents (procarbazine, carmustine, busulfan), vinca alkaloids (vincristine, vinblastine), antimetabolites (pemetrexed, fludarabine), medications that interfere with DNA and RNA synthesis (doxorubicin, daunorubicin, L-asparaginase), and mitotic inhibitors (taxanes including paclitaxel, docetaxel) may cause depression. Biologic agents including IL-2, corticosteroids, tyrosine kinase inhibitors (imatinib, dasatinib, cetuximab, sorafenib, sunitinib), and hormonal agents (tamoxifen, anastrozole, gonadotropin-releasing hormone [GnRH] agonists) are associated with
depression. Broadly speaking, depressed persons complain of a pervasive dysphoric mood, anhedonia, apathy and disinterest in normal activities, sleep problems, low energy, and in severe cases suicidal ideation. Approximately 20% to 30% of cancer patients meet the criteria for a psychiatric diagnosis, mainly depressive disorders, anxiety, and adjustment and stress-related disorders, across the trajectory of their disease, whereas the prevalence of depression in primary care patients approximates 6% to 10% for outpatients and 10% to 14% for inpatients. Depression is one of the strongest predictors of subsequent development of regular opioid use for treatment of chronic pain, and multifocal pain is especially likely to be associated with depression and with opioid use.

DETECTING AND ASSESSING DEPRESSION IN THE CANCER PATIENT

It is important for the physician treating cancer pain to recognize and address depression. Untreated depression has a significant impact on patient QOL, health care utilization, disease outcome, and influences care and participation in treatment. Depression may go unnoticed or unaddressed in the cancer patient. Few oncologists or supporting consultants feel qualified to address depression, and for those who do, time limits on patient contact time make it difficult to engage in extensive questioning about psychological well-being. Patients and family members may add to the problem by assuming that care providers concern themselves solely with controlling the disease and wish to avoid the distractions that psychological management entails.

Depressive disorders include disruptive mood dysregulation disorder, major depressive disorder (including major depressive episode), persistent depressive disorder (dysthymia), premenstrual dysphoric disorder, substance/medication-induced depressive disorder, and depressive disorder due to another medical condition. The common feature of all of these disorders is the presence of sad, empty, or irritable mood accompanied by somatic and cognitive changes that significantly affect the individual’s capacity to function. Depression may have two components: the
psychological or “cognitive” component (e.g., mood) and the physical or “somatic” component (e.g., loss of appetite). Diagnostic and Statistical Manual of Mental Disorders (5th edition; DSM-5) criteria requires either depressed mood or loss of interest or pleasure with four other depressive symptoms (changes in sleep, appetite or weight, activity, guilt/worthlessness, death/suicide, fatigue/loss of energy, decreased focus or concentration) for at least 2 weeks. Diagnosing depression in the cancer patient is not straightforward because there is symptom overlap between the psychiatric disorder, the toxicities of treatment, and the effects of the primary disease. Anxiety and depression may also mimic physical symptoms of cancer or treatments, and consequently, emotional distress may not be detected. Many clinicians tend to focus on somatic rather than psychological problems in patients with life-threatening illness, and some erroneously regard reactive depression in a patient who has received a diagnosis of cancer to be a normal response. Mitchell et al. analyzed the diagnostic significance of somatic and nonsomatic symptoms indicative of depression in 279 patients within 9 months of first presentation with a diagnosis of cancer. No single symptom was a good proxy for depression. Emphasis on the presence of somatic symptoms (appetite loss, weight loss, insomnia, fatigue, loss of energy, and diminished ability to think or concentrate), feelings of worthlessness, and suicidal ideation may not be useful, among the DSM (4th ed.; DSM-IV) criteria, for diagnosing and/or judging the severity of depression among cancer patients. Many of the traditional physical symptoms of depression such as fatigue, diminished appetite, and weight loss also occur in emotionally healthy cancer patients.

The prevalence of depression in oncology varies widely by study and is often attributable to differences in assessment procedures. Common assessment methods for depressive spectrum disorders in cancer settings are listed in Table 42.3. In practice, the diagnosis of depression is too complex for any screening tool, used in isolation, to be of diagnostic certainty. Structured clinical interviews have traditionally been considered the standard for identifying the prevalence, clinical significance, and potential treatment of depression because of their rigorous criteria. Common interview tools include the Structured Clinical Interview for
DSM disorders (SCID) and Research Diagnostic Criteria. A disadvantage of such tools includes the lack of validation in a population without significant comorbid physical illness such as cancer. A variety of written self-report measures have been used to identify symptoms of depression in cancer patients. These include the Hospital Anxiety and Depression Scale (HADS), the Rotterdam Symptom Checklist (RSCL), the Beck Depression Inventory (BDI) (regular and short forms), the Brief Symptom Inventory-Depression scale, Center for Epidemiologic Studies Depression Scale (CES-D), and the Zung Self-Rating Depression Scale (both full and brief forms). The majority of research on depression in cancer patients has used the HADS, with much of this research focused on identifying the optimal cutoff scores for depressed patients with cancer. The Patient Health Questionnaire-9 (PHQ-9) and briefer versions, the PHQ-2 and PHQ-8, are easily administered, commonly used depression screening tools. In a study of 463 patients from 35 community-based radiation oncology sites and 2 academic radiation oncology sites, the PHQ-2 demonstrated good psychometric properties for screening for mood disorders, which were equivalent to the PHQ-9. Some authors suggest that the CES-D and BDI-II may be most feasible given their time efficiency, administrative simplicity, and strong psychometric properties. Others have suggested that the PHQ-9 with a cutoff score ≥8 is a good screening tool in cancer outpatients.

DSM, Diagnostic and Statistical Manual of Mental Disorders; DSM-IV, DSM 4th edition; DSM-5, DSM 5th edition; ICD-10, International Statistical Classification of Diseases and Related Health Problems, 10th revision; MDD, major depressive disorder; NPV, negative predictive value; PPV, positive predictive value.

Screening for depression should focus primarily on the cognitive/affective features of depression because these are not confounded with treatment-associated toxicities. In palliative care patients, several studies have found that the single question “Are you depressed?” was used as a screening tool with the high sensitivity, specificity, and positive predictive value.\textsuperscript{160,161}
Cancer-Related Fatigue

Cancer-related fatigue (CRF) may be defined as a common, persistent, and subjective sense of tiredness related to cancer or to treatment for cancer that interferes with usual functioning.\(^{162}\) It may be perceived as a feeling of extraordinary exhaustion associated with a high level of distress, disproportionate to activity, and is not relieved by sleep or rest. Patients may describe fatigue as feeling tired, weak, worn-out, heavy, slow, or that they have no energy or get-up-and-go. CRF and sleep disturbances may occur as distinct symptoms but are often comorbid.\(^{163}\) Fatigue is also a nonspecific symptom that may be found in association with most mental and physical disorders. It is prevalent among all types of cancer, but breast, lung, and pancreatic are among the most frequently associated with persistent fatigue.\(^{164}\) Abrahams et al.\(^{165}\) estimated that 1:4 breast cancer survivors suffer from severe fatigue and identified higher disease stages, chemotherapy and receiving the combination of surgery, radiotherapy, and chemotherapy, both with and without hormone therapy, as risk factors.

Fatigue may be an issue during all phases of treatment and into survivorship for extended periods of time.\(^{166}\) It is estimated that fatigue is present at the time of diagnosis in approximately 40% of cancer patients.\(^{167}\) It occurs in up to 75% of patients if bone metastases already are present.\(^{168}\) An estimated 60% to 96% of cancer patients in treatment experience fatigue, including 90% of patients on radiation treatment and 80% of patients on chemotherapy. Except for chemotherapy-induced anemia, the pathogenesis of fatigue in patients with cancer is understood poorly, but proposed mechanisms include the direct effects of cancer and the various modes of cancer treatment plus a wide variety of concomitant diseases (such as anemia, infections, dehydration, and electrolyte disorders), sleep disorders, chronic pain, immobility and lack of exercise, and a variety of psychosocial disorders. Because of the high prevalence of anemia in oncology patients, the association of anemia with fatigue has been extensively studied. Sobrero et al.\(^{169}\) indicated that general scores for QOL, fatigue, and sensations of physical and functional well-being are significantly higher among patients with hemoglobin (Hb) levels >12 g/dL, but Bremberg et al.\(^{170}\) found that physical and functional aspects
may be more important to consider than increasing the Hb level to reduce the fatigue.

Screening for fatigue is an important issue in the overall care of the oncology patient. Various tools for assessing CFR have been used (Table 42.4). The most widely used of these scales are the Functional Assessment of Cancer Therapy: Fatigue (FACT-F) and the European Organisation for Research and Treatment of Cancer Quality of Life Care Questionnaire (EORTC QLQ-C30) fatigue subscale which have data from over 10,000 patients between them and have been widely used in intervention studies to treat CRF. The FACT-F has the advantage of having a validated clinically significant score change—it also covers the social impact of CRF but takes longer to administer than the 3-item EORTC QLQ-C30 fatigue subscale.

</table>
Once fatigue is identified, a detailed clinical evaluation should be performed. Components of the evaluation should include details of the cancer including the type and duration of the treatment and its capacity to induce fatigue. Other components include documenting the characteristics of the fatigue such as when it started, what factors aggravate it, etc. Emotional and psychological components should be identified, and the effect of the fatigue on the performance of normal, daily life activities should be determined. Then, various clinical organic conditions that can cause fatigue should be evaluated. If a specific cause of CRF is identified (anemia, insomnia, depression, metabolic disorders, etc.), then this should be treated first. Antidepressants and analgesics should be prescribed for patients with depression and pain. After common causes of anemia have been excluded, patients with low levels of Hb should receive treatment with erythropoietic agents. Patients with sleep disorders should receive appropriate instructions for improving sleep quality or carefully prescribed drugs. Educating patients about fatigue is extremely useful. Moderate exercise can be more effective than continuous rest. Aerobic exercises can increase overall muscle tone, and it may be wiser to advise such exercise than rest.

Sleep Disturbance in Cancer

Sleep disturbances include reduced nocturnal sleep time, sleep fragmentation, nocturnal wandering, and daytime sleepiness. Acute insomnia is characterized as lasting up to a month and insomnia syndrome is defined as insomnia occurring more than three nights per week, difficulty falling asleep or nighttime awakenings (>30 minutes), ratio of sleep time to time spent in bed <85% (sleep efficiency), impaired daytime functioning, and marked distress. Insomnia syndrome is also called chronic insomnia, as it usually persists nightly for >4 weeks. A history of cancer increases the likelihood of having sleep disturbance. Insomnia is
a prominent problem for patients with cancer and 25% to 60% of patients may be affected\textsuperscript{178–180} and a prevalence rate almost twice that of the general population.\textsuperscript{181} The prevalence of sleep disturbance varies depending on the cancer type, cancer stage, treatment received, and time since completion of treatment. Compared with other types of cancer, breast cancer is associated with an exceptionally high rate of reduced sleep quality.\textsuperscript{182,183} Insomnia in patients with lung cancer undergoing chemotherapy may be as high as 52%.\textsuperscript{184} Sleep disturbance is one of the five most common symptoms reported as moderate to severe by primary brain tumor patients and occurs anywhere between 17% and 54% of patients.\textsuperscript{185} Despite its prevalence and importance, insomnia is often unrecognized and poorly managed. Insomnia refers to difficulty falling or staying asleep, whereas sleep impairment refers to sleepiness, tiredness, and perceived functional impairments during wakefulness associated with sleep problems or impaired alertness. Insomnia typically occurs as a transient inability to initiate or maintain sleep or as hyperarousal, often in response to a situation or event. Daytime consequences of fatigue and insomnia are similar and include dysphoric states, such as irritability, impaired cognition (poor concentration and memory), and interference with usual activities.

Identification of sleep disturbance typically involves screening for the problem followed by a comprehensive assessment for those who screen positive. The National Institutes of Health recommends that screening may include asking two questions: (1) Do you have problems with your sleep or sleep disturbance on average for three or more nights a week? If yes, (2) does the problem with your sleep negatively affect your daytime functioning? If the answer is yes to both questions, a more focused assessment of sleep disturbance is indicated.\textsuperscript{186} Use of the Insomnia Severity Index (7-item, self-report questionnaire) was also recommended to screen for cases of insomnia in cancer patients and for assessing the effects of treatment (\textit{Table 42.5}).\textsuperscript{187} Once identified, the Pittsburgh Sleep Quality Index (PSQI) can be administered for a more detailed assessment. The PSQI is a 19-item questionnaire evaluating sleep quality and disturbances over the past month.\textsuperscript{188} The first 4 items are open questions, whereas items 5 to 19 are rated on a 4-point Likert scale. Individual items
scores yield 7 components (subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleeping medication, and daytime dysfunction). A total score (global PSQI), ranging from 0 to 21, is obtained by adding the 7 component scores. A score >5 suggests poor sleep quality.

For each question, please CIRCLE the number that best describes your answer. Please rate the CURRENT (i.e., LAST 2 WEEKS) SEVERITY of your insomnia problem(s).

From Charles M. Morin, PhD, Université Laval.
Treatment of insomnia favors the use of pharmacologic aids. The common hypnotics including barbiturates, benzodiazepines, the “Z” drugs (eszopiclone, zaleplon, zolpidem, zopiclone), and other benzodiazepine-receptor agonists bind to γ-aminobutyric acid (GABA) receptors. However, a European study demonstrated that publication bias exists for insomnia trials and that the positive trials are two times more likely to be published than the negative ones.\textsuperscript{189} There is little controlled evidence that long-term uses of hypnotics produce benefits of any sort.\textsuperscript{190} A study of almost 2,000 cancer patients found that 22.6\% were taking hypnotic medication for sleep problems, and half of those were taking medication every night for periods longer than 6 months.\textsuperscript{191} Use of hypnotic drugs is associated with a greatly increased risk of all-cause mortality. Some of this mortality has been documented as deaths caused by hypnotics by medical examiners, attributed to respiratory arrests resulting from “overdose.” However, it is likely that many deaths from respiratory depression occur among patients never seen by coroners, especially when the death is caused by a combination of hypnotics with other contributing factors, so that the lethal hypnotic dosage may by itself have been within customary dosage ranges.\textsuperscript{192} In addition to respiratory depression, hypnotics appear to be causally related to serious illnesses and premature deaths from cancer, serious infections, mood disorders, accidental injuries, suicides, and homicides.\textsuperscript{193} Cognitive-behavior therapy for insomnia (CBT-I) includes components of sleep restriction (limiting time in bed), stimulus control (conditioning the bed for sleep by restricting behaviors incompatible with sleep in the bedroom), and cognitive restructuring (addressing maladaptive thoughts and beliefs about sleep) to reestablish a regular sleep pattern. CBT-I was superior to zopiclone both in short- and long-term management of insomnia in older adults.\textsuperscript{194}

### Sources of Pain in the Cancer Patient

Pain in the oncology patient can arise from different sources (Table 42.6):
- Direct or indirect tumor involvement
- Cancer-directed therapy
- Mechanisms unrelated to cancer or its treatment

Patients may present with complex patterns of pain that result from combinations of these categories, thus complicating the diagnosis. Factors influencing the pain complaint include the primary tumor type, stage of disease, tumor site, and mood factors (anxiety and depression). Although estimates vary, the prevalence of pain in cancer survivors has been reported to be as high as 40% with variable durations of painful symptoms and with disparities in race and sex. The prevalence of pain in patients with cancer varies with tumor type, treatment phase, and stage of disease. Van den Beuken-van Everdingen et al. estimated the pain prevalence rates were 39.3% after curative treatment; 55% during anticancer treatment; and 66.4% in advanced, metastatic, or terminal disease with 50.7% in all cancer stages. Moderate to severe intensity pain (numerical rating scale score ≥5) was reported by 38.0% of all patients. Of note, lower pain prevalence rates occurred in prostate cancer patient compared to head and neck, lung, and breast cancer patients. In 2007, the authors previously reported prevalence rates of 33% after curative treatment; 59% during treatment; 64% in advanced, metastatic, or terminal disease; and 64% in all cancer stages with approximately 33% grading.
pain intensity as moderate to severe and the highest prevalence in head/neck cancer patients.\textsuperscript{201} High prevalence of pain has also been documented in hematologic tumor patients initially at diagnosis, during treatment, and in the last month of life.\textsuperscript{202,203}

Many patients with advanced disease frequently have multiple pain complaints at different sites and were more common in patients with breast, lung, and prostate cancer compared with gastrointestinal cancers.\textsuperscript{204} In a prospective study of 2,266 cancer patients, Grond et al.\textsuperscript{61} assessed localization, etiology, and pathophysiologic mechanisms of pain syndromes associated with cancer. Thirty percent of the patients presented with one, 39\% with two, and 31\% with three or more distinct pain syndromes. The majority of patients had pain caused by cancer (85\%) or antineoplastic treatment (17\%); 9\% had pain related to cancer disease and 9\% due to etiologies unrelated to cancer. These investigations classified pain as originating from nociceptors in bone (35\%), soft tissue (45\%) or visceral structures (33\%), or of neuropathic origin (34\%). Patients had localized pain syndromes in the lower back (36\%), abdominal region (27\%), thoracic region (23\%), lower limbs (21\%), head (17\%), and pelvic region (15\%). Regions and systems affected by the main pain syndrome varied widely depending on the site of cancer origin, whereas the cancer site did not markedly influence the pain’s temporal characteristics, intensity, or etiology.

Many metastatic bone lesions cause few or no symptoms and are diagnosed incidentally during an initial staging workup or at follow-up restaging evaluations.\textsuperscript{205} Bone cancer pain is the most common pain in patients with advanced cancer, and approximately two-thirds of patients with metastatic bone disease experience severe pain.\textsuperscript{206} Many of the most common tumors (breast, prostate, thyroid, kidney, and lung) have a strong predilection for bone metastasis, and an estimated 70\% of patients with breast and prostate cancers develop bone metastases compared with 20\% to 30\% of patients with lung or gastrointestinal cancers.\textsuperscript{207} Although pain is frequently associated with the presence of metastases, certain tumor types are exceptions, notably breast and prostate cancers. Neither the prevalence nor the severity of pain among breast cancer patients varied directly as a function of metastatic sites of disease.\textsuperscript{118,119} Palmer et al.\textsuperscript{208}
evaluated the sensitivity of pain as an indicator of bone metastases in patients with breast or prostate cancer. Pain was a common finding, whether or not metastatic disease was present, and it occurred in over half of the patients. Although most patients with bone metastases reported bone pain, some (21% of breast and 22% of prostate patients) were asymptomatic.

The majority of neoplasms are responsible for symptoms caused by mass effects to surrounding tissues and/or through the development of metastases. Paraneoplastic syndromes arise from tumor secretion of hormones, peptides, or cytokines or from immune cross-reactivity between malignant and normal tissues and may affect different organ systems, most notably the endocrine, neurologic, dermatologic, rheumatologic, and hematologic systems. The most commonly associated malignancies include small-cell lung cancer (SCLC), breast, gynecologic, and hematologic malignancies. Hypertrophic pulmonary osteoarthropathy (HPO) is characterized by periostosis and subperiosteal new bone formation along the shaft of long bones and the phalanges (“digital clubbing”), joint swelling, and pain and may be present in 1% to 10% of patients with lung tumors and may also been seen in patients with mesothelioma and lymphoma. Classically, HPO is diagnosed based on clinical symptoms (severe pain, edema, and erythema in the extremities) and radiologic findings. Periostitis is the hallmark of HPO, and imaging shows periosteal membrane thickening and periosteal new bone formation particularly in the distal long bones (especially the tibia). Bone scan is also useful for the detection of HPO. Peripheral nerves are a common target in paraneoplastic syndromes. Antibodies directed against neural antigens expressed by the tumor (onconeural antibodies) may occur in most of those affected by classical paraneoplastic syndromes, suggesting that an autoimmune process underlies these disorders. Subacute sensory neuronopathy (SSN) is a classical paraneoplastic syndrome. The neuropathy generally develops subacutely accompanied by pain and rapidly progressive paresthesia. Involvement of the upper extremities may occur with asymmetric sensory deficit or multifocal with facial, thoracic, and abdominal involvement. Many patients with SSN also have signs and symptoms suggestive of multifocal involvement including areas of the
CNS. Paraneoplastic vasculitis of the peripheral nervous system usually precedes the tumor diagnosis and presents as multineuritis or asymmetric distal sensory-motor neuropathy with pain as a commonly reported symptom. This form is generally associated with lymphoma or cancer at various sites (lung, prostate, uterus, kidney, or gastric).213

Cancer-directed therapy pain syndromes may result from chemotherapy, radiation therapy, or surgery. Chemotherapy-induced peripheral neuropathy (CIPN) is well described with a variety of agents.214 Sensory symptoms tend to be greater than motor or autonomic, and the majority of signs and symptoms due to CIPN arise from damage to dorsal root ganglion neurons or their axons, leading to acral pain, sensory loss, and sometimes sensory ataxia. With platinum compounds, as many as 30% of patients experience worsening of neuropathy for a few months following completion of therapy, and a sizable cohort report persistent symptoms lasting years. Paclitaxel-associated CIPN usually improves in the months following treatment cessation but still has been associated with long-term persistence of some degree of neuropathy in up to 80% of patients, with roughly a third of these patients reporting severe symptoms.215

Chemotherapeutic toxicity may be attributable to steroids, which are coadministered in many chemotherapeutic protocols. In particular, avascular necrosis is a well-described complication of steroid use. Morbidity is related to progressive joint damage often leading to decreased range of motion, pain with movement, and arthritis. Weight-bearing joints are most commonly involved. The shoulder, elbow, wrist, hand, and vertebral bodies can also be involved. The total cumulative dose and daily dose of glucocorticoids, and likely the underlying condition, affect the risk of developing avascular necrosis. Short-term, low-dose protocols are occasionally associated with necrosis. It most commonly occurs in the femoral and humeral heads. Pain is usually the first symptom, but the clinical presentation is variable and depends on the site and size of the infarct. Persistent hip or shoulder pain, especially with joint movement, tenderness, or reduced range of motion, warrants magnetic resonance imaging (MRI) which can visualize aspects of the necrotic lesion (necrosis, reactive zone/granulation tissue, sclerotic changes, edema). Bone marrow signal abnormality, the double-line sign, and subchondral fracture are characteristic MRI findings of avascular necrosis.

Combined medical and radiation therapies, both sequential and concurrent, are improving clinical outcomes for locoregional tumor control, with enhanced patient survival and delay of recurrence. During the course of external radiation therapy, treatment generally influences normal tissue function in tissues that have more rapid self-renewing proliferative index (e.g., mucosal surfaces such as skin, head/neck, and esophagus) and other surface tissues that have more limited potential for

*a*Instrumental ADL include preparing meals, shopping, using the telephone, managing money. Self-care ADLs include bathing, dressing, using the toilet, and taking medications. Paresthesia is characterized by functional disturbances of sensory neurons resulting in abnormal cutaneous sensations of tingling, numbness, pressure, cold, and warmth that are experienced in the absence of a stimulus. Peripheral motor neuropathy is characterized by inflammation or degeneration of the peripheral motor nerves. Peripheral sensory neuropathy is characterized by inflammation or degeneration of the peripheral sensory nerves.

ADL, activities of daily living.
self-renewal (e.g., hair, nails, and surface glands). Injuries to these tissues are often self-limited and heal without specific intervention secondary to stem cell renewal. Acute effects from radiation therapy do not uniformly predict for late effects from treatment. Late effects generally affect tissues that have limited potential for self-renewal, and injury is often more permanent, requiring surgical débridement and possibly resulting in functional damage.

Radiation-induced neural damage and pain may become apparent sometime after completion of radiation therapy confounding the diagnosis in some cases. Postsurgical pain syndromes come in many varieties, including postmastectomy, postamputation, postthoracotomy, and other chronic pain states. Treatments for head and neck cancer have the potential to cause persistent pain and discomfort. Radical surgery, such as resection of portions of the tongue, palate, and mandible, and radical neck dissection (RND) cause major structural changes. Radiation therapy, which frequently is the primary therapy, may cause mucositis, xerostomia, loss of taste, and decreased QOL. Subsequent late fibrosis of skin and soft tissues may lead to temporomandibular joint dysfunction and MPSs. Eating difficulties and persistent pain are frequent issues in head and neck cancer survivors.

Cancer patients and, in particular, cancer survivors may experience chronic non–tumor-related pain. The challenge for the treating clinician is to distinguish between tumor-associated and non–tumor-associated pain. Many of the same interdisciplinary treatment paradigms apply to cancer survivors as apply to all chronic pain patients, but an appreciation for the disabilities associated with treatments of cancer is essential. Long-term management of pain associated with cancer and its treatment poses a substantial challenge for the clinician. Pain complaints frequently change over time, involve multiple sites, stem from several origins including chronic disabilities, involve several causes simultaneously, and may relate loosely or not at all to the tumor.

Classification of Cancer Pain by Feature

Several schemata exist for classifying pain in the cancer patient and are
potentially useful for diagnosis and management. One such scheme is presented in Table 42.8.

**CHRONICITY**

Acute pain is the normal, predicted physiologic response to a noxious stimulus and typically is associated with invasive procedures, trauma, and disease. Various anticancer therapies, particularly postoperative pain following surgical intervention and radiation therapy, can cause acute pain (Table 42.9). The course of acute pain is usually predictable and self-limiting, and the pain does not represent a difficult diagnostic problem. In contrast, assessment of patients with chronic pain tends to be much more difficult and complex. Chronic pain is best considered as persistent pain beyond the expected healing time. As healing times vary for different stimuli and trauma, conventional definitions of chronic pain based on arbitrary intervals between 3 months and 6 months are less useful. One exception to this is the development of postherpetic neuralgia (PHN) after the development of herpes zoster. Several cancers including oral, esophageal, stomach, colorectal, lung, breast, ovarian, prostate, kidney, bladder, and CNS cancers as well as lymphoma, myeloma, and leukemia were associated with an increased risk of zoster, particularly within the first 2 years after diagnosis and among younger individuals. Some have proposed that only clinically relevant pain be defined as PHN to avoid overestimation of the problem and as pain ≥3 on a 10-point scale persisting 120 days after rash healing.

GI, gastrointestinal.

**INTENSITY/SEVERITY**

Health care providers underestimate the severity of a patient’s pain, particularly when relying on their own observations.\(^{230–232}\) This tendency is problematic because pain is often undertreated when patients and physicians differ in their judgment of the pain’s severity.\(^{233}\) Patient self-report is always the primary source of information for the measurement of symptoms, and subjective reporting of pain is considered a key component of pain assessment.\(^{234}\) Observer ratings of symptom severity correlate poorly with patient ratings and are generally inadequate substitutes for patient reporting. The discrepancies were most pronounced in those patients reporting severe pain.\(^{233}\) Although clinicians can monitor some objective signs to clarify the manifestations and impact of certain symptoms, these signs only complement subjective assessment and self-reporting. An assessment of pain intensity should include an evaluation of not only the present or average pain intensity but also pain at its least and worst over a defined time period.

The three most commonly used instruments for assessing cancer pain
intensity are the following:

- **Visual Analogue Scale (VAS):** A slash mark corresponding to intensity of pain is placed on a 100 mm line ranging at one end from “No Pain,” to the other end, “Pain as bad as it could possibly be.”

- **Numeric Rating Scale (NRS):** A number is assigned to the intensity of pain on a scale of 0 to 10; 0 reflecting “No Pain” and 10 reflecting the “Worst Pain Possible.”

- **Verbal Rating Scale (VRS):** The patient chooses one of the following words that best describes pain: “No Pain,” “Mild Pain,” “Moderate Pain,” “Severe Pain,” “Worst Possible Pain.”

All three measures correlate highly with one another. For pain assessment in clinical settings, the VAS, VRS, and NRS approach equivalency so that clarity, ease of administration, and simplicity of scoring become justifiable criteria in response scale selection. On the basis of relatively few studies in cancer, results or recommendations did not differ conclusively from those in other populations. In clinical scenarios, the NRS or VRS has proven more popular than the VAS and scales has high correlations, especially with less educated patients. Numerical scales as measures of QOL end points work well as cancer clinical trial instruments because they are easier to understand and easier to score.

Several studies have shown that differences between categorical pain severity items are not linear. For instance, when pain severity is rated at the midpoint or higher on numeric rating scales, patients report disproportionately more interference with daily function. Many patients, both with and without cancer, function quite effectively with a background level of mild pain that does not seriously impair or distract them. As pain severity increases to moderate intensity, pain passes a threshold beyond which it is hard for the patient to ignore the pain. At this point, it disrupts many aspects of the patient’s life. When pain is severe, it becomes a primary focus of attention and prohibits most activities. Pain severity and the degree to which the patient’s function is impaired are highly associated. As a way of delineating different levels of cancer pain severity, Serlin et al. explored the relationship between numerical ratings of pain severity and ratings of pain’s interference with such functions as activity,
mood, and sleep. Based on the degree of interference with function, ratings of 1 to 4 correspond to mild pain, 5 to 6 to moderate pain, and 7 to 10 to severe pain. In a follow-up study in categorizing the severity of cancer pain, Paul et al.\textsuperscript{123} confirmed a nonlinear relationship between cancer pain severity and interference with function and that the boundary between a mild and a moderate level of cancer pain was at 4. However, they failed to confirm the boundary between moderate and severe cancer pain and reported that a rating of 7 was in the moderate category and ratings >7 being in the severe category.

**PATHOPHYSIOLOGY/MECHANISMS**

A general classification by pathophysiology distinguishes nociceptive (somatic and visceral) from neuropathic pain (see “Pain and the Cancer Patient” section). This distinction is fundamental in assessment because it may determine and guide therapy. In principle, pain results from stimulation of nociceptors or by lesions of afferent nerve fibers. Pain is nociceptive if the sustaining mechanisms are related to ongoing tissue pathology. Pain is neuropathic when there is evidence that the pain stems from injury to neural tissues and aberrant somatosensory processing in the periphery or in the CNS. Physical influences such as pressure, traction, compression, and tumor infiltration as well as metabolic or chemical disturbances produce pain. Obviously, classification by physiologic mechanism would be an improvement, but sufficient information to do this is not available.

**Tumor Involvement of Encapsulated Organs**

Primary or secondary tumors of the liver are the most frequent examples of tumors of encapsulated organs. These can enlarge the organ to several times the normal size. Because the organ capsule of connective tissue grows less rapidly than the tumor, the intracapsular pressure rises as capsular distention develops. In addition, tumor infiltrates the capsule locally, producing dull, and rarely also stabbing, pains. The massive growth of the organ not only stimulates intracapsular nociceptors, but it also irritates larger nerves by pressure or traction on the tissue suspending the organ. Similar organ-enlarging processes in the spleen and kidneys do
not lead to pain to the same extent as in the liver, perhaps because of the more stable suspension or embedding of these organs, which are farther away from the midline with its abundant nerve pathways. The initial presentation of renal tumors can include pain, weight loss, and hematuria but typically occurs in only 9% of patients and is often indicative of advanced disease with approximately 30% of patients with renal carcinoma present with metastatic disease, 25% with locally advanced renal carcinoma, and 45% with localized disease. The detection of kidney pain relies on input from sympathetic, parasympathetic, and sensory nerves. The sympathetic nerves supplying the kidneys originate in spinal cord segments T10–L1 and travel via white rami to the paravertebral ganglia. The sympathetic nerves travel via the lesser splanchnic nerves from the T10–T11 thoracic paravertebral ganglia to the synapse at the ipsilateral aorticorenal and celiac ganglia. From the 12th thoracic paravertebral ganglion, nerves travel via the least splanchnic nerve to the synapse either in the aorticorenal ganglion or in the renal plexus. The first lumbar splanchnic nerve and the postganglionic sympathetic nerves from the aorticorenal and celiac plexus synapse in the renal plexus. The parasympathetic innervation originates from the vagus nerve. These parasympathetic nerves traverse through the celiac plexus or pass directly to the renal plexus. Sensory renal nerves travel via the renal plexus, splanchnic nerves, thoracic sympathetic ganglia, T10–T12 spinal nerves, and spinal cord dorsal horn neurons. Patients may complain of abdominal, back, and flank pain in addition to the sensation of flank heaviness.

Pain-sensitive structures in the head include extracranial structures such as the skin, muscles, and blood vessels in the head and neck; mucosa of the sinuses and dental structures; and intracranial structures including the regions of the large arteries near the circle of Willis, the great intracranial venous sinuses, parts of the dura and dural arteries, and cranial nerves (particularly glossopharyngeal, vagus, and trigeminal). The cranium (except the periosteum), brain parenchyma, ependymal lining of the ventricles, and choroid plexus are all pain insensitive. The brain is also an encapsulated organ. Its special feature is that the bony skull capsule prevents any enlargement. Pain arises here, not by destruction of
parenchyma, but by the increase of intracranial pressure with stimulation of the meningeal nociceptors. Such an increase of intracranial pressure occurs in space-occupying tumor growth or in focal or generalized brain edema. Focally, edema can develop around isolated tumors. Generalized edema develops in diffuse metastatic invasion of the meninges due to disturbance of the circulation of CSF. Such a tumor invasion of the leptomeninges is frequent in malignant lymphomas. However, metastatic invasion of the leptomeninges occurs in patients with solid tumors (e.g., bronchial carcinoma and malignant melanoma), with the predominant symptom being headache. In such cases, tumor infiltration of cranial nerves may also occur.

**Tumor Infiltration of Peripheral Nerves**

Because peripheral nerves can usually evade pressure from a tumor on one side, infiltration by tumor tissue is the quintessential tissue trauma stimulus. In addition, indirect damage of unknown pathogenesis might also occur to peripheral nerves in the context of tumor conditions such as occur with paraneoplastic syndromes. Paraneoplastic syndromes may affect diverse organ systems, most notably the endocrine, neurologic, dermatologic, rheumatologic, and hematologic systems. The best described paraneoplastic syndromes are attributed to tumor secretion of functional peptides and hormones (endocrine paraneoplastic syndromes) or immune cross-reactivity between tumor and normal host tissues (neurologic paraneoplastic syndromes) and may affect up to 8% of cancer patients. In paraneoplastic neurologic syndromes, tumor-directed onconeural antibodies are produced and may result in permanent damage to neural tissue.

Tumor tissue often infiltrates the perineural cleft; however, this does not regularly cause pain. A massive and then painful entrapment of the nerve plexus or individual nerves sometimes occurs, especially in extensive breast carcinomas and their recurrences or in chest wall metastases of bronchial carcinomas. The perineural cleft widens tumor infiltration, and infiltration of the tumor into the nerve itself is common. Degenerative changes of the axis cylinders are sometimes visible with conventional screening methods. Primary tumors of the peripheral nerves themselves
lead to painful destruction. Tumor compression regularly elicits pain when the affected nerve cannot give way (e.g., a spinal nerve).

**Tumor Infiltration of Soft Tissues**
Tumor infiltration of soft tissues causes pain via the mechanisms described in the earlier discussion, as with massive infiltrations of the retroperitoneum. Infiltration and destruction of mobile structures (e.g., of the skeletal musculature) can lead to pain via disturbance of function. Here, the tumor spreads in the interstitium and destroys blood vessels, lymphatics, and nerves.

**Tumor Infiltration of Bone**
The most frequent cause of pain in tumor patients is infiltration of bone. This applies to primary and secondary neoplasias originating from the bone marrow as well as to neoplasias of the bone itself. Such tumors always cause pain when they lead to an elevation of the intraosseous pressure, to loss of stability, or to a lesion of the periosteum resulting in periosteal elevation, or with the release of chemical mediators of nociception. The neural structures that generate nociception reside in the bone marrow, in the bone, and in the periosteum.

In metastatic processes, the degree of bone destruction is often extensive. Vertebral spread of tumor may involve intervertebral foramina, where it can compress nerve roots. Further spread posteriorly leads to encroachment of the spinal cord and the spinal nerves. In the bone, metastases localized to the bone marrow result in osteolysis or osteosclerosis. Necroses and hemorrhages occur frequently in bone metastases and doubtless play a role in the etiology of pain. The hemorrhages probably result from microfractures. Metastatic bone disease is discussed in detail later.

**Tumor Infiltration of Abdominal Hollow Organs**
Tumor involvement in abdominal hollow organs causes pain. This applies to all primary and secondary intestinal tumors. However, their pain-eliciting potency differs widely from individual to individual. The pain results from ulcerations, motility disorders, dilatations, and disorders of
blood flow. In accordance with the extent of the lymphatic tissue, large
tumors with extensive ulceration and hemorrhage occur in malignant
lymphomas of the gastrointestinal tract. Perineural tumor infiltration,
arthritis, or perineural inflammatory reactions are common in tumors of the
abdominal and urogenital hollow organs. Tumor infiltration of the urinary
bladder can vary from a sense of uneasiness felt in the suprapubic region
or a severe, constant agonizing deep pelvic pain. The pain may also radiate
and extend into the thighs. Intolerable cystitis may occur with tumor
infiltration of the bladder wall.

Tumor Infiltration and Inflammation of Serous Mucosa
The parietal pleura lines the inner chest wall, whereas the visceral pleura
covers the lung surface including interlobar fissures. The peripheral part of
the diaphragm and costal portion of the parietal pleura are innervated by
somatic intercostal nerves with the central portion of the diaphragm
innervated by the phrenic nerve. The visceral pleura are extensively
innervated by pulmonary branches of the vagus nerve and the sympathetic
trunk. Pleural carcinomatosis with infiltration of both parietal and visceral
surfaces can be extremely painful and difficult to manage. Somatic
nerves innervate the parietal peritoneum. These nerves also supply the
muscles and skin of the overlying body wall. Afferent nerves that travel
with the autonomic supply of the underlying viscera innervate the visceral
peritoneum. Nociceptive information from diseases that affect the parietal
or visceral peritoneum reflects these different patterns of innervation.
Animals with peritoneal carcinomatosis exhibit hypersensitivity to
mechanical stimulation and visceral pain-like behavior.

TUMOR TYPE AND STAGE OF DISEASE
Factors influencing the pain complaint include the primary tumor type,
stage of disease, and tumor site. When metastatic disease appears, about
one in three patients report significant pain. Vainio and Auvinen reported that moderate to severe pain was present in 51% of patients with
advanced cancer with severe pain more commonly seen in patients with
prostate, esophageal, gynecologic, colorectal, head/neck, breast, and lung
cancers. At least half of lung and breast cancer patients had at least
moderate intensity pain. Although pain tends to reflect the presence of metastases, this may not always be the case for certain tumor types, particularly for patients with breast or prostate cancers. Although many patients with bone metastases report bone pain, a significant fraction (21% of breast and 22% of prostate patients) was asymptomatic. Levren et al. examined the relationship between pain and bone metastases in patients with prostate or breast cancer referred for bone scintigraphy. In patients with prostate cancer, metastases were found in 47% of the patients with pain but only in 12% of the patients without pain ($P = .01$). In patients with breast cancer, metastases were more common in patients without pain (71%) than in patients with pain (34%; $P = .02$).

Pain caused by tumor may occur at the onset of disease or at an advanced stage. Although rarely one of the early indicators of the onset of disease, pain is not a significant problem for the majority of patients in the early stages of disease, with 5% to 10% of patients with solid tumors reporting pain at a level that interferes with mood and activity. However, pain is obviously a major concern that often prompts the patient to seek medical consultation. Vuorinen found that 28% of newly diagnosed unselected cancer patients reported pain. Cleeland reported that the majority of patients with end-stage disease have pain of a severity that interferes with several aspects of the patient’s QOL. Daut and Cleeland found that pain was an early symptom of cancer in 40% to 50% of patients with cancer of the breast, ovary, prostate, colon, and rectum, and in about 20% of patients with cancer of the uterus and cervix.

Knowing the natural history of the disease facilitates an understanding of the pain process and is important in determining the nature and timing of treatment. Examples of the more common disease processes follow.

**Pancreatic Cancer**

Most pancreatic tumors are exocrine tumors, including ductal adenocarcinoma, acinar cell carcinoma, cystadenocarcinoma, adenosquamous carcinoma, signet ring cell carcinoma, hepatoid carcinoma, colloid carcinoma, undifferentiated carcinoma, pancreatoblastoma, and pancreatic mucinous cystic neoplasm. The most common form is ductal adenocarcinoma characterized by moderately to
poorly differentiated glandular structures, comprising 80% to 90% of all pancreatic tumors. Endocrine pancreatic tumors are rare and account for only 1% to 2% of all pancreatic tumors. Pancreatic ductal adenocarcinoma is the fourth leading cause of cancer-related death in the United States. Surgical resection is the only potentially curative treatment, but because of the late presentation, only 15% to 20% of patients are candidates for surgical intervention. Even after complete resection, prognosis is poor with only 6% of patients (ranges from 2% to 9%) surviving 5 years after diagnosis. The highest incidence and mortality rates of pancreatic cancer are found in developed countries. Resectable cancers typically have no vascular or regional spread. Borderline cancers have regional spread into vessels (i.e., portal vein) or other organs (i.e., stomach), which would make surgery difficult, and locally invasive cancers have invasion into structures (e.g., celiac artery), which make curative surgery impossible. Up to 90% of patients with pancreatic cancer experience significant abdominal pain during the course of their illness. Incidence rates for pancreatic cancer in 2012 were highest in Northern America (7.4 per 100,000) and Western Europe (7.3 per 100,000), followed by other regions in Europe and Australia/New Zealand (equally about 6.5 per 100,000). In the United States, whites and blacks experienced opposite trends in pancreatic cancer death rates between 1975 and 2013 with white men death rates decreased by 0.7% per year from 1970 to 1995 and then increased by 0.4% per year through 2009. Among white women, rates increased slightly from 1970 to 1984, stabilized until the late 1990s, then increased by 0.5% per year through 2009. In contrast, the rates among blacks increased between 1970 and the late 1980s (women) or early 1990s (men) and then decreased thereafter. Pancreatic cancer is difficult to diagnose. The appearance of symptoms usually indicates an advanced stage and the most frequent presentations are progressive weight loss, anorexia, abdominal pain, and jaundice. These symptoms are nonspecific and varied in different regions of pancreas. Tumor in the head of the pancreas (75%) produces weight loss, painless jaundice, nausea, and vomiting. If cancer is located at the body/tail of the pancreas, patients usually present with abdominal pain that radiates to the sides or through to the back. Local tumor extension almost invariably
involves the peripancreatic fat tissue through direct invasion of lymphatic channels and perineural spaces. Duodenum, stomach, gallbladder, and peritoneum are infiltrated by tumors located in the pancreatic head; body and tail tumors can invade liver, spleen, and left adrenal gland. Lymphatic spread to adjacent and distant lymph nodes seems to precede hematogenous spread, which affects, in descending order, liver, peritoneum, lungs, adrenals, kidneys, bones, and brain. At diagnosis, 30% to 40% of patients report abdominal pain, 80% develop pain with disease progression, and 44% of these describe the pain as severe. The presence of pain in newly diagnosed patients with potentially operable pancreatic cancer is an ominous predictor of resectability and of survival.

A number of factors contribute to the generation and maintenance of pancreatic cancer pain. One of the most striking neural alterations in pancreatic cancer is neural invasion, which occurs in up to 100% of patients. Pancreatic cancer is characterized by invasion of nerves by cancer cells (neural invasion), pancreatic nerve damage, pancreatic neuroinflammation (neuritis), and noticeable hypertrophy with sprouting of intrapancreatic nerves. Cancer cells that invade nerves express a large set of neurotrophic factors such as NGF, artemin, neurturin that are similarly released by mast cells or other inflammatory cells and can strongly sensitize nociceptive nerve endings. Intrapancreatic nerves increase in size (neural hypertrophy) and number (increased neural density). The proportion of autonomic and sensory fibers (neural remodeling) is switched and is invaded by pancreatic cancer cells (neural invasion). These neuropathic alterations also correlate with neuropathic pain.

Pain due to pancreatic cancer is usually abdominal, typically referred to the epigastric region or the upper abdominal quadrants, but it can also involve the lower quadrants or be diffuse. Back pain is associated with abdominal pain in 50% to 65% of cases, but only 5% to 10% of patients report it as their only complaint. In one series, 67% of patients could not describe their pain location better than as over the “diffuse abdomen.” Eating often aggravates the pain. Tumors of the head of the pancreas may cause epigastric pain with right flank radiation more often, whereas pain from tumors in the tail has left-sided radiation. Lying flat typically
exacerbates it and sitting relieves it. This pain probably comes from retroperitoneal tumor involvement, and it may not respond to celiac plexus block. It often merges with similar syndromes caused by nodal or other soft-tissue tumor involvement in the retroperitoneal region (Table 42.10). The impact of pancreatic pain can be profound. It is commonly associated with depressed mood and contributes to the rapid decline in function that characterizes this disease. In addition, severe pain can influence survival.

**Ovarian Cancer**

Ovarian cancer may be subdivided into different histologic subtypes, which include epithelial cancer serous, endometrioid, clear-cell, and mucinous carcinomas. Of these types, high-grade serous carcinoma is the
most commonly diagnosed. Histologically and clinically, low-grade endometrioid carcinoma and low-grade serous carcinoma are different compared with their high-grade counterparts. Other more rare pathology includes small-cell carcinoma (predominantly occurs in younger women) and carcinosarcoma. Nonepithelial ovarian cancers include germ cell tumors and sex cord stromal tumors, which account for approximately 10% of ovarian cancers. Estimated new cancer cases in the United States for 2017 were 22,440 with 14,080 deaths (fifth most common cause of death from cancer in women). Overall survival varies greatly based on stage at initial diagnosis with a 92% survival for stage I and 25% for stage IV. Epithelial ovarian cancer can spread by intraperitoneal, lymphogenous, and hematogenous mechanisms.

The lifetime risk of ovarian cancer in women by the age 70 years is approximately 40% for BRCA1 and 18% for BRCA2. Most of these cancers are high-grade serous cancers. Other inherited disorders, such as Lynch syndrome, can increase the risk of ovarian cancer. Lynch syndrome is associated with colorectal, endometrial, and ovarian cancers but is also associated with cancers of the urinary tract, stomach, small intestine, and biliary tract. The symptoms of ovarian cancer are relatively nonspecific and often occur when the disease has spread throughout the abdominal cavity or with the presence of ascites. Abdominal discomfort or vague pain, abdominal fullness, bowel habit changes, early satiety, dyspepsia, and bloating are frequent presenting symptoms. Occasionally, patients may present with bowel obstruction due to intra-abdominal masses or shortness of breath due to pleural effusion. Early-stage disease is usually asymptomatic, and the diagnosis is often incidental, although such patients may occasionally present with dyspareunia or pelvic pain due to ovarian torsion. Serum CA-125 level has been widely used as a marker for a possible epithelial ovarian cancer in the primary assessment of a pelvic mass. Although CA-125 is the best known serum ovarian cancer biomarker, it is not the only one: Carcinoembryonic antigen (CEA) (mucinous), lactate dehydrogenase (LDH) (dysgerminoma, mixed germ cell tumors), β-human chorionic gonadotropin (β-hCG) (choriocarcinoma, mixed germ cell tumors), inhibin B (granulosa cell tumors), α-fetoprotein (yolk sac tumors, embryonal cell tumors), and HE4 are also available.
The prevalence of pain associated with ovarian cancer resembles the prevalence rates in populations with other solid tumors.\textsuperscript{267} Ovarian cancer spreads by intraperitoneal, lymphatic, and locally invasive pathways. Lymphatic pathways may extend from the abdominal retroperitoneum to the groin via the inguinal/femoral canals or across the diaphragm to the pleural space. Intraperitoneal spread of tumor begins with extension of tumor through the ovarian capsule, allowing implantation of tumor throughout the abdomen. Intraperitoneal metastases show a predilection for the omentum and diaphragm, but no organ is spared, and concomitant ascites is frequent. Portenoy et al.\textsuperscript{267} noted that pain, fatigue, and psychological distress were the most prevalent symptoms in patients with advanced (stage III or IV) ovarian cancer. Patients generally describe pain as occurring in the abdominopelvic or lower back region, as being frequent or almost constant and moderate to severe in intensity. Patients with advanced disease may experience pain in the lower extremities either from invasion of the lumbosacral plexus by tumor or by lymphedema secondary to iliac vessel occlusion.

**Cervical Cancer**

Cervical cancer is the fourth most common malignancy diagnosed in women worldwide. Nearly all cases result from infection with the human papillomavirus (HPV), and prevention includes screening and vaccination. Rates have declined in the United States with an estimated 12,820 new cases in 2017 and 4,210 deaths.\textsuperscript{3} Disparities in incidence and mortality still occur, with black and Hispanic women continuing to have higher rates of cervical cancer than white women.\textsuperscript{268} There are several histologic subtypes of cervical carcinoma, but the majority of cases tend to be HPV-associated malignancies including adenocarcinoma, squamous cell carcinoma, or adenosquamous carcinoma. Neuroendocrine (small-cell or large-cell) carcinomas are not associated with HPV exposure and clear cell carcinoma and are rare. Computed tomography (CT) or MRI is often used to define lymph node status and to assess extent of local disease. Combined positron emission tomography (PET) and CT imaging may be useful for detecting smaller nodal disease.\textsuperscript{269} Cervical cancer usually spreads to regional lymph nodes, and parametrial invasion is common. The
common sites of distant spread include the aortic (para-aortic, periaortic), lateral aortic and mediastinal nodes, lungs, and skeleton. Recurrent cervical cancer is almost always incurable.

**Prostate Cancer**

Prostate cancer is one of the most prevalent cancers in men worldwide. Estimated new cancer cases in the United States for 2017 were 161,360 with 26,730 deaths. The majority of prostate cancer survivors (64%) tend to be older (aged 70 years or older) with less than 1% under the age of 50 years. Prostate cancer varies widely in its intrinsic development, ranging from indolent to aggressive. Once clinically significant disease is established, surgery, radiation, and androgen deprivation therapy (ADT), which all carry substantial morbidities, are considered standard treatment options for localized disease. It is often insidious and asymptomatic even when advanced and for detection, MRI is currently the best imaging modality.

Prostate cancer is a heterogeneous group of malignant tumors and 95% are adenocarcinoma originating from the glands and ducts in the prostate. Most adenocarcinomas are of the acinar type, typically referred to as prostate carcinomas. More than 1% consist of other variants that often have a poor prognosis such as ductal carcinoma, mucinous carcinoma, signet ring cell carcinoma, and small cell carcinoma. Five percent of prostate cancer cases are of other types originating from transitional epithelial cells in the urethra or pars prostatic urethra (urothelial carcinoma), support tissue (sarcomas), or lymphoid tissue (lymphomas).

Prostate adenocarcinoma may spread locally, by direct invasion of seminal vesicles, urinary bladder, or surrounding tissues or distantly. Distant metastases can derive from an initial lymphatic spread or from a direct hematogenous spreading, mainly to the bones. The Gleason system is the most widely used grading system for prostate cancer (adenocarcinoma only). Prostate cancers are stratified into five grades (1 to 5) on the basis of the glandular pattern and degree of differentiation. The Gleason score is derived from the sum of the most represented grade (primary grade) with the second most represented grade (secondary grade) (e.g., 3 + 4 = 7); this correlates better with prognosis than the single Gleason grade. The Gleason system can be applied to biopsy and surgical specimens, but not
to fine needle biopsy (FNB), which lack architectural data. Most prostate cancers in the United States are diagnosed by prostate-specific antigen (PSA) testing, although many expert groups, including the American Cancer Society, have concluded that data on the efficacy of PSA screening are insufficient to recommend routine use of this test and recommend that for the average risk asymptomatic male over 50 years, a PSA with or without a digital rectal examination after receiving information about the benefits, risks, and uncertainties associated with prostate cancer screening is appropriate. Digital rectal examination is recommended along with PSA for men with hypogonadism because of reduced sensitivity of PSA. Men at higher risk, including African American men and men with a family member (father or brother) diagnosed with prostate cancer before age 65 years, should receive this information beginning at age 45 years.

The clinical behavior of prostate cancer ranges from indolent, localized disease to aggressive, disseminated disease associated with significant morbidity and mortality. Although the majority of prostate cancer cases present while the disease is localized to the prostate, some patients have evidence of metastatic disease at diagnosis. Typically, metastases are found in the axial skeleton, pelvic lymph nodes, and the lungs. Because of the predilection of prostate cancer to spread to bony sites, a significant proportion of patients with metastatic disease will have bone pain. Metastases from prostate cancer, most of which are adenocarcinomas, nearly always form osteoblastic lesions in bone; in contrast, bone metastases from kidney, lung, or breast cancers more often are osteolytic. However, metastases from the relatively uncommon neuroendocrine tumors of the prostate also produce osteolytic lesions. Approximately 90% of patients who die from prostate cancer have evidence of bone metastases. Radiographically, bone metastases are detected on technetium-99m (99mTc) bone scintigraphy scans. Newer modalities for detection include $^{18}$sodium fluoride PET and $^{18}$fluorodeoxyglucose PET (FDG-PET). Five-year relative survival varies with stage at diagnosis from 80% or more when malignancy is confined to the prostate to about 25% where bone metastases are present. Radium-223 ($^{223}$Ra) is an $\alpha$ emitter with a half-life of 11.4 days. It is a calcium mimetic and forms complexes with bone mineral hydroxyapatite in areas of active bone remodeling. The
α particles cause double-strand DNA break of cells. With a range of penetration of <0.1 mm, $^{223}$Ra is able to achieve localized killing of cancer cells with less collateral damage to the nearby bone marrow$^{273}$ and is the first radiopharmaceutical agent demonstrated to improve survival among patients with symptomatic bone-metastatic castrate-resistant prostate cancer with no known visceral disease.

Prostate cancer rarely spreads to vital organs, and the disease tends to progress slowly. Exceptions are spinal cord compression or ureteral obstruction secondary to retroperitoneal lymph node metastases. Tumors of the prostate gland may produce local rectal, urethral, suprapubic, and penile pain as a result of expansion and inflammation of the prostate, pain referred to the back, lower extremities, and abdominal area resulting from tumor growth within the pelvis, and distant bone pain with associated neurologic dysfunction associated with long bone, vertebral, and skull metastases (Table 42.11). The regional lymph nodes of the prostate are the nodes of the true pelvis, which are the pelvic nodes below the bifurcation of the common iliac arteries. Distant lymph nodes are outside the confines of the true pelvis. They are the aortic (para-aortic, periaortic, lumbar), common iliac, inguinal, superficial inguinal (femoral), supraclavicular, cervical, scalene, and retroperitoneal nodes.

Clinical syndromes may be identified by the site of bony involvement, the coexistence of mechanical instability secondary to fractures, and the neurologic dysfunction caused by tumor infiltration of contiguous neurologic structures. Bone metastases to the hip and pelvis often produce
local pain that is exacerbated by movement, especially during weight bearing. Local invasion of tumor from the pelvis into the sacrum may produce the syndrome of perineal pain. Patients with this syndrome complain of local and perirectal pain that is accentuated by pressure on the perineal region, such as that caused by sitting or lying prone. In its most extreme form, the patient cannot sit or lie flat. Dysfunction of the parasympathetic sacral innervation to bladder and bowel impairs continence early in the course of this syndrome. Local spread of tumor from the prostate into other pelvic and abdominal structures often produces visceral and neuropathic pain. Tumor invasion of the lumbosacral plexus may occur.

**Breast Cancer**

Breast cancer is the most commonly diagnosed cancer and the second leading cause of cancer-related mortality among North American women. Estimated new cancer cases for women in the United States for 2017 were 252,170 with 40,610 deaths.\(^3\) Seventy-five percent of breast cancer survivors (more than 2.6 million women) are 60 years or older, whereas 7% are younger than 50 years.\(^8\) Breast cancer tends to be diagnosed at a younger age than other common cancers, with a median age at diagnosis of 61 years with 19% of breast cancers are diagnosed in women ages 30 to 49 years, and 44% occur among women who are age 65 years or older. Lymphedema of the upper extremity occurs in 20% of women who undergo axillary lymph node dissection and in about 6% of women after sentinel lymph node biopsy.\(^{274}\)

Gene expression profiling of human tumors has provided a new paradigm for classifying breast carcinomas, predicting response to treatment, and risk of recurrence. Women diagnosed with breast cancer undergo receptor testing for estrogen (ER), human epidermal growth factor 2 (HER2) receptor tests, and progesterone (PR) status. Approximately 75% of breast cancers are hormone receptor positive and 15% to 25% are HER2 positive.\(^{275}\) Approximately 15% to 20% of all breast cancers do not have hormone or HER2 receptors (triple negative) and are typically more aggressive and difficult to treat. Breast MRI has become a widely used second-line imaging modality with well-defined roles in assessing multifocal tumor and planning surgery and in monitoring...
local tumor response to neoadjuvant chemotherapy. MRI screening is used in high-risk young women such as those with a BRCA gene mutation or with previous mantle irradiation for lymphoma. PET scanning can be used to evaluate primary lesions, regionally metastatic and systemic metastases of breast cancer.

All breast cancers are adenocarcinomas arising from the terminal duct lobular units. Breast cancers are divided into two main categories, noninvasive and invasive. Infiltrating ductal carcinoma is the most common breast cancer histology, accounting for approximately 80% of all breast cancers. Lobular carcinoma constitutes 10% of the breast cancers. Ductal carcinoma in situ (DCIS) is the most common type of noninvasive breast cancer, accounting for about 15% of all newly diagnosed breast cancer cases. DCIS is classified into five histologic subtypes associated with varying prognostic implications. These include solid, papillary, cribriform, micropapillary, and comedo. Most lesions represent a combination of at least two of these subtypes. Comedocarcinoma is considered high grade and predictive of recurrence. Lobular carcinoma in situ (LCIS) is characterized as a benign-appearing proliferation of terminal ducts and ductules that is often multifocal and bilateral. LCIS is much less common and is associated with less risk of the development of invasive cancer than DCIS. Invasive ductal carcinoma (IDC) is the most common type of breast cancer. About 80% of invasive breast cancers are classified as IDC. Tubular carcinoma is a highly differentiated invasive carcinoma with limited metastatic potential and better than average prognosis. Medullary carcinoma is a relatively uncommon type of invasive carcinoma, accounting for less than 5% to 7% of all invasive breast cancers. Mucinous carcinoma is an invasive form of breast cancer characterized by large amounts of extracellular mucin production and is associated with a relatively favorable prognosis. Invasive cribriform carcinoma is a well-differentiated cancer that shares some features with tubular carcinoma and is also associated with better than average prognosis. Adenoid cystic carcinomas similarly rarely spread to the lymph nodes or distant areas and have a very good prognosis.

Breast cancer can metastasize to any organ in the body: Bone, lung, liver, and brain are frequent sites. Metastases usually appear within a few
years but recurrence may occur, particularly in bone, many years later.

Approximately, 5% of women present with metastatic disease during breast cancer diagnosis,\textsuperscript{276} and bone is the most frequent site of metastatic lesions.\textsuperscript{206} In population-based cohort studies of patients with newly diagnosed breast cancer, 1% to 2% have bone metastases at diagnosis and another 5% to 6% are diagnosed to have bone metastases within the next 5 years.\textsuperscript{277,278} In a Danish study of women with metastatic bone disease secondary to breast cancer, 1-year survival was just over 52%. Approximately, 13% survived 5 years after diagnosis of bone metastases, and shorter bone metastases free interval was independently associated with decreased survival among patients with breast cancer who were diagnosed with bone metastases ≥1 year following their breast cancer diagnosis. Survival among patients with metastatic breast cancer may vary according to the site of metastasis and receptor status. Risk of death within 1 year was highest for brain-only (62%) and liver-only (43%) involvement and nearly the same for patients with lung-only (32%), bone-only (32%) involvement, and other/combination of sites (34%). Positive hormonal receptor status on the primary tumor was a favorable prognostic factor for all metastatic sites.\textsuperscript{279}

Bone metastases are predominantly osteolytic (50%) or mixed osteolytic and osteoblastic (40%), with only a small proportion (about 10%) being osteoblastic alone.\textsuperscript{280} Although metastatic disease may be asymptomatic, the most common site of metastases, bone, typically are painful. Between 40% and 60% of patients with metastatic breast cancer will have bony disease, and in many of these patients, the involved bones (vertebrae, femoral and humoral shafts, the acetabular area) are those that are involved with motion. Metastatic breast cancer is currently an incurable yet treatable disease. Although median survival is of the order of 18 to 24 months, survival ranges from a few weeks to several years.\textsuperscript{281} This biologic variability means that for many women, metastatic breast cancer can be viewed as a chronic relapsing and remitting disease that may respond for a time to an array of cytotoxic and endocrine therapies.

The clinician will most likely have a long relationship with the patient with metastatic breast cancer and will have the opportunity to follow the course and progression of disease. The course of disease in patients with
metastatic breast cancer fits one of two patterns: an indolent course or disease not immediately life threatening and that which is rapidly progressing or with extensive vital organ disease. Knowledge of the natural history of the disease is important in determining the nature and timing of treatment. Table 42.12 lists some of the common causes of pain in patients with breast cancer.

**Lung Cancer**

The two major forms of lung cancer are non–small-cell lung cancer (NSCLC) (85% of all lung cancers) and SCLC (15%). NSCLC can be divided into three major histologic subtypes: squamous cell carcinoma, adenocarcinoma, and large-cell lung cancer. Smoking causes all types of lung cancer but is most strongly linked with SCLC and squamous-cell carcinoma; adenocarcinoma is the most common type in patients who have never smoked. NSCLC is the leading cause of cancer death in the United
States. Nearly 60% of NSCLC cases are metastatic at diagnosis, and the 5-year relative survival rate for metastatic disease is 4.2%. SCLC is a very aggressive malignancy characterized by high cellular proliferation and early metastatic spread. Most patients with SCLC receive chemotherapy. Unfortunately, SCLC initially exhibits a good response to chemotherapy and radiation therapy, but inevitably, relapses decrease patients’ chance of survival. Metastases initially occur in the lymph nodes and thereafter in other organs such as the lung itself, liver, adrenal glands, brain, bone, and bone marrow. Histologically, SCLCs include small cell anaplastic carcinoma, which includes the oat cell type. Small cell anaplastic carcinoma is an aggressive and rapidly growing neoplasm and is limited to the thorax at presentation in only 25% of patients.

NSCLCs are a morphologically diverse group that includes squamous cell carcinoma, adenocarcinoma, and large cell anaplastic carcinoma. For stage I and II NSCLC, the majority of patients (69%) undergo surgery, and about 25% of surgical cases also receiving chemotherapy and/or radiation therapy. Most patients with stage III and IV NSCLC receive chemotherapy with or without radiation (53%). Squamous cell carcinoma is less likely to metastasize early. Adenocarcinoma metastasizes widely and frequently to the other lung, liver, bone, kidney, and the CNS. Large cell anaplastic carcinoma metastasizes in a pattern quite similar to adenocarcinoma with a predilection for mediastinal lymph nodes, pleura, adrenals, CNS, and bone. Lung cancers, particularly SCLC, often entail clinical paraneoplastic syndromes. Malignancy-associated hyponatremia is commonly associated with excessive production of arginine vasopressin (AVP) by tumor cells, and a large fraction of new cases of syndrome of inappropriate antidiuretic hormone secretion (SIADH) in elderly smokers are due to SCLC. Approximately, 10% of all lung cancer patients have hypercalcemia, and of these patients, 10% to 15% do not have evident bone metastases. Humoral hypercalcemia of malignancy is more common in NSCLC especially squamous cell carcinoma. The neurologic syndromes associated with lung cancer are rare disorders such as subacute cerebellar degeneration, optic neuritis and retinopathy, subacute necrotizing myelopathy, and peripheral neuropathy. The 1-year relative survival for lung cancer increased from 34% during 1975 through 1977 to 45% during
2008 through 2011, largely because of improvements in surgical techniques and chemoradiation. The majority of lung cancers (57%) are diagnosed at a distant stage because early disease is typically asymptomatic; only 16% of cases are diagnosed at a local stage. The 5-year survival rate is 55% for cases detected when the disease is still localized, 27% for regional disease, and 4% for distant stage disease. The 5-year survival for SCLC (7%) is lower than NSCLC (21%).

Pleural involvement by tumor can be a source of intractable severe pain. Diagnosis of pleural disease can be challenging and involve a variety of imaging modalities including CT, PET, MRI, and ultrasound. CT is widely used as the primary imaging modality with the most common CT findings being pleural thickening with or without pleural effusion, involvement of the interlobar fissures and/or mediastinal pleural involvement, volume reduction of the chest, mediastinal shift, and mediastinal lymph node invasion.

Pain is a major symptom in patients with all types of advanced lung cancer. Chest pain is the most common site of pain in patients with small cell cancer. The pain complaint is often poorly localized, dull in character, may radiate to the neck or back, and exacerbates with coughing. Mercadante et al. reported that patients with advanced lung cancer commonly reported chest wall (including ribs and shoulder blade) pain, followed by lower extremities and lumbar regions, then abdomen and upper extremities, and the head area.

Renal Cell Cancers
Renal cell carcinoma (RCC) encompasses a heterogeneous group of cancers derived from renal tubular epithelial cells with the major subtypes being clear cell RCC (ccRCC), papillary RCC (pRCC), and chromophobe RCC (chRCC). The remaining subtypes are very rare (each with ≤1% total incidence), and in cases in which a tumor does not fit any subtype in the diagnostic criteria, it is designated as unclassified RCC. ccRCC is the most common subtype (75%) and accounts for the majority of deaths from kidney cancer. The majority of diagnoses result from incidental findings. Paraneoplastic syndromes—symptoms caused by hormones or cytokines excreted by tumor cells or by an immune response against the tumor—are
not uncommon in RCC and symptoms include hypercalcemia, fever, and erythrocytosis. CT imaging with contrast enhancement of the chest, abdominal cavity, and pelvis is required for optimal staging.

Approximately 30% of people with RCC have already developed metastatic RCC at presentation, and another 20% of people with clinically localized RCC eventually develop metastases during the course of the disease despite treatment. Frequent sites include the lung (50% to 60%), bone (30% to 40%), liver (30% to 40%), and brain (5%). Unusual sites of metastases characterize renal cancer, however, and may involve virtually any organ site, including the thyroid, pancreas, skeletal muscle, and skin or underlying soft tissue. Regional and distant lymph nodes may also be involved. The regional lymph nodes of the kidney are renal hilar, paracaval, aortic (para-aortic, periaortic, lateral aortic), and retroperitoneal. Metastatic bone disease is often highly osteolytic and particularly destructive causing substantial morbidity, including pain, pathologic fracture, spinal cord compression, and hypercalcemia. The presence of bone metastasis in RCC is associated with a poor prognosis.

Colorectal Cancer
CRC is one of the most common malignancies in the Western world and is the third most commonly diagnosed cancer among men and women in the United States. Incidence and mortality rates have been declining for several decades because of historical changes in risk factors (e.g., decreased smoking/red meat consumption, increased use of aspirin), the introduction and dissemination of screening tests, and improvements in treatment. The 5-year relative survival rate for patients diagnosed from 2006 to 2012 (all followed through 2013) was 65% declining to 58% at 10 years after diagnosis. The median age at diagnosis for CRC is 66 years for males and 70 years for females. Patients with rectal cancer tend to be younger at diagnosis than those with colon cancer (median age, 63 years).

CRC often develops over more than 10 years, and dysplastic adenomas are the most common form of premalignant precursor lesions. The two most common forms of hereditary CRCs are hereditary nonpolyposis colon cancer (Lynch syndrome) and familial adenomatous polyposis coli. The vast majority of these tumors are adenocarcinoma (>90%) and, to a
lesser degree, carcinoid tumors, leiomyosarcomas, and lymphoma. Spread to regional lymph nodes generally correlates to depth of invasion by the primary tumor and the grade of differentiation. Nodal spread occurs in 10% to 20% of tumors confined to the bowel wall. Hematogenous spread is usually to the liver via portal venous transmission.

The liver is the prime organ for metastatic spread (65%); extra-abdominal metastases in lung (25%) and brain and bone (10%) are much less common. Approximately, 15% to 20% of patients with CRC will present with metastatic liver disease, and half of all patient with CRC will develop liver metastases, with a median survival of 8 to 12 months in untreated patients. Liver imaging should be done for all patients with CRC. MRI had a significantly higher sensitivity than did CT for lesions less than 10 mm. Surgical resection represents the only chance of long-term survival, but only 20% to 25% of patients may be eligible for resection. Systemic chemotherapy and/or intra-arterial locoregional techniques may be options for patients not eligible for surgery. These techniques include hepatic arterial infusion, transarterial chemoembolization (TACE), embolization with drug-eluting beads (DEBTACE), selective internal radiation therapy with $^{90}$Y (SIRT), and percutaneous ablation with radiofrequency or microwave ablation.

The majority of patients with stage I and II colon cancer undergo partial or total colectomy alone (84%), whereas about two-thirds of those with stage III disease (as well as some with stage II disease) receive chemotherapy in addition to colectomy to lower their risk of recurrence. For patients with rectal cancer, proctectomy or proctocolectomy is the most common treatment (61%) for stage I disease, and about one-half also receive radiation and/or chemotherapy. Stage II and III rectal cancers are often treated with neoadjuvant chemoradiation therapy.

**Leukemias and Lymphomas**

The majority of patients with leukemia (92%) are diagnosed aged 20 years or older. Acute myeloid leukemia (AML) and chronic lymphocytic leukemia (CLL) are the most common types in adults. Chemotherapy with or without stem cell transplantation (SCT) is the standard treatment for AML. Approximately 60% to 85% of adults aged 60 years and younger
with AML can expect to attain complete remission status after the first phase of treatment, and 35% to 40% of patients in this age group will be cured. In contrast, 40% to 60% of patients aged older than 60 years will achieve complete remission, but only 5% to 15% will be cured.

The two types of lymphoma are Hodgkin lymphoma (HL) and NHL. NHLs may be indolent or aggressive and each include subtypes that progress and respond to treatment differently. Prognosis and treatment depend on the stage and type of lymphoma. The two major types of HL are classical HL (CHL) and nodular lymphocyte-predominant HL (NLPHL). CHL is the most common and is characterized by the presence of Reed-Sternberg cells. NLPHL comprises only about 5% of cases and is a more indolent disease with a generally favorable prognosis. The 5-year and 10-year survival rates for HL are 86% and 80%, respectively. The 5-year survival rate is 94% for NLPHL and 85% for CHL. The most common types of NHL are diffuse large B-cell lymphoma (DLBCL), representing 37% of cases, and follicular lymphoma, representing 20% of cases. DLBCLs grow quickly, but most patients with localized disease and about 50% of those with advanced-stage disease are cured. In contrast, follicular lymphomas tend to grow slowly and often do not require treatment until symptoms develop, but many are not curable. Some cases of follicular lymphoma transform into DLBCL. The 5-year survival rate is 86% for follicular lymphoma and 61% for DLBCL; 10-year survival declines to 77% and 53%, respectively.

**Multiple Myeloma**

Multiple myeloma (MM) is a clonal plasma cell malignancy that accounts for 10% of all hematologic malignancies. MM usually progresses from asymptomatic precursor stages, namely monoclonal gammopathy of undetermined significance (MGUS) and smoldering multiple myeloma (SMM) with possible progression to MM. Some patients experience rapid progression from MGUS/SMM to MM, whereas others may remain indolent with minimal progression during their lifetimes. The median age of diagnosis is 69 years. The 5-year survival rate of patients with MM is 48.5%, and despite the introduction of immunomodulatory drugs and proteasome inhibitors, many patients with high-risk features still have low
progression-free survival rates and poor overall survival. CT imaging is useful for detecting early bone destruction but not for detecting myeloma activity in areas of prior destruction. MRI can detect early marrow infiltration. The first biomarker for MM was the Bence Jones protein. Other markers included M protein, plasmacytosis of the bone marrow, and β2 microglobulin. Serum free light chain (FLC) assays were developed to aid the diagnosis of MM and to monitor treatment response and disease progression. Treatment plans are guided by serially measuring serum FLC levels and the FLC ratio to define a complete response or progressive disease in oligosecretory myeloma.

**Tumor Markers**

A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention and are important tools for diagnosis, prognosis, and management of malignancies. Most tumor markers are produced by normal cells (tumor-associated) as well as by cancer cells (tumor-derived); however, they are produced at much higher levels in cancerous conditions. Markers include a variety of substances like cell surface antigens, cytoplasmic proteins, enzymes, hormones, oncofetal antigens, receptors, oncogenes, and their products. These substances can be found in the blood, urine, stool, tumor tissue, or other tissues or bodily fluids of some patients with cancer. Most tumor markers are proteins, but patterns of gene expression and changes to DNA are also used as tumor markers. Predictive biomarkers, which include somatic mutations in BRAF and EGFR genes where the presence of certain molecular targets helps identify the appropriate, targeted therapy and thus predict the response to these agents. They can also be beneficial to identify patients with high susceptibility to certain cancers through detection of germline mutations, such as BRCA or somatic mutations. DNA sequencing and gene expression studies have shown that at a molecular level, almost every case of breast cancer is unique and different from other breast cancers. For optimal management, patients should receive treatment that is guided by the molecular composition of their tumor. Mandatory biomarkers for every newly diagnosed case of breast cancer include...
cancer are ER receptors and PR receptors in selecting patients for endocrine treatment and HER2 for identifying patients likely to benefit from anti-HER2 therapy. Examples of tumor markers in malignancy are shown in Table 42.13.

**NOTE:** Neu is derived from a rodent glioblastoma cell line.

BRAF, gene that encodes protein B-Raf; BRCA1 and BRCA2, breast cancer gene and protein product; CA, cancer antigen; CLL, chronic lymphocytic leukemia; CSF, cerebrospinal fluid; EGRF, epidermal growth receptor factor; HER2/neu, human epidermal growth factor receptor; KRAS, proto-oncogene for Kirsten rat sarcoma viral oncogene; MM, multiple myeloma.

**PATTERNS OF CANCER PAIN**

Cancer patients may have constant or intermittent pain. The term
breakthrough pain (BTP) was popularized by Portenoy and Hagen\textsuperscript{294} in 1990 and refers to sudden increases in the base level of pain or different but recurring pains. BTP was originally defined as “a transitory exacerbation of pain that occurs in addition to otherwise stable persistent pain or one that interrupts a tolerable background level of pain” or as “a transitory exacerbation of pain that occurs on a background of otherwise stable pain in a patient receiving chronic opioid therapy.”\textsuperscript{295} However, most definitions consider BTP only after the background pain is adequately controlled. BTP should be distinguished from crescendo pain, which largely results from poorly controlled baseline pain.\textsuperscript{296} The estimated prevalence of BTP in cancer patients may be more than 50\%,\textsuperscript{297} but the prevalence is difficult to estimate because of difference between studies in the definitions and diagnostic criteria and the inclusion of patients with poorly controlled background pain.\textsuperscript{298} Different terms for BTP have been used in some studies including incident pain, incidental pain, episodic pain, and transitory pain.\textsuperscript{295}

The cause and anatomical site of BTP is often, but not always, the same as that of the baseline persistent pain.\textsuperscript{299} Typical features of BTP include rapid onset (the time from onset of BTP to peak severity is usually within 3 to 5 minutes), short duration (approximately 30 minutes), and of variable intensity.\textsuperscript{300} There are three types of BTP:

1. Incident pain: pain that is precipitated, stimulus dependent, or triggered such as turning in bed, weight bearing, a bowel movement, coughing, swallowing meals, etc. Often, incident pain is well defined and predictable, so that clinicians can anticipate and treat the problem prophylactically. Incident pain may be volitional or nonvolitional.

2. End of dose failure: pain that emerges because of too much time between doses of medication. This pattern is predictable for the individual patient and readily preventable by using time-contingent dosing at an appropriate interval. The key is monitoring symptoms in relation to the dosing schedule.

3. Spontaneous pain: pain that occurs spontaneously without relationship to particular events or procedures. These pains are more difficult because of their unpredictable nature and often fleeting
Cancer-related BTP has high interference with activity, mood, ability to walk and work, social relations, sleep, and enjoyment of life.\textsuperscript{300–302} Uncontrolled or poorly controlled pain of any etiology is strongly associated with impairment of sleep, walking, daily activities, enjoyment of life, and relationships with others. It also is correlated with worsening of anxiety and depression, dissatisfaction with opioid therapy, and poor medical outcomes.\textsuperscript{303} In addition, patients with cancer-related BTP or uncontrolled pain are likely to use more health care resources, have more pain-related hospitalizations and emergency department visits, and have greater direct and indirect treatment costs than those without BTP.\textsuperscript{304}

**CANCER PAIN SYNDROMES**

Tables 42.14 to 42.17 list the common pain syndromes in the patient with cancer.

**Reflex sympathetic dystrophy**
- Compression, infiltration, or damage of major nerve or plexuses
- Severe burning pain not limited to a segmental or peripheral nerve distribution; aggravated by touch and emotional stress
- Hyperalgesia, vasomotor, and sudomotor disturbances and other symptomatology of causalgia

**Leptomeningeal carcinomatosis**
- Tumor infiltration of the cerebrospinal leptomeninges with or without invasion of the meninges of the brain
- Pain in 40% of patients of two types: headache, with or without neck stiffness and pain in the low back and buttock regions
- Malignant cells in cerebrospinal fluid, elevated protein and low glucose levels

**Epidural spinal cord compression**
- Tumor compression of cervical, thoracic, or lumbosacral parts of spinal cord and involvement of vertebra or roots of spinal nerves
- Local dull, aching pain, and tenderness in the region of involved vertebral body or radicular pain, which is unilateral with cervical or lumbosacral compression and bilateral with thoracic cord compression
- Depends on site of epidural compression, includes motor weakness progressing to paraplegia, sensory loss, and loss of bowel and bladder function

**Tumor Involvement of Viscera**
- Contraction of smooth muscle under isometric conditions → intense distention of smooth muscles
- Diffuse, poorly localized, dull, aching, or colicky pain referred to abdominal wall or chest wall
- Dyspnea and cough with thoracic viscera; abdominal distention, nausea, vomiting with abdominal visceral pathology

### Bone Metastases

Common locations for metastasis are the lung, liver, brain, and bone. Bone is the third most common site for tumor cells to spread and is most prevalent in advanced breast (70% to 80%), prostate (70% to 80%), thyroid (60%), lung (10% to 50%), and renal cancers (30%). Prostate, lung, breast, kidney, and thyroid cancer account for 80% of skeletal metastases and MM favors involvement of the bone marrow. The most common sites of bone metastases are the spine, ribs, pelvis, proximal femur, and skull. Breast cancer preferentially metastasizes to the lungs and

2088
bones, whereas prostate cancer almost exclusively metastasizes to the bones. Bone metastases may be classified according to the primary mechanism of interference with bone remodeling as osteolytic, osteoblastic, or mixed. In osteolytic lesions, bone destruction is primarily mediated by osteoclasts and not a direct effect of tumor cells, whereas osteoblastic (or osteosclerotic) lesions are characterized by the deposition of new bone. Osteolytic bone metastases are presumed to be caused by the release of osteoclastogenic agents by tumor cells in the bone microenvironment, whereas osteoblastic metastases are the result of the release of factors that stimulate osteoblast proliferation, differentiation, and uncontrolled bone formation by metastatic cancer cells. Accordingly, bone metastases are typically characterized as “lytic,” “sclerotic,” or “mixed,” according to radiographic appearances. Metastasis to the bones is facilitated by the fenestrated structure of the bone marrow sinusoid capillaries, high blood flow in the areas of red marrow, and adhesive molecules on tumor cells that bind to the bone marrow stromal cells such as osteoblasts and osteoclasts as well as the bone matrix. Bone homeostasis is maintained by balanced production of osteoblasts and osteoclasts. Tumor cells influence bone cells in two predominant ways. Most often, cancer cells stimulate the osteoclast lineage to increase osteoclast differentiation and activity while simultaneously inhibiting osteoblasts. Osteoclastic bone resorption then exceeds osteoblastic bone formation resulting in bone degradation and the formation of osteolytic lesions (as may be seen in breast, lung, and MM). In some cases, instead of inhibiting osteoblasts, tumor cells release substances to stimulate the osteoblast lineage to increase osteoblast differentiation and new bone deposition causing osteoblastic lesions. Mechanistically, osteoclasts and osteoblasts play significant roles in the formation of both lesion types.

In osteolytic bone metastases, tumor cells secrete factors that stimulate osteoclast activity through the activation of the receptor activator of nuclear factor–κB ligand (RANKL)/RANK pathway, a primary mediator of osteoclast-mediated bone resorption. Osteoblasts secrete receptor activator of RANKL which interacts with osteoclast precursors displaying RANK receptor on their surface, resulting in their activation and finally maturation into functional osteoclasts. Osteoblasts also produce
osteoprotegerin (OPG), a soluble decoy receptor which can block RANK/RANKL signaling by scavenging of RANKL. The activation of osteoclasts is triggered by the balance between RANKL and OPG. RANKL also can induce factors involved in migration, invasion, and angiogenesis such as matrix metalloproteinases 1 and matrix metalloproteinases 9 (MMP1, MMP9), matrix metalloproteinase inducer EMMPRIN/CD147, intercellular adhesion molecule-1 (ICAM-1), IL-6 and IL-8, and VEGF and decrease the expression of metastasis suppressor serpin 5b/maspin. RANKL can also promote the function of regulatory T cells (Tregs) and macrophages. Osteolysis is based on a self-perpetuating signaling system (vicious cycle) that is maintained by mitogenic factors for tumor cells such as TGF-β, insulin-like growth factor-1 (IGF-1), fibroblast growth factors (FGFs), PDGFs, and Ca-ions released from demineralized bone as well as parathyroid hormone-related peptide (PTHrP) derived from tumor cells. PTHrP acts as a promotor of osteolysis by osteoclasts (Fig. 42.8).

**FIGURE 42.8** Mechanism of osteolytic bone metastases. Metastatic cancer cells are attracted to spindle-shaped N-cadherin positive osteoblasts (SNO) and remain dormant. Quiescent cells can become activated and grow giving rise to an overt metastasis. The metastatic cells produce factors, which include parathyroid hormone-related peptide (PTHrP), interleukins (ILs), PGEs, and CXCR4 that mediate their interaction with osteoblastic cells of the metastatic microenvironment. Osteoblasts, in turn, communicate with preosteoclasts, primarily via the receptor activator for
nuclear factor κB (RANK)–receptor activator for nuclear factor κB ligand (RANKL) axis and promote osteoclastic morphologic and functional maturation. PTHrP can also induce osteoclastic maturation via non-RANK/RANKL-dependent pathways. Fully activated osteoclasts resorb bone causing osteolytic bone disease. Hypoxic conditions and factors that are released during the degradation of the bone extracellular matrix further stimulate cancer cells, feeding the “vicious circle” of lytic bone metastasis. β2AR, β2 adrenergic receptor; ECM, extracellular matrix; IGF, insulin-like growth factor; IKK, inhibitor of NF-κB kinase; MAPK, mitogen-activated protein kinase; OBL, osteoblast; OCL, osteoclast; OPG, osteoprotegerin; PGE, prostaglandin E; PLC, phospholipase C; SC, stromal cell; SNS, sympathetic nervous system; TGF-β, transforming growth factor-β; TNF-α, tumor necrosis factor-α. (From Papachristou DJ, Basdra EK, Papavassiliou AG. Bone metastases: molecular mechanisms and novel therapeutic interventions. Med Res Rev 2012;32[3]:611–636. Copyright © 2010 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Osteoblastic bone metastases are preferentially associated with prostate cancer but may also occur with breast, lung, carcinoid, and medulloblastoma tumors and produce sclerotic lesions. Endothelin-1 has been implicated in osteoblastic metastasis from breast cancer. It stimulates the formation of bone and the proliferation of osteoblasts in bone organ cultures, and serum endothelin-1 levels are increased in patients with osteoblastic metastasis from prostate cancer. Furthermore, in an animal model of osteoblastic metastasis, treatment with a selective endothelin-1A–receptor antagonist decreased both osteoblastic metastasis and the tumor burden. A vicious circle may also be involved in osteoblastic metastasis in which tumors induce osteoblast activity and thus the subsequent release from the osteoblasts of growth factors that increase tumor growth. In addition to endothelin-1, PDGF, a polypeptide produced by osteoblasts in the bone microenvironment, urokinase, and PSA may also be involved. Overproduction of urokinase-type plasminogen activator (u-PA) by prostate-cancer cells increases bone metastasis. Human PC3 prostate-cancer cells produce a factor that is homologous to u-PA. Prostate-cancer cells also release PSA, a kallikrein serine protease. PSA can cleave parathyroid hormone–related peptide at the N-terminal, which could block tumor-induced bone resorption. It may also activate osteoblastic growth factors released in the bone microenvironment during the development of bone metastases, such as IGF-I and IGF-II or TGF-β (Fig. 42.9).
Mechanisms of osteoblastic bone metastases. Cancer cells secrete a series of factors that augment osteoblast activation and bone formation at the site of metastasis. Two of the major signaling cascades involved in this process are the endothelin-1A/endothelin-1A receptor and the Wnt/β-catenin, which target osteoblast-specific genes such as c-jun, runx2, osterix, and c-myc. In addition, cancer cells produce urokinase plasminogen activator (uPA) that activates proteases such as prostate-specific antigen, further enhancing the osteosclerotic process either via activation of the quiescent forms of TGF-β and IGF-1 or via degradation of parathyroid hormone-related peptide (PTHrP). ET-1, endothelin-1A; ETAR, endothelin-1A receptor; IGF, insulin-like growth factor; LRP-F, low-density lipoprotein receptor–related proteins-Frizzled complex; MAPK, mitogen-activated protein kinase; PLC, phospholipase C; TGF-β, transforming growth factor-β. Imaging modalities available for diagnosing bone metastases are CT, MRI, bone scintigraphy, and PET imaging with tumor-specific or bone-specific tracers. Bone scintigraphy with 99mTc-labeled diphosphonates has limited sensitivity and poor specificity for identifying bone metastases particularly in the early stages of the disease when tumor is confined to the marrow. This is improved by the addition of single-photon emission computed tomography (SPECT), which has the advantage of providing anatomic localization of abnormal tracer uptake with better contrast resolution. An alternative strategy is PET-based radionuclide imaging. The commonly used radiopharmaceuticals are 18F-fluoro-2-deoxyglucose...
(FDG) and 18F/11C-choline as tumor-specific agents or sodium fluoride as a bone-specific tracer (NaF).

**CHARACTERISTICS OF METASTATIC BONE PAIN**

Adult bone receives a restricted and unique innervation as it is only innervated largely by thinly myelinated, TrkA+ sensory nerve fibers (Aδ) and TrkA+ C fibers, and receive little, if any, innervation by the larger more rapidly conducting Aβ fibers or the TrkA-negative, unmyelinated peptide poor C fibers. Most of the sensory nerves that innervate the bone appear to only be activated by injury or damage to the bone (i.e., silent nociceptors). The initial sharp pain experienced from a fracture of any bone is probably detected by mechanotransducers expressed by the Aδ and C-sensory fibers. The dull aching pain following injury, bruising, or stabilization of the fractured bone is likely associated with activation of unmyelinated C fibers present in the periosteum. Cortical bone and bone marrow are also innervated by the same population of Aδ and C-sensory nerve fibers that innervate the periosteum, although the relative density of sensory nerve fibers per unit area is markedly lower. Osteoclasts resorb bone by forming a highly acidic resorption area between the osteoclast and bone that stimulates the TRPV1 or ASIC3 channels expressed by a significant population of nerve fibers that drive bone cancer pain. Tumor-associated bone pain is usually first described as dull in character and constant in nature with the pain gradually intensifying over time. Nociception from bony metastases can produce a variety of symptoms such as muscle spasms or paroxysms of stabbing pain. Hematologic malignancies (especially acute leukemias) may produce a syndrome of generalized and migrating bone pain as a result of marrow infiltration. Limb pain is the most common presentation, and local bone tenderness (especially on long bone diaphyses) is a frequent finding. The vertebrae are the most common sites of bone metastases. The thoracic spine is affected in more than 66% of cases, the lumbosacral spine in 20%, and the cervical spine in 10%. Multiple vertebral lesions are common. Pain from metastases involving T12 and L1 often is referred to the iliac crest or SI joint unilaterally or bilaterally. Patients with tumor invasion of the upper cervical vertebrae may present with pain in the neck that is referred to the
occipital region and skull vertex. Neck flexion typically exacerbates the pain.

Osteolytic bone metastases often present with bone pain, pathologic fractures, hypercalcemia, and, more rarely, swelling or neurologic complaints. The vertebrae, pelvis, ribs, femur, and skull are the sites most frequently involved. Pain gradually develops during a period of weeks or months, becoming progressively more severe. The pain is usually well localized in a particular area and is often strongest at night or on weight bearing. Patients describe the pain as dull in character, constant in presentation, and gradually progressive in intensity. Pain increases with pressure on the involved area. Continuous pain may be moderate on resting and then increase with different movements or positions, such as standing, walking, or sitting. BTP can result from weight bearing or instability due to incipient or actual pathologic fractures. Although the locus of bone pain usually corresponds to the site of the underlying lesion, characteristic patterns of referral to noncontiguous cutaneous areas occurs. By way of example, hip pain due to a hip lesion may refer to the knee.

Fractures are common through lytic lesions in weight-bearing bones. Damage to both cortical and trabecular bone is structurally important. Radiologic features that may predict imminent fracture include large, predominantly lytic lesion that erode the cortex. The main complications of vertebral metastases are vertebral collapse, radiculopathy, and metastatic epidural spinal cord compression (MESCC). Collapse of vertebral bodies is particularly frequent in the thoracic spine metastases. Back pain is a frequent symptom in patients with advanced cancer and in 10% of cases is due to spinal instability. The pain, which can be severe, is mechanical in origin, and frequently, the patient is only comfortable when lying still. Radiculopathies can occur at any level; patients feel the pain in the spine, deep in the muscles innervated by the affected nerve root, and in the corresponding dermatome. Metastatic spinal cord compression is a serious complication of vertebral metastases (see section in the following text).

**PROGNOSIS**

A real estimate of the impact of bone metastases is difficult to assess
because incidence is influenced by factors including the sensitivity of diagnostic tools and by the length of survival of the patients. In general, the prognosis for patients presenting with bone metastases is poor (Table 42.19).
Patients with fewer metastases or solitary lesions appear to have a better outlook than those with multiple metastatic deposits. Once tumor cells spread to the skeleton, the disease is usually incurable. Issues related to bone metastases include reduced survival, morbidity, and pain that negatively affect the patient’s QOL as well as skeletal-related events (SREs). In prostate cancer, skeletal metastases are associated with overall survival ranging from 12 to 53 months. In a Danish study of approximately 36,000 breast cancer patients, the 5-year survival was 75.8% for patients without bone metastases, 8.3% for patients with bone metastases, and 2.5% for those with both bone metastases and SREs. The adjusted mortality rate ratio (MRR) was 10.5 (95% confidence interval [CI] 9.5, 11.6) for breast cancer patients with bone metastases and 14.4 (95% CI 13.1, 15.8) for those with bone metastases and SREs, compared with breast cancer patients with no bone metastases but possibly other sites of metastases. Bone metastases can be a major cause for morbidity, characterized by pain, impaired mobility, pathologic fractures, spinal cord compression, myelosuppression, and hypercalcemia with the most disability caused by long bone fracture or epidural extension of tumor into the spine. Both osteolytic and osteoblastic bone metastases are prone to fracture either because of increased bone resorption or because newly deposited bone is mostly immature is less mechanically competent than mature, lamellar bone.
Factors that influence prognosis in patients with metastatic disease include the interval between primary diagnosis and the development of metastases and the Karnofsky performance status (Table 42.20). The Karnofsky score after palliative irradiation reliably predicts survival.\textsuperscript{318–320} Other factors that predict survival include the site of the primary disease and whether single or multiple bone metastases are present.\textsuperscript{321,322} The distribution of metastases on bone scans also has prognostic significance. Bone involvement offers specific measurability criteria for tumor response assessment.\textsuperscript{323} Patients with metastatic prostate carcinoma survive significantly longer if their metastases respond to therapy and do not spread beyond the pelvis or lumbar spine.\textsuperscript{324} The use of \textsuperscript{223}Ra dichloride for metastatic castration-resistant prostate cancer reduced symptomatic skeletal events\textsuperscript{325} and significantly improved survival.\textsuperscript{326}

### SACRAL INSUFFICIENCY FRACTURES

Insufficiency fractures represent a special category of stress fractures that occur in bones with reduced mineral content and elastic resistance. They are often observed in osteoporosis, rheumatoid arthritis, prolonged glucocorticoid treatment, pelvic radiation therapy, and metabolic bone diseases. Pelvic radiation therapy has a reported prevalence of 21\% to 34\%\textsuperscript{327–329} and may occur because of a direct effect on bone and an indirect effect associated with vascular changes.\textsuperscript{330} Following radiation therapy, the reduction of the number of osteoblasts induces a reduction of
collagen production and decreased alkaline phosphatase activity, key mechanisms involved in bone mineralization. Radiation-induced occlusion of bone microvascularization also results in ischemia, which contributes to the formation of insufficiency fractures. Osteoporosis is also a major risk factor because of a greater susceptibility to injury with normal repetitive activities and minor trauma. Trabecular bone is more affected by osteoporosis than cortical bone, but cortical bone is also significantly attenuated; hence, the vertebral bodies, pelvis, and sacrum are particularly susceptible to fractures as the ratio of trabecular to cortical bone is highest in the sacral alae and lower in the central portion of the sacrum. Common areas for insufficiency fractures include weight-bearing areas such as the sacral ala, sacral body, and pubic limb. Typically, patients present with acute onset severe diffuse sacral pain and tenderness, frequently with radiation to the hips/buttocks and groin, and classically worsen with axial loading. Many patients have pain intense enough to render the patient nonambulatory. Physical examination may reveal low back or groin tenderness with restricted hip movement. Physical examination may reveal tenderness to palpation in the region of the sacral ala, but diagnosis is usually made radiologically in patients with a prior history of pelvic radiation treatment (Fig. 42.10). CT images should include coronal and sagittal reconstruction views. Patients with sacral insufficiency fractures may be misdiagnosed as having pathologic fractures from metastatic disease. Biopsy of the lesion is not recommended because of low diagnostic yield. On MRI, stress fractures present an easily recognizable edema signal in contrast to metastases that disorganize the bone and form a real replacement tissue. The most commonly used classification system for sacral fractures is the Denis classification and subclassification system (Fig. 42.11). Zone I and II fractures can cause injury to the L5 nerve root in the lumbosacral tunnel (space between the lumbosacral ligament and the S1 ala). Zone II and III fractures can cause injury to the S1 nerve root or pudendal nerve. S1 nerve injury in this setting is usually not isolated and tends to be associated with a lumbosacral plexus injury. Zone III fractures have the highest rate of neurologic deficit including bowel, bladder, and sexual dysfunction.
FIGURE 42.10 Magnetic resonance imaging (MRI) and computed tomography (CT) images of pelvis showing sacral insufficiency fracture. A: MRI axial T1 imaging shows H-shaped sacral fracture (type 1 transverse zone 3). Green arrows indicate fractures bilaterally. B: CT images of same fracture. Minimally displaced zone 1 sacral ala fractures. The fracture on the left is intra-articular and extends into the sacroiliac joint (red arrow heads). The fracture on the right is barely visible on this view with evidence of disruption of the cortex (green arrow head).

FIGURE 42.11 Denis classification and subclassification system of sacral fractures. The classification is based on the direction, location, and level of sacral fractures. The fractures are based on the sacrum’s division into three anatomic zones: zone I (alar region), zone II (foraminal region), and zone III (region of the central sacral canal). A zone II fracture can involve zone I but cannot extend into zone III, whereas a zone III fracture can involve zones I and II. Zone 3 fractures morphologically include “H”-, “U”-, “A”-, and “T”-shaped fractures.
GRANULOCYTE COLONY-STIMULATING FACTORS–ASSOCIATED BONE PAIN

Granulocyte colony-stimulating factor (G-CSF) agents act on the hematopoietic system to stimulate the proliferation and differentiation of neutrophil precursors and produce mature functional neutrophils. Agents such as filgrastim and pegfilgrastim are used as primary or secondary prophylaxis to reduce the risk of febrile neutropenia and allow the dose maintenance in patients receiving myelosuppressive chemotherapy. Pegfilgrastim is a long-acting, pegylated formulation of filgrastim that is given as a 6-mg dose subcutaneously on a once-per-cycle administration 24 to 72 hours after the administration of cytotoxic chemotherapy. Filgrastim is administered subcutaneously once daily. Pegfilgrastim causes proliferation of immature progenitor and mature myeloid cells within the bone marrow. Bone pain is the most commonly reported adverse event associated with pegfilgrastim occurring in approximately 26% of patients with severe bone pain reported in 3% to 7% of patients with the highest incidence in the first cycle. Although the exact mechanism of associated bone pain is unknown, inflammatory processes within the bone marrow, stimulation of osteoclasts and osteoblasts, and expansion of the bone marrow are potential sources of pain. The incidence of bone pain between filgrastim and pegfilgrastim was similar between patients receiving either formulation of G-CSF when used as support with chemotherapy in breast cancer.

Visceral Pain

Visceral infiltration is a common cause of pain in cancer patients. Table 42.21 lists the common pain syndromes associated with tumor infiltration.

MECHANISM
Visceral pain is defined as pain emanating from organs in the thorax, abdomen, or pelvis. The main factors capable of inducing pain in visceral structures include abnormal distention and contraction of hollow visceral walls, rapid stretching of the capsules of solid visceral organs, ischemia of visceral musculature, formation and accumulation of algogenic substances, direct action of chemical stimuli on compromised mucosa, and traction or compression of ligaments, vessels, or mesentery. Gastric acid is a noxious stimulus that contributes to pain arising from the esophagus, stomach, and upper small intestine. Mechanical trauma to normal mucosa causes no pain, implying that preceding inflammation is necessary.

There are two distinct classes of nociceptive sensory receptors in viscera. One population of afferents can code nonnoxious, as well as noxious stimuli, and a second population is not activated unless more intense and potentially damaging stimuli are encountered. These relatively insensitive fibers are normally silent and only become active following injury or in disease. The first class is composed of “high-threshold” receptors that respond to mechanical stimuli within the noxious range. These have been identified within many viscera, including the heart, lungs, gastrointestinal tract, ureters, and urinary bladder. The second class is composed of receptors that have a low threshold to natural stimuli and encode the stimulus intensity in the magnitude of their discharges, the so-called “intensity-encoding” receptors. Both receptor types are mainly concerned with mechanical stimuli such as stretch and are involved in the peripheral encoding of noxious stimuli in viscera. In the presence of local inflammation or tissue injury, these afferents become sensitized and respond to previously innocuous natural stimuli. High-threshold afferents signal acute visceral pain. Local ischemia, hypoxia, and inflammation cause pain by sensitizing high-threshold receptors and these previously
“silent” or unresponsive receptors. Pain in visceral structures is not necessarily linked to tissue injury but is more dependent on the nature of the provoking stimulus. Adequate stimuli that induce pain are distention, ischemia, and inflammation. Hollow organs such as the colon are very sensitive to luminal distention or inflammation but are totally insensitive to cutting or burning stimuli. Visceral structures from the esophagus to the transverse colon are innervated not only by DRG located in the cervical, thoracic, and upper lumbar regions but also by sensory neurons arising from the superior and inferior vagal ganglia.\textsuperscript{343} Visceral structures located distal to the transverse colon, particularly the distal colon, rectum, and bladder, are also innervated by two populations of afferents; however, these are both of spinal origin arising from two different levels of the spinal cord (thoracolumbar and lumbosacral). Sensory neurons arising from these two spinal locations appear to convey different aspects of the complex sensation that humans identify as visceral pain.\textsuperscript{343} Poorly localized visceral pain may be explained by the low density of visceral nociceptors, the functional divergence of visceral input with the CNS, and viscerovisceral convergence in the spinal cord.

Localization of visceral pain is difficult. Afferent nerves from viscera to the spinal cord are relatively few in number and comprise only 2\% to 15\% of all afferents to the spinal cord.\textsuperscript{344,345} These visceral nociceptive afferents can excite many second-order neurons in the spinal cord which in turn generate extensive divergence within the CNS, sometimes involving supraspinal loops. Such a divergent input activates several systems—sensory, motor, and autonomic—and thus triggers the general reactions that are characteristic of visceral nociception: a diffuse and referred pain and prolonged autonomic and motor activity.\textsuperscript{340} The dorsal column in the spinal cord contains an ascending excitatory pathway that plays a crucial role in the perception of visceral pain, especially under the conditions of peripheral inflammation.\textsuperscript{346} Activation of thalamic neurons by the dorsal column pathway, through a relay in the dorsal column nuclei, may be an important element in this mechanism. The dorsal column pathway may contain an ascending part of an amplification loop that enhances the responsiveness of spinal cord neurons through a descending facilitatory pathway, possibly originating in the rostroventral medulla.\textsuperscript{347} This
amplification circuit could lead to potentiation of the responses of different projection neurons, including spinothalamic and postsynaptic dorsal column neurons. The effectiveness of the midline myelotomy in visceral pain patients could thus be explained by a direct reduction in the activation of thalamic neurons mediated by postsynaptic dorsal column neurons as well as by an interruption of the amplification loop, thereby preventing the potentiation of the visceral responses of other projection neurons such as spinothalamic tract cells.

The origin of nociceptive impulses determines the site and type of pain. Visceral pain is either true, referred, nonreferred parietal, or referred parietal. True parietal abdominal pain is dull and poorly localized; it occurs in the region of the epigastric, periumbilical, or lower mid-abdominal region. Patients may describe the pain as gnawing or cramping, and often, it is associated with nausea, sweating, pallor, and, occasionally, vomiting. Referred visceral pain is more precisely localized, usually in the dermatomal or myosomal regions of the same segments of the spinal cord involved. Parietal pain may localize directly over the organ without referral. Patients locate referred parietal pain in a body region distant from the nociceptive site. For example, patients complain of pain in the shoulder area when the cause is inflammation of the middle diaphragm.

Tumor invasion of adjacent blood vessels can generate nociception. Mechanisms include perivascular lymphangitis causing vasospasm, occlusion with resultant ischemia, venous engorgement, and edema.

Obstruction of hollow viscera from tumor with resultant distention may cause pain. Distention causes intense contraction of smooth muscle that generates nociception. Patients experience visceral pain that is poorly localized and diffuse but usually localized in same dermatomal area of the cord segments of the viscera.

Pain from tumor involvement of parenchymal viscera such as liver, spleen, pancreas, and kidney typically results from acute distention of the pain-sensitive fascia. These fascia contain many mechanical receptors, and nociception occurs when they are acutely stretched or placed under tension. This type of pain is poorly defined, dull, and generally located in the dermatomal region of the involved organ. The properties of visceral pain are discussed in Chapters 61–65.
VISCERAL PAIN DESCRIPTIONS BY SITE

Esophageal cancer usually elicits a history of heartburn: a burning or gnawing substernal discomfort. Patients usually describe the pain as being located in the epigastric or retrosternal areas, which often radiates to the back or interscapular region. The pain occurs often after eating and possibly relates to body position changes such as reclining or bending forward.

Gastric pain has a colicky quality associated with delayed emptying and slowed motility and digestive symptoms. The pain also localizes in the epigastrium, is usually sharply focused, and may radiate into the back.

Small intestine pain is usually crampy or colicky and localized in the periumbilical area. The cause of pain is usually a lesion causing distention with resultant abnormal mobility. Eating usually precipitates the pain, and defecation or fasting may afford relief. Colon pain tends to occur in the lower abdomen, varying according to which portion of the colon is affected. Change in bowel habits and occult blood in the stool often accompanies symptoms of discomfort. Peritoneal carcinomatosis is frequently found with abdominal tumors and advanced ovarian cancer. Pain may result from peritoneal irritation, mesenteric involvement, and abdominal distention with ascites. Bowel obstruction often complicates peritoneal carcinomatosis.

Liver parenchyma is insensitive to tumor distention and associated chemical changes. Right upper quadrant pain from liver pathology occurs only when there is acute distention of the liver capsule. It is usually a dull, aching sensation in the right upper abdominal quadrant and flank and is often referred to the right scapula and shoulder.

Perineal pain, worse when sitting and with aching and pressure-like quality is the first and, can be for a long time, the only symptom of pelvic tumors. The pain may be associated with tenesmus. Fistulas and recurrent infections can aggravate the pain syndrome. Ureteral obstruction is frequent. Direct invasion of the sacrum, sacral roots, plexus, or cauda equina are frequent complications. Pain from the fundus of the uterus typically occurs in the hypogastrium. Pain originating from the uterine cervix is commonly referred to the low back and sacral area as well as to the hypogastrium. Ovarian pain results from stretching of the surrounding
peritoneum to which the ovaries adhere.

**Neuropathic Pain**

The following are among the most common cancer pain syndromes that present with a major neuropathic component.

**NEUROPATHIC PAIN SECONDARY TO CANCER-RELATED PATHOLOGY IN CRANIAL NERVES**

Painful cranial neuralgias may occur secondary to base of skull metastases, LMs, or head and neck cancers. Base of skull metastases produce several well-described pain syndromes and are often associated with primary tumors of the breast, lung, and prostate. Constant localized aching pain from bone destruction and neurologic deficits from progressive cranial nerve palsies are cardinal manifestations. Orbital and parasellar syndromes were characterized by frontal headache, diplopia, and first-division trigeminal sensory loss. Proptosis may occur with the orbital syndrome. The middle-fossa syndrome was characterized by facial pain or numbness or dysesthetic neuropathic pain in the distribution of the second or third divisions of the trigeminal nerve. Associated motor deficits include weakness in the masseter or temporalis muscles or abducens palsy. The jugular foramen syndrome was characterized by hoarseness and dysphagia, with paralysis of the 9th through 11th cranial nerves and may present as glossopharyngeal neuralgia. This pain is distributed over the ear or mastoid region and may radiate to the neck or shoulder. Associated deficits include a Horner syndrome and paresis of the palate, vocal cords, sternocleidomastoid muscle, or trapezius muscle. It is sometimes associated with syncope. The occipital condyle syndrome was characterized by unilateral occipital pain and unilateral tongue paralysis with patients complaining of a continuous, severe, unilateral, occipital pain which kept them with the head rotated to the side of the pain and held with their hands and occipital region pain typically preceding the hypoglossal paresis by several days to 10 weeks. Occipital condyle syndrome, clinically mimics classical trigeminal neuralgia, can occur secondary to tumors in the middle or posterior
Middle fossa tumors may present as trigeminal neuralgia but usually cause severe pain of an atypical nature and a progressive neurologic deficit. Trigeminal neuralgia secondary to tumor usually presents as a constant, dull, well-localized pain related to the underlying pathology involving bone and other somatic structures associated with paroxysmal episodes of lancinating or throbbing pain. A higher incidence of hypesthesia in the trigeminal nerve regions as well as a reduced corneal reflex was noted in patients with a mass lesion compared to those with vascular compression. Posterior fossa tumors are most likely to cause trigeminal neuralgia and are usually accompanied by subtle neurologic deficits. This association between trigeminal neuralgia and tumor is uncommon, and cancer patients with a new onset of trigeminal neuralgia should have careful imaging of the base of skull.

**Cervical Plexopathy**

Tumor infiltration of the cervical plexus can produce several pain syndromes, depending on the pattern of nerve involvement. The upper four cervical ventral rami join to form the cervical plexus, which has both cutaneous and muscular branches. The plexus lies close to C1–C4 vertebrae. Cutaneous branches include the lesser occipital nerve which innervates lateral part of the occipital region; the great auricular nerve (innervates skin near auricle and external acoustic meatus); the transverse cervical nerve which innervates anterior region of the neck; and the suprACLAVICULAR nerves which innervate shoulder, suprASCAPULARIS, and upper thoracic region. The main contributor among muscular branches is ansa cervicalis. Because sensory afferents from the cervical plexus enter the spinal tract of the trigeminal along with the sensory afferents from cranial nerves V, VII, IX, and X, nociceptive referral patterns from the face and neck overlap. Symptoms usually include local pain with lancinating or dysesthetic components referred to the retroauricular and nuchal areas (lesser and greater auricular nerves), preauricular area (greater auricular nerve), anterior neck and shoulder (transverse cutaneous and supraCLAVICULAR nerves), and the jaw. Associated findings may include ipsilateral Horner syndrome or hemidiaphragmatic paralysis. Due to the proximity to the cervical spine, CT or MRI evaluation may be
necessary to rule out associated epidural cord compression. Common clinical settings include local extension of a head and neck tumor or cervical lymph node metastases. In patients with head and neck tumors who have undergone RND followed by radiation treatment, new onset or worsening pain includes a differential diagnosis of post-RND syndrome or tumor recurrence.

**Tumor-Related Mononeuropathy**
The most commonly described tumor-related painful mononeuropathy is intercostal nerve injury secondary to rib metastases with local extension. Patients with tumor invasion of the sciatic notch may present with symptoms resembling sciatica. Isolated mononeuropathies particularly from lymphomas are reported.\(^{358-360}\)

**Radiculopathy**
Radiculopathy is compression of a nerve root. Frequent signs and symptoms include varying degrees of sensory, motor, and reflex changes as well as pain, dysesthesias, and paresthesias related to nerve root(s) without evidence of spinal cord dysfunction (which is myelopathy). Patients with radiculopathy may not have pain. Evaluation includes history and physical examination. Imaging modalities commonly used for evaluation include MRI, CT, and myelography. For lower extremity issues, the most commonly used physical tests include Lasègue test* straight leg raising or crossed straight leg raising; tendon reflexes; and signs of weakness, atrophy, or sensory deficits.\(^ {361}\) For cervical/upper extremity radiculopathy, Spurling test\(^ {†}\) is a provocative maneuver suggestive of radiculopathy. Patients with cancer-related radiculopathy may present with pain on either or both sides of the midline. The pain tends to be unilateral in the cervical and lumbosacral regions and bilateral in the thorax. Radiculopathy may result from epidural tumor mass effects with encroachment on exiting nerve roots or LMs. Coughing, sneezing, recumbency, and strain exacerbate the pain, which often has dysesthetic qualities. Radiculopathy may also develop secondary to LMs. Clinically, LMs may produce multifocal neurologic signs and symptoms at a variety of levels, including cranial neuralgias.\(^ {362}\)
Leptomeningeal Metastases
LM is defined as the appearance of tumor cells in the leptomeninges or CSF distant from the site of a primary tumor. It is also known as carcinomatous meningitis, neoplastic meningitis, neoplastic meningosis, leukemic meningitis (for leukemia), lymphomatous meningitis (for lymphoma), and meningeal carcinomatosis (for carcinoma). This complication occurs most commonly with cancers of the breast and lung, melanoma, lymphomas, and acute lymphocytic leukemia with an estimated survival at 1 year of approximately 10% that varies with the primary tumor. Clinical evaluation, MRI, and CSF assessment including cytology are the most important diagnostic measures.

Neurologic dysfunction most commonly involves one or more segments of the neuraxis, including cerebral hemispheres, cranial nerves, spinal cord, or spinal roots. Clinical manifestations that strongly suggest the diagnosis of LM include cauda equina symptoms or signs, communicating hydrocephalus, and cranial neuropathies. Early in the disease, neurologic involvement can be subtle, such as an isolated diplopia or radicular pain. Cerebral hemisphere symptoms such as altered mental status or seizures may predominate. Symptoms may also include headache, back and radicular pain, and multiple cranial and spinal nerve involvement. Pain may occur in 30% to 76% of cases. Table 42.22 lists the frequency of spinal cord symptoms and signs in patients with LMs. The most common symptom is pain (80%), and patients may report a diffuse headache (25%) or pain in a spinal, radicular, or meningeal pattern (>50%). Localizing symptoms include cranial neuropathies, mononeuritis, radiculopathy, urinary incontinence, and visual disturbance.

Solid tumors have the propensity to adhere to neural structures and form nodules that become visible on MRI. MRI appearances include the presence of subarachnoid nodules, leptomeningeal enhancement, nerve root enhancement, parenchymal disease (intramedullary metastases), and epidural metastases. These changes may occur intracranially and along the spinal canal. T1-weighted gadolinium-enhanced sequence of the entire neuraxis (brain and spine) plays an important role in supporting the diagnosis, demonstrating the involved sites, and guiding treatment. MRI images typically show enhancing nodular lesions.

Nearly all patients have some abnormality of CSF opening pressure, protein, glucose, or cell count. The finding of tumor cells in CSF establishes a definitive diagnosis. In patients with hematologic cancers, CSF flow cytometry is more sensitive than CSF cytology and additionally requires a comparatively smaller volume of CSF (<2 mL) for analysis.

**Myelopathies in Cancer**

Spinal cord involvement may occur by direct or indirect mechanisms. Direct mechanisms can be parenchymal (intradural intramedullary), subarachnoid (intradural extramedullary), or epidural (extradural). Intramedullary involvement can result from metastases or a primary spinal cord tumor, intradural extramedullary may occur from leptomeningeal disease or primary tumors such as peripheral nerve sheath tumors or meningiomas, and extradural disease is primarily related from MESCC. Indirect mechanisms may result from radiation therapy (radiation myelitis) and intrathecally administered chemotherapy resulting in spinal cord injury. Paraneoplastic neurologic disorders may also result in indirect injury.
**Brachial Plexopathy**

The brachial plexus is formed from the C5–T1 ventral rami; the nerve roots pass between the anterior and middle scalene muscles with the subclavian artery to form the trunks. Trunks then split into anterior and posterior divisions, form cords, and travel with the subclavian artery and vein within the infraclavicular region. The cords form terminal branches at the lateral margin of the pectoralis minor muscle and continue through the axilla. Most tumors involving the brachial plexus originate from the lung or breast (Fig. 42.12 and Table 42.23). Clinical features result from either compression or tumor infiltration of the brachial plexus from contiguous structures, such as axillary/supraclavicular nodes or vascular structures. Neuropathic pain due to tumor infiltration of the brachial plexus usually stems from lymph node metastases from breast carcinoma or lymphoma or direct extension from lung carcinoma (i.e., Pancoast tumor). Lung cancers that occur in the apex of the chest and invade chest wall structures are called superior sulcus tumors or Pancoast tumors. The classical description of such patients involves a syndrome of pain radiating down the arm as a manifestation of brachial plexus involvement. A Pancoast tumor occurs when it invades any of the structures at the apex of the chest, including the most superior ribs or periosteum, the lower nerve roots of the brachial plexus, the sympathetic chain near the apex of the chest, or the subclavian vessels. These tumors are divided into anterior, middle, and posterior compartment tumors depending on the location of the chest wall involvement in relation to the insertions of the anterior and middle scalene muscles on the first rib. A syndrome of pain radiating down the arm is not a prerequisite for an apical tumor to be designated a Pancoast tumor. However, patients may complain of severe pain in the shoulder radiating toward the axilla and/or scapula and along the ulnar distribution of the upper arm and demonstrate atrophy of hand and arm muscles with obstruction of the subclavian vein resulting in edema of the upper arm.

The key features of malignant plexopathy are the neuropathic nature of the pain, with numbness, paresthesias, allodynia, and hyperesthesias. Typically, the pain begins in the shoulder girdle where it is often described as pressure-like or aching and may radiate to the elbow, medial forearm, and fourth and fifth fingers. It may also appear to localize at the posterior arm or elbow. The patient may report a burning quality to the pain, with hyperesthesia along the ulnar aspect of the forearm. Involvement of the lower plexus occurs when tumor arises from the lung apex; associated pain and dysesthesias involve the elbow, medial forearm, and fourth and fifth fingers (C7, C8, and T1). Upper plexus involvement (C5, C6), if it occurs
alone, will usually develop into a panplexopathy. Upper plexus pain typically involves the shoulder girdle, with burning pain in the tips of both the index finger and thumb. Lung tumors can also present with pain involving the axilla and upper chest wall in the distribution of the intercostobrachial nerve.\textsuperscript{374}

Neuroradiologic evaluations for brachial plexopathy are CT, PET/CT, and MRI. MRI is the preferred modality for imaging the brachial plexus. Most commonly, a combination of fat-suppressed T2-weighted (either frequency selective or short tau inversion recovery [STIR]) sequences and T1-weighted MR sequences are used.\textsuperscript{375} FDG-PET scanning may also be useful in distinguishing between radiation-induced and metastatic plexopathy. Imaging the contiguous epidural space is recommended, particularly with paraspinal involvement. Electromyography (EMG) can also help distinguish malignant brachial plexopathy from radiation-induced brachial plexopathy (RBP) or cervical radiculopathy (Table 42.24). In patients with brachial plexopathy, EMG usually shows fibrillation potentials and positive waves (evidence of denervation) in affected muscles. RBP is discussed later.

**Lumbosacral Plexopathy**

The lumbosacral plexus is formed from the L1–L5 ventral rami with contributions from T12 and S1–S4. The lumbar roots emerge from the psoas major muscle, form anterior and posterior divisions, and finally form anterior and posterior branches to innervate the muscles of the anterior and medial thigh. Anterior and posterior divisions also arise from the sacral roots and course over the sacral promontory posterolateral to the internal iliac vessels to form branches that innervate the muscles of the gluteal region, lateral and posterior thigh, and lower leg. The sciatic nerve exits the pelvis through the greater sciatic foramen usually below but sometimes dividing the piriformis muscle. Direct tumor infiltration from adjacent soft tissues or lymph nodes or by compression from metastases in the adjacent bony pelvis can damage the lumbosacral plexus. Most lumbosacral plexopathy reflects local extension or nodal metastases from colorectal and other pelvic tumors (cervix, uterus, bladder, prostate), sarcomas, and lymphomas, but it may also occur with metastases from breast or lung cancer.\textsuperscript{376}

Complete plexopathy causes weakness, sensory loss, and flaccid loss of tendon reflexes in regions innervated by nerves in the L1–L4 distribution. Sacral plexopathy causes the same abnormalities in segments L5–S3, resulting in weakness and sensory loss in the gluteal (motor only),
peroneal, and tibial nerve areas. The distribution of pain varies and may localize in the pelvis, low back or hip, or refer in a radicular or nonradicular pattern into the lower extremity. The local pain quality is pressure-like or aching. Referred pain varies with the site of plexus involvement and can be burning, cramping, or shooting. Sensory symptoms of numbness and paresthesias as well as weakness and leg edema usually develop. A “hot and dry foot” syndrome may result from lumbosacral plexopathy and may reflect sympathetic fiber dysfunction. The most common clinical findings on examination include lower extremity weakness (86%), sensory loss (73%), reflex loss (64%), and leg edema (47%). Positive straight leg raising tests and sciatic notch tenderness are often present.

Lumbosacral plexopathy may cause different clinical syndromes depending on the level of nerve involvement. Infiltration of the upper plexus occurs in approximately one-third of patients, who present with pain in the back, lower abdomen, flank, iliac crest, or anterolateral thigh. This syndrome has associated L1–L4 distribution neurologic deficits. Involvement of the lower plexus occurs in approximately one half of patients, and these present with pain in the buttocks and perineum, with referral to the posterolateral leg and thigh. Examination may reveal associated L4–S1 neurologic deficits, leg edema, and bowel or bladder dysfunction. Sacral plexopathy can signal direct bony extension of a bony sacral lesion or a presacral mass. Numbness of the dorsal medial foot and sole with associated weakness of knee flexion, ankle dorsiflexion, and inversion is typical of lumbosacral trunk extension. Involvement of the coccygeal plexus results in sphincter dysfunction and perineal sensory loss. Panplexopathy occurs in one-fifth of patients, and pain may refer anywhere in the territory of the plexus. Associated leg edema is relatively common.

Jaeckle et al. studied 85 cancer patients with lumbosacral plexopathy and documented pelvic tumor by CT or biopsy. They discerned three clinical syndromes: lower (L4–S1), 51%; upper (L1–L4), 31%; and panplexopathy (L1–S3), 18%. Seventy percent of patients had the insidious onset of pelvic or radicular leg pain, followed weeks to months later by sensory symptoms and weakness. The quintet of leg pain,
weakness, edema, rectal mass, and hydronephrosis suggests plexopathy due to cancer. CT showed pelvic tumor in 96%. On myelography, epidural extension, usually below the conus medullaris, occurs in 45%. With treatment, only 28% of patients had objective responses on CT and 17% on examination.

In previously treated patients, the main differential diagnostic consideration is radiation-induced plexopathy (see in the following discussion). MRI is the choice for the diagnostic workup of patients with clinical and electrophysiologic evidence of plexopathy and suspected systemic cancer. Studies should include the L1 vertebral body through to the true pelvis. Neurologic findings include leg weakness, sensory loss, reflex asymmetry, focal tenderness (in the lumbar region in an upper plexopathy, sciatic notch and sacrum in a lower plexopathy, and lumbosacral region in panplexopathy), rectal mass, decreased sphincter tone, and positive direct and reverse straight leg raising signs.

**Tumor Infiltration of the Sacrum and Sacral Nerves**

Pain in a sacral distribution occurs usually as a result of the spread of bladder, gynecologic, or colonic cancer. There is dull aching midline pain and usually burning or throbbing pain in the soft tissues of the rectal or perineal region. Sitting or lying usually exacerbates the pain. With bilateral involvement, sphincter incontinence and impotence are common. There may be tenderness over the sacrum and in the regions of the sciatic notches. Sometimes there is limitation of both direct and reverse straight leg raise exam maneuvers. Involvement of S1 and S2 roots will produce weakness of ankle plantar flexion, and the ankle jerks may be absent. There is usually sensory loss in the perianal region and in the genitalia, and this may be accompanied by hyperpathia.

**Spinal and Radicular Pain**

Patients perceive radicular pain as arising in a limb or trunk wall. The cause is ectopic activation of nociceptive afferent fibers in a spinal nerve or its roots or other neuropathic mechanisms. The pain is lancinating in quality and travels along a narrow band. It may be episodic, recurrent, or paroxysmal according to the causative lesion or any superimposed
aggravating factors. Although patients may experience radicular pain as a deep tissue pain, it also has a cutaneous quality in proportion to the number of cutaneous afferent fibers ectopically activated. Radicular pain differs from nociception in the axons stimulated along their course; their peripheral terminals are not the sites of stimulation. Ectopic activation may occur as a result of mechanical deformation of a dorsal root ganglion, mechanical stimulation of previously damaged nerve roots, inflammation of a dorsal root ganglion, and possibly by ischemic damage to the DRG. Acute spine pain may be described as cramping or knifelike but may also be merely dull or aching. It is worse with movement. Chronic spine pain without a radicular component is generally aching, dull, or burning, or any combination of these three features. It also tends to be made worse with movement.

Central Pain Syndromes Caused by Cancer
Central pain syndromes are relatively infrequent in the cancer population. Although epidural spinal cord compression is almost always painful, central pain is not the predominant symptom; nociceptive input from progressive bony destruction by metastases is the usual cause of pain, with or without concurrent radicular pain from nerve root compression. Radiation myelopathy is also a possible cause of central pain syndrome.

Paraneoplastic Peripheral Neuropathy
Paraneoplastic syndrome refers to a group of disorders (caused by, or associated with, cancers) that are neither direct effects of the primary tumor mass nor metastatic to the involved organs. Various antibodies discovered in paraneoplastic syndromes target proteins shared by both the tumor cells and neurons. Antibodies directed against neural antigens expressed by tumor (onconeural antibodies) may occur in most of those affected by classical paraneoplastic syndromes, suggesting that an autoimmune process underlies these disorders. In patients with anti-Hu antibodies, infiltration by T cells is seen in the peripheral and the CNS. Clinically significant peripheral neuropathy in cancer patients is common, but only a small minority is paraneoplastic in origin. These disorders can affect virtually any portion of the nervous system. Peripheral nerves are a
common target in paraneoplastic syndromes.\textsuperscript{211} SSN is a classical paraneoplastic syndrome.\textsuperscript{212} The neuropathy generally develops subacutely, accompanied by pain and rapidly progressive paresthesia. Involvement of the upper extremities may occur with asymmetric sensory deficit or multifocal with facial, thoracic, and abdominal involvement. Many patients with SSN also have signs and symptoms suggestive of multifocal involvement including areas of the CNS. Paraneoplastic vasculitis of the peripheral nervous system usually precedes the tumor diagnosis and presents as multineuritis or asymmetric distal sensory-motor neuropathy with pain as a commonly reported symptom. This form is generally associated with lymphoma or cancer at various sites (lung, prostate, uterus, kidney, or gastric).\textsuperscript{213} Four types of polyneuropathy constitute most of the cases of paraneoplastic peripheral neuropathy: motor, sensory, sensorimotor, and autonomic. Most paraneoplastic peripheral neuropathies are sensorimotor and axonal. A pure sensory neuronopathy (i.e., pathology in the dorsal root ganglion) strongly suggests a paraneoplastic syndrome associated with the anti-Hu antibody. A pure motor neuropathy subacutely developing could be the Guillain-Barré syndrome associated with Hodgkin disease or a multifocal motor neuropathy with conduction block associated with plasma cell dyscrasias. An autonomic neuropathy is sometimes associated with the anti-Hu syndrome. Paraneoplastic disorders of the autonomic nervous system usually arise in the setting of encephalomyelitis. However, autonomic symptoms may predominate or rarely be the only symptoms or signs of a paraneoplastic neuropathy. The most common symptom is pseudo-obstruction of the bowel, but anhidrosis, orthostatic hypotension, hypoventilation, sleep apnea, and cardiac arrhythmias can also present either alone or, more commonly, as part of a more widespread autonomic neuropathy. Most autonomic neuropathies are associated with SCLC and the anti-Hu syndrome. Mononeuritis multiplex suggests a vasculitis, possibly paraneoplastic in origin. The classic paraneoplastic polyneuropathy is sensory neuronopathy. Typically, patients with this disorder initially have an asymmetrical and painful sensory neuropathy, which evolves into complete loss of proprioception. The pseudoathetotic movement of the hands and severe sensory ataxia is very severe in most
cases. Motor neuropathies may be acute or chronic, progressive or remitting, demyelinating, axonal, or neuronal. Clinically, they are indistinguishable from the more common nonparaneoplastic motor neuropathies, unless they resolve after treatment of the cancer or are associated with a paraneoplastic antibody. These disorders include the Guillain-Barré syndrome, which occurs more frequently in patients with Hodgkin’s disease than in the general population; a remitting and relapsing polyneuropathy resembling relapsing chronic inflammatory demyelinating polyneuropathy; and a subacute motor neuronopathy affecting patients with Hodgkin’s disease or other lymphomas. The sensory neuropathies include a subacute pan-sensory neuropathy and a predominantly distal sensory neuropathy. Paraneoplastic vasculitis neuropathy may occur in malignancy (solid tumors including gastric cancer), and the presentation is similar to connective tissue-related vasculitic neuropathy with a painful, asymmetrical polyneuropathy or mononeuritis multiplex pattern.  

Paraneoplastic peripheral neuropathies are important because they may be the first sign of an otherwise occult cancer and/or because they may substantially disable the patient even when the cancer itself is asymptomatic. In about two-thirds of cases, patients with paraneoplastic neurologic disorders present to the neurologist without a known tumor. Polyneuropathy, organomegaly, endocrinopathy, myeloma protein, and skin changes (POEMS) syndrome is a paraneoplastic syndrome due to an underlying plasma cell neoplasm. The major criteria for the syndrome are polyradiculoneuropathy, clonal plasma cell disorder (PCD), sclerotic bone lesions, elevated VEGF, and the presence of Castleman disease. Minor features include organomegaly, endocrinopathy, characteristic skin changes, papilledema, extravascular volume overload, and thrombocytosis. POEMS syndrome should be distinguished from the Castleman disease variant of POEMS syndrome, which has no clonal PCD and typically little to no peripheral neuropathy but has several of the minor diagnostic criteria for POEMS syndrome.  

NEUROPATHIC PAIN SECONDARY TO THERAPEUTIC INTERVENTIONS
Many pain syndromes occur in the course of or subsequent to treatment of
cancer with surgery, chemotherapy, or radiation therapy. In most cases, there is injury to the peripheral nervous system or spinal cord, with pain as a major and often presenting complaint. In some cases, these syndromes occur long after the therapy is implemented, resulting in a difficult differential diagnosis between recurrent disease and a complication of therapy.

**Postsurgical Neuropathic Pain**

1. Postmastectomy: Pain can be a prominent postsurgical finding in breast cancer patients. It tends to appear in the postmastectomy period, a consequence of the disruption of normal neural pathways, or it may follow the development of lymphedema or the presence of metastases. In most situations, however, pain occurs primarily as a result of persistent restrictions in range of motion of the shoulder girdle in the region of surgery with findings of tender or trigger points in the associated muscle groups suggesting a nonneuropathic source that is misdiagnosed as neuropathic. The IASP defines postmastectomy pain syndrome as persistent pain soon after mastectomy/lumpectomy affecting the anterior thorax, axilla, and/or medial upper arm, but patients may experience persistent postsurgical pain affecting one or more regions involving the scar, breast, chest wall, shoulder, and upper arm with an incidence ranging from 25% to 80%. Chronic neuropathic pain with inherent sensory changes and somatosensory disturbances may overlap with persistent postsurgical pain, and definitive diagnosis can be challenging.

   Chronic pain after mastectomy may occur in patients whose surgery included axillary dissection, although the problem can occur in women who undergo any surgical procedure on the breast from lumpectomy to radical mastectomy. Postaxillary dissection pain is probably a more appropriate name than the usual postmastectomy pain for this syndrome. A neuropathic pain pattern typically involves paroxysms of lancinating pain against a background of burning, aching, tight constriction in the axilla, medial upper arm, and/or chest. Hyperesthesia, dysesthesia, hyperalgesia, allodynia, or hypoesthesia in the intercostobrachial nerve distribution may
The exact cause is unclear, but various theories include dissection of the intercostobrachial nerve, intraoperative damage to axillary nerve pathways, and pain caused by neuroma formation. The intercostobrachial nerve is a cutaneous sensory branch of T1 and T2. The nerve is highly variable in size and distribution, making it difficult to avoid in these surgical procedures. Usually, the pain develops shortly after surgery, but it can emerge months after surgery. Late onset should prompt a search for other causes such as recurrent chest wall disease or bone metastases. Postmastectomy pain syndrome differs from metastatic or RBP in which there is a different pattern of sensory loss, lymphedema, and, usually, more severe pain.

2. Neck dissection: Head and neck cancer encompasses tumors of the upper aerodigestive tract and the skin of the region. Surgical management may include the removal of lymph nodes from the neck and is referred to as a neck dissection. A large spectrum of surgical procedures is available for treatment of cervical lymph nodes. These may be classified as RND, extended RND, modified RND, and selective neck dissection. RND for head and neck cancers can result in an iatrogenic syndrome characterized by ipsilateral face and neck pain with associated paresthesias. Pain usually emerges weeks to months after surgery, consequent to injury to the cervical plexus or cervical nerves. The most relevant functional sequel from RND is impairment of shoulder function due to sectioning the spinal accessory nerve and to the ensuing denervation of the upper trapezius muscle. Sacrifice of the spinal accessory nerve during RND is considered a critical factor in determining postoperative shoulder function. Injury to the nerve and subsequent denervation of the trapezius muscle reduces capacity to elevate the shoulder girdle (scapular dyskinesis) and has been associated with patient reported shoulder pain and functional loss. Patients who undergo a nerve-sparing procedure (i.e., selective neck dissection or a modified RND) exhibit significantly better shoulder function than did patients who undergo RNDs. In patients treated for head and neck cancer, neck dissection was considered a risk factor for the development of MPS. Neck dissection was a predictive factor for reduced
sensitivity in the neck, reduced range of motion of the neck, and MPS was strongly related to shoulder pain.\textsuperscript{390} 

Nahum et al.\textsuperscript{391} coined the term “shoulder syndrome” to describe a clinical picture consisting of pain and limited abduction of the shoulder, full passive range of motion, and anatomic deformities such as scapular flaring, droop, and protraction. Pain is attributed to strain placed on other supporting muscles, such as the rhomboids and levator scapulae, as a consequence of shoulder drooping. A frequent ancillary sign of shoulder syndrome is sternoclavicular joint hypertrophy, due to the abnormal torque-like forces applied to the medial head of the clavicle, potentially complicated by stress fracture of the middle third of the clavicle. Recurrent tumor can also be a cause of pain that occurs or escalates after neck dissection.

3. Postthoracotomy pain: Most surgical procedures can potentially cause persistent pain which last months or years, and breast surgery (including interventions for breast cancer, augmentation, and reduction) and thoracic surgery (including open thoracotomies, video-assisted thoracoscopic surgery [VATS], sternotomies) are two with the highest reported prevalence (31\% and 34\%, respectively) with the prevalence of probable or definite neuropathic pain being approximately 66\%.\textsuperscript{392} Shortly following thoracotomy, a neuropathic pain can develop in the distribution of one or several intercostal nerves near the thoracotomy scar.\textsuperscript{392,393} The pain may remain stable after onset and gradually decreases over a period of months or years. Hetmann et al.\textsuperscript{394} noted in patients who underwent thoracotomies by an open posterolateral technique that the presence of preoperative pain was a predominant predictor for persistent pain 12 months after the procedure. Persistent postsurgical pain following anterior thoracotomy occurred in 19\% of lung cancer patients for up to 10 years postoperatively.\textsuperscript{395} Steegers et al.\textsuperscript{396} noted the prevalence of chronic pain was 40\% after thoracotomy and 47\% after VATS. Definite chronic neuropathic pain was present in 23\% of the patients with chronic pain, with an additional 30\% having probable neuropathic pain. The probability of neuropathic pain correlated with more intense chronic pain and predictive factors for chronic pain
were younger age, radiation therapy, pleurectomy, and more extensive surgery. Pain is most profound around the scar, as 82% to 90% of pain patients relate their pain directly to the surgical site\textsuperscript{397,398} and is primarily described as aching, tender, with numbness, and to a lesser degree burning.\textsuperscript{399} Guastella et al.\textsuperscript{400} noted in patient who underwent a lateral/posterolateral thoracotomy for cancer that the clinical picture in most patients with neuropathic pain included electric shocks and severe multimodal hypoesthesia in the sensory area of fifth/sixth intercostal nerves. Patients may also have higher depression and anxiety scores and lower self-rated health and demonstrate more evoked pain to mechanical stimuli and in particular to pinprick hyperalgesia.\textsuperscript{401}

In my experience, many patients experience chronic pain in the shoulder girdle region following thoracic surgical procedures not primarily from intercostal nerve damage but from a persistent inability to normally range the shoulder girdle region. In effect, these patients demonstrate persistent myofascial tenderness in the muscles of the shoulder girdle region (pectoralis, trapezius, rhomboids, and deltoid).

4. Phantom pains: After amputation, patients may experience phantom sensations (including temperature changes, itching, tingling) and/or phantom pain. Phantom pain is typically associated with amputation of limbs but may follow the amputation or loss of many body parts including the eyes,\textsuperscript{402} teeth,\textsuperscript{403} tongue,\textsuperscript{404} nose,\textsuperscript{405} breast,\textsuperscript{406} genitals,\textsuperscript{407} or parts of the gastrointestinal tract.\textsuperscript{408,409} The onset is within 1 week after amputation in the majority of patients, with 50% of patients experiencing pain within 24 hours after amputation.\textsuperscript{410,411} Phantom pain should be distinguished from residual limb pain that is localized to the residual limb. Patients may report that phantom sensations are present all the time and that phantom limb pain is intermittent with short episodes (lasting only seconds or minutes) of pain (often severe) which can occur several times a day. Patients may also report “telescoping” of their phantom which is a sensation in which the body of the limb shortens into the stump often completely, leaving the sensation of hands or feet very close to the stump.
Phantom pain disables a significant number of patients undergoing amputation of different body parts for malignancy. Two years after mastectomy, the percentage of patients with phantom breast sensations was stable around 20%, and those with phantom breast pain reduced from 7% in the first year to 1%. Phantom rectal sensation (including pain) occurs in up to 18% of patients after surgery for rectal carcinoma. The reappearance or worsening of pain a long while after amputation can indicate tumor recurrence.

**Radiation Myelopathy, Plexopathy, and Neuropathy**

Tolerance of nervous system tissues to radiation therapy depends on several factors such as volume, total dose, dose per fraction, duration of irradiation, prior radiation, concomitant neurotoxic chemotherapy, and genetic susceptibility. Radiation treatment may cause pain by damage to peripheral nerves or spinal cord by altering the microvascular of connective tissue surrounding peripheral nerves, via fibrosis and chronic inflammation in connective tissues, or bringing about demyelination and focal necrosis of the white and gray matter in the spinal cord. Typically, these changes occur late in the course of a patient’s illness. The differential diagnosis should always include recurrent tumor. In most instances, pain is a component of the clinical picture, but it is rarely as severe as that associated with recurrent tumor. Myelopathy is a devastating late effect of radiation treatment and if the spinal cord dose does not exceed a total of 45 to 50 Gy in 1.8 to 2 Gy daily fractions, the risk of permanent injury is very low, estimated from 0.03% to 0.2%. The pathologic findings of radiation-induced progressive myelopathy may include demyelination, focal necrosis and axonal loss, and vascular abnormalities such as telangiectasias, endothelial swelling with fibrin exudates, hyaline degeneration, thickening and fibrinoid necrosis of vessel walls with perivascular fibrosis, and sometimes vasculitis. Early delayed radiation myelopathy occurs from 6 weeks to 6 months after treatment, and improvement follows in most cases within 2 to 9 months, although in some instances, symptoms may persist for prolonged periods. The cervical and thoracic spinal cord is the most commonly involved. Clinical signs are generally limited to a Lhermitte’s sign. The spinal cord MRI is usually
normal. Transient demyelination, probably resulting from radiation injury of oligodendrocytes, is likely the main pathogenic mechanism of early delayed myelopathy.\(^{418}\) Late-delayed radiation-induced spinal cord disorders complications include progressive myelopathy and spinal hemorrhage. Progressive myelopathy or delayed radiation myelopathy may follow radiation treatment by 6 months to approximately 10 years. Risk factors include older age, previous irradiation (incidental or medical) particularly during childhood, large radiation port involving the dorsal or lumbar spinal cord, and large radiation dose and fractions. The clinical onset of delayed radiation myelopathy may be acute, but it is more often progressive. Patients can present with para- or tetraparesis with rapid development of sensory and/or motor deficits. The development of a Brown-Séquard syndrome\(^*\) is a classic presentation. Another possible presentation is an ascending transverse myelopathy with bilateral leg weakness and sensory loss up to the level of irradiation. Patients may develop bladder or bowel dysfunction; pain has been occasionally reported. The involvement of the upper cervical spinal cord can cause diaphragm dysfunction. The course of symptoms is difficult to predict; some patients improve and others deteriorate. Despite its lack of specificity, MRI findings are important. Other potential causes of myelopathy should be carefully investigated.

Neuropathic syndromes associated with chest wall/axillary radiation therapy include brachial plexopathy, malignant peripheral nerve tumors, nerve entrapment in a lymphedematous shoulder, and ischemia. Both early onset and late-onset brachial plexopathy occur. Clinically, the plexopathy involves mixed sensory and motor deficits, with or without pain.

Most reports of radiation-induced plexopathy involve the brachial plexus and, although much less common, radiation-induced injury of the lumbosacral plexus has also been reported.\(^{419}\) The risk of RBP from conventionally fractionated radiotherapy (i.e., 5,000 cGy in 200-Gy fractions) is <1% and when the dose per fraction increases to between 2,200 and 4,580 cGy with a total dose of 4,350 and 6,000 Gy, the risk of brachial plexus injury increases to 1.7% to 73%.\(^{420}\) Olsen et al.\(^{421}\) described the incidence and latency period of RBP in 79 patients with breast cancer. Thirty-five percent of patients developed RBP. Fifty percent
had involvement of the entire plexus, 18% of the upper plexus alone, 4% of the lower plexus alone, and a definite level of involvement could not be determined in 28% of patients. RBP began in most patients either during or immediately after radiation treatment. RBP was more common in patients who received combination treatment with chemotherapy and radiation than with radiation alone. Clinically, plexopathy presents with subjective paresthesia or dysesthesia and progresses with the development of hypesthesia then anesthesia. Neuropathic pain is generally considered rare and moderate in intensity. Motor weakness is progressive, often delayed by several months, and then associated with fasciculations and amyotrophy. Zeidman et al. estimate that up to 20% of patients with radiation-induced plexopathy may report severe pain. Mondrup et al. noted that the most prominent symptoms for RBP were numbness or paresthesia (71%) and pain (41%), whereas the most prominent objective signs were decreased or absent muscle stretch reflexes (93%) closely followed by sensory loss (82%) and weakness (71%). The neurologic deficits are relentlessly progressive and ultimately result in a useless limb. In contrast to malignant infiltration, patients with radiation injury to the plexus tend to have abnormal sensory and normal motor nerve conduction studies and characteristically manifest more fasciculations or myokymia on EMG than patients with neoplastic disease.

Radiation induced of the lumbosacral plexus has been reported after intracavitary radium implants for carcinoma of the cervix. Paresthesias, distal weakness progressing proximally, but rarely pain occur in the lower extremities 2 to 3 months after radiation of the sacral plexus. Weakness commences distally in the L5–S1 segments and slowly progresses. Painless, indolent leg weakness occurs early in radiation disease, whereas pain with or without unilateral weakness usually characterizes tumor plexopathy. Radiation disease often results in serious neurologic disability.

The diagnosis of radiation plexopathy can be supported by various studies. Approximately 60% of patients with radiation-induced plexopathy will show myokymia on EMG. MRI imaging of the plexus is also helpful. Enhancement of nerve roots and T2-weighted hyperintensity usually suggests tumor; generally, radiation plexopathy does not produce nerve enhancement, MRI appearances for RBP are isointense of
hypointense relative to muscle on T2-weighted images and thus distinguishable from tumor infiltration which is usually hyperintense, although increase in T2 signal may be present. PET/CT scanning is also helpful in distinguishing tumor from radiation changes. Features distinguishing radiation plexopathy from neoplastic plexopathy are listed in Table 42.24.

**Chemotherapy-Induced Peripheral Neuropathy**

Drug-induced neurotoxicity can affect nerve fibers or neuronal bodies (generally the DRG of the primary sensory neurons). Among the toxicities associated with chemotherapy, damage of the peripheral nervous system is particularly frequent and potentially severe. CIPN causes numerous debilitating symptoms, impairs functional capacity, and results in dose reductions or possible cessation of chemotherapy. CIPN is a predominantly sensory neuropathy that may be accompanied by motor and autonomic changes. The drugs most commonly reported to cause CIPN include the platinum-based drugs (particularly oxaliplatin and cisplatin), the vinca alkaloids (particularly vincristine and vinblastine), the epothilones (ixabepilone), the taxanes (paclitaxel, docetaxel), the proteasome inhibitors (bortezomib), and immunomodulatory drugs (thalidomide) (Table 42.25). The prevalence of CIPN is 68% in the first month after starting chemotherapy, 60% at 3 months, and 30% at 6 months or more with different drugs were associated with differences in CIPN prevalence.

The clinical manifestations of CIPN are frequently predominantly subjective and manifest as pure sensory symptoms and are most commonly reported as progressive distal symmetrically distributed symptoms of numbness, tingling, pins and needles, burning, decreased or altered sensation, or increased sensitivity that may be painful in the feet and hands. The primary clinical objective in assessing patients is to determine the presence and severity of CIPN-associated symptoms that result in interference with activities of daily living because this finding is critical for treatment decisions. Symptoms of motor weakness due to CIPN are less commonly reported and when present are observed in patients with more persistent and severe sensory findings. If the patient has coexisting
diabetes, it can be quite difficult to differentiate the onset or progression of diabetic neuropathy from CIPN, which may be mitigated in some instances if the physician has carefully evaluated and recorded the patient’s baseline neurologic findings and symptoms prior to initiation of the neurotoxic chemotherapy. Diabetic neuropathy can be asymmetrical or symmetrical, focal or diffuse, or manifests as mononeuritis multiplex in its involvement and has many different clinical forms. The most common form of diabetic neuropathy, distal symmetrical polyneuropathic form, has clinical symptoms similar to CIPN.

The most commonly observed clinical findings of CIPN are symmetrical progressive onset of the following sensory symptoms and findings in a stocking-glove distribution: paresthesias, hyperesthesias, hypoesthesias, and dysesthesias, which more commonly appear earlier and with more pronounced symptoms in the toes and feet, with later involvement of the fingers and hands. Concurrent loss of deep tendon reflexes (loss of distal usually earlier than proximal) in the affected extremities with sensory deficits is an important diagnostic sign associated with greater neurosensory damage. Sensory findings, including diminished or absent proprioception, vibration, touch, two-point discrimination, sharp/dull discrimination, temperature, and touch/pain are typically diminished in the stocking-glove distribution in symptomatic patients (Table 42.25).

<p>| TABLE 42.25 Summary of the Most Frequent Symptoms and Signs Associated with the Administration of Commonly Used Chemotherapy Drugs |
|---|---|---|
| Class | Drug | Symptoms/Signs |
| Platinum | Cisplatin (carboplatin) | Distal, symmetric, upper and lower limb impairment/loss of all sensory modalities. Large myelinated fibers are more severely involved so that sensory ataxia and gait imbalance are frequent. Early reduction/loss of DTR. Coasting phenomenon is frequent. Carboplatin is generally much less neurotoxic than cisplatin. |
| Oxaliplatin | Acute | Cold-induced transient paresthesias in mouth, |</p>

**NOTE:** Coasting is worsening of neuropathy signs/symptoms over months after drug withdrawal. DTR, deep tendon reflex.

CIPN has a high degree of similarity in the pattern and spectrum of clinical manifestations caused by different chemotherapeutic agents (e.g., vinca alkaloids, platinum agents, thalidomide, bortezomib, and taxanes), which includes the length-dependent, symmetrical stocking-glove distribution with predominantly sensory symptoms noted by the patient. CIPN generally arises as a consequence of the disruption of axoplasmic microtubule-mediated transport, distal axonal (wallerian) degeneration, and direct damage to the sensory nerve cell bodies of the DRG. Demyelination (diffuse or segmental) secondary to chemotherapy is an uncommon finding (but occasionally observed with cisplatin), and when observed, it is typically a secondary and isolated finding relative to the extent of axonal and DRG pathologic findings. It is important to recognize that CIPN commonly follows the administration of chemotherapeutic agents that cannot appreciably distribute across the blood–brain barrier (e.g., taxanes, platinum agents, vinca alkaloids, thalidomide, and bortezomib). CIPN is commonly characterized as a distal axonopathy, more less commonly as a neuronopathy, and may simultaneously manifest with both forms in some patients. To improve accurate and reliable reporting of chemotherapy-induced neuropathy, various grading systems have been developed. Table 42.7 is an example of a grading scale for evaluation of CIPN.

ORAL MUCOSITIS
Ulcerative lesions in the mucosa of patients undergoing chemo- or radiation therapy characterize oral mucositis. Oral lesions can result in dysphagia, dysarthria, and odynophagia. Patients may complain of oral burning or severe pain that may disrupt oral intake resulting in parenteral or enteral nutritional supplementation. The risk of oral mucositis increases as a function of the type of cancer therapy used, with the lowest risk occurring with “gentler” chemotherapeutics such as gemcitabine (Gemzar) and the higher risk occurring with more aggressive agents such as 5-fluorouracil (5-FU) and cisplatin and/or radiation therapy. It may drastically affect cancer treatment as well as the patient’s QOL. The incidence and severity of mucositis has both interpatient and treatment variability. It is estimated that there is 40% incidence of mucositis in
patients treated with standard chemotherapy, and this will increase not only with the number of treatment cycles but also with previous episodes.\textsuperscript{435} Oral mucositis is one of the most frequent adverse effects of allogenic or autologous hematopoietic stem cell transplant with 67\% to 80\% developing a severe grade of mucositis particularly with allogenic transplants.\textsuperscript{436,437} The overall incidence of oral mucositis and xerostomia is approximately 80\% in patients with squamous cell carcinoma of the head and neck who are treated with radiation therapy directed at the oral and pharyngeal regions\textsuperscript{438} and is a frequent cause of treatment breaks.\textsuperscript{439} Oral mucositis is typically diagnosed based on the clinical appearance, location, timing of oral lesions, and use of certain types of therapy known to be associated with mucositis. Other common conditions can have a similar clinical presentation to oral mucositis and may confuse the differential diagnosis. They include oral candidiasis, herpes simplex virus, and graft-versus-host disease (GVHD) in transplant patients.

Commonly used scales for the assessment of oral mucositis include National Cancer Institute Common Toxicity Criteria Stomatitis and WHO toxicity grading scale. The WHO oral toxicity scale is a relatively simple assessment for oral mucositis with grades 3 and 4 considered as evidence of severe mucositis (Table 42.26).

GRAFT-VERSUS-HOST DISEASE

Indications for SCT include the treatment of many different malignant and nonmalignant hematologic conditions, solid tumors, and metabolic and autoimmune diseases. SCT may be autologous, syngeneic, or allogeneic depending on whether the owner patient, another genetically identical or nonidentical individual, donates the hematopoietic stem cells (of bone marrow, peripheral blood, or cord blood origin) to reconstitute hematopoiesis. After transplantation, donor-derived T cells, GVHD can result in a range of issues from a mild skin rash to a life-threatening and, in some instances, life-ending complication. GVHD primarily occurs in many organs but most notably in the skin, lungs, gastrointestinal tract, liver, eyes, mucosa, and musculoskeletal system. GVHD is an immune-mediated reaction in which donor T cells recognize the host as antigenically foreign, causing donor T cells to expand and attack host tissues. GVHD may be acute or chronic based on the time of onset after SCT. Acute GVHD typically occurs within 100 days after transplantation and classically presents as erythema, maculopapular rash, nausea, vomiting, anorexia, profuse diarrhea, ileus, or cholestatic liver disease. Clinical manifestations of chronic GVHD nearly always present during the first year after transplantation, but some cases develop many years after transplant. Chronic GVHD may occur in 30% to 70% of allogenic hematopoietic cell transplantation patients. Chronic GVHD is a syndrome of variable clinical features resembling autoimmune and other immunologic disorders, such as scleroderma, Sjögren’s syndrome, primary biliary cirrhosis, wasting syndrome, bronchiolitis obliterans, immune cytopenias, and chronic immunodeficiency. All parts of the eye may be affected, and keratoconjunctivitis sicca is the most common presenting manifestation of chronic ocular GVHD. Manifestations of chronic GVHD may be restricted to a single organ or site or may be widespread, with profound impact on QOL. Unlike the acute form of the disease that is mediated by direct cytotoxic T-cell attack on host tissues, pathophysiology of chronic GVHD
is significantly more complex and the mechanisms of dysregulated adaptive and innate immune responses are poorly understood.\textsuperscript{441}

**Metastatic Epidural Spinal Cord Compression**

MESCC is compression of the dural sac and its contents, spinal cord or cauda equina, or both, by an extradural tumor mass. Because of a rich vascular supply of the bone marrow and extensive lymphatic drainage, the spine is a common site for metastatic disease and up to 40\% of patient with cancer developing spinal metastases and 10\% to 20\% progressing to symptomatic cord compression.\textsuperscript{442} The vast majority of spinal metastases in people with MESCC are found in the vertebral body with or without extension into the posterior elements and also into paravertebral regions and the epidural space; these metastases most commonly affect the thoracic spine (70\%), followed by the lumbar spine (20\%), multiple spinal regions (20\% to 35\%), and less commonly the cervical spine and sacrum.\textsuperscript{443,444} MESCC is the most common neurologic complication of cancer after brain metastases. MESCC usually occurs in patients with disseminated disease but may present as an isolated finding in patients not diagnosed with cancer. Even though the progression of nearly all types of malignancies can be complicated by the occurrence of spinal cord compression, the most common tumors arise from breast, lung, or prostate cancer, followed by renal cell cancer, gastrointestinal, thyroid, sarcoma, and lymphoreticular malignancies.\textsuperscript{445,446} Patients may present with malignant epidural spinal cord compression without a known history of a primary cancer.\textsuperscript{447} If left untreated, virtually 100\% of patients will become paraplegic. Although most patients with MESCC have limited survival, up to one-third will survive beyond 1 year.\textsuperscript{448}

**MECHANISM**

Most epidural spinal cord compression comes from a solid tumor metastasis to the vertebral body, which spreads posteriorly to the epidural space (observed in 85\% to 90\% of cases) and presents as an osteolytic bony lesion in 70\% of patients resulting in anterior compression of the spinal cord. Other tumors such as lymphoma, paragangliomas, and
neuroblastomas invade the epidural space through the intervertebral foramina from the paravertebral tissues account for 10% to 15% of cases. The frequency of metastasis appears to correlate with the volume of bone in that region of the spine, presumably related to blood flow and blood-borne metastasis. As such, the thoracic spine is most likely to have a metastatic lesion due to its 12 vertebral bodies; the lumbosacral spine is the next most likely to have involvement due to the large size of the vertebral bodies, and the small cervical vertebral bodies are the least likely to be affected. MESCC damages the cord by direct compression, which causes demyelination and axonal damage, and by secondary vascular compromise. The most significant damage caused by MESCC appears to be vascular in nature. The epidural tumor causes epidural venous plexus compression, which leads to spinal cord edema. The increased vascular permeability and edema lead to increased pressure on the small arterioles. Capillary blood flow diminishes as the disease progresses, leading to white matter ischemia. Prolonged ischemia eventually results in infarction and permanent cord damage. The early mechanism of injury is vasogenic edema of white matter with direct involvement of cytokines, inflammatory mediators, and neurotransmitters. Production of VEGF is associated with spinal cord hypoxia and has been implicated as a potential mechanism of damage after spinal cord injury. The beneficial effects of dexamethasone in the CNS are at least partly mediated by its downregulation of VEGF expression. In the later stages of MESCC, vasogenic edema is replaced by ischemic-hypoxic neuronal injury and by onset of cytotoxic edema, a transition associated with the glutamate system that is characterized by release of presynaptic glutamate, influx of calcium through N-methyl-D-aspartate (NMDA)-linked ion channels, excitotoxic neuronal injury, and neuronal disintegration.

**PATTERN OF PAIN**
The pattern of pain associated with epidural metastases may be local, radicular, referred, or funicular. The majority of patients have local pain. Local pain over the involved vertebral body, which results from involvement of the vertebral periosteum, is dull and exacerbated by recumbency. The worsening of pain on recumbency is the most distinctive
feature of the pain of epidural spinal cord compression. Many patients with
cord compression find they must sleep in a sitting position. Even if pain is
absent in the lying position, movements such as turning over in bed or
rising from a lying position may be particularly painful.

Radicular pain from compressed or damaged nerve roots is usually
unilateral in the cervical and lumbosacral regions and bilateral in the
thorax, where patients often describe it as a tight band across the chest or
abdomen. The pain is experienced in the overlying spine, deep in certain
muscles supplied by the compressed root, and in the cutaneous distribution
of the injured root. The pain is usually least severe when the patient is in a
position that minimizes compression of the root and most severe in
positions that compress or stretch the root. Increasing
intraspinal/intracranial pressure, for example, coughing, sneezing, and
straining, can also increase pain.

Referred pain in the midscapular region or in both shoulders may
accompany cervicothoracic epidural disease, and bilateral SI and iliac crest
pain occurs with L1 vertebral compression. The pain has a deep aching
quality and is often associated with tenderness of subcutaneous tissues and
muscles at the site of referral. Maneuvers that affect local pain usually
have the same effect on referred pain. When pain is referred from
pathologic processes in the low back, it is usually appreciated in the
buttocks and posterior thighs. Pain from the upper lumbar spine is often
referred to the flank, groin, and anterior thigh.

Funicular pain may be an early complaint in patients with cord
compression and presumably results from compression of the ascending
sensory tracts in the spinal cord. It usually occurs some distance below the
site of compression and has hot or cold qualities in a poorly localized
nondermatomal distribution. The pain is less sharp than radicular pain but
like root pain is usually exacerbated by movements that stretch the
compressed structure (neck flexion, straight leg raising) or that increase
intraspinal pressure (coughing, sneezing, straining). Funicular pain may be
experienced some distance from the site of compression. Patients with
cervical cord compression may present with lower extremity pain only or
sciatica-type symptoms with cervical or thoracic cord compression.
PRESENTATION AND PHYSICAL FINDINGS
The vast majority of patients have a known cancer diagnosis. Even without a prior cancer diagnosis, MESCC should be suspected in anyone who presents with progressively worsening back pain, incontinence, or paraplegia, especially in the high-risk population such as long-time smokers or women with a strong family history of breast cancer. The clinical picture of MESCC is uniformly reported as various combinations of pain, weakness, sensory loss, and autonomic dysfunction. Table 42.27 summarizes the signs of spinal cord compression.

</table>

Severe, local back pain that gradually increases in intensity over time is the earliest and most common symptom. In general, pain occurs an average of 7 weeks before other neurologic deficits. As the bone marrow does not contain pain receptors, discomfort usually occurs only when the enlarging mass invades the periosteum, paravertebral soft tissues, or nerves. Pain may also be caused by the mass effect of the spinal cord compression itself, spinal instability, pathologic fracture, and the inflammatory and nociceptor stimulating substances that malignant cells secrete. Progressive pain occurs practically always in patients with MESCC. Weakness is the second most common symptom, which develops in approximately 60% to 80% of patients. As the thoracic cord is the most common site of epidural metastases, weakness usually involves the lower limbs causing gait disorders. Gait difficulties may also be caused by sensory ataxia presumably due to posterior column compression. Certain spinal tracts appear to be more vulnerable to compression than others.
The corticospinal tracts and posterior columns are particularly vulnerable, the spinothalamic tracts and descending autonomic fibers less so. As a result, weakness, spasticity, and reflex hyperactivity tend to be the earliest signs of spinal cord compression, with paresthesias and vibratory and position sense loss occurring soon thereafter. Loss of pain and temperature sensation and of bladder and bowel function usually occur late in the course of spinal cord compression. The spinocerebellar pathways are also sensitive to compression, and at times, ataxia may be the only sign of spinal cord compression. Sensory symptoms are less common and may predate objective sensory signs. Patients may complain of paresthesias, decreased sensation, and numbness of the toes and fingers which may extend one to five dermatomes below the true level of cord compression. Cauda equina syndrome may occur when the site of the lesion is below the first lumbar vertebra. The main clinical signs are decreased sensation over the buttocks, posterior thighs, and perineal region in a saddle distribution, with most patients exhibiting decreased anal sphincter tone on examination. Urinary retention with overflow incontinence can be an important predictor.\textsuperscript{458}

Ventafridda et al.\textsuperscript{459} reported an association between Lhermitte’s sign and epidural spinal cord compression. In their series, the sign appeared at an early stage of compression, particularly with thoracic lesions but may also be seen with cervical MESCC. Lhermitte’s sign, however, lacks specificity and also occurs in patients with radiation myelopathy,\textsuperscript{460} following cisplatin\textsuperscript{461} or oxaliplatin\textsuperscript{462} chemotherapy, and in noncancer-related problems such as multiple sclerosis\textsuperscript{463} and subacute combined degeneration of the cord from vitamin B\textsubscript{12} deficiency.\textsuperscript{464}

Differential diagnosis for the individual patient with back pain includes intramedullary metastases, herniated disks, epidural hematoma or abscess, transverse myelopathy, and subluxation of the spine from pathologic fractures.

\textbf{INVESTIGATIONS}

Definitive diagnosis of MESCC is by radiographic investigation. Bone scan is an effective screening procedure of vertebral involvement, but definitive diagnosis is by MRI. MRI not only demonstrates the extent of
epidural involvement but also allows visualization of the degree of involvement of bony structures and surrounding tissues. Epidural metastases are best visualized with postcontrast imaging, which allows clear delineation of the border of the metastasis in most cases.\textsuperscript{465}

**PROGNOSIS**

MESCC is associated with reduced life expectancy and QOL.\textsuperscript{452} Outcome of MESCC can be paraplegia or paraparesis. Without treatment, all patients would develop paraplegia and survival rates for nonambulatory patients are lower than for ambulatory patients.\textsuperscript{466} Treatments for MESCC are intended to maintain or improve QOL by alleviating pain, preserving neurologic function, and assuring spinal stability. The most predictive factors for survival are primary tumor site and pretreatment neurologic and functional status.\textsuperscript{467} The time lapse between diagnosis of the primary cancer and first symptoms of MESCC directly correlated with survival (e.g., a long interval denoted higher survival rate and vice versa). The most important prognostic indicator for the prediction of ambulatory outcome is a patient’s pretreatment motor function.\textsuperscript{467,468} The median survival time for patients with MESCC is 3 to 6 months.\textsuperscript{469,470} Factors associated with longer survival times are the ability to walk before and after treatment,\textsuperscript{467,469,471} radiosensitive tumor histologies,\textsuperscript{469,472,473} no visceral or brain metastases,\textsuperscript{469,474} and a single site of epidural cord compression rather than more than one site.\textsuperscript{475} Survival is also related to the systemic spread of the neoplastic disease. The presence of multiple spinal epidural metastases (around 25\% to 40\% of patients) has been reported as an independent prognostic factor for poorer survival.\textsuperscript{476}

**Stepwise Approach to Pain Assessment**

Assessing cancer pain is more than quantifying pain with a tool and recording it. A stepwise approach to cancer pain assessment begins with data collection and ends with a clinically relevant diagnosis, which will require a thorough understanding of the various components contributing to the pain complaint. At a minimum, this involves determining the etiology of the pain and forecasting its future trajectory. It also involves
determining the number of sites from which pain originates and the probable mechanisms involved. Assessment must include evaluation of the impact of pain on sleep, functional capability, activity level, and psychological well-being. In addition, the clinician must determine the nature, course, and impact of the cancer on the patient. This is an imposing challenge because of the multiple causes of cancer and its impact on the patient. The clinician managing the patient’s pain complaint must have an understanding of the disease process and the management strategy for that disease. A thorough evaluation will allow the clinician to obtain a basis for evaluating therapeutic intervention and determining the long-term goals of the patient and/or the patient’s family.

The goals of the pain-related history are listed in Table 42.28. Optimal assessment includes a detailed description of these goals and classification by both pain syndrome and likely underlying mechanisms (see the following discussion).

**FEATURES OF PAIN HISTORY**

Table 42.29 lists the key components to assessing the characteristics of the pain complaint.
Onset
The onset of tumor-associated pain frequently correlates to the diagnosis of cancer. Preexisting chronic pain complaints need to be differentiated from tumor-associated pain and defined accurately. In cancer survivors, the onset of new pain may indicate the possibility of disease recurrence.477

Location
Many patients with advanced disease have multiple pains at different sites. Pain of tumor origin may be characterized by its location. For example, somatic pain resulting from bone metastases tends to be well localized, whereas visceral pain tends to be diffuse and is often referred. Neuropathic pain may be radicular in location.

Intensity
Numerous professional bodies recommend regular assessment of pain intensity in cancer patients.478–482 These recommendations urge clinicians teach patients and families to use assessment tools in the home to promote continuity of pain management in all settings. Assessment tools for determining the intensity of pain are discussed previously.

Quality
Tumor-associated pain can be nociceptive (somatic or visceral structures) or neuropathic in origin. Each source of pain has distinguishing qualities.
For example, patients tend to describe pain that is neuropathic in origin as burning, shock-like, or shooting in quality, whereas they often describe pain originating from somatic structures as aching, nagging, throbbing, or sharp.

**Timing**
Cancer patients may have constant or intermittent pain. Constant pain is present continuously and usually fluctuates in intensity. Intermittent pain implies that pain is present for definite periods of time and that the patient is relatively pain free between episodes of pain. Patients and their caregivers need to understand the concept of BTP, as should health care providers. BTP is discussed previously.

**Exacerbating/Relieving Factors**
Cancer patients with pain may experience a worsening of their pain over a wide range of activities. Commonly, patients with metastatic disease to weight-bearing bones experience an increase of their pain upon standing or sitting. Patients with breast cancer metastatic to the axillary nodes may have severe pain upon abduction of their upper extremity on positioning for external beam radiation therapy. Knowledge of these factors helps clinicians to design an appropriate pain treatment plan.

**Responses to Previous Analgesic and Disease-Modifying Therapies**
It is important to determine previous opioid use and benefits or side effects encountered during use. Previous unacceptable side effects to a particular opioid may limit successful future titration with the same opioid. Successful tumor shrinkage to chemotherapy or radiation therapy may indicate the need for further evaluation on tumor recurrence.

**Impact of Pain**
The initial pain assessment should elicit information about changes in activities of daily living, such as work and recreational activities, sleep patterns, mobility, appetite, sexual functioning, and mood. Numerous instruments, including symptom checklists and QOL measures may prove
useful in this evaluation and are detailed in Chapter 22.

**Effects of Pain on Activities of Daily Living**

Many patients function quite effectively with a background level of mild pain that does not seriously impair or distract them. As pain severity increases, the pain passes a threshold beyond which it is hard to ignore. At this point, it becomes disruptive to many aspects of the patient’s life. Constant daily pain can significantly impact on a patient’s daily activities. Williamson and Schulz showed that as pain increased over time, restriction in activity occurred, which in turn predicted increases in depressed affect. General measures of functioning should include indicators of physical, psychological, social functional status, and, when appropriate, vocational status. Some impact factors may include interference on general activity, mood, walking, ability to work, relations with others, and sleep. The Pain Disability Index was developed as a self-report measure of general and domain-specific, pain-related disability and is considered to be reliable and valid as a brief measure of pain-related disability (Table 42.30).484

<table>
<thead>
<tr>
<th>TABLE 42.30 Pain Disability Index</th>
</tr>
</thead>
<tbody>
<tr>
<td>The rating scales below are to measure the degree to which several aspects of your life are presently disrupted due to chronic pain. In other words, we would like to know how much your pain is preventing you from doing what you would normally do, or from doing it as well as you normally would. Respond to each category by indicating the overall impact of pain in your life, not just when the pain is at its worst.</td>
</tr>
<tr>
<td>For each of the seven categories of life activity listed, please circle the number on the scale, which describes the level of disability you typically experience. A score of 0 means no disability at all, and a score of 10 signifies that all of the activities in which you would normally be involved have been totally disrupted or prevented by your pain.</td>
</tr>

no disability total disability

6. **Self-care**
   This category includes activities which involve personal maintenance and independent daily living (e.g., taking a shower, driving, getting dressed, etc.).

no disability total disability

7. **Life-support activity**
   This category refers to basic life-supporting behaviors such as eating, sleeping, and breathing.

no disability total disability

Multiple clinical and physiologic factors influence prognosis for patients with advanced cancer. These include symptoms such as anorexia, dyspnea, and fatigue; disease characteristics such as cancer diagnosis, site of metastasis, and comorbidity; laboratory values such as hypoalbuminemia, leukocytosis, and anemia; the clinician’s overall prediction of survival; and performance status.\(^1\) Performance status represents a global assessment of the patient’s level of function. Assessment of performance status is used routinely in oncology and may be used to assess eligibility for clinical trials, determine level of fitness to receive chemotherapy, and follow treatment response. Performance status tables (Tables 42.20 and 42.31) can help the physician assess physical activity levels.\(^2\)\(^3\)

**Psychological State**
Psychological assessment of the cancer patient with pain is imperative and should reflect an understanding of the many factors that modulate distress, such as personality, coping, and both past and present psychiatric disorders. Knowing that the patient has received outpatient or inpatient psychiatric care helps to clarify the psychological risk. Information on how the patient handled previous painful events may provide insight into whether the patient has demonstrated chronic illness behavior.

**Familial, Vocational, Social Function**
The clinician must inquire about the patient’s familial and social resources, financial situation, and the physical environment in which he or she lives. Knowledge of the patient’s and family’s previous experience with cancer, or other progressive medical disease, may provide useful insights into the response to physical illness or the genesis of psychological symptoms. Inquiry into a family history of addiction is helpful to define risk for pain management strategies. Yellen and Cella demonstrated that positive social well-being, as well as having children living at home, predicted patient willingness to accept aggressive treatment.

**QUALITY OF LIFE ASSESSMENT**
Prolongation of survival and maintenance or improvement of health-related QOL is the two important goals within the treatment of individual patients. Due to the severity of symptoms and the toxicity of treatment, QOL is a major area of concern when treating cancer patients in general and elderly patients in particular. QOL is defined as the person’s
evaluation of his or her well-being and functioning in different life domains. It is a subjective, phenomenologic, multidimensional, dynamic, evaluative, and yet quantifiable construct. The routine assessment of QOL may have clinical uses at the individual patient level. These uses include fostering patient–provider communication, identifying frequently overlooked problems, prioritizing problems, and evaluating the impact of palliative and rehabilitative efforts. QOL is sensitive to the treatment of pain and treatment modalities, although pain is not synonymous with poor QOL and constitutes only one important factor determining QOL. In addition, pain reduction is not always attended by the expected improvement in QOL. The Functional Assessment of Cancer Therapy: General (FACT-G) was first developed in 1987 for adult cancer patients and has become one of the most widely used health-related QOL measures in clinical trials and other medical treatment evaluation studies. It has also been validated in thousands of patients of different cancer types. FACT-G is self-reported and consists of questions on physical, functional, emotional, and social/family well-being. Patient responses are recorded on a 5-point Likert-type scale (Table 42.32)

**GENERAL ASSESSMENT**

The initial step in the general assessment of the cancer patient is a complete medical history that reviews the cancer diagnosis; the chronology of significant cancer-related events; previous therapies; and all relevant medical, surgical, and psychiatric problems (Table 42.33). A
detailed history of drug therapy should include current and prior use of prescription and nonprescription drugs, drug allergies/adverse drug reactions, including current side effects. The clinician should inquire about prior treatment modalities for pain. In the course of this assessment, the interviewer should document the patient’s understanding of his or her current disease status. Discussion with other providers involved with the patient’s care will also help determine disease status. Table 42.34 lists the different possible categories for a patient’s clinical status. Because of the high use of opioids and other psychoactive substances in oncology care, a risk assessment for opioid use should be performed. Opioid use risk assessment tools generally are designed to detect opioid misuse prior to initiating long-term opioid therapy, detection of signs of misuse in patient currently using opioids, and general substance (e.g., alcohol) or illicit substance abuse (Table 42.35).

A physical examination, including a neurologic evaluation, is a necessary part of the initial pain assessment (see the following text). A careful review of previous laboratory and imaging studies can provide information about the cause of pain and the extent of the underlying disease (see the following text). Evaluation of concurrent concerns includes other symptoms and related psychosocial problems. Additional investigations are often needed to clarify uncertainties in the provisional assessment. The extent of these investigations must be appropriate to the patient’s general status and the overall goals of care (Table 42.36). In the case of the patient illustrated in Table 42.36, monitoring of the patient’s disease status required specialized testing over a period of time.

NOTE: Patients with chronic myeloid leukemia have BCR-ABL gene (a.k.a. the Philadelphia chromosome). The Philadelphia chromosome produces the BCR-ABL gene that signals the bone marrow to continue making abnormal white blood cells. Polymerase chain reaction (PCR) is used to detect and sometimes to quantify this gene. The clinical BCR-ABL assays for both p210 and p190 previously showed undetectable transcripts for both assays. The patient was then identified as having a rare e13/e14-a3 (also known as b2/b3-a3) transcript that is not detectable by. This transcript cannot be detected using commercially available quantitative PCR assays 9 standard P210 or P190 assays and requires a special qualitative assay to detect it. In this case, disease is monitored by BCR-ABL fluorescence in situ hybridization and qualitative PCR that detects rare variants. Over time, the patient went into complete remission after treatment with bosutinib.

ASSOCIATED SYMPTOMS
Cancer patients may experience multiple symptoms with symptoms varying by type of treatment, gender, age, and cancer type. Cancer treatment and survivorship can result in multiple concurrent symptoms resulting in cognitive dysfunction, fatigue, insomnia, pain, dyspnea, appetite loss, constipation, diarrhea, nausea, and vomiting. Some data suggest that fatigue, cognitive limitations, depression, anxiety, sleep problems, pain, and sexual difficulties persist, for up to 10 years after treatment, regardless of cancer type. Not surprisingly, cancer patients have a much greater symptom burden completed to a noncancer general medical population. Symptoms can affect pain management, and it is important to clarify the degree to which each symptom induces or exacerbates other physical or psychological symptoms. The evaluation should determine whether symptoms are concurrent but unrelated in etiology, concurrent and related to the same pathologic process, concurrent
with the one symptom directly or indirectly a consequence of a pathologic process initiated by another symptom, or concurrent with one symptom a consequence or side effect of therapy directed against the other. Fatigue may be the most prevalent symptom reported by cancer patients with one study suggesting that 45% of patients undergoing active treatment and 29% of survivors have moderate to severe levels of fatigue. Disease progression increases the number of factors diminishing QOL as well as the prevalence and severity of physical and psychological symptoms. In addition to pain, patients with advanced cancer have fatigue, generalized weakness, dyspnea, delirium, nausea, and vomiting. These symptoms may have a major impact on both pain reporting and QOL. The Memorial Symptom Assessment Scale (MSAS) is a patient-rated instrument that was developed to provide multidimensional information about a diverse group of common symptoms. The MSAS is a reliable and valid instrument for the assessment of symptom prevalence, characteristics, and distress.

LABORATORY AND IMAGING DATA
Careful review of previous laboratory and imaging studies can provide important additional information. Specific radiologic or laboratory tests may help the clinician understand the pathophysiology of symptoms and their relationships to the disease. This information provides the basis for a provisional pain diagnosis that clarifies both the status of the disease and the nature of other concurrent concerns that may require therapeutic focus.

Some patients require multiple studies to evaluate the pain problem, clarify extent of disease, or to assess other symptoms. Assistance from physicians in other disciplines, nurses, social workers, psychologists, or others may prove necessary to evaluate related physical or psychosocial problems identified during the initial assessment. It is appropriate and useful to review the findings of this evaluation with the patient, family, and other appropriate persons, so that they can prioritize problems according to their importance for the patient. It is also useful to identify potential outcomes that would benefit from contingency planning, including the need for advanced medical directives, the evaluation of home care resources, and prebereavement interventions with the family.
PHYSICAL EXAMINATION
A physical examination, including a neurologic and musculoskeletal examination, is a necessary part of the initial pain assessment. The need for a thorough neurologic assessment is justified by the high prevalence of painful neurologic conditions in the cancer population. The physical examination should clarify the underlying causes of the pain problem, detail the extent of the underlying disease, and discern the relation of the pain complaint to the disease. The examination should also help define biomechanical problems that impair or impede function.

DIAGNOSIS
The provisional pain diagnosis includes inferences about the pathophysiology of the pain and an assessment of the pain syndrome. Evaluation of concurrent concerns includes other symptoms and related psychosocial problems. Additional investigations can often clarify uncertainties in the provisional assessment. Accuracy in pain diagnosis results in appropriate and disease-directed pain management.

Summary
Cancer is one of the medical conditions that patients fear the most. In addition to anxiety about cancer as a potentially lethal disease, patient and family expectancies that pain is an inevitable and untreatable consequence are major sources of distress. Controlling pain associated with cancer is a major health care problem. Lack of expertise by clinicians in assessing pain is an important cause of poor pain control. A stepwise approach to cancer pain assessment begins with a systematic clinical interview and ends with a clinically relevant diagnosis that outlines the mechanisms and contributing factors to the pain complaint. It involves determining the etiology of the pain and forecasting its future trajectory. It also involves determining the number of sites from which pain originates and the probable mechanisms involved. Assessment must include evaluation of the impact of pain on sleep, functional capability, activity level, and psychological well-being. In addition, the clinician must determine the nature, course, and impact of the cancer on the patient. A thorough
evaluation will allow the clinician to obtain a basis for evaluating therapeutic intervention and determining the long-term goals of the patient and/or the patient’s family.

As many different health care professionals become involved with the cancer pain patient before, during, and after cancer care, successful pain management requires that the person or persons responsible for pain management adopt, or at least, become familiar with an interdisciplinary longitudinal approach to care. Pain management should never assume the primary focus of oncology care but should be an important supportive service throughout the care paradigm.

*Lasègue test (straight leg maneuver) is performed when the clinician lifts the extended leg of a patient in a supine position. A positive response occurs when the pain pattern of the lumbar radiculopathy is reproduced. The test should be stopped when the pain is reproduced or maximum flexion is achieved. The crossed straight leg maneuver is performed by raising the unaffected leg in a similar manner to the straight leg test. The examiner looks for the reproduction of radicular pain with elevation of the opposite leg.

†Spurling test requires the examiner to patient extends the neck and rotates and laterally bends the head toward the symptomatic side; an axial compression force is then applied by the examiner through the top of the patient’s head; the test is considered positive when the maneuver elicits the typical radicular arm pain.

‡Short, unpleasant sensation of numbness, tingling, and often electric-like discharge going down from the neck to the spine and extremities, triggered by neck flexion.

**Brown-Séquard syndrome results in ipsilateral pyramidal deficit and posterior column signs and, contralaterally, loss of spinothalamic function.

††Myokymia represents spontaneous discharges accompanied by wavelike muscle quivering.

‡‡An abnormality in peripheral nerve function resulting in degeneration of the terminal regions of sensory axons and also to motor axons.

***The result of direct toxic damage of neuronal cells in the DRG.

In 2008, the International Association for the Study of Pain (IASP) launched a global year against cancer pain to focus attention on the pain and suffering affecting patients with cancer. In 2011, the Institute of Medicine\(^1\) recognized chronic noncancer pain management as a public health challenge. In spite of increased attention on assessment and management, pain continues to be a prevalent symptom in patients with cancer.\(^2\) The consequences of unrelieved cancer pain can be devastating and include functional impairment, social isolation, and emotional distress. Inadequate treatment of cancer pain persists despite decades of efforts to provide clinicians with information about analgesics and pain-relieving techniques. The problems associated with undertreatment of cancer pain are outlined in Table 43.1. Although the reasons for inadequate treatment of cancer pain are complex, certain barriers to adequate pain relief are identified. These barriers primarily relate to health care professionals; patients, families, and the public; health care implementation and reimbursement; and drug regulatory systems.\(^3\)

|                   | ○ Perceived lack of time or inadequate amount of time spent in physician’s office discussing pain problems |
|                   | ○ Poor compliance with prescribed medications                 |
|                   | ○ Fear of addiction                                           |
Cancer pain management guidelines typically incorporate pharmacologic, anesthetic, neurosurgical, and behavioral approaches. The World Health Organization (WHO) developed the most widely accepted approach for the treatment of cancer pain. The WHO algorithm largely focuses on pain intensity and the use of pharmacotherapy. Some have questioned the current appropriateness of the WHO guidelines, which may be considered outdated and not specific to the pharmacologic and interventional options used in contemporary pain management practices. Although the amount and quality of evidence regarding the use of opioids for treating cancer pain is low, opioid therapy remains the cornerstone for pain management in oncology. In the United States, physicians’ concerns about regulatory scrutiny and the possibility of unwarranted investigation by regulatory agencies negatively affect their prescribing of opioid analgesics to treat pain. In addition, it is widely reported that the United States is experiencing an epidemic of drug overdose deaths particularly from the use of opioid medications. The past two decades have been characterized by increasing abuse and diversion of prescription drugs, including opioid medications (see “Substance Abuse in Oncology” section). In a study of malpractice claims associated with medication management for chronic pain, issues in care (including death) were noted when patients did not cooperate in their care and with inappropriate medication management by physicians. Factors associated with death in this study included the use of long-acting opioids, additional concomitant psychoactive medications, and the presence of three or more factors commonly associated with medication misuse. In 2016, the U.S. Drug Enforcement Administration indicated that prescription drugs, heroin, and fentanyl were the most significant drug-related threats to the United States. The misuse of prescription opioids is associated with misuse of
illicit opioids and nonmedical use of prescription opioids is a significant risk factor for heroin use,\textsuperscript{20} emphasizing the need for continued prevention efforts around prescription opioids. Regardless of age, gender, or type of user, the majority who misuse prescription pain relievers obtained the drugs from a friend or relative with the second most common source from a doctor.\textsuperscript{21} Particularly for chronic noncancer pain, there is insufficient evidence to determine the effectiveness of long-term opioid therapy for improving pain and function, but there is increasing evidence to support the evidence for a dose-dependent risk for serious harm.\textsuperscript{22} Higher opioid doses (50 mg per day or more of morphine) are associated with increased risk of opioid overdose death or adverse drug-related events.\textsuperscript{23,24} Although the overall rate of overdose is lower among patients with cancer compared with other patients, there was a statistically significant association of prescribing patterns with overdose risk among patients with cancer receiving opioid therapy.\textsuperscript{23} In response to persistent public health concerns regarding prescription opioids, the U.S. Food and Drug Administration (FDA) developed a multipart action plan in response to the opioid epidemic,\textsuperscript{25} and many states and health care systems have implemented legislation and policies intended to regulate or guide opioid prescribing.\textsuperscript{26} Unfortunately, data on state policy and systems-level interventions are limited and inconsistent.\textsuperscript{27} Patients with cancer and other significant comorbidities have a higher prevalence for polypharmacy and greater risk for drug–drug interactions, adverse drug events, hospitalizations, and increased mortality.\textsuperscript{28–31} Concurrent sedative-hypnotic use even at low opioid doses poses substantially greater risk of opioid overdose.\textsuperscript{32,33} In spite of these concerns, clinicians have an ethical and professional responsibility for safe and appropriate pain management in cancer patients.

Pain management and relief can be achieved by several means (Table 43.2). Successful pain management requires an accurate diagnosis of the etiology of the pain complaint(s) and tailoring treatment to the individual patient: matching drug treatment, anesthetic, neurosurgical, psychological, and behavioral approaches to the patient’s needs. Successful management requires that the person or persons responsible for pain management be familiar with all these aspects of care and with the uniqueness and challenges of pain in oncology patients. Evidence-based medicine,
systematic reviews, meta-analyses, and guidelines are increasingly incorporated into modern pain management. Scientific data and relevant evidence employing methodologic, rational judgments, analysis, and understanding of current knowledge can then be applied in clinical settings. In the areas of chronic noncancer and cancer-associated pain, evidence-based decision making for pharmacotherapy is lacking and decisions for pain management in oncology is frequently extrapolated or inferred from chronic pain situations. Often, practitioners must rely on clinical practice guidelines, limited clinical trial data, case reports, or anecdotal information for clinical decision making. Clinical practice guidelines are systematically developed statements that aim to help physicians and patients reach the best health care decisions. Guidelines and recommendations for management of cancer pain have largely focused on relieving acute pain or pain associated with advanced disease. Not all patients with cancer experience tumor-related pain, and management principles differ depending on the source of pain and these recommendations are not appropriate for oncology patients with nonmalignant sources of pain or for pain management in cancer survivors. However, pharmacotherapy remains the optimal and preferred modality for symptomatic pain management in oncology, but safe and effective drug prescribing practices must be observed and implemented. Since 1986, the focus of cancer pain treatment has been the use of strong opioids based on the WHO’s analgesic ladder. Changing societal factors in the last 15 years suggest changes in the distribution of drug use disorders in the general US adult population. Prescriptions for opioid analgesics and other psychoactive medications with addiction potential have increased greatly, with consequences such as drug overdoses. Comparisons of 12-month and lifetime Diagnostic and Statistical Manual of Mental Disorders (4th ed., DSM-IV) drug use disorder prevalence in the general adult population in 2001 to 2002 (2.0% and 10.3%, respectively) and 2012 to 2013 (4.1% and 15.6%, respectively) indicate that rates of 12-month drug use disorders more than doubled, whereas rates of lifetime drug use disorders increased by 50%. Using Diagnostic and Statistical Manual of Mental Disorders (5th ed., DSM-5) criteria drug use in 2012 to 2013 disorder, prevalence of 12-
month and lifetime drug use disorder were 3.9% and 9.9%, respectively.\textsuperscript{43} Drug use disorder was generally greater among men, white and Native American individuals, younger and previously or never married adults, and those with lower education and income. A lower prevalence of drug abuse has been reported in the cancer population, with 3% of psychiatry consultations in a single cancer center in 1990 being requested for managing issues related to drug abuse.\textsuperscript{44} Similarly, a low prevalence of drug abuse was reported by the Psychiatric Collaborative Oncology Group study in 1983, in which fewer than 5% of patients in ambulatory care met the criteria for a substance abuse disorder.\textsuperscript{45} This low prevalence may not be an accurate reflection of the true prevalence because of underreporting. The prevalence of substance abuse in cancer patients is largely understudied and needs clarification. Patients with cancer are known to have an increased risk of psychiatric symptoms and disorders, cardiovascular diseases, and suicide.\textsuperscript{46–48} Living or being diagnosed with cancer can induce severe psychological stress.\textsuperscript{49} In a retrospective review of 204 supportive care clinic oncology patients (with the majority having active cancer) considered to be at risk for substance abuse based on history or behaviors, 46% had evidence of use of nonprescribed opioids, benzodiazepines, or illicit drugs such as heroin or cocaine, and 39% had inappropriately negative urine toxicology, raising concerns for diversion.\textsuperscript{50}

2179
Safe and appropriate medication prescribing practices are of paramount importance in the oncology pain population. The challenges presented to clinicians are numerous and include educational deficits, time restraints, and limited access to all types of care. New challenges to access are occurring as a result of interventions designed to combat the prescription drug abuse epidemic, with fewer clinicians willing to prescribe opioids, pharmacies reluctant to stock the medications, and payers placing strict limits on reimbursement. In the era of personalized medicine, Hui and Bruera suggested that pain management may be tailored to the individual need by use of a personalized pain goal, and this can be obtained by asking a patient to identify the maximal intensity of pain from 0 to 10 (0, no pain; 10, worst pain) that would still be considered comfortable. The concept is a personalized pain goal is attractive but managing pain by pain scores can be problematic, and more appropriate goals may be to identify a pain management plan that results in a reduction in interference in activities of daily living and improvement in quality of life and overall functional ability.

**Cancer Pain Management Overview**

Successful management of the cancer patient with pain ultimately depends on the ability of the clinician to accurately assess problems, identify and evaluate the components that contribute to the pain complaint, and formulate a plan for continuing care that is responsible for the evolving goals and needs of the patient and the patient’s family (see Chapter 42). In general, the goals of patient care in oncology are often complex, but they broadly include prolonged survival, and optimizing comfort and function with associated improved quality of life. Adoption of these goals logically leads to a multimodality treatment approach targeted to specific problems (Fig. 43.1).
Comprehensive cancer care encompasses a continuum that progresses from disease-oriented, curative, life-prolonging treatment through symptom-oriented, supportive, and palliative care extending to terminal-phase hospice care. Pain management is, and should be, an integral component of comprehensive cancer care. Designing an effective pain control strategy for the individual patient requires knowledge of the ways in which a patient’s cancer, cancer therapy, and pain therapy can interact. Collaboration with different health care providers (such as medical oncologists and radiation oncologists) is essential to successful pain management.

Two important aspects of cancer affect management and include the oncologist’s ability to treat the cancer and the ability to assess the components of the tumor pathophysiology that of themselves do not cause pain (the cancer’s “nonpain” pathophysiology). The ability to treat cancer modifies the need for pain management (successful treatment reduces the likelihood of persistent tumor-related pain) and the appropriateness of invasive pain procedures. Cancer nonpain pathophysiology can interfere with the oral administration of medications, narrow the patient’s therapeutic window for analgesic drugs, limit the effectiveness of psychological pain therapies, and complicate or preclude invasive pain-reducing procedures. In addition, cancer therapy can interfere with, or enhance, pain therapy and vice versa. Antineoplastic treatment can interfere with pain therapy by causing additional pain or by producing other adverse effects such as fatigue and gastrointestinal (GI)
disturbances. Cancer treatment can enhance pain therapy by reducing the extent of tumor burden, by acting as an adjuvant analgesic, and, often times, by providing intravenous access for parenteral drug administration to patients who require it. Pain therapy can sometimes interfere with cancer therapy by increasing or complicating the adverse effects of cancer therapy, for example, opioid-related bowel dysfunction. It can enhance cancer therapy by improving patient function or sense of well-being, and certain palliative surgical procedures may have the ancillary effect of improving organ function.

The basic principles of tumor-directed pain control include:

1. Modifying the source of pain by treating the cancer and the inflammatory effects of cancer
2. Altering the central perception of pain, for example, by the use of analgesics, antidepressants, anxiolytics, and psychotherapy
3. Interfering with nociceptive transmission outside of and within the central nervous system (CNS), for example, with anesthetic techniques (e.g., neurolytic celiac plexus block, neuraxial analgesia, and spinal neurolysis) or neurosurgery procedures (e.g., cordotomy and myelotomy)

The pain experienced by most cancer patients responds to direct and indirect modification of the source of the pain combined with pharmacologic and nonpharmacologic alteration of the central perception of pain. The guiding principle in developing pain management goals is to individualize the approach to the patient’s needs. Part of the process of developing treatment goals is to take into consideration the burdens (adverse effects; opportunity costs) and benefits of different treatment options. Clinicians may find that patient treatment goals differ from their own, either because patients feel that pain is inevitable or because patients expect pain to be relieved with minimal effort on their part. Issues that physicians should discuss with patients include expected lifestyle; cost and reimbursement issues; and concerns about opioid tolerance, addiction, and side effects. Discussing these issues in advance may uncover and address potential barriers to treatment. Moreover, treatment goals may change during the course of the patient’s illness, and all health care providers interacting with the patient during the course of
the illness need to keep abreast of such changes. Medication adherence has major implications for the effective treatments of different diseases.\textsuperscript{64–67} Inadequate adherence with an analgesic regimen is problematic in oncology\textsuperscript{68,69} and adherence rates for scheduled around-the-clock (ATC) regimens better than for as needed regimens.\textsuperscript{70} Most interventions to improve cancer pain outcomes rely on psychoeducational approaches which focus on knowledge transfer to address attitudes and barriers to opioid use.\textsuperscript{71–74} However Bennett et al.\textsuperscript{75} found that patient-based educational interventions resulted in modest benefits in the management of cancer pain and did not have significant benefit on medication adherence or on reducing interference with daily activities. A large variety of approaches have been used with varying effect, and attempts to understand the reasons for heterogeneity between results have so far been unsuccessful.\textsuperscript{76} A patient-centered approach that includes good communication between health providers and patients can promote adherence and improve outcomes.\textsuperscript{74,77}

**PRIMARY ANTICANCER TREATMENT**

Pain produced by tumor infiltration may respond to antineoplastic treatment with radiation treatment and chemotherapy. These approaches to pain control are elaborated in Chapters 42 and 48.

**Surgery**

The surgeon treating a patient with newly diagnosed cancer must meet several responsibilities: biopsy for tissue diagnosis, adequate staging, consultation with medical and radiation oncologists for adjuvant therapy, and surgical resection. Surgery may also play a role in the relief of symptoms caused by specific problems, such as obstruction of a hollow viscus, unstable bone structures, and compression of neural tissues. A variety of surgical disciplines (e.g., general surgery, orthopedic, neurosurgical, plastic, and reconstructive) may participate in the care of the cancer patient.

Although the development of metastatic cancer usually indicates incurable disease, curative surgical resection is possible in rare instances. These instances must meet several criteria before the surgeon can operate:
the primary lesion must be controlled, there must be the potential for complete resection of the metastases, there must be no other equally effective or better antitumor therapy available, metastases should involve only one organ, one should anticipate reasonable postoperative function, expected survival should be better than if left untreated, and the patient must be able to tolerate the surgical procedure. Sometimes, excision of the primary tumor is indicated in the presence of unresectable metastatic disease. Locally advanced tumor can be very painful and unsightly, can interfere with vital functions such as breathing and swallowing, and produce complications such as bleeding and local infection. Resection of isolated metastatic colorectal cancer, GI stromal tumors, neuroendocrine cancers, renal cell cancer, and sarcoma is associated with longer survival or even cure. Most of the available information on metastasectomy relates to disease involving the liver, lung, and brain. Resection of primary renal cell cancer localized to the kidney has a 5-year survival rate approaching 95%. However, the presence of metastasis reduces the median survival to only 10 months. At the time of diagnosis of primary renal cell cancer, about 20% of individuals will have metastases. The benefit of resection of isolated colorectal cancer metastases to the liver and lung and results in a 5-year survival reported in the range of 27% to 58%. Surgical interventions for osseous (nonvertebral) disease depend on the severity of symptoms, location of tumor, expected associated morbidity if a fracture occurred, and availability of alternative or adjuvant treatments. The goal is primarily to decrease pain and to improve mobility and quality of life. The most obvious indication for surgery is the presence of a pathologic fracture in a weight-bearing long bone. Asymptomatic lesions may be followed clinically and radiographically. For metastatic spinal tumors, surgery can improve mechanical stability, cord compression, and pain. Complications may occur in up to 25% of patients who undergo surgery for spinal metastases, the most common being wound infection. Life expectancy is usually determined by the overall extent of disease and, to be of benefit, surgery must improve quality of life.

**Stenting, Drainage Procedures, and Antibiotics**

2184
Common complications of advanced cancer include GI, hepatobiliary, and ureteric obstructions. Stents and laser treatment have a place in both upper GI and rectal obstruction due to advanced malignancy (Fig. 43.2). Decompression for obstructive uropathy from advanced disease usually involves placement of nephrostomy tubes or ureteral stents. Malignant obstruction of the bile duct from cholangiocarcinoma, pancreatic adenocarcinoma, or other tumors may cause debilitating symptoms. Treatment of obstruction can be performed endoscopically, percutaneously, or surgically. Stents, nasobiliary drainage, or percutaneous drains may be used for liver hilar strictures. Endoscopic catheter-based therapies such as photodynamic therapy or radiofrequency ablation may prolong patient survival by achieving local tumor control.

![FIGURE 43.2](image)

FIGURE 43.2 Patient with metastatic prostate cancer who presented with large bowel obstruction. Endoscopy revealed extrinsic tumor compression of the proximal sigmoid colon that required placement of a 10-cm metal stent (red arrows) with complete relief of obstruction. Patient has also bilateral percutaneous nephrostomies (yellow arrows) for relief of bilateral hydronephrosis.

The goals of antibiotic use in terminally ill patients are sometimes to prolong life and always to relieve symptoms. Treatment for cystitis, for instance, does not usually prolong life but may relieve the patient from painful dysuria and troublesome polyuria. Antibiotics may also have pain-relieving effects when the source of pain involves infection, as illustrated by the treatment of pyonephrosis or osteitis pubis.
Symptomatic Cancer Pain Management

Successful management strategies usually require a team approach focusing not only on the nociceptive processes but also on other factors that influence the final perception of pain. Figure 43.3 outlines an approach to tumor-related nociceptive and neuropathic pain.

**Figure 43.3** Tumor pain management algorithm.

Increasing severe pain and/or increasing and intractable side effects determine the appropriate treatment strategy. Most patients will respond satisfactorily to relatively simple oral pharmacotherapeutic strategies. When the patient requires drug treatment, therapy should comply with two basic principles: use oral analgesics and other noninvasive routes of administrations (e.g., transdermal and transmucosal) whenever possible and administer them in accordance with the principles in the WHO analgesic ladder (see later). Titrate opioid and adjuvant analgesics to maximally effective doses or to the appearance of dose-limiting side effects before considering alternative medications (e.g., opioid rotation) or more specialized (and usually) invasive approaches. As an adjunct—and occasionally as an alternative—to medication management, patients with certain pain syndromes will benefit from relatively simple anesthetic blocks, such as celiac and superior hypogastric plexus blocks, neurolytic subarachnoid and intercostal blocks, and selected peripheral nerve blocks (see Chapter 44).
Severe, uncontrolled pain and/or intractable side effects require interventional pain management to achieve rapid pain control. Such interventions may include neuraxial (epidural or intrathecal) analgesia and/or parenteral opioid therapy (usually intravenous administration). As many of these patients have large systemic opioid requirements, it is not unusual to combine neuraxial and parenteral therapies. A small percentage of patients may fail these therapies and should then be treated with intrathecal drugs and/or cordotomy or myelotomy (see Chapter 44).

Occasionally, patients will have pain refractory to all interventional measures outlined, and palliative sedation should be considered (see Chapter 13).

WORLD HEALTH ORGANIZATION ANALGESIC LADDER

In 1986, WHO proposed a method for relief of cancer pain, based on a small number of relatively inexpensive drugs, including morphine. Ten years later, a second edition took into account many of the advances in understanding and practice that have occurred since the mid-1980s. The groundwork for this revision was started in 1989, in the context of the meeting of a WHO Expert Committee on Cancer Pain Relief and Active Supportive Care.

The WHO “analgesic ladder” is a simple and effective method for controlling cancer pain (Fig. 43.4). The purpose was to make pain relief readily available to patients with cancer by using effective and inexpensive drugs. Opioid-based pharmacotherapy is the most important of these options. In many countries, access to opioid treatment is limited by governmental regulation intended to prevent misuse. Advocacy for improved and affordable access to opioids for legitimate medical reasons must continue. At the same time, clinicians have to acknowledge the serious nature of drug misuse and addiction and the obligation to minimize these outcomes. This obligation is particularly pertinent in the United States because of the troubling increase in prescription drug misuse during recent decades. Codeine and morphine were selected for the original WHO analgesic ladder but have fallen from favor because of the genetically established variation in the effects of codeine and the potential effect of
morphine metabolites in patients with renal impairment. The WHO analgesic ladder approach selects different opioids on the basis of pain intensity and any single-entity full µ-agonist opioid is appropriate. According to a Cochrane review, the amount and quality of evidence around the use of opioids for treating cancer pain is low, but 19 out of 20 people with moderate or severe pain who are given opioids and can tolerate them should have that pain reduced to mild or no pain within 14 days. Because of opioid-related side effects, 1 to 2 in 10 patients treated with opioids will find adverse events intolerable resulting in a change in treatment. Somnolence, dry mouth, and anorexia were common adverse events in people with cancer pain treated with morphine, fentanyl, oxycodone, or codeine. Historically, the proportion of cancer patients who report effective pain relief varies from 75% to 90%. 

Treatment for cancer pain should begin with a straightforward explanation to the patient of the causes of the pain or pains. Many pains
respond best to a combination of drug and nondrug measures. Nevertheless, opioids, nonopioid analgesics and adjuvant agents, alone or in combination are the mainstay of cancer pain management (Table 43.3).

Pharmacologic strategies for the control of tumor pain appear in Table 43.4.

### TABLE 43.4 Pharmacologic Strategies for the Control of Tumor Pain

- Select the appropriate analgesic drug.
- Prescribe the appropriate dose of that drug.
- Administer the drug by the appropriate route.
- Schedule the appropriate dosing interval.
- Prevent persistent pain and treat breakthrough pain.
- Titrate the dose of drug aggressively.
- Prevent, anticipate, and manage drug side effects.

Table 43.5 lists the principles of pharmacotherapy endorsed by WHO.
These principles are as follows:

**By Mouth**
When possible, patients should take analgesic medications by mouth. However, alternative routes such as rectal, transdermal, transmucosal (buccal, intranasal, sublingual), and parenteral (subcutaneous and intravenous) administration may better serve patients with dysphagia, uncontrolled vomiting, or GI obstruction.

**By the Clock**
After titration to optimal effect, patients with continuous pain should take analgesic medications on an ATC schedule. Once baseline pain is controlled, many patients will require breakthrough pain (BTP) therapy with immediate or rapid-onset opioids because BTP is a common occurrence in cancer patients.

**By the Ladder**
The WHO analgesic ladder\(^{93}\) is based on the premise that most patients throughout the world will gain adequate pain relief if health care professionals learn how to use a few effective and relatively inexpensive drugs well (Fig. 43.4). Step 1 of the ladder involves the use of nonopioids. If this step does not relieve pain, add an opioid for mild to moderate pain (Step 2). When the opioid for mild to moderate pain in combination with a nonopioid fails to relieve the pain, substitute an opioid for moderate to severe pain (Step 3). Use only one drug from each of the groups at the same time. Give adjuvant drugs for specific indications (see later).

**For the Individual**
There are no standard doses for opioids. The “right” dose is the dose that relieves the patient’s pain with the minimum of side effects. Adequate pain relief may be judged by patient satisfaction with pain management and/or meeting predefined functional goals. Combination opioid formulations (i.e., those with the nonopioid analgesic acetaminophen or a nonsteroidal anti-inflammatory drug [NSAID] are commonly used for mild- to moderate-intensity pain. These have a dose limit due to toxic effects of the coanalgesic.

With Attention to Detail
Carefully determine and monitor the patient’s analgesic regimen. Follow-up regularly with the patient by monitoring adherence, drug efficacy, functional outcomes, side effects, and aberrant drug-related behaviors. Anticipate adverse effects, such as opioid-induced bowel dysfunction, and treat them prophylactically or as soon as they become problematic.

The WHO ladder advocates the use of three classes of analgesics—nonopioid, adjuvant, and opioid. Each of these classes will be considered separately.

Nonsteroidal Anti-Inflammatory Drugs
NSAIDs are essential drugs for the management of a wide variety of acute and chronic pain conditions. Clinicians should be familiar with the use, efficacy, and adverse effects of these agents. NSAIDs include a variety of drugs that differ in their clinical effects and pharmacokinetics. In general, they have high bioavailability, with peak concentrations occurring within the first 4 hours when administered orally. Intravenous forms of ibuprofen and ketorolac are available in the United States. NSAIDs may function to control pain independently (e.g., in the management of mild- to moderate-intensity bone or muscle pain) or may help reduce the dose of opioid required for pain control (opioid-sparing effect). A wide range of drugs with varying effects and side effects are available. These medications are discussed extensively in Chapter 78.

Cyclooxygenase (COX) is the pivotal enzyme in prostaglandin biosynthesis. It exists in two isoforms, constitutive COX-1 (responsible for physiologic functions) and inducible COX-2 (involved in inflammation
and upregulated by cytokines, growth factors, and shear stress). Pharmacologic inhibition of COX explains both the therapeutic effects (inhibition of COX-2) and side effects (inhibition of COX-1) of NSAIDs. COX-1 and COX-2 both metabolize arachidonic acid to an unstable precursor, prostaglandin (PG) H$_2$. A variety of PG isomerases use PGH$_2$ as the substrate to form PGs, prostacyclin (PGI$_2$), and thromboxane (Tx) A$_2$. The analgesic and anti-inflammatory effects of NSAIDs are dependent on the extent and duration of COX-2 inhibition in the spinal cord and inflammatory sites. Aspirin differs from NSAIDs because aspirin irreversibly acetylates the enzyme. Most NSAIDs inhibit both COX isoenzymes with little selectivity, although some (coxibs, meloxicam) mainly block COX-2.

PGE$_2$ is the most physiologically abundant product of COX-2 as it exists at some level in nearly all cell types. Apart from biologic effects, such as induction of pain and inflammation, PGE$_2$ also participates in the mechanisms of cell proliferation, apoptosis, and metastasis, contributing to the progression of several human cancers, including colon cancer, breast cancer, and lung cancer, suggesting that NSAID use may be beneficial in these cancers.$^{102-105}$ COX-2 is markedly overexpressed in colorectal neoplasm and multiple epidemiologic studies clearly demonstrated that NSAID consumption prevents adenoma formation and decreases the incidence of, and mortality from, colorectal cancer.$^{106}$ COX-2 inhibition can reduce proliferation, induce apoptosis, suppress tumor angiogenesis, prevent immune suppression, and inhibit carcinogen conversion.$^{106,107}$ The efficacy of aspirin differs significantly according to COX-2 expression. Aspirin reduces the risk of colorectal cancer in COX-2–expressing cancers, but it is not an effective chemopreventive agent for cancers with weak or absent COX-2 expression.$^{108}$ In animal models, NSAIDs decrease the number and risk of metastasis$^{109}$ with some data now emerging of a reduced risk of metastasis development in humans.$^{110}$

**Efficacy in Cancer Pain**

Although many NSAIDs are available to treat various painful conditions, it is unclear which agent is most clinically efficacious for relieving cancer-related pain, and if there are clinical differences between these agents that
justify their cost differences. In a Cochrane review of the use of NSAIDs either alone or in combination with opioids, the quality of evidence supporting the use of NSAIDs was poor and suggested that moderate to severe cancer pain was reduced to no worse than mild pain after 1 to 2 weeks in approximately 1 of 3 patients. One in 4 patients stopped taking NSAIDs because the drug did not work, and 1 of 20 stopped because of side effects. In effect, there is no evidence to support or refute the use of NSAIDs alone or in combination with opioids for cancer pain. McNicol et al. assessed and compared the efficacy of various NSAID and NSAID plus opioid combinations in the treatment of cancer pain. They concluded that most studies were of insufficient duration to demonstrate that the long-term use of NSAIDs is safe and effective in patients with cancer. They advised that clinicians should be as cautious in using NSAIDs in this population as they would any other population, especially given additional bleeding risks in cancer patients, and the probability that a patient with cancer may be on a broad regimen of medications, some of which may increase NSAID-related toxicity.

**Acetaminophen**

Acetaminophen (APAP) is one of the most popular antipyretic and analgesic medications worldwide. It is used either alone or in combination with other drugs. Its low cost and favorable side effect profile is attractive for use in a variety of painful conditions. The mechanism of action of the drug is not fully understood. However, it is known that acetaminophen is a weak inhibitor of the synthesis of PGs. It may have a selective COX-2 inhibitor effect or a central effect, possibly due to activation of descending serotonergic pathways. On average, APAP is considered a weaker analgesic than NSAIDs or COX-2 selective inhibitors but is often preferred because of its better tolerance. High use of APAP was associated with an almost twofold increased risk of incident hematologic malignancies such as myeloid neoplasms, non-Hodgkin lymphoma, and plasma cell disorders excluding chronic lymphocytic leukemia/small lymphocytic lymphoma but not for other nonhematologic malignancies. Severe liver injury can occur when acetaminophen use
exceeds maximum dosage (currently 4,000 mg within a 24-hour period) or when an individual takes the drug and also consumes alcohol,\textsuperscript{116} and with additional warnings that the drug may cause severe skin reactions including Stevens-Johnson syndrome, toxic epidermal necrolysis, and acute generalized exanthematous pustulosis.\textsuperscript{117} Of note, the use of concentrated prescription APAP-containing medications (>500 mg) in combination with other sources of APAP can result in severe liver injury and death.\textsuperscript{118} Acute liver failure secondary to APAP is most often associated with unintentional overdose, the use of a single product, an opioid-APAP combination, duration of use <7 days, and a median dose of 7.5 g per day.\textsuperscript{119} Daily doses of APAP of 4 g for 10 days resulted in a maximum increase of serum alanine aminotransferase (ALT) more than 3 times normal in over 30% of patients,\textsuperscript{120} and daily use of acetaminophen at half the maximum recommended daily dose for 12 weeks in a healthy adult population was associated with a small elevation in mean ALT of no probable clinical significance.\textsuperscript{121} There is no high-quality evidence to support or refute the use of APAP alone or in combination with opioids for cancer-related pain\textsuperscript{122} or with advanced disease.\textsuperscript{123}

**Opioid-Induced Bowel Dysfunction**

Constipation is prevalent in oncology patients even among patients not on opioid therapy.\textsuperscript{124} GI side effects such as nausea, vomiting, diarrhea, and constipation is associated with chemotherapy including alkylating agents, antimetabolites, immunomodulating agents, and mitotic inhibitors.\textsuperscript{125} The prevalence of constipation after cytotoxic chemotherapy may be as high as 16% with 5% classified as severe.\textsuperscript{126} Posttreatment constipation and diarrhea among cancer (particularly colorectal) survivors is prevalent with episodes persisting up to 10 years after treatment.\textsuperscript{127,128} Opioid-induced constipation (OIC) and opioid-induced bowel dysfunction (OBD) are associated with opioid therapy. OBD is a distressing condition that may persist indefinitely in the clinical setting. Hard dry stool, gas distention, incomplete evacuation, and straining are common sequelae. OBD can affect quality of life significantly and result in hospitalization, pain, and frequent changes in opioid and laxative treatment.\textsuperscript{129}
Clinical reviews on OIC indicate the lack of a common definition\textsuperscript{130} and may be defined as a change when initiating opioid therapy from baseline bowel habits that is characterized by reduced bowel movement frequency, development or worsening of straining to pass bowel movements, a sense of incomplete rectal evacuation, or harder stool consistency.\textsuperscript{131} OBD reflects the overall impact of opioids on the GI tract and include symptoms such as dry mouth, gastroesophageal reflux–related symptoms (heartburn), nausea, vomiting, chronic abdominal pain, bloating, constipation-related symptoms: straining, hard stools, painful, infrequent and incomplete bowel movements (BM), and diarrhea-related symptoms: urgency, loose and frequent BMs.\textsuperscript{132,133} OIC is the most common form of OBD.

Endogenous opioids and opioid receptors are widely distributed throughout the body, with strong expression in the CNS, peripheral nervous system, and enteric nervous system (ENS) and also within the endocrine and immune systems. The ENS has a network of small ganglia that can regulate GI motility and secretion independently of the CNS. Neurons in the ENS form plexuses between the circular and longitudinal muscle layers (the myenteric plexus) and between the mucosal and circular muscle layers (the submucosal plexus). The myenteric plexus innervates both the longitudinal and the circular muscle layers, and its primary role is to coordinate motility patterns. Submucosal plexuses are found in the small and large intestine and are primarily involved in the regulation of secretion and local blood flow. Opioids inhibit enteric neuronal activity in both the small intestine and the colon. The expression of µ-opioid receptors on myenteric and submucosal ganglia suggests that receptor agonists cause constipation by inhibiting peristaltic smooth muscle contractions by effects on the myenteric ganglia and also by inhibiting water and electrolyte movement across the lumen via effects on the submucosal ganglia. Opioid receptors and endogenous opioid agonists are altered in GI disease.\textsuperscript{134} The mechanisms for OBD are associated with delays in gastric emptying, oral-cecal transit and colonic transit time, and inhibition of defecation, all of which are predominately mediated through peripheral µ receptors.\textsuperscript{135–137} The effects of opioids on the gut also are partly a result of their ability to accumulate in the intestinal tissue and have a direct local effect on the bowel.\textsuperscript{135} Centrally mediated antitransit effects...
are implicated in the pathophysiology of OBD. Opioids act centrally through alterations in autonomic outflow to the gut; however, their overall impact on GI motility appears to be correlated to their ability to penetrate the CNS. Opioids mainly exert their action on the ENS where they bind to opioid receptors in the myenteric and submucosal plexuses and on immune cells in the lamina propria. The coordination of the contractile and propulsive gut motility is determined by a balance between acetylcholine and nitric oxide/vasoactive intestinal peptide release. Because opioids inhibit neurotransmitter release, administration will directly disrupt this balance, resulting in abnormal coordination of motility.

The Bowel Function Index (BFI numerical analogue scale 0 to 100), calculated as the mean of three variables (ease of defecation, feeling of incomplete bowel evacuation, and personal judgment of constipation), was developed to evaluate bowel function in opioid-treated patients with pain. This clinician-administered tool allows easy measurement of OIC from the patient’s perspective.

Metoclopramide is commonly prescribed for patients with symptoms of gastroparesis. It is a dopamine receptor antagonist, serotonin 5-hydroxytryptamine type 4 (5-HT4) receptor agonist, and weak inhibitor of 5-hydroxytryptamine type 3 (5-HT3) receptors. Activity appears to be by both peripheral (in the upper GI tract) and central mechanisms by inducing antidopaminergic effects. Recommended use of metoclopramide at the lowest effective dose for each patient beginning with 5 mg three times daily up to a maximum recommended dose of 40 mg per day. Adverse events include restlessness, drowsiness, fatigue, and extrapyramidal effects, especially in younger patients and in children. Patients may experience extrapyramidal side effects at doses greater than 20 mg daily. Metoclopramide is an inhibitor of CYP2D6 enzyme. Concurrent use of antidepressants such as tricyclics, selective serotonin reuptake inhibitors (SSRIs), and antidepressants acting as serotonin-norepinephrine reuptake inhibitors (SNRIs) (venlafaxine or duloxetine) may enhance adverse effects associated with metoclopramide.

The goals of therapy typically are threefold: keep stool volume maximized to trigger enterochromaffin cell serotonin release via mucosal
stretch, keep stool softer and mechanically make it easier to move, and enhance peristalsis. Most treatment for constipation begins with encouraging exercise, activity, fluid intake, and dietary fiber and the use of stool softeners and laxatives. Fiber-bulking agents are organic polymers that retain water in stool. It is important that adequate water be taken concomitantly with fiber. Without sufficient fluid, fiber may worsen constipation. Many practitioners recommend a combination of a stool softener with a stimulant laxative for patients on chronic opioid therapy. Stool softeners, such as docusate sodium, are detergents that allow better water penetration into stool, making it softer and more voluminous. Stimulant laxatives, such as senna and bisacodyl, induce peristalsis via mechanisms that are not well understood. In vitro, applying senna to intestinal mucosa leads to immediate contraction. After optimal titration of these agents with persistent constipation, oral osmotics are commonly added to enhance laxation by pulling along water due to osmotic forces. Osmotics include sugars, such as lactulose or sorbitol; magnesium salts, such as magnesium citrate; or inert substances, such as polyethylene glycol. When unsuccessful, rescue oral and rectal interventions are also often needed. Rectal interventions include such agents as bisacodyl suppositories and phosphosoda enemas to soften, lubricate, and mobilize hard, dry distal stool. Often, synergism of multiple categories of agents is required for successful laxation. Another strategy has been the development of peripherally acting µ-opioid receptor antagonists (PAMORAs) that selectively target µ receptors in the GI tract. PAMORAs agents currently available include oral naloxegol and alvimopan and subcutaneously administered methylnaltrexone.

Naloxegol is a polymer conjugate of naloxone. The polyethylene glycol (PEG) moiety limits the ability to cross the blood–brain barrier. PEGs are also used as osmotic laxatives (e.g., macrogol 3,350/4,000), where they act as nonmetabolized, nonabsorbable, osmotic agents, forming hydrogen bonds with water in the intestinal lumen. PEGylation makes naloxegol a substrate for the P-glycoprotein (P-gp) transporter. Due to the reduced permeability and increased efflux of naloxegol across the blood–brain barrier, related to P-gp transporter, the CNS penetration of naloxegol is negligible and it reduces OIC in the GI tract without reversing the central
analgesic effect.\textsuperscript{149} Administration of naloxegol with food is associated with increased bioavailability. The concentration and activity of naloxegol are increased by the concurrent use of CYP3A4 inhibitors and reduced by CYP3A4 inducers. Naloxegol is administered at a dose of 25 mg once daily on an empty stomach at least 1 hour before the first meal of the day or 2 hours after the first meal of the day. Cancer patients with symptoms of bowel obstruction and those with increased risk of GI perforation including GI or peritoneal tumors, recurrent or advanced ovarian cancer, and patients treated with vascular endothelial growth factor (VEGF) inhibitors should avoid the use of naloxegol.

Methylnaltrexone-bromide is a PAMORA and a quaternary methyl derivative of naltrexone. The addition of a methyl group to the nitrogen ring increases polarity and reduces lipophilicity such that the drug does not pass the blood–brain barrier. It is administered subcutaneously and is rapidly absorbed, with the peak plasma concentration attained within 30 minutes, and plasma elimination half-life ($t_{1/2}$) is approximately 8 hours.\textsuperscript{150} It induces bowel movement in approximately 50% to 60% treated patients within 4 hours of its administration.\textsuperscript{151,152} It is indicated for OIC patients with advanced disease who are receiving palliative care with inadequate response to laxative therapy.\textsuperscript{153} Recommended dosing is 8 mg for patients weighing 38 to less than 62 kg and 12 mg for patients between 62 to 114 kg. Usual dosing is one dose every other day and not more than one dose per day. Common side effects include abdominal pain, flatulence, and nausea. Contraindications include administration to patients with known or suspected mechanical bowel obstruction. Rare cases of GI perforation involving various regions of the GI tract have been reported in advanced illness patients.\textsuperscript{154} Alvimopan is another orally administered PAMORA that does not cross the blood–brain barrier at clinically relevant doses and does not reverse analgesia or cause opioid withdrawal symptoms. The FDA approved alvimopan for postoperative ileus following partial small or large bowel resection with primary anastomosis in hospitalized patients.

\textbf{Antiemetics}
Nausea and vomiting is a common problem in oncology. Although opioids,\textsuperscript{155} chemotherapy,\textsuperscript{156} and radiation therapy\textsuperscript{157} are commonly associated with nausea and vomiting, advanced disease is also frequently associated with nausea particularly in the last week of life.\textsuperscript{158} Depending on the anatomic area irradiated, an estimated 50\% to 80\% of patients undergoing radiation therapy develop radiation therapy–induced nausea and vomiting (RINV).\textsuperscript{159} Total body irradiation, half body irradiation, or abdominal radiotherapy are at a major risk of nausea and vomiting. The pathophysiology of nausea and vomiting is a complex process. The act of vomiting is coordinated by the vomiting center of the brain located in the lateral reticular formation of the medulla with efferent pathways through the vagus, phrenic, and spinal nerves. The vomiting center receives afferent input from various sources including the chemoreceptor trigger zone (CTZ) in the area postrema in the floor of the fourth ventricle, the vagus and sympathetic nerves, as well as impulses directly from the GI tract and other sources. The CTZ is also activated by mediators in the circulation, which may include hormones, peptides, medications, or toxins. The act of vomiting involves neurotransmitters (including serotonin, substance P, and dopamine found in the CTZ), the vomiting center, and enterochromaffin cells in the GI tract release efferent impulses that are transmitted to the abdominal musculature, salivation center, and respiratory center. CTZ effects are largely mediated through central dopamine type 2 (D2) receptors.

Opioids have emetogenic effects by central stimulation, vestibular effects and by inhibiting gut motility. The primary mechanism of opioid-induced nausea and emesis is central with direct stimulation of the CTZ.\textsuperscript{160} Although opioid stimulation of the CTZ involve opioid receptors, signaling from the CTZ involves D2 and 5-HT\textsubscript{3} receptors and opioid stimulation of the vestibular apparatus and sensory input to the vomiting center may involve H1 and muscarinic acetylcholine pathways (Fig. 43.5).\textsuperscript{161} The peripheral inhibitory effect of opioids on GI transit and stimulation of the pyloric sphincter delays gastric emptying or causes gastroparesis. Chemotherapy likely causes nausea and vomiting through stimulation of the CTZ mediated by 5-HT\textsubscript{3} and neurokinin type 1 (NK1) receptors. Because of these effects, 5-HT\textsubscript{3} and NK1 receptor antagonists
are the most effective agents currently available. In most cases of chemotherapy-induced nausea and vomiting (CINV), these agents are used in conjunction with glucocorticoids.\textsuperscript{162–165} Glucocorticoids are effective only for preventing nausea and vomiting and not for treating established nausea and vomiting.\textsuperscript{166}

**FIGURE 43.5** Opioid-induced nausea and vomiting pathophysiology and antiemetic therapy. 5-HT\textsubscript{3}, 5-hydroxytryptamine type 3; CTZ, chemoreceptor trigger zone; D2, dopamine type 2; DRA, dopamine receptor antagonist; GI, gastrointestinal; H1, histamine H1; M1, O-desmethyl tramadol; NK1, neurokinin type 1; NK1R, neurokinin type 1 receptor. (Modified from Smith HS, Laufer A. Opioid induced nausea and vomiting. Eur J Pharmacol 2014;722:67–78. Copyright © 2014 Elsevier. With permission.)

Typical strategies for management and minimization of opioid-induced nausea and vomiting include dose reduction, dose titration, opioid rotation, and the use of antiemetics. Commonly used antiemetics are listed in Table 43.6. It is not uncommon for patients to experience nausea and/or vomiting when starting opioid therapy, but these side effects tend to subside within days or weeks\textsuperscript{167} unless opioid-induced bowel dysfunction develops. Until the late 1970s, dopamine-receptor antagonists, such as metoclopramide, prochlorperazine, and haloperidol, formed the basis of antiemetic therapy. In 1991, the first 5-HT\textsubscript{3}–receptor antagonist, ondansetron, was approved by the FDA for the treatment of chemotherapy-induced emesis followed by two additional 5-HT\textsubscript{3}–receptor antagonists, granisetron and dolasetron, in 1997. Droperidol and ondansetron have an FDA black box warning after reports of prolonged rate-corrected QT (QTc) interval. Palonosetron is a
second-generation 5-HT\textsubscript{3}–receptor antagonist that has a prolonged t\textsubscript{1/2} with higher receptor binding affinity than other antiemetic agents. Aprepitant, the first NK1 receptor antagonist, was approved for chemotherapy-induced emesis in 2003. In 2008, fosaprepitant, a prodrug and intravenous form of aprepitant, was approved by the FDA. Dronabinol (Schedule III) and nabilone (Schedule II) are cannabis-derived pharmaceuticals indicated for the treatment of nausea and vomiting associated with cancer chemotherapy and of anorexia associated with weight loss in patients with acquired immune deficiency syndrome.\textsuperscript{168}

Postoperatively, ondansetron is more effective than metoclopramide for the treatment of opioid-induced emesis. Nausea and vomiting after acute administration of opioids may be partly related to serotonin receptor signaling. Many consider dopamine receptor antagonists, including prochlorperazine and haloperidol as the preferred drugs for managing opioid-induced nausea and vomiting. Olanzapine, an atypical thienobenzodiazepine antipsychotic agent that is indicated for the treatment of schizophrenia and bipolar disorder, is also useful for the treatment of intractable nausea particularly at reducing during the delayed and overall phase of the CINV prevention. It is also useful for the treatment of morphine-induced emesis and as an adjunct for the treatment of neuropathic pain associated with sleep disturbance. It blocks multiple neurotransmitter receptors, including dopaminergic (D2), serotonergic (5-HT₃), adrenergic, histaminergic, and muscarinic receptors. Dose titration of olanzapine is over a period of 7 to 10 days (in the range of 2.5 to 7.5 mg) given at bedtime.

Many of the commonly prescribed antiemetic agents (e.g., phenothiazines, antihistamines, anticholinergic drugs, and metoclopramide) are generally effective but are often associated with undesirable side effects such as sedation, blurred vision, dysphoria, and extrapyramidal reactions. 5-HT₃ receptors are located centrally in the CTZ as well as peripherally on vagal nerve terminals. Ondansetron is effective for the control of opioid-induced nausea and vomiting. The antiemetic actions noted from cannabinoids and endocannabinoids have been linked to CB1 effects, where antagonists can provoke acute emesis and agonists reduce acute nausea and vomiting.

**Adjuvant Analgesics**

An adjuvant analgesic is a medication with a primary indication other than pain relief, but it may provide or enhance analgesia in certain
circumstances. In the area of cancer pain, the common adjunctive analgesics are corticosteroids, anticonvulsants, and antidepressants. These drugs play an important role for some patients who cannot otherwise attain an acceptable balance between relief and opioid side effects. Adjuvant analgesics divide broadly into general purpose analgesics, adjuvants used for musculoskeletal pain, and those with specific use for neuropathic, bone, or visceral pain. Although ketamine has been used in the treatment of cancer pain refractory to opioid therapy, it is not licensed for this purpose and the evidence supporting its use is very low quality with potentially serious adverse events at higher doses and will not be considered further.

GENERAL PURPOSE ADJUVANTS
Corticosteroids are the most widely used general purpose adjuvant analgesics and are available in a wide variety of formulations. Various guidelines recommend the use of steroids as adjuvants for cancer pain but these guidelines are based on expert opinion. Steroids are used to treat pain associated with increased intracranial pressure, acute spinal cord compression, superior vena cava syndrome, metastatic bone pain, neuropathic pain due to infiltration or compression, symptomatic lymphedema, and hepatic capsular distension. The mechanism for pain relief is unknown but the anti-inflammatory effect of steroids is often proposed as the putative mechanism. The available data suggest that moderate doses of corticosteroids equivalent to methylprednisolone 32 mg or dexamethasone 8 mg daily are well tolerated for up to 7 days but that high doses equivalent to methylprednisolone 125 mg daily administered over 8 weeks have a significantly adverse impact and may even increase mortality. Overall, data supporting the role of steroids for cancer pain control is weak and likely with only short-term benefit.

Topical agents (see Chapter 80) may also be useful as an adjunctive form of pharmacotherapy, without increasing systemic toxicity. These agents are used for a variety of painful conditions such as strains or sprains, muscle aches, osteoarthritis of hand or knee, or neuropathic pain. Typical topical analgesic drugs include NSAIDs, salicylate rubefacients, capsaicin, and lidocaine. Agents such as diclofenac Emulgel, ketoprofen
gel, piroxicam gel, and diclofenac plaster work reasonably well for strains and sprains. For hand and knee osteoarthritis, topical diclofenac and topical ketoprofen rubbed on the skin for at least 6 to 12 weeks help reduce pain by at least half in a modest number of people. For postherpetic neuralgia, topical high-concentration capsaicin can reduce pain by at least half in a small number of people.¹⁸⁴ There are a number of drugs in the area of pain management that have been formulated and compounded to treat conditions such as diabetic neuropathy, fibromyalgia, postherpetic neuralgia, joint pain, arthritis, and others. Significant portions of these compounded analgesic preparations are topical/transdermal dosage forms such as gels and creams. Although the efficacy and doses of these drugs in systemic dosage forms have been widely established, little is known about the permeation and efficacy of these compounds from these gels. A multicenter, phase III, randomized, double-blind, placebo-controlled trial was to investigate the efficacy of 2% ketamine plus 4% amitriptyline cream for reducing chemotherapy-induced peripheral neuropathy (CIPN) in 462 cancer survivors was ineffective for this problem.¹⁸⁵ A study examining topical 5% amitriptyline and 5% lidocaine in the treatment of mixed sources (noncancer) neuropathic pain showed that topical lidocaine reduced pain intensity but the clinical improvement was minimal and that topical 5% amitriptyline was not effective.¹⁸⁶ Although anecdotally, topical lidocaine may benefit some patients, there is no evidence from good quality randomized controlled studies to support the use of topical lidocaine to treat neuropathic pain.¹⁸⁷

MUSCULOSKELETAL PAIN ADJUVANTS
The term muscle relaxants or muscle relaxers is broad and includes a wide range of drugs with different indications and mechanisms of action. Muscle relaxers are either antispasmodic or antispasticity medications. The antispasmodic agents are further subclassified into the benzodiazepines and the nonbenzodiazepines. Nonbenzodiazepines include a variety of drugs that can act at the brain stem or spinal cord level and include carisoprodol, chlorzoxazone, cyclobenzapr ine, metaxalone, meprobamate, methocarbamol, tizanidine, zopiclone, and orphenadrine. Only three muscle relaxants—baclofen, dantrolene, and tizanidine—are FDA
approved to treat spasticity. Tizanidine is an agonist at $\alpha_2$-adrenergic receptor sites and presumably reduces spasticity by increasing presynaptic inhibition of motor neurons. It has linear pharmacokinetics over a dose of 1 to 20 mg.\(^{188}\) In multiple dose, controlled clinical studies, 48% of patients receiving any dose of tizanidine reported sedation as an adverse event and sedation appears to be dose related.\(^{189}\) A single dose of 8 mg of tizanidine reduces muscle tone in patients with spasticity for a period of several hours. The effect peaks at approximately 1 to 2 hours and dissipates between 3 and 6 hours.

The FDA-approved muscle relaxers for spasms (including carisoprodol, cyclobenzaprine, orphenadrine, metaxalone, chlorzoxazone, and methocarbamol) have only been approved for short-term use (up to 21 days), and their long-term efficacy is unknown. Evidence supporting the effectiveness of these drugs for muscle spasm is sparse; most trials are old and not of good quality. Much of the evidence from clinical trials regarding the use of these agents is limited because of poor methodologic design, insensitive assessment methods, and small numbers of patients.\(^{190}\) These drugs are often used for treatment of musculoskeletal conditions, whether muscle spasm is present or not. Pharmacologic and nonpharmacologic approaches do not differ significantly from patients with musculoskeletal pain who do not have cancer (see Chapters 80 and 89), other than disease- or treatment-specific issues relevant to the cancer patient. Drug–drug and drug–disease interactions must always be considered and be an ongoing component of reassessment.

**NEUROPATHIC PAIN ADJUVANTS**

Neuropathic pain, caused by a lesion or disease affecting the somatosensory nervous system, is a common and oftentimes very debilitating source of distress in patients with cancer (see Chapters 24 to 28 and 42). In cancer and chronic noncancer pain, there is a large variety of causes. Most treatment strategies for cancer-related neuropathic pain are extrapolated from noncancer-related neuropathic pain (see Chapters 24 to 28).\(^{191–194}\) Table 43.7 summarizes those agents that are used to treat neuropathic pain in noncancer patients. Of note, opioids are recommended as third line contrasting with previous recommendations.\(^{195}\) This is largely
because of the potential risk of abuse, particularly with high doses, and concerns about prescription opioid–associated overdose mortality, diversion, misuse, and other opioid-related morbidity. In addition, high-concentration capsaicin patches and cannabinoids are considered for the first time in therapeutic recommendations for neuropathic pain.

aDuloxetine is the most studied, and therefore recommended, of the serotonin-norepinephrine reuptake inhibitors.

bTricyclic antidepressants generally have similar efficacy; tertiary amine tricyclic antidepressants (amitriptyline, imipramine, and clomipramine) are not recommended at doses greater than 75 mg per day in adults aged 65 years and older because of major anticholinergic and sedative side effects and potential risk of falls; an increased risk of sudden cardiac death has been reported.
with tricyclic antidepressants at doses greater than 100 mg daily.

The long-term safety of repeated applications of high-concentration capsaicin patches in patients has not been clearly established, particularly with respect to degeneration of epidermal nerve fibers, which might be a cause for concern in progressive neuropathy.

Sustained-release oxycodone and morphine have been the most studied opioids (maximum doses of 120 mg per day and 240 mg per day, respectively, in clinical trials); long-term opioid use might be associated with abuse, particularly at high doses, cognitive impairment, and endocrine and immunologic changes.

The causes of neuropathic pain in noncancer patients are diverse and generally can be considered as central or peripheral. Neuropathic pain has been extensively discussed in Chapters 24 to 28. Although chronic noncancer neuropathic pain occurs in oncology patients, unique sources of pain including disease infiltration of central and peripheral nervous tissue, paraneoplastic peripheral neuropathy, pain resulting from leptomeningeal metastases and neuropathic pain secondary to therapeutic interventions (postsurgical, radiation therapy, and CIPN) occur in cancer patients. Furthermore, combinations of different sources of pain may also occur. For example, a patient with persistent CIPN-associated pain may develop both central and peripheral sources of pain (brachial plexus tumor infiltration extending to the spinal canal causing cord compression).

Management of such pain complaints may require multiple approaches including disease control (chemotherapy, radiation therapy) and symptomatic pharmacologic approaches. Extrapolation of treatment guidelines from noncancer pain patients are not appropriate for the management of oncology-associated neuropathic pain. Data relating to the use of neuropathic pain adjuvant medications for the management or prevention of CIPN-associated pain is inconsistent. Chemotherapeutic agents causing nerve dysfunction mainly target axons, dorsal root ganglia, and terminal trees of intraepidermal nerve fibers. Purported chemoprotective agents (acetylcysteine, amifostine, calcium and magnesium, diethylthiocarbamate, glutathione, Org 2766, oxcarbazepine, retinoic acid, or vitamin E) for platin drug toxicity were not beneficial. Typical medications used for management of CIPN are antidepressants (tricyclics, SNRIs) or antiepileptic drugs (AEDs)
(gabapentin, pregabalin). Venlafaxine is a reasonably well-tolerated antidepressant and is a serotonin reuptake inhibitor and weak norepinephrine reuptake inhibitor. Although some studies suggest benefit for use in acute oxaliplatin-induced or acute taxane-oxaliplatin-related neuropathy, others have found little compelling evidence to support the use of venlafaxine in neuropathic pain. Because of the lack of effective management for CIPN, the National Cancer Institute sponsored a series of trials aimed at prevention and management. A total of 15 studies were approved, evaluating use of various neuromodulatory agents (including nortriptyline, gabapentin, and lamotrigine) which have shown benefit in other neuropathic pain states. Gabapentin doses were targeted to 2,700 mg per day for a total of 6 weeks. Aside from duloxetine, none demonstrated therapeutic benefit for patients with CIPN. Smith et al. studied the effect of duloxetine at initial doses of 30 mg for 1 week then 60 mg for 4 additional weeks for painful CIPN induced by paclitaxel, other taxane, or oxaliplatin. Fifty-nine percent of patients experienced some decrease in pain after 5 weeks of taking duloxetine, and more duloxetine-treated patients decreased their opioid analgesic intake. In a retrospective review on the use of duloxetine for paclitaxel-induced CIPN, some benefit was observed in younger patients, but elderly patients (>60 years) tended to be less responsive and experienced more drug-related adverse events. It should also be noted, especially in breast cancer patients, that if duloxetine and tamoxifen are taken together, duloxetine-induced CYP P450 2D6 enzyme inhibition could inhibit tamoxifen conversion to its active metabolite, endoxifen.

**BONE PAIN ADJUVANTS**

NSAIDs, corticosteroids, calcitonin, radiopharmaceuticals, and bisphosphonates all have a potential place in the treatment of cancer-related bone pain. The use of calcitonin has been disappointing in the management of painful bone metastases. Dexamethasone is useful for the management of radiation-induced bone pain flares, but there is no evidence of benefit for management of painful bone metastases. The risk of bone loss and fractures is increased with systemic glucocorticoid use with the highest rate of bone loss that occurs within the first 3 to 6
months of therapy. More than 10% of patients who receive long-term steroid therapy are diagnosed with a fracture, and 30% to 40% have radiographic evidence of vertebral fractures. Exposure to steroids is also a leading cause of osteonecrosis (avascular necrosis).

**VIScerAL PAIN ADJUVANTS**

The literature offers little support for the potential efficacy of adjuvant agents for the management of bladder spasm, tenesmoid pain, and colicky intestinal pain. Although there is no well-established pharmacotherapy for painful rectal spasms, diltiazem can help in the management of proctalgia fugax. Inhaled salbutamol also shortened the attack of severe pain in a randomized double-blind trial in 18 patients with proctalgia fugax. Most treatments for proctalgia fugax (e.g., oral diltiazem, topical glycercyl nitrate, nerve blocks) act by relaxing the anal sphincter spasm. The effectiveness of these treatments is supported only by case reports or case series. For chronic proctitis associated with radiation therapy, anti-inflammatory agents such as sulfasalazine or 5-aminosalicylic acid (mesalamine) are usually first-line treatments, but they have low efficacy even in combination with other agents such as steroids and antibiotics. Belladonna and opium suppositories have been used in the management of moderate to severe pain associated with ureteral spasm. The recommended adult dose of belladonna and opium rectal suppositories for the treatment of moderate to severe pain associated with ureteral spasm is 1 suppository (each suppository: belladonna 16.2 mg/opium 30 mg OR belladonna 16.2 mg/opium 60 mg) rectally once or twice a day; maximum of 4 doses per day. Belladonna and opium rectal suppositories have not been found by the FDA to be safe and effective and are not recommended for use.

**Psychotropic Drugs**

Psychoactive substances are substances that affect mental processes, for example, cognition or affect. This and its equivalent, psychotropic drug, are the most neutral and descriptive term for the whole class of substances, licit and illicit, of interest to drug policy. In a large population study in The Netherlands, cancer patients were often prescribed psychotropic drugs
including benzodiazepines, antidepressants, and antipsychotics. The pattern of use was more common soon after diagnosis with increases in the terminal stage of the disease. The presence of pain and (to a greater extent) poor pain control were associated with increased use of certain psychotropic drugs, such as anxiolytics and hypnotics. Use of hypnotics or anxiolytics drugs is associated with increased mortality and should be used cautiously. Among drugs most frequently involved in drug overdose deaths in the United States, alprazolam and diazepam are featured. Concurrent benzodiazepine use was also associated with an increased risk of death from overdose in patients receiving opioids. Cancer patients often require the use of a psychoactive drug. Some need it for pain relief (e.g., tricyclic antidepressants for nerve injury pain), whereas others need an antiemetic (e.g., lorazepam for CINV). Still, others require an anxiolytic, such as clonazepam or alprazolam. Some require a night sedative and others an antidepressant for identifiable depression. The concurrent use of two centrally acting drugs (e.g., opioid with psychotropic drug or two psychotropic drugs together) is more likely to produce sedation in ill and malnourished cancer patients than in others. A comprehensive review of psychotropic drugs in pain management appears in Chapters 31 and 81.

Cannabinoids

Cannabis sativa contains over 450 compounds, with at least 70 classified as phytocannabinoids. Of medical interest are delta 9-tetrahydrocannabinol (THC) and cannabidiol (CBD). THC is the main active constituent, with psychoactive and pain-relieving properties. CBD not only has lesser affinity for the cannabinoid (CB) receptors and the potential to counteract the negative effects of THC on memory, mood, and cognition but also has an effect on pain modulation. The discovery of the endocannabinoid system (cannabinoid receptors CB1 and CB2 and their endogenous ligands) resulted in studies concerning the pharmacologic activity of cannabinoids. Endocannabinoids act as ligands at cannabinoid receptors within the nervous system (primarily but not exclusively CB1 receptors) and in the periphery (primarily but not exclusively CB2 receptors).
Cannabinoids have been recommended for the prevention of CINV\textsuperscript{223} and may be effective in cancer patients who respond poorly to commonly used agents.\textsuperscript{224} In a 2015 review, patients who received cannabinoids were 5 times as likely to report complete absence of vomiting, and three times as likely to report complete absence of nausea and vomiting but when compared with conventional antiemetic drugs, there was no evidence of a difference for nausea, vomiting, or nausea and vomiting.\textsuperscript{225}

The DEA lists marijuana and its cannabinoids as Schedule I controlled substances, which means that they cannot legally be prescribed under federal law. Two cannabinoids (dronabinol, nabilone) are approved by the FDA and therefore can be legally prescribed in the United States. Dronabinol contains the trans isomer of THC within a gelatin capsule. Marijuana can be used to make hashish and hash oil, which contain concentrated cannabinoids. Both marijuana and hash oil can be consumed by inhalation (smoking and vaporizing) and by mouth (drinking it as a tea or eating after it is mixed into foods, such as baked goods). Smoked cannabis has been found to contain Aspergillosis, and immunosuppressed patients should not use it.\textsuperscript{226} Vaporizing marijuana by heating it to temperatures between 180°C and 200°C releases substantial amounts of cannabinoids with only trace amounts of a few other chemicals. Maida et al.\textsuperscript{227} assessed the effectiveness of nabilone in managing pain in advanced cancer patients which significantly improved pain, nausea, anxiety, and total distress. Johnson et al.\textsuperscript{228} compared the efficacy of a THC:CBD extract (2.7 mg THC, 2.5 mg CBD delivered by oromucosal spray) and a THC extract (2.7 mg THC delivered by oromucosal spray), with placebo in 177 patients with refractory cancer pain to chronic opioid therapy (average daily oral morphine equivalent dose [MED] 271 mg) and reported that the THC:CBD extract was efficacious, but the number of THC responders was similar to placebo. In a pilot study of 18 patients with pain related to CIPN, nabiximols (THC/CBD oral mucosal spray) had an efficacy comparable to the use of gabapentin for this problem.\textsuperscript{229} Both cannabis and cannabinoid pharmaceuticals can be helpful for a number of problems affecting patients with cancer.\textsuperscript{230,231} Data supporting the use of these products for cancer-related pain is lacking.
Opioid Analgesics

Opioids are the mainstay of pharmacotherapy for patients with moderate or more intense pain resulting from virtually any cancer-related etiology. A detailed discussion of opioid pharmacology and principles of prescribing is found in Chapter 79.

SELECTION OF OPIOID THERAPY IN CANCER PAIN MANAGEMENT

As in all patients who may have pain-related indications for opioid therapy, the effective clinical use of opioid drugs requires familiarity with drug selection, routes of administration, dosage guidelines, and potential adverse effects. Several factors must be considered if opioids are to be used effectively. These include:

- Previous opioid exposure and preference
- Severity, nature, and stage of disease
- Age of patient
- Extent of cancer, particularly hepatic and renal involvement altering normal opioid pharmacokinetics
- Concurrent disease
- Available formulations
- Risk assessment for problematic opioid use (see “Substance Abuse in Oncology” section)

The presence of renal impairment or failure affects the pharmacokinetics of opioids (Table 43.8). Renal failure has different effects on individual opioids with some opioids having active or toxic metabolites. The effects from dialysis should also be considered with the likelihood of removal of any molecule in blood by dialysis dependent on the molecular weight, water solubility, degree of protein binding, and volume of distribution. Fentanyl, for example, has high protein binding and low water solubility, as well as a high volume of distribution, and a moderately high molecular weight suggesting poor removal by dialysis.232,233 Glomerular filtration rate (GFR) approximates the renal excretion of many drugs, and some authors recommend adjustment of opioid dosage based on the GFR.234 Unlike estimates of GFR in renal
disease, adequate biomarkers relating to hepatic function and drug elimination capacity, are not available. The most commonly used systems to assess the severity of hepatic impairment are the Child-Pugh classification and the Model for End-Stage Liver Disease (MELD) system. Opioids used in patients with severe liver disease in patients with a history of hepatic encephalopathy may precipitate or aggravate encephalopathy. Methadone is metabolized by oxidation, with principal involvement of CYP3A4 and CYP2B6. The elimination of methadone and its metabolites is urinary and fecal. The use of methadone was studied in 11 patients with severe liver disease and although the $t_{1/2}$ was longer, peak plasma levels were lower. None of the patients had signs or symptoms of overdose and six patients had flattened plasma methadone concentration-time curves (Table 43.9).

The specific pathogenic mechanism that underlies a patient’s cancer pain should not be a factor in deciding which opioid to use because the mechanism of pain does not reliably predict the response to opioid therapy. This particularly applies to situations in which tumor-associated neuropathic mechanisms dominate the pain complaint. Opioids should be used as first-line therapy in such situations, particularly if the pain is considered moderate to severe in intensity. Haumann et al. demonstrated a beneficial effect from methadone compared to fentanyl on head-and-neck cancer patients with neuropathic pain. Oxycodone/naloxone and pregabalin were also deemed effective in lung cancer patients with neuropathic pain. Controlled-release oxycodone (average daily dose 28 mg with range 20 to 80 mg) was effective and well-tolerated in patients with bortezomib-associated painful CIPN. There is limited data on the use of opioids for neuropathic nonmalignant pain.
Extended-release oxycodone was used for the management of painful diabetic neuropathy and postherpetic neuralgia, but the data was considered very low quality. Morphine was also studied for use in painful diabetic neuropathy, CIPN, postherpetic neuralgia, phantom limb or postamputation pain, and lumbar radiculopathy again with insufficient evidence to support or refute use. Similarly, the data support the use of methadone and fentanyl for diverse neuropathic pain syndromes including postherpetic neuralgia is also inconclusive. Short-term studies provide only equivocal evidence regarding the efficacy of opioids in reducing the intensity of neuropathic pain. Intermediate-term studies demonstrated significant efficacy of opioids over placebo, but these results are likely to be subject to significant bias because of small size, short duration, and potentially inadequate handling of dropouts.

Patients surviving cancer typically experience a shift in the use of opioids from the routine prescribing that occurred in the active treatment phase to an approach more consistent with prescribing patterns for chronic noncancer pain when pain is expected to persist for years. However, the rate of opioid prescribing was significantly higher among survivors of cancer compared with age/sex-matched controls without a prior cancer diagnosis and higher prescribing rate persisted, even for survivors more than 10 or more years postdiagnosis. The rate of prescriptions was greater for survivors of lung, GI, genitourinary, or gynecologic cancer compared with their corresponding controls.

There is little high-grade data on opioid use specifically in the elderly cancer patient. Elderly patients are more likely to have multiple comorbidities, the potential for drug interactions, and are physiologically more vulnerable to opioid use than younger patients. There are also age-related differences in the perception of, and response to, pain. Because the elderly have a higher incidence of cognitive impairment, confusion, and memory loss, either from pathology or medication use, and confounded by sight and hearing impairment, problems with prescription adherence and medication-related adverse effects can occur. The tolerability profile of opioids is important in elderly patients, as adverse events such as drowsiness, dizziness, and motor imbalance can have serious consequences in patients who are already more prone to falls and
fractures.\textsuperscript{249} Daily use of three or more psychoactive medications was associated with recurrent falls in the elderly.\textsuperscript{250} High-risk medications, in particular benzodiazepines and benzodiazepine-receptor agonists, often administered at higher-than-recommended geriatric daily doses, were associated with falls in elderly, hospitalized patients.\textsuperscript{251} In general, the clinical circumstance dictates the choice of a short- or long-acting opioid. For example, the treatment of acute or postoperative pain usually requires frequent titration, and short-acting opioids, with duration of action of 2 to 4 hours, are preferred. Short-acting agents may be favored initially for the management of mild- to moderate-intensity tumor pain as they are easier to titrate than long-acting or ATC opioids. Short-acting opioids are characterized by a rapid rise and fall in serum opioid levels, whereas serum levels of long-acting opioids increase slowly to therapeutic levels, remain there for an extended period, and then slowly decline.\textsuperscript{252} Conversely, the treatment of cancer pain or chronic, moderate to severe nonmalignant pain usually can be treated with a long-acting oral agent, with a duration of action of 12 to 24 hours, with less need for daily titration. In patients treated with long-acting agents, short-acting opioids should be provided as rescue medication for breakthrough pain, which is very common in patients with cancer pain.\textsuperscript{253,254} An ongoing opioid regimen should include provisions for rescue doses for the treatment of breakthrough pain. The rationale for providing rescue medication instead of increasing the dose of the ATC opioid is to prevent overmedication and associated adverse events. Often, there is a narrow therapeutic window between an opioid dose sufficient to achieve pain relief and one that is associated with unacceptable adverse events.\textsuperscript{255} For patients treated with a long-acting opioid, an immediate-release (IR) or short-acting opioid formulation (often the same drug) may be used as the rescue medication. In general, the rescue drug should be started at a dose equivalent to approximately 10\% of the 24-hour baseline dose and titrated upward to achieve adequate pain relief.\textsuperscript{256} The dosing frequency of the rescue drug depends on the time to peak effect and the route of administration; in general, oral rescue doses can be administered as frequently as every 2 hours if needed but typically tend to be given every 3 to 4 hours as needed.\textsuperscript{257} Generally, three types of breakthrough pain should be
considered—spontaneous, incident, or end-of-dose failure. A key principle in treating breakthrough pain is to optimize the background pain control by appropriately adjusting the ATC opioid regimen. With end-of-dose failure, the clinician can increase the dose or shorten the dosing interval of the ATC opioid or increase the dose of the rescue opioid. Similar strategies may be employed for spontaneous pain, but successful management of spontaneous or incident pain may require the use of short-acting, rapid-onset opioids (“Oral Transmucosal/Intranasal/Sublingual Fentanyl” section).

Because of the substantial interpatient variability in opioid responsiveness, clinicians who prescribe opioids for the treatment of cancer pain should be familiar with at least three different agents appropriate for the management of moderate to severe pain. The pharmacology of these agents can be reviewed in Chapter 79.

The regimen for opioid medications should generally provide ATC analgesia with provision for rescue doses for the management of exacerbations of the pain not covered by the regular dosage. Various extended-release oral and transdermal opioids are listed in Table 43.10. At all times, causes of new or uncontrolled pain should be determined and addressed by disease-modifying treatments and a gradual increase in the opioid dose until either pain control is achieved or intolerable and unmanageable adverse effects supervene. The management of pain with opioid analgesics demands frequent patient assessment and a readiness to reevaluate the therapeutic plan in the setting of either inadequate relief or adverse effects. Predicting effectiveness of extended-release opioids requires knowledge of associated pharmacokinetics. In particular, the onset time and time to maximal concentration ($T_{\text{max}}$) is particularly helpful. Table 43.11 lists $T_{\text{max}}$ for various doses of transdermal fentanyl. After initial application, the maximal concentration (peak analgesic effect or associated side effects) is not reached until approximately 32 hours. The dosing interval is determined by steady state. For the extended-release opioids, the $t_{\frac{1}{2}}$ is not particularly helpful because of altered absorption characteristics into the central compartment.

Janssen MD. Duragesic (Fentanyl Transdermal System) for Transdermal Administration. Titusville, NJ: Janssen MD; 2014.
There is no single optimal or maximal dose of an opioid analgesic drug. In general, for progressive, tumor-related pain, the appropriate dose of an opioid is one that relieves a patient’s pain throughout the dosing interval without causing unmanageable or intolerable adverse events. The initial dose may be based on the severity of pain and known response to prior analgesic therapy, if any. Aggressive upward titration to a stable dose (i.e., one that provides adequate pain relief throughout the dosing interval) is predicated on continuing assessment of the effectiveness of therapy. Patients rarely benefit from combinations of different opioids given in suboptimal doses; ideally, clinicians should prescribe a single opioid analgesic and titrate to a stable dose. However, it is important to recognize that there is significant interpatient variability with regard to responsiveness to different opioid drugs, and patients who respond poorly to one opioid may respond favorably to another. In situations in which pain is not related to the tumor or its treatment, a dose limit should be considered.

**TOLERANCE AND HYPERALGESIA**

Opioid tolerance is a phenomenon in which repeated exposure to an opioid results in decreased therapeutic effect of the drug or need for a higher dose to maintain the same effect. Tolerance can be overcome by increase the opioid dose. Opioid-induced hyperalgesia (OIH) is a state of nociceptive sensitization caused by opioid exposure and is characterized by a paradoxical response to opioid treatment where patients become more sensitive to pain. In contrast to tolerance, dose increases make the pain complaint worse. OIH is more commonly seen in patients receiving high opioid doses. The majority of reports not only involve the use of systemic (oral, intravenous, intramuscular) or intrathecal morphine but may also occur with intrathecal sufentanil, fentanyl, remifentanil, and hydromorphone. In this setting, patients report increased pain as well as allodynia and myoclonus. OIH has been reported in various clinical settings including acute pain, chronic noncancer pain, cancer pain, and opioid addiction. Very high intravenous and intrathecal opioid doses can cause OIH. OIH should be recognized as a syndrome of neuroexcitatory effects, which includes hyperalgesia, allodynia,
myoclonus, and seizures. The predominant symptom of OIH is severe allodynia (touch-evoked pain) and is often accompanied by myoclonus. Placing a blanket on or gently turning a bedridden patient can evoke excruciating pain. The diagnosis is confirmed if further dose escalation exacerbates pain complaints or symptoms and temporarily holding opioid therapy eliminates or reduces symptoms. Management strategies for hyperalgesia usually require a reduction in opioid dosage and/or switching to a different opioid, especially one that does not have known toxic metabolites. However, the occurrence of OIH with normal clinical doses is questionable.\textsuperscript{275,276} In a study on the presence of OIH following oral administration of opioids (oxycodone and morphine in daily doses up to 200 mg) in both cancer and noncancer pain patients, OIH was not observed.\textsuperscript{277} Not all patients develop OIH and the detection and occurrence of OIH poses a significant clinical challenge in acute, chronic, and cancer pain settings.

Theoretically, prolonged use of opioids is known to result in antinociceptive tolerance, in which higher doses of the opioid are required to elicit the same amount of pain relief or antinociception.\textsuperscript{278–280} Chu et al.\textsuperscript{281} showed that patients receiving sustained-release morphine to an end titration dose of 78 mg morphine per day developed tolerance after 1 month with an average 42% reduction in analgesic potency. Long-term exposure to one drug often results in the development of tolerance to the effects of other structurally similar drugs in the same pharmacologic class, a phenomenon termed cross-tolerance. Opioids exhibit cross-tolerance, but it is rarely complete, as evidenced by opioid rotation particularly in the treatment of cancer pain.\textsuperscript{282–286} Clinically, opioid rotation is challenging because of a lack of evidence-based medicine to support the dose conversions with switching regimens largely based on anecdote or on observational and uncontrolled studies.\textsuperscript{287} In practice, physical dependence and tolerance does not prevent the effective use of these drugs in patients with cancer pain. The evidence for the development of tolerance to the analgesic effects of opioids with chronic administration in oncology is mixed. Many of the studies were in cancer patients with severe pain and showed that they maintained a stable opioid dose (for weeks to years) even with different routes of administration.\textsuperscript{279,288} Patients with stable disease
often remain on a stable dose for weeks or months. Collin et al. demonstrated a relationship between tumor progression and escalation of opioid doses over time such that the development of opioid tolerance from chronic opioid use was unlikely in cancer patients with pain.

**MORPHINE**

Morphine is the oldest opioid and is generally considered to be the gold standard. In a Cochrane review, Wiffen et al. reported that morphine was an effective analgesic for cancer pain and that pain relief did not differ between extended (modified) release and IR preparations. Modified-release morphine was effective for 12- or 24-hour dosing depending on the formulation. Daily doses in studies ranged from 25 to 2,000 mg with an average of between 100 and 250 mg. A small number of patients did not achieve adequate analgesia with morphine and although adverse events were common, they were predictable with approximately 6% stopping treatment because of intolerable adverse events. The main disadvantage of morphine in cancer patients who require high opioid doses, or who have reduced renal clearance, is the accumulation of active (morphine-6-glucuronide) and toxic (morphine-3-glucuronide), which may complicate the clinical picture with excessive sedation or neurotoxic adverse effects. Early signs of these effects should trigger consideration for switching to a different opioid.

**OXYCODONE**

Oxycodone may exert its analgesic effects through \( \mu \)-opioid receptor and \( \kappa \) receptors. Modified-release oxycodone (OxyContin) reaches \( T_{\text{max}} \) at approximately 4.6 hours with an apparent \( t_{1/2} \) of 4.5 hours. OxyContin was reformulated in 2010 with inactive ingredients intended to make the tablet more difficult to manipulate for misuse and abuse and has an oral bioavailability of 60% to 87%. With reformulation, the immediate component (estimated up to 30% of the total dose) was eliminated. Unlike morphine, the drug is not glucuronidated but metabolized primarily by CYP3A4. Concomitant use of with a CYP3A4 inhibitor, such as macrolide antibiotics (e.g., erythromycin), azole-antifungal agents (e.g., ketoconazole), and protease inhibitors (e.g., ritonavir), may increase
plasma concentrations of oxycodone. Use with serotonergic drugs may result in serotonin syndrome. Oxycodone is extensively metabolized by multiple metabolic pathways to produce noroxycodone, oxymorphone, and noroxymorphone. Oxymorphone is present in the plasma only at low concentrations. Cancer cachexia can increase the plasma exposure of oxycodone through the reduction of CYP3A metabolic pathway.\textsuperscript{293} Oxycodone offers similar levels of pain relief and adverse events to other opioids including morphine for cancer-related pain.\textsuperscript{11,294} Like any opioid, the benefits of recommending oxycodone as an alternative opioid for moderate to severe cancer pain are in choice and flexibility.\textsuperscript{295} Choice includes cost, perceptions, social or cultural factors, and availability. Flexibility is having the ability to offer an alternative should another opioid prove ineffective or poorly tolerated.

**OXYMORPHONE**

Oxymorphone is a semisynthetic $\mu$-opioid agonist that exhibits greater specificity for the $\mu$-opioid receptor than for the $\delta$- or $\kappa$-opioid receptors.\textsuperscript{296,297} In 2006, the FDA-approved extended-release oxymorphone HCl for the control of moderate to severe chronic pain. The pharmacokinetic profile is predictable, linear, and dose-proportional.\textsuperscript{298} The t$_{1/2}$ is 9 to 11 hours. The T$_{\text{max}}$ varies from 3 to 6 hours.\textsuperscript{299} The absolute oral bioavailability is approximately 10%. Oxymorphone undergoes minimal CYP450 metabolism, and is metabolized primarily by UGT2B7 (and potentially UGT1A3) to the inactive metabolite noroxymorphone. Consequently, oxymorphone ER, along with morphine and hydromorphone, lacks significant potential for CYP-mediated drug interactions and is unaffected by genetic factors influencing these enzymes. In contrast, other opioids including methadone, oxycodone, buprenorphine, and others metabolized by CYP enzymes have the potential for clinically important pharmacokinetic interactions with other drugs that share this metabolic pathway. Slatkin et al.\textsuperscript{300} evaluated the effectiveness and tolerability over 52 weeks of oxymorphone ER in patients with cancer and noted that the drug was well tolerated and provided long-term stable pain control. Oxymorphone IR has a t$_{1/2}$ longer than that of morphine, hydromorphone, and oxycodone and a T$_{\text{max}}$ of 30
minutes. Food does not affect the shape of concentration time curve.\textsuperscript{297}

**HYDROMORPHONE**

Hydromorphone is a semisynthetic derivative of morphine. It primarily acts on µ receptors and to a lesser degree on δ receptors.\textsuperscript{301} Hydromorphone binds more specifically to µ receptors than structurally related morphine. The IR form is absorbed in the upper small intestine and is extensively metabolized by the liver. Approximately 60\% of the oral dose is eliminated by the liver on first pass, partly accounting for oral bioavailability in the range of 1:2 to 1:8.\textsuperscript{302} For orally administered, IR preparations, the onset of action is approximately 30 minutes, $T_{\text{max}}$ 0.75 hours and duration of action is approximately 4 hours. Hydromorphone is glucuronidated into hydromorphone-3-glucuronide, a metabolite that may have neuroexcitatory effects.\textsuperscript{291,303} Hydromorphone-3-glucuronide follows a similar time course to hydromorphone in plasma. Of note there is an extended-release hydromorphone product (Exalgo). Hydromorphone in clinically relevant concentrations has minimal potential to inhibit CYP enzymes. After oral intake, plasma concentrations gradually increase over 6 to 8 hours, with a $T_{\text{max}}$ ranging from 12 to 16 hours and concentrations are sustained for 18 to 24 hours. Mean $t_{1/2}$ is approximately 11 hours, and linear pharmacokinetics occur over a dose range from 8 to 64 mg. Steady state is reached 3 to 4 days after once-daily dosing. The safety and tolerability of Exalgo has been reported in opioid-tolerant patient with moderate to severe chronic cancer and noncancer pain.\textsuperscript{304} The mean duration of exposure was 43.1 days (range 1 to 396 days), and mean daily dose was 43.4 mg. Patients demonstrated a safety and tolerability profile consistent with the known safety profiles of opioids. Bao et al.\textsuperscript{305} reported that in oncology pain, hydromorphone provides similar pain relief to morphine and oxycodone and has similar side effects.

**METHADONE**

Methadone is a synthetic opioid and is a potent agonist at the µ- and δ-opioid receptors. In animal studies, it has antagonist activity at the N-methyl-D-aspartate (NMDA) receptor, resulting in interest in the clinical application of the drug in neuropathic pain syndromes.\textsuperscript{306–309} In most
countries, it is available as a racemic mixture of two isomers, levorotatory (L) methadone and dextrorotatory (D) methadone. Following oral administration, the drug is rapidly absorbed with measurable plasma levels between 15 and 45 minutes. The peak plasma levels after an oral dose occur at four hours and begin to decline 24 hours after dosing. Oral bioavailability is over 85%. The primary route of elimination is oxidative biotransformation. It is N-demethylated to 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP). The major enzyme involved in N-demethylation is CYP3A4 and CYP2B6. CYP2D6 genetic status affects steady-state blood concentrations. The $t_{1/2}$ ranges from 5 to 130 hours with a mean of 20 to 35 hours. Concomitant administration of CYP3A4 inducers will increase methadone metabolism potentially causing a reduction in methadone plasma concentrations. This may result in the need for larger doses of methadone during the period of interaction. In addition, doses of methadone may need to be reduced when a CYP3A4 inducer is discontinued. Known inducers of CYP3A4 include rifampin, rifabutin, carbamazepine, phenytoin, phenobarbital, and abacavir. The commonly used dietary supplement for depression, St. John’s Wort, has also been shown to lower the plasma concentrations of methadone. CYP2B6 plays a significant role in the stereoselective metabolism of (S)-methadone to 2-ethyl-1,5-dimethyl-3,3-diphenylpyrrolidine, an inactive methadone metabolite. Elevated (S)-methadone can cause cardiotoxicity by prolonging the QT interval. One or more single nucleotide polymorphisms (SNPs) located within the CYP2B6 gene can contribute to a poor metabolizer phenotype with higher than predicted methadone levels and can be associated with fatalities.

Methadone is implicated in the prolongation of the QTc interval, which is considered a marker for arrhythmias such as torsade de pointes (TdP). Indications on the association between methadone, even at therapeutic dosages, and TdP or sudden cardiac death are reported. A QTc of 500 milliseconds is generally accepted as a threshold of increased danger for TdP. Evidence implicating the relationship between methadone and TdP is limited, and the contributions of other known risk factors (including other medications, drugs, electrolyte abnormalities, structural heart disease, and others) are also implicated. In a pediatric oncology patient
population, methadone dosage, and duration (mean dose was 27.0 mg per day with range, 5 to 125 mg per day; mean duration of therapy was 49 days) were not correlated with QTc prolongation, even in the presence of other risk factors at clinically effective analgesic doses. In a pilot study on adult oncology patients treated with oral methadone (median dose 23 mg, range 3 to 90 mg) over an 8 week period, 28% of patients had evidence of QTc prolongation prior to initiation of methadone and only 1 patient demonstrated a QTc >500 milliseconds without evidence of a clinically significant arrhythmia. Of note, conventional chemotherapy and targeted therapies are associated with an increased risk of cardiac damage, including LV dysfunction and heart failure, treatment-induced hypertension, vasospastic and thromboembolic ischemia, as well as rhythm disturbances, including conduction system damage and potentially QTc prolongation that may be rarely life-threatening. In addition, the use of some medications used in supportive care during cancer therapy (e.g., antiemetics, antidepressants) in combination with cancer treatments can lead to QT prolongation.

Methadone is a versatile and potentially useful analgesic for cancer pain control. It has no known active metabolites, and it is relatively inexpensive compared with other modified-release opioid formulations. Because of a highly variable t_{1/2}, the use of methadone is complicated with potential for accidental overdose if not titrated appropriately. Because steady state is not attained for 3 to 5 days, dose changes need to be slow and situations that require frequent dose changes (e.g., rapidly escalating tumor pain) are not ideal for methadone use. Prescribers should be experienced with the use of methadone in oncology, and patients need to be carefully counseled and cautioned to use methadone only as directed in order to prevent unintended dose accumulation. Based on very limited amounts of data, there were no clear differences in participant-reported pain intensity or pain relief between methadone and morphine or transdermal fentanyl. In a relatively small number of patients (146 patients) with cancer-related pain, methadone was considered effective as a second-line alternative opioid for patients with a lack of efficacy or intolerance issues with their previous opioid.
LEVORPHANOL

Leverphanol is considered a full µ-opioid agonist and is relatively selective for µ-opioid receptors although it also has multiple receptor activity including δ, κ₁, and κ₃, with NMDA receptor antagonism and reuptake inhibition of both norepinephrine and serotonin. It is well absorbed after PO administration with peak plasma concentrations occurring approximately 1 hour after dosing. Leverphanol has a t₁/₂ of 11 to 16 hours with a duration of analgesic effect between 6 and 15 hours. Expected steady-state plasma concentrations for a 6-hour dosing interval can reach 2 to 5 times those following a single dose, depending on the patient’s individual clearance of the drug. It has no known effect on QTc interval or drug–drug interactions involving CYP450 enzymes. It is metabolized to leverphanol-3-glucuronide which is inactive. From a relative potency perspective at steady state, 2 mg oral dose of leverphanol is approximately equivalent to 10 mg oral oxycodone. Dose conversion suggestions for leverphanol are listed in Table 43.12. Typical initial doses are 1 to 2 mg every 6 to 8 hours and are available as a 2-mg tablet. Information on the use of leverphanol in cancer pain is limited. McNulty reported on its use in a case series of 31 patients, 20 with chronic nonmalignant pain in a palliative care clinic and 11 terminally ill patients enrolled in hospice care whose severe chronic pain was not relieved by treatment with other opioids, were treated with oral leverphanol. Of those 31 patients, 16 (52%) reported excellent relief of pain and 7 (22%) reported fair relief.

FENTANYL

Fentanyl is a synthetic full agonist at µ-opioid receptors and has a high lipophilicity allowing rapid transfer from the plasma to cerebrospinal fluid (CSF). Nonparenteral fentanyl products first became available in the last 1980s as a transdermal patch and then as a transmucosal product in 1993. Nonintravenous formulations deliver fentanyl by transmucosal, intranasal, or by transdermal routes. The main advantage of the patch was maintenance of a steady-state plasma concentration ideal for the treatment of background cancer pain. The main advantage of the transmucosal product was its associated rapid absorption is ideal for the management of breakthrough cancer pain. The pharmacokinetic and clinical parameters of nonparenteral fentanyl formulations are listed in Table 43.13.

<p>| Table 43.13 Pharmacokinetic and Clinical Parameters of Nonparenteral Fentanyl Formulation |

**Transdermal Fentanyl**

Transdermal therapeutic system fentanyl (fentanyl-TTS) patches are rectangular transparent units each comprising a protective liner and four functional layers. These layers consist of a backing layer of polyester film, a drug reservoir of fentanyl and alcohol USP gelled with hydroxyethyl cellulose, an ethylene-vinyl acetate copolymer membrane that controls the rate of fentanyl delivery to the skin surface, and a fentanyl-containing silicone adhesive. The amount of fentanyl released from each system per hour is proportional to the surface area (25 µg per hour per 10 cm²). Each patch contains a proportional fentanyl content, for example, the 12 µg per hour patch has a total fentanyl content of 1.25 mg and the 25 µg per hour patch 2.5 mg fentanyl content. The Duragesic patch has a protective liner and four functional layers consisting of a backing layer of polyester film, a drug reservoir of fentanyl and alcohol USP gelled with hydroxyethyl cellulose, an ethylene-vinyl acetate copolymer membrane that controls the
rate of fentanyl delivery to the skin surface, and a fentanyl-containing
silicone adhesive. The initial formulation consisted of a liquid fentanyl
drug reservoir separated from the adhesive layer by a rate-limiting
membrane, and ethanol as coabsorbent to provide controlled drug release.
This formulation was problematic because of the high concentration of
fentanyl present, which could be easily syphoned off.\textsuperscript{327–330}
Newer transdermal fentanyl formulations exclusively use the matrix technique,
with the drug dissolved in an inert polymer matrix that diminishes the risk
of incidental drug leakage and complicates the extraction of the drug for
abuse.\textsuperscript{331}

The transdermal system releases fentanyl from the reservoir at a nearly
constant amount per unit time. The concentration gradient existing
between the saturated solution of drug in the reservoir and the lower
concentration in the skin drives drug release. Fentanyl moves in the
direction of the lower concentration at a rate determined by the copolymer
release membrane and the diffusion of fentanyl through the skin layers. A
cutaneous depot of fentanyl forms in the upper layers of the skin, the
stratum corneum, from where it passively diffuses to the dermis and
ultimately removed by the cutaneous microcirculation. Although the actual
rate of fentanyl delivery to the skin varies over the application period, each
system is labeled with a nominal flux, which represents the average
amount of drug delivered to the systemic circulation per hour across
average skin. Although there is variation in dose delivered among patients,
the nominal flux of the systems is sufficiently accurate to allow individual
titration of dosage for a given patient. Following patch application, the
skin under the system absorbs fentanyl, and a depot of fentanyl
concentrates in the upper skin layers. Fentanyl then becomes available to
the systemic circulation. There is a lag time of approximately 2 hours
before plasma levels of fentanyl are detected with therapeutic levels after
12 to 16 hours postapplication.\textsuperscript{332} T_{max} for the patch is approximately 34
hours (see Table 43.13). The system delivers fentanyl continuously for up
to 72 hours with a bioavailability of approximately 92\%. After sequential
48- or 72-hour applications, patients reach and maintain steady-state serum
concentrations that are determined by individual variation in skin
permeability and body clearance of fentanyl. A number of studies
demonstrate that constant serum levels are maintained with the second transdermal system and that fluctuations of serum levels are small after the first 72 hours.\textsuperscript{333,334} After system removal, serum fentanyl concentrations decline gradually and has an apparent $t_{1/2}$ of 17 hours. Because of the possibility of temperature-dependent increases in fentanyl release from the system, it is important to advise patients to avoid exposing the application site to direct external heat sources, such as heating pads, heat lamps, and heated waterbeds. Prolonged exposure to heat or use in patients who are febrile can cause a toxic overdose.\textsuperscript{335,336} Fentanyl is metabolized primarily via cytochrome P450 3A4 isoenzyme system. Concomitant use of CYP3A4 inhibitors may increase fentanyl plasma concentrations. Fentanyl undergoes rapid and extensive first-pass metabolism that accounts for its poor oral bioavailability (less than 30\%) and the lack of oral products. The patch should not be used in patients who are not opioid-tolerant, for acute pain issues, for postoperative pain management and in the management of intermittent pain.

BTP, breakthrough pain.

The transdermal patch is widely used in the treatment of both malignant and nonmalignant chronic pain. Clinically, cachectic cancer patients may require higher transdermal doses for adequate pain relief than normal weight or obese patients. Heiskanen et al.\textsuperscript{337} studied the pharmacokinetic profile in 10 cachectic (mean body mass index [BMI] 16 kg/m\textsuperscript{2}) and noted that plasma fentanyl concentrations adjusted to dose were significantly lower at 48 and 72 hours in cachectic patients than normal weight patients suggesting that the absorption was impaired in cachectic patients. The cachectic patients had a significantly thinner upper arm skin fold, but no differences were found in local blood flow, sweating, or skin temperature. Hypoalbuminemia (albumin <3.5 g/dL) is also associated with poor absorption from fentanyl-TTS.\textsuperscript{338} Although fentanyl-TTS is widely used in palliative care settings, there are relatively few studies in its use in cancer pain making judgment on efficacy difficult.\textsuperscript{339} Rash and pruritus, commonly a concern with transdermal preparations, were infrequent and improved with time. A number of studies compared the impact of constipation between fentanyl-TTS and slow-release morphine.\textsuperscript{340–342} Fewer study participants experienced constipation with fentanyl (28%) than with oral morphine (46%). Tassinari et al.\textsuperscript{343} assessed the role of
transdermal fentanyl as a first-line approach for moderate to severe cancer pain bases on the GRADE approach and concluded that the risk/benefit ratio was uncertain and that the quality of evidence was low. Finally, there is insufficient evidence to support or refute the suggestion that fentanyl has any efficacy in any neuropathic pain condition. In the absence of any supporting evidence, it should probably not be recommended, except at the discretion of a pain specialist with particular expertise in opioid use.

**Oral Transmucosal/Intranasal/Sublingual Fentanyl**

IR fentanyl is available in oral transmucosal and intranasal preparations (see Table 43.13). The oral products include lozenge (Actiq), sublingual tablet (Abstral), sublingual spray (Subsys), buccal tablet (Fentora), and buccal film (Onsolis). The intranasal product is a metered nasal spray (Lazanda). The first IR fentanyl was the lozenge. Compared to IR morphine, this drug with its rapid onset of action (5 minutes) and relatively short duration of effect was significantly better in treating breakthrough cancer pain. There are no head-to-head trials comparing any of the newer transmucosal formulations with each other. Oral and nasal transmucosal fentanyl formulations were an effective treatment for breakthrough pain. When compared with placebo or oral morphine, study participants reported lower pain intensity and higher pain relief scores for transmucosal fentanyl formulations at all time points. Global assessment scores also favored transmucosal fentanyl preparations.

In 2011, the FDA approved a single shared-system risk evaluation and mitigation strategy (REMS) for the entire class of transmucosal immediate-release fentanyl (TIRF) medications. TIRF medicines include Abstral (fentanyl) sublingual tablet, Actiq (fentanyl citrate) oral transmucosal lozenge and its generic equivalents, Fentora (fentanyl citrate) buccal tablet, Lazanda (fentanyl) nasal spray, and Onsolis (fentanyl) buccal soluble film. The TIRF REMS program required prescribers, pharmacies, distributors, and outpatients to enroll in order to prescribe, dispense, or receive all drugs in the category. In outpatient settings, all health care providers must complete and sign a TIRF REMS Access Patient-Prescriber Agreement Form with each new patient before writing the patient’s first TIRF prescription. Health care providers must also
provide patients with a copy of the Medication Guide during counseling about the proper use of their TIRF medicine. Health care providers who prescribe TIRF medicines for inpatient use only (e.g., hospitals, hospices, or long-term care facilities) are not required to enroll in the TIRF REMS Access program. TIRF medications are approved only to manage breakthrough pain in adults with cancer who are routinely taking and are tolerant to other opioid pain medicines ATC for pain. Opioid tolerance is the use of an opioid for one week or longer in doses equivalent to 60 mg oral morphine per day or an equianalgesic dose of another oral opioid. TIRF medications are contraindicated in the management of acute or postoperative pain, including headache/migraine and dental pain. Of note, TIRF medications are not interchangeable with each other nor equivalent to any other fentanyl product including another TIRF medication on an µg-per-µg basis. The only exception is the substitution of a generic equivalent for a branded TIRF medication. Dose conversions with initial dosing and titration schedules are listed in Table 43.14.

Fentanyl-Associated Deaths
Drug overdose is an important, yet an inadequately understood, public health problem with substantial increase in incidence and prevalence in several countries worldwide over the past decade, contributing to both increased costs and mortality. The increase of fentanyl abuse (both legally and illegally produced) is a growing public health problem with multiple states reporting increases in fentanyl-involved overdose deaths. One hundred and twelve fentanyl-related deaths were identified in Canada between 2002 and 2004. Routes of administration included transdermal application of patches, intravenous injection of patch contents or fentanyl citrate solution, oral/transmucosal administration, and volatilization and inhalation of Duragesic systems. The high potency and narrow therapeutic range of fentanyl compounds and patches available may explain the potential of fentanyl abuse and associated deaths. In the United States, between 2013 and 2014, the age-adjusted rate of deaths involving synthetic opioids increased by 80% and by 250% among younger people. Several fentanyl derivatives (initially sufentanil, alfentanil, remifentanil, carfentanil, and, more recently, acetylfentanyl, 6-
butyrfentanyl, 4-MeO-butyrfentanyl, isobutyrylfentanyl, furanylfentanyl, α-methylfentanyl, 3-methylfentanyl or TMF, p-methylfentanyl, methylacetylfentanyl, acrylfentanyl, 2-fluorofentanyl, fluoroacetylfentanyl, ocfentantanyl, and many others) are illegally manufactured. The catastrophic emergence of potent fentanyl analogs mixed with street heroin is a major public safety concern. Concerns about legally prescribed fentanyl have also been expressed for some time. In July 2005, FDA issued a Public Health Advisory and Information for Healthcare Professionals that emphasized the appropriate and safe use of the fentanyl transdermal system (fentanyl patch), marketed as Duragesic and generics. Despite these efforts, FDA has continued to receive reports of death and life-threatening adverse events related to fentanyl overdose that have occurred when the fentanyl patch was used to treat pain in opioid-naive patients and when opioid-tolerant patients have applied more patches than prescribed, changed the patch too frequently, and exposed the patch to a heat source. There is also a variety of methods associated with intentional abuse of fentanyl patches including attempts to extract the drug from the patch and inject intravenously, chewing or swallowing patches, inserting patches into the rectum, and inhaling fentanyl gel. Aberrant behaviors have been associated with the use of transmucosal fentanyl in chronic pain patients. Concerns about abuse and death have also been expressed with transmucosal fentanyl even among cancer patients with active disease.

**BUPRENORPHINE**

Buprenorphine is a semisynthetic derivative of thebaine. It is available in the United States for the treatment of addiction and for the treatment of chronic pain. It is a potent partial agonist of the µ-opioid receptor with high affinity but low intrinsic activity. The slow dissociation (t$_{1/2}$ association/dissociation is 2 to 5 hours) accounts for its prolonged therapeutic effect. It is metabolized in the liver through CYP3A4 N-dealkylation. The relative bioavailability of the sublingual tablet is 29% with a t$_{1/2}$ of 20 to 73 hours. The transdermal buprenorphine product Butrans is available in strength of 5, 7.5, 10, 15, and 20 µg per hour delivering 7-day dosing and is indicated for pain severe enough to require
daily, ATC opioid therapy. The 10 µg per hour patch corresponds to
approximately 30 to 80 mg per day of oral morphine equivalents. The
maximum recommended dose is 20 µg per hour. The median time for the
10 µg per hour patch to deliver quantifiable buprenorphine concentrations
(≥25 pg/mL) was approximately 17 hours. After removal of the patch,
mean buprenorphine concentrations decrease approximately 50% within
10 to 24 hours, followed by decline with an apparent terminal t\textsubscript{1/2} of
approximately 26 hours. Sublingual formulations of buprenorphine are
available in the United States market as monotherapy (generic tablet) and a
combination therapy of buprenorphine with naloxone (Suboxone, Zubsolv
as a tablet or film) for opioid addiction. One Zubsolv 5.7 mg/1.4 mg
sublingual tablet provides equivalent buprenorphine exposure to one
Suboxone 8 mg/2 mg sublingual tablet.

Buprenorphine should not be used for acute pain management, for
example, when there is a need for rapid dose titration for severe pain in
cancer and palliative care settings. One potential issue is that because of
the high affinity for µ-opioid receptors with a slow dissociation profile,
buprenorphine may potentially displace or prevent the binding of
competing µ-opioid receptor agonists, including IR opioids, in a dose-
dependent manner. This may be less of an issue with the relatively lower
doses of transdermal buprenorphine used in the United States\textsuperscript{359,360} There
is insufficient evidence to make buprenorphine a valid first-line choice for
the management of cancer-related pain with no clear dose-response
relationship for transdermal buprenorphine\textsuperscript{361,362}

**HYDROCODONE**

Hydrocodone is a prodrug opioid, and the parent compound is a full µ-
opioid receptor agonist and can interact with other opioid receptors at
higher doses. It is metabolized into its active moiety, hydromorphone, by
CYP2D6 and also by CYP3A to the inactive metabolite, norhydrocodone,
although the extent of CYP3A metabolism of hydrocodone is unclear.

In 2013, the FDA approved the use of extended-release hydrocodone
(Zohydro ER). Hydrocodone ER is a hard gelatin capsule. Measurable
drug levels are obtained within 30 minutes after oral intake. The T\textsubscript{max} is
between 6 and 8 hours, and mean t\textsubscript{1/2} was 4.9 and 6.5 hours\textsuperscript{363} IR
hydrocodone exists in various combinations with acetaminophen or ibuprofen. The most common forms of hydrocodone-acetaminophen preparations are 5/325 mg, 7.5/325 mg, and 10/325 mg. The common hydrocodone-ibuprofen preparations are 2.5/200 mg, 5/200 mg, 7.5/200 mg, and 10/200 mg. In oncology patients, hydrocodone at higher doses (≥40 mg per day) is equipotent to morphine and at lower doses (<40 mg per day) may be twice as potent as morphine and just as potent as oxycodone.364 There are relatively few studies on the use of hydrocodone for cancer pain. Hydrocodone/acetaminophen at starting doses of 25 mg/2,500 mg per day was not more effective than tramadol 200 mg per day on patients with chronic cancer pain.365

**CODEINE**

Codeine is a synthetic opiate alkaloid. It is considered a prodrug that lacks intrinsic antinociceptive activity and must be metabolically converted to active forms. Eighty percent of codeine is conjugated with glucuronic acid to codeine-6-glucuronide with only 5% O-demethylated by CYP2D6 to morphine suggesting that the majority of its analgesic effect is from codeine-6-glucuronide.366,367 The value of codeine is limited in cancer pain management by the increasing incidence of side effects at doses above 1.5 mg per kilogram of body weight.62,368 Codeine is rapidly absorbed from the GI tract reaching a peak level within 1 hour with a clinical duration of 4 to 6 hours.369 The available evidence (which is of low quality) indicates that codeine is more effective against cancer pain than placebo but with increased risk of nausea, vomiting, and constipation.370 The principal adverse effect associated with chronic dosing is constipation.

Dihydrocodeine is an equianalgesic semisynthetic analogue of codeine. It is used as an analgesic, antitussive, and antidiarrheal agent. The analgesic effect is probably twice as potent as that of codeine for the parenteral and slightly stronger for an oral route.371 Dihydrocodeine has active metabolites (dihydromorphine and dihydromorphine-6-glucuronide).372 The most common side effect that occurs in patients treated with dihydrocodeine is constipation.373 Duration of effect is approximately 6 hours. In the United States, it is available only in
combination with acetaminophen, caffeine, or aspirin.

**TRAMADOL**

Tramadol is a centrally acting analgesic with a µ-opioid receptor activity and also has weak effects on serotonin and norepinephrine reuptake inhibition. Opioid activity of tramadol is due to both low affinity binding of the parent compound and higher affinity binding of the O-desmethyl tramadol metabolite (M1) to µ-opioid receptors. The analgesic activity is due to both parent drug and the M1 metabolite. Oral formulations include those designed for immediate release and for modified release. Side effects associated with tramadol include typical opioid adverse events of nausea, dizziness, and dry mouth, although vomiting and constipation are considered to be less of a problem than with traditional opioids. Tramadol may also cause orthostatic hypotension. Use of tramadol with concurrent serotonergic therapy poses a risk of serotonin syndrome. Seizures can occur with the recommended dosage range, and the risk is increased with concomitant use of SSRIs and tricyclic antidepressants. The daily maximum recommended dose of tramadol IR is 400 mg and 300 mg per day for tramadol ER. Tramadol ER should not be used concomitantly with other tramadol products. The IR preparation has a bioavailability of 75%, $T_{\text{max}}$ 2.3 hours, and $t_{1/2}$ of 7 hours. The bioavailability of tramadol ER 200 mg tablet administered once daily relative to a 50 mg IR tramadol hydrochloride administered every 6 hours is approximately 85% to 90%. $T_{\text{max}}$ of tramadol ER and M1 is 12 hours and 15 hours, respectively. Steady state is achieved within 4 days of once-daily dosing. The mean terminal plasma elimination half-lives of racemic tramadol and racemic M1 after administration of extended-release tablets are approximately 7.9 and 8.8 hours, respectively. The metabolic pathways are N-demethylation (mediated by CYP3A4 and CYP2D6), O-demethylation (mediated by CYP2D6), and glucuronidation or sulfation in the liver. Concomitant administration of CYP2D6 and/or CYP3A4 inhibitors may reduce metabolic clearance of tramadol increasing the risk for serious adverse events including seizures and serotonin syndrome.

Although advocated for the management of neuropathic pain, the information supporting use is modest from small largely inadequate
studies with potential for risk bias. Overall, patients with cancer who are most likely to benefit from tramadol appear to be those with mild to moderate pain not relieved by acetaminophen, who cannot tolerate NSAIDs, and wish to avoid taking opioids that are more potent.

**TAPENTADOL**

Tapentadol is a centrally acting opioid agonist. The exact mechanism of action is unknown, but it has both µ-opioid receptor activity and is a norepinephrine reuptake inhibitor. It is available in both immediate- and extended-release formulations. FDA-approved indications are for pain severe enough to require daily ATC opioid use and also pain diabetic peripheral neuropathy. The $T_{\text{max}}$ for tapentadol IR is approximately 1.25 hours with a $t_{1/2}$ of 4 hours. It is available in both tablet form and solution. The mean absolute bioavailability after single-dose administration of Nucynta ER is approximately 32% due to extensive first-pass metabolism with a $T_{\text{max}}$ between 3 and 6 hours. Steady-state exposure of tapentadol is achieved after the third dose (i.e., 24 hours after first twice-daily multiple-dose administration). The oral equivalent dose of tapentadol to morphine is approximately 2.5:1. The major pathway of tapentadol metabolism is conjugation with glucuronic acid to produce glucuronides. Drug metabolism mediated by CYP450 system is of less importance than phase 2 conjugation. Initial dosing for patients who are not opioid-tolerant is 50 mg bid. Doses greater than 600 mg daily are not recommended. In a small study of 22 patients with CIPN-associated pain, patients initially were treated with tapentadol 50 mg bid and then titrated as tolerated over a 3-month period. Nineteen patients showed a response to treatment (30% reduction in pain intensity) with 15 patients showing a 50% reduction in pain intensity over the study period, but 7 patients stopped therapy during the first week because of side effects (drowsiness, nausea, dizziness, dry mouth). In a Cochrane review of four studies with 1,029 patients with chronic tumor-related pain with twice-daily dosing varying from 50 mg to 500 mg, effects were comparable to those of equivalent doses of morphine or oxycodone. The most common events were GI including nausea, vomiting, or constipation, and there was no advantage of tapentadol over morphine or oxycodone in terms of serious adverse events.
OPIOIDS NOT RECOMMENDED FOR ROUTINE USE IN CANCER PAIN CONTROL

There are several opioids that should be avoided in cancer pain management, including meperidine, pentazocine, butorphanol, dezocine, and nalbuphine. Meperidine has a short $t_{1/2}$, and its metabolite, normeperidine, is toxic.\textsuperscript{381} Mixed agonist-antagonists such as pentazocine, butorphanol, dezocine, and nalbuphine present other problems. Although these agonist-antagonists are often classified as a $\kappa$ receptor agonist and a $\mu$-receptor antagonist, they are more accurately described as a partial agonist at both $\kappa$ and $\mu$ receptors. These agents have a low maximal efficacy and have the potential to reverse $\mu$-receptor analgesia and even precipitate a physical withdrawal syndrome when taken by patients already receiving full agonists such as morphine.\textsuperscript{382} In addition, agonist-antagonist opioids have a ceiling effect.\textsuperscript{382,383}

OPIOID-RELATED SIDE EFFECTS

Prevention or Minimizing Opioid-Related Side Effects

Appropriate dosing of opioids requires minimizing or preventing opioid-related side effects. For patients with constant pain, the early use of a long-acting opioid in preference to short-acting opioids as soon as dose titration permits may help attenuate side effects. If side effects are significant, the clinician should allow time for tolerance to develop. This may require a period of 3 to 7 days. Minimizing severe side effects during this period is appropriate. For example, a patient with nausea could benefit from a 1-week course of antiemetic medication at the outset of opioid therapy.

If side effects do not diminish satisfactorily over time, there are two alternatives: changing drugs and introducing supplementary medications that control the side effects. Changing from one opioid to another may enhance pain relief and reduce opioid-related side effects, particularly if incomplete cross-tolerance to opioid effect is experienced.\textsuperscript{384–386} In some cases, changing the route of administration for a particular drug may eliminate certain difficult side effects. It is possible to alleviate many of the most difficult side effects pharmacologically when necessary. For example, prudent administration of methylphenidate to the cancer patient can help protect the cognitive functioning of patients using high doses of.
opioids. Table 43.15 lists opioid-related side effects and their treatments. In cancer patients, certain pathophysiologic conditions commonly contribute to side effect problems or masquerade as side effect problems. For example, renal insufficiency in patients using morphine can lead to accumulation of morphine-6-glucuronide, which in turn can exacerbate side effects. Nausea is a frequent opioid toxicity, but it has other potential causes: gastric irritation, constipation or other changes in gut motility, chemotherapy, or hypercalcemia induced by bone metastases. Similarly, opioid-induced changes in mental status become less probable when the patient has been on a stable dose without recent significant dose escalation.

**OPIOID EFFECTS ON COGNITION, MOTOR SKILLS, AND DRIVING ABILITY**

Patients with advanced cancer may develop a wide range of symptoms, including cognitive dysfunction, which interfere with their daily life, compliance to treatment, social interactions, and quality of life. Causes for development of cognitive alterations are multiple and may be attributed to the cancer disease itself, comorbidities, and treatments including opioid therapy. The spectrum of cognitive dysfunction attributed to opioid use can vary from subtle evidence of cognitive impairment, largely related to initial dosing or dose increases to delirium. Opioids can interfere with acquirement, processing, storage, retrieval of information, altering cognitive processes associated with memory, psychomotor function, mood, concentration, and other mental capabilities. Patients receiving daily opioid doses of 400 mg or more (oral morphine equivalents) had 1.75 (95% confidence interval [CI], 1.25 to 2.46) times higher odds of having lower Mini-Mental State Examination (MMSE) scores compared with those receiving daily doses less than 80 mg. In addition, patient with
lung cancer, older age, lower performance status, time since diagnosis (<15 months), and absence of breakthrough pain were more at risk of developing opioid-induced cognitive dysfunction. Opioids may cause measurable cognitive impairment, even at low doses (especially during initial or occasional use), and equianalgesic doses of different opioids may have nonequivalent adverse cognitive effects.\textsuperscript{392} Although sedation and confusion may accompany opioid use, other potential causes in the cancer patient such as raised intracranial pressure, metabolic disturbances (e.g., hypercalcemia), sepsis, or concomitant psychoactive medication use merit consideration and should be excluded. Cognitive dysfunction can be associated with opioid dose increases and use of supplemental doses of short-acting opioids. However, the use of benzodiazepines has substantial more effects on cognitive and psychomotor function compared to opioid use.\textsuperscript{393,394} In cancer survivorship, the evidence is mixed regarding long-term cognitive deficits associated with the use of chemotherapy. Studies in patients with breast cancer previously treated with chemotherapy suggest observed cognitive deficits are small in magnitude and limited to the domains of verbal ability and visuospatial ability.\textsuperscript{395} The presence of chronic pain can also be a factor in cognitive dysfunction. Basic neurocognitive function is impaired in a substantial portion of patients with persistent severe pain.\textsuperscript{396} Use of psychostimulants (e.g., methylphenidate, modafinil) has been reported to be helpful in overcoming daytime drowsiness and mental clouding, but their use must be monitored carefully, both for adverse effects and overuse.\textsuperscript{397} Modafinil in a single-dose regimen was beneficial for improving psychomotor speed and attention and for improving subjective scores of depression and drowsiness in patients with advanced cancer.\textsuperscript{398}

An additional major concern that has arisen from long-term opioid therapy is the effect of long-term opioid use on motor skills such as driving.\textsuperscript{399,400} Driving is considered an important activity affecting quality of life for many patients. Often, both prescribing clinicians and patients are unaware of the legal risk associated with driving and the use of legally prescribed opioids. Driving under the influence of drugs other than alcohol (DUID) is of concern to the medical and legal communities. “Under the influence” typically describes a level of impairment that interferes with
driving abilities and is therefore considered criminal; however, this level of impairment is interpreted differently among various states. Of the prescribed psychoactive medications, benzodiazepine use is associated with a significant increase in the risk of traffic accidents with the association being more pronounced in the younger driver. The motor vehicle accident risk is markedly increased with the coingestion of alcohol. The prevalence of prescription opioids detected in fatally injured drivers has increased in the past two decades but of the drivers testing positive for prescription opioids, 30% had elevated blood alcohol concentrations (≥0.01 g/dL), and 66.9% tested positive for other drugs. Results have been inconsistent regarding decrements in cognitive performance. Patients with chronic pain who have been using opioids for more than 3 days exhibit relatively few differences when cognitive performance is compared with performance before taking opioids or with that of a comparable patient population not taking opioids. The majority of research has revealed that the greatest potential impairment in cognitive function from opioids occurs during the first several days of use. During longer periods, impairment has been demonstrated primarily in studies that have compared patients with significant pain with healthy volunteers. Twenty chronic pain patients using long-term stable doses of opioids, and 19 healthy controls were studied using standardized on-the-road driving tests in normal traffic. Performance of controls with a blood alcohol concentration of 0.5 g/L was used as a reference to define clinically relevant changes in driving performance. Driving performance of the chronic pain patients did not significantly differ from that of controls suggesting that in clinical practice determination of fitness to drive in patients who receive opioids should be based on an individual assessment. Gomes et al. found among drivers prescribed opioids that a significant relationship existed between opioid dose and risk of road trauma. Compared with patients prescribed very low opioid doses (MED <20 mg), those prescribed low (20 to 49 mg MED) and moderate (50 to 99 mg MED) doses had a 21% and 29% increased odds of road trauma, and patients prescribed high (100 to 199 mg MED) and very high (≥200 mg MED) doses of opioids had a 42% and 23% increased odds of road trauma, respectively, when compared with patients prescribed very low doses. The
effects of opioid use specifically on driving ability has become a contentious issue, predictably because a growing number of patients are taking opioids and driving, and also because insurers may seek to assign liability in cases of motor vehicle accidents involving drivers who use opioids. Vainio et al.\textsuperscript{408} examined the effects of continuous morphine medication on the driving ability of cancer patients. They conducted psychological and neurologic tests, originally designed for professional motor vehicle drivers, in two groups of cancer patients who were similar apart from their experience of pain. Twenty-four patients received continuous morphine (mean 209-mg oral morphine daily) for cancer pain, and 25 were pain-free without regular analgesics. Although the results were a little worse in the patients taking morphine, there were no significant differences between the groups in intelligence, vigilance, concentration, fluency of motor reactions, or division of attention. Of the neural function tests, reaction times (auditory, visual, associative), thermal discrimination, and body sway with eyes open were similar in the two groups; only balancing ability with closed eyes was worse in the morphine group. These results indicate that in cancer patients receiving long-term morphine treatment with stable doses, morphine has only a slight and selective effect on functions related to driving. Galski et al.\textsuperscript{409} published a structured, evidence-based review on the issue of opioids and driving. Overall, the majority of studies in the evidence-based review appeared to indicate that patients who use opioids are not impaired by the opioids with regard to driving ability. Byas-Smith et al. reported that many patients with chronic pain, even if treated with potent analgesics such as morphine and hydromorphone at equivalent average daily morphine doses of 118 mg, showed comparable driving ability as normal subjects.\textsuperscript{409}

Clearly, opioids may affect cognitive function and impair driving ability in patients who are opioid-naive or in patients who are not on stable opioid regimens. Whether some degree of “cognitive tolerance” develops with chronic opioid use is unknown. Other unresolved questions include the effects of different types of opioids, dose effects, and interactions with other medications on driving ability. Each of these areas deserves further study, and clinicians need to counsel patients about potentially dangerous activities on a case-by-case basis. Guidelines are provided regarding
opioid medications and driving (Table 43.16).

### Table 43.16 Driving Instructions for Patients Taking Opioids

Opioid medications can cause side effects that impair your ability to drive. Driving while taking opioid medication is controversial. The final decision on whether you should drive while taking them is a legal issue and should be addressed with your automobile insurance carrier. Out of concern for your safety and the safety of others, please observe the following guidelines:

- Do not drive for 4–5 d after beginning opioid treatment or following a dose increase.
- Never drive if you feel sedated or if you feel your thinking is impaired. Take any concerns that others express regarding your ability to drive safely seriously.
- Report sedation, unsteadiness, or unclear thinking to our office as soon as possible.
- Please remember that the use of alcohol or other drugs such as cannabis (“marijuana”) can increase the effects of opioid medications.

Avoid taking over-the-counter medications that may cause drowsiness such as cold and allergy medications.

### OPIOID ROTATION IN CANCER PAIN

Opioid rotation refers to the practice of converting from one opioid to a second when the opioid analgesic response is inadequate and/or if opioid-related adverse events are intolerable or unmanageable. Reasons for initiating opioid rotation are listed in Table 43.17. In cancer patients, the most common reasons for opioid rotation are intolerable side effects such as, cognitive failure, hallucinations, myoclonus, nausea, and uncontrollable pain. In all cases of opioid rotation, patients must be followed closely to assess the adequacy of pain relief and the effect on opioid-related adverse events. As with any opioid regimen, subsequent dose adjustments will probably be necessary. Use of opioid rotation requires familiarity with a range of opioids and with the use of equianalgesic dose tables (see Chapter 79). However, it is also important to consider that the evidence to support dose ratios in standard equianalgesic tables refers largely to the context of single-dose administration; they do not necessarily reflect the clinical realities of chronic opioid administration in the treatment of cancer pain with repeated dosing of opioids at steady state. Thus, the doses listed in most standard equianalgesic dose tables may not be accurate in patients who have developed tolerance or have been taking...
opioids for long periods of time. In addition, the phenomenon of incomplete cross-tolerance can lead to unexpected potency in the newly introduced agent.\textsuperscript{262,384,385,413}

CNS, central nervous system.

Special care is required with methadone rotations. The process of switching from a high-dose opioid agonist to methadone is complex and should and should only be attempted by experienced physicians.\textsuperscript{414–416} Even among experienced physicians, serious toxicity can occur during the administration of methadone.\textsuperscript{417,418} Various studies provide guidelines for opioid dose conversions in cancer pain.\textsuperscript{284,386,419–422}

**PARENTERAL OPIOID THERAPY**

Parenteral routes (subcutaneous or intravenous) should be considered for patients who require rapid onset of analgesia and for highly tolerant patients who require doses that cannot otherwise be conveniently administered.\textsuperscript{423} Intravenous opioids allow for rapid control of pain. Ideally, patients with severe, uncontrolled pain who require intravenous
therapy should start treatment in a monitored in-patient setting. High doses of intravenous opioids via patient-controlled analgesia (PCA) and/or by continuous infusion offers a means of rapidly controlling increasing severe pain. Intravenous therapy can employ any of several opioids: morphine, hydromorphone, fentanyl, and, less commonly, methadone. A brief hospitalization for stabilization of the intravenous regimen is preferable.

Continuous subcutaneous infusion of opioids is both an efficacious and safe method to control the chronic pain of the homebound and hospitalized patient.\textsuperscript{424,425} Administration of opioids by continuous infusion via intravenous or subcutaneous routes have equal effects in similar doses.\textsuperscript{426} In a pilot study in cancer patients comparing the efficacy of hydromorphone administered subcutaneously by continuous infusion only versus basal rate infusion with PCA, both methods provided adequate overall pain control in most patients, but a large interindividual variation was noted with some patients reporting marked discomfort during hydromorphone administration by PCA and few patients preferring the PCA modality.\textsuperscript{427} Stuart-Harris et al.\textsuperscript{428} studied the pharmacokinetics of 5 mg of morphine (and its metabolites) given intravenously, by subcutaneous bolus, and by subcutaneous infusion over 4 hours. After a single intravenous bolus, plasma morphine was typically detected up to 6 hours with a maximal concentration ($C_{max}$) of $283 \pm 74 \text{ nmol/L}$ with a $T_{max}$ of 0.08 hour. After subcutaneous bolusing, plasma morphine was typically detected up to 8 hours, the $C_{max}$ was similar to intravenous bolus, but the $T_{max}$ was significantly longer (0.25 vs. 0.08 hour). Morphine administered by subcutaneous infusion was first detected in all subjects after 2 hours and was still detectable at 12 hours in some subjects at end of sampling. The median $T_{max}$ was longer at 4 hours, and $C_{max}$ was lower at $46 \pm 8 \text{ nmol/L}$. The authors concluded that although intravenous and subcutaneous bolusing is bioequivalent with regard to their pharmacodynamic effects, it was likely that circulating morphine concentrations would have been higher immediately after the intravenous bolus was completed than at the first sampling point at 0.08 hour, and these early high concentrations may influence penetration into the brain. In contrast, the bioavailability of morphine was less after subcutaneous infusion versus bolusing by either method. Moulin et al.\textsuperscript{429} noted that
mean bioavailability from subcutaneous infusion of hydromorphone was 78% of that with intravenous infusion. This in combination with its solubility and the availability of a high-concentration preparation (10 mg/mL) makes hydromorphone a good choice for subcutaneous infusion. Parenteral hydromorphone is six times as soluble in aqueous solutions as morphine and five times as potent, allowing for smaller injection or infusion volumes in patients who require parenteral opioids. Moulin et al. compared the safety and efficacy of subcutaneous versus intravenous infusion of hydromorphone in cancer patients. Pain intensity, pain relief, mood, and sedation did not differ between the two techniques. Paix et al. described the successful substitution of subcutaneous fentanyl and sufentanil for morphine, noting the benefits of sufentanil when the patient needs a very high dose of opioid that can be infused in a relatively small volume. Nelson et al. compared continuous intravenous and subcutaneous morphine for chronic cancer pain and concluded that both routes were equianalgesic for most patients when administered as a continuous infusion.

Most patients will require a weekly change of the site of subcutaneous infusion. The usual initial concentrations of morphine and hydromorphone are 5 mg/mL and 1 mg/mL, respectively, calculated according to the hourly infusion rate. Ideally, the subcutaneous rate should not exceed 2 mL per hour, although some have established considerably higher rates (rates of 20 to 80 mL per hour by adding hyaluronidase to the infusion to promote hypodermoclysis). Due to a longer time to peak plasma levels after bolus injection with subcutaneous use than with intravenous use, the subcutaneous route requires a longer lockout interval (10 to 15 minutes compared to 6 to 8 minutes for the intravenous). PCA doses may equal 25% to 50% of the hourly infusion rate every 10 to 15 minutes as needed. Subcutaneous administration of opioids may prove impractical in patients with generalized edema, who develop erythema, soreness, or sterile abscesses with subcutaneous administration; in patients with coagulation disorders; and in patients with very poor peripheral circulation.

**INTRACEREBROVENTRICULAR OPIOIDS**
Intracerebroventricular (ICV) opioid delivery may be beneficial for highly selected cancer patients who are not obtaining adequate relief or experiencing intolerable side effects via other routes. The site of action of opioids via the ICV route appears to be predominantly supraspinal although spinal effects are also observed. After ICV administration of morphine 0.28 to 0.61 mg, peak lumbar CSF morphine levels were observed after 4.5 ± 1.3 hours. Ventricular morphine was approximately 20,000 ng/mL and declined to approximately 10 ng/mL at 24 hours. Lumbar morphine reached approximately 200 ng/mL at about 4 hours and declined to about 10 ng/mL at 24 hours. A short latency to onset of pain relief (20 minutes) corresponds to high levels of morphine in periventricular tissues and the duration of effect is enhanced by the morphine at the spinal level. With neurosurgical consultation, it is possible to deliver opioids directly into cerebral ventricles through ICV catheters from subcutaneous reservoirs. Morphine sulfate, the usual drug, gains a marked increase in potency when delivered ICV as compared to intrathecal or epidural infusion routes, and the ICV route appears to affect supraspinal pathways for analgesia. Daily morphine doses for ICV delivery range from 0.3 to 2.5 mg per day with an average daily dose of 1 mg per day although higher doses have also been reported. For administration, an Ommaya reservoir is placed subcutaneously and connected to the ventricular catheter placed into the lateral ventricle. The duration of pain relief after ICV injections appears to be significantly longer than with intraspinal delivery, and some patients gain adequate relief via an implanted ventricular catheter connected to a subcutaneous Ommaya reservoir–type device with 1 to 2 injections per day. This form of drug delivery is indicated for head and neck cancer pain, or, rarely, for patients with a good initial response to intraspinal infusions of opioids and subsequent development of apparent tolerance, but with limited (1 to 3 months) remaining survival time. The safety and side effects of ICV injections or infusions resemble those for intraspinal infusions with reservoir infection being the most common. In a meta-analysis of 2,402 cancer patients, Ballantyne and Carwood compared ICV (337 patients) with the more common epidural (1,343 patients) and intrathecal (722 patients) opioid treatments in an attempt to establish the utility and safety
of ICV therapy. All patients considered had intractable cancer pain that proved resistant to systemic treatment. Persistent nausea, urinary retention, and pruritus occurred more frequently with the two spinal treatments than with ICV therapy but respiratory depression (4.3%), sedation (11%), and confusion (13% protracted, 20% transient) were most common with ICV.

Data from these uncontrolled studies reported excellent pain relief among 73% of ICV patients compared with 72% epidural and 62% subarachnoid catheters. Unsatisfactory pain relief was low in all treatment groups. The incidence of major infection when pumps were used with epidural and subarachnoid catheters was zero. There was a lower incidence of other complications with ICV therapy than with epidural or subarachnoid catheters.

**Substance Abuse in Oncology**

The misuse or abuse of prescription medications should be of particular concern to oncology care providers, opioid therapy is central to the management of cancer-related pain, and benzodiazepines are frequently prescribed for a variety of issues (predominantly sleep disturbance, anxiety disorders, and nausea control). Although substance use disorders may be diagnosed via detection of aberrant behaviors displayed by patients, patient reporting and documentation of issues in the medical record are inadequate to screen for these issues. In a retrospective review of 82 oncology patients at high risk for substance misuse, 46% had evidence of nonprescribed opioids, benzodiazepines or potent illicit drugs such as heroin or cocaine, and 39% had inappropriately negative urine drug screening, raising concerns for diversion. In a study of urine drug testing in over 900,000 test samples in patients on chronic opioid therapy for chronic pain, 75% of patients were unlikely to be taking their medications in a manner consistent with their prescribed pain regimen. Thirty-eight percent of patients were found to have no detectable level of their prescribed medication, 29% had a nonprescribed medication present, 27% had a drug level higher than expected, 15% had a drug level lower than expected, and 11% had illicit drugs detected in their urine. In a study to determine the frequency of undiagnosed alcoholism among patients with
advanced cancer referred to palliative care and to explore its correlation with alcoholism, tobacco abuse, and use of illegal drugs, alcoholism was highly prevalent and frequently underdiagnosed. Using the CAGE questionnaire as a screening tool, CAGE-positive patients were more likely to have a history of, or to actively engage in, smoking and illegal recreational drug use. Passik et al. indicated in oncology and HIV patients seldom reported current aberrant drug-related behaviors and that many cancer patients would consider behaving aberrantly if pain or symptom management was suboptimal. One hundred and eleven patients were randomly selected from a group of 215 patients who underwent urine toxicology screening in a cancer center. Fifty-six of the 111 patients had evidence of one or more illicit drug use, a prescription medication that had not been ordered, or alcohol use.

Opioid abuse and misuse may manifest as self-medication, use for reward, compulsive use because of addiction, and diversion for profit. Risk factors for opioid misuse are listed in Table 43.18. There is a clear association between opioid prescription and opioid overdose, abuse, and death. Among opioid-related deaths, approximately half involved a prescription opioid. Prescription opioid-related overdose deaths and admissions for treatment of opioid use disorder have increased in parallel with increases in opioids prescribed in the United States, which quadrupled from 1999 to 2010. Because of these associations, health care providers are advised to carefully weigh the benefits and risks when prescribing opioids, follow evidence-based guidelines, and consider nonopioid therapy for chronic pain treatment. Safe prescribing practice guidelines for noncancer patients suggest screening for the risk of substance abuse, the use of prescription monitoring programs, and monitoring with urine drug screens. In addition, clinicians are advised to avoid concurrent opioids and benzodiazepines whenever possible, prescribe the lowest effective dose, and carefully reassess benefits and risks when considering increasing dosage to 50 morphine milligram equivalents or more per day. There are relatively few guidelines in this area for cancer patients, and standard screening tools are not validated in oncology populations. Anghelescu et al. suggest patients undergo evaluation through clinical psychological interview
and/or Revised Screener and Opioid Assessment for Patients with Pain (SOAPP-R) assessment at the initiation of chronic opioid therapy for chronic cancer pain, and follow-up risk evaluation with Current Opioid Misuse Measure (COMM) assessment. Urine drug testing is recommended at the initiation of chronic opioid therapy and periodically throughout treatment to augment objective data about the patient’s behaviors. Table 43.19 suggests establishment of policies for all patients being considered for chronic opioid therapy.

• Consequences for unsanctioned substance/nonprescribed medication use including alcohol |

| High-risk patients —evidence of current substance use | • No initiation of controlled substance prescriptions with ongoing illicit substance use including alcohol  
• Referral for addiction assessment and management  
• Frequent urine drug screening (to include alcohol, illicit drug, comprehensive panel for opioids)  
• Elimination of other psychoactive medications when possible  
• Consequences for unsanctioned substance/nonprescribed medication use including alcohol. |

NOTE: The use of an opioid contract is not considered mandatory in oncology care. High-risk patients include patients with ORT score >7, history of chemical coping, or issues with prescription adherence. Aberrant drug-related behavior is behavior suggestive of a substance abuse and/or addiction disorder. Examples include diversion, prescription forgery, stealing or “borrowing” drugs from others, obtaining prescription drugs from nonmedical sources, multiple episodes of prescription “loss,” repeatedly seeking prescriptions from other clinicians, evidence of deterioration in function not explained by illness (work, home, and family), and repeated resistance to changing therapy despite evidence of physical and psychological problems.

**Home Infusion Therapy**

Advances in pain management technology, such as ambulatory PCAs and the use of silicone subcutaneously tunneled neuraxial catheters, have expanded the scope and success of interventional pain management beyond the hospital to the home. Potential benefits of home infusion therapy include decreased health care costs, patient/caregiver convenience, less time spent in hospital with the ability to extend interventional pain management strategies into the patient’s home. A possible disadvantage to home infusion therapy may include the additional burden placed on the patient/caregiver in terms of role responsibilities and schedules. Home care agencies must have explicitly defined policies and procedures consistent with regulatory bodies and national and regional standards of practice.

A provider of infusion therapy must be a licensed pharmacy or work in conjunction with a licensed pharmacy. Skilled and qualified home nursing
services are an essential component of home-based care, necessary to educate patients and their caregivers regarding administering the drug therapy, complying with the prescribed dosing schedule, understanding the drug delivery device being used (an infusion pump or other device), and other important information regarding the treatment regimen. Additional roles include monitoring for adverse effects, infection, displacement of catheters, and equipment malfunction.

Drug therapies commonly administered via infusion at home include antibiotics, chemotherapy, analgesics, parenteral nutrition, and immune globulin. Diagnoses commonly requiring infusion therapy include infections that are unresponsive to oral antibiotics; cancer and cancer-related pain; GI diseases or disorders, which prevent normal functioning of the GI system; congestive heart failure; immune disorders; growth hormone deficiencies; and more.

Ambulatory infusion pumps are either designed to be therapy-specific, or are multipurpose, enabling treatments such as chemotherapy, systemic antibiotics, total parenteral nutrition, hydration therapy, and opioid pain control. Recent developments in pump design include remote access capability by modem with the ability to change pump settings and download data.

Home-based PCA therapy provides select patients with the ability to deliver analgesia based on their own perception of need. PCA therapy may be superior to oral analgesia, especially in the treatment of severe oscillating pain. Patient selection criteria include intact cognition and proper supervision from a family member or health professional. A collaborative interdisciplinary approach is necessary for effective pain control for the cancer patient receiving interventional pain management at home. Collaboration between the patient, the patient’s family, the home care nurse and home care agency, and the patient’s physician is necessary. The physician remains responsible for determining the appropriate drug, bolus dose, background infusion rate, and lockout interval.

PCA is increasingly more common in the home setting as an effective option in pain management. As discussed in the preceding text, the subcutaneous and intravenous routes are the primary methods of administration. The availability of a central vascular access device such as
a tunneled or peripherally inserted central catheter (PICC) offers advantages over peripheral access to ensure safe and consistent administration of intravenous analgesia.

The safety and efficacy of home-based PCA opioid therapy has not been extensively reported as in-hospital use. One study reported on the use of morphine PCA in the home environment of 143 preterminally and terminally ill tumor patients suffering either from excruciating chronic pain or severe chronic/acute complex pain that could not be relieved adequately by oral analgesia. After initial dose adjustment, which lasted 2 to 3 days, the median morphine dose was 93 mg per day (range 12 to 464 mg per day). This median was 28% lower than the median dose administered orally prior to PCA therapy. During the course of treatment, morphine requirements increased by a median of 2.3 mg per day (range 29–52 mg per day). Most patients were treated continuously in the home care setting until death; the median duration of treatment was 27 days (range 1 to 437 days). Terminal morphine demands reached a median of 188 mg per day (range 15 to 1,008 mg per day). The authors concluded that PCA was both safe and effective in the home environment, attaining excellent results in 95 (66%) patients and satisfactory pain relief in 43 (30%). PCA was considered insufficient in five (4%) cases. Side effects, in general, were considered mild: the most common being constipation, fatigue, and nausea. PCA use has also been reported in outpatients with cancer during the last week of life and deemed to be effective.

Integrative Oncology

Integrative oncology, the diagnosis-specific field of integrative medicine, addresses symptom control with nonpharmacologic therapies. Known commonly as complementary and alternative medicine (CAM), these therapies are used widely among cancer patients, but patients frequently do not discuss CAM therapies with physicians. These therapies have been used as an alternative to conventional medicine (alternative medicine) and complementary to conventional medicine (complementary medicine). Most cancer patients use CAM with the hope of boosting the immune system, relieving pain, and controlling side effects related to
disease or treatment. Only a minority of patients include CAM in the treatment plan with curative intent. Integrative therapies have been used during and after breast cancer treatment and include indications for managing anxiety/stress, depression/mood disorders, fatigue, quality of life/physical functioning, CINV, lymphedema, CIPN, pain, and sleep disturbance. For example, music therapy, meditation, stress management, and yoga are recommended for anxiety/stress reduction. Meditation, relaxation, yoga, massage, and music therapy are recommended for depression/mood disorders. Meditation and yoga are recommended to improve quality of life. Acupressure and acupuncture are recommended for reducing CINV. The CAM domains of mind–body medicine, CAM botanicals, manipulative practices, and energy medicine are widely used as complementary approaches to palliative cancer care and cancer symptom management. Psychoeducational interventions, music interventions, acupuncture plus drug therapy, Chinese herbal medicine plus cancer therapy, compound Kushen injection, reflexology, lycopene, transcutaneous electrical nerve stimulation (TENS), qigong, cupping, cannabis, Reiki, homeopathy, and creative arts therapies might have beneficial effects on cancer pain, but there is a lack of multi-institutional randomized controlled trials evaluating CAM therapies for cancer pain. In a systematic review of CAM therapies for cancer-related pain, Bardia et al. demonstrated a paucity of well-designed, multi-institutional trials with most being of short duration, with small numbers, without sample size justification, and inadequate reporting of adverse effects of CAM intervention. A National Institutes Health (NIH) consensus conference on the use of acupuncture for pain concluded that although there have been many studies of its potential usefulness, many of these studies provide equivocal results because of design, sample size, and other factors. However, promising results have emerged, for example, showing efficacy of acupuncture in adult postoperative and chemotherapy nausea and vomiting and in postoperative dental pain. There are other situations such as addiction, stroke rehabilitation, headache, menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma, in which acupuncture may be useful as an adjunct treatment or an acceptable alternative or be
included in a comprehensive management program. Guidelines have been proposed to assist clinicians in making decisions about acupuncture treatment for cancer pain patients and to promote best practice. Three systematic reviews and two meta-analyses on the use of acupuncture on cancer-related pain have generated equivocal results. Because patients use acupuncture for other benefits and it is considered an intervention with few side effects, it can be used provided patients are aware of its limitations.

Summary

Although pain control is a high-priority goal of cancer care, the ultimate goal of most cancer patients is cure from disease and in most situations pain is often an undesirable by-product of treatment or disease. Pain management should be integrated into oncology care, but it should not become the focus of care. As a very common and debilitating component of disease or treatment, aggressive treatment of pain to maximize both quality and quantity of the patient’s life with functional improvement is imperative. The ability to integrate this requires a detailed assessment of the pain complaint with accurate diagnosis of the cause or causes of pain and other quality-of-life concerns. Typically, the pain experience is multidimensional, and treatment must address physical, psychological, social, and existential components and not focus on a single component. Failure to sufficiently understand the etiology of the pain complaint will invariably result in poor pain management. Interdisciplinary collaboration is essential for comprehensive care of the cancer patient. Disciplines and specialties involved in care commonly include pain management specialists, oncologists, surgeons, psychiatrists, psychologists, physical therapists, pharmacists, nurses, and social workers. Aggressive therapy of both cancer and pain are mutually beneficial and are best done by skilled, interdisciplinary teams that understand and respond to the changing demands of oncology care.

Most patients can attain adequate symptomatic relief of cancer pain using appropriate oral pharmacotherapy. Comparatively, opioids are very effective for pain management compared to other agents, and the focus on
pharmacotherapy should be safe, appropriate, and effective opioid use irrespective of the source of pain. Long-term use of opioid therapy is controversial and continued use of opioids requires a system that can assess, monitor, modify, and, if appropriate, reduce or taper opioid therapy as required. Modern guidelines on long-term opioid therapy commonly suggest upper limits of opioid therapy that are useful reminders of the potential hazards and risks that can occur with inappropriately high-dose opioid therapy particularly in the setting of failure to meet anticipated functional gains from therapy. The concurrent use of adjunctive or specialized therapies or complementary therapies is sometimes necessary, however, and referral for specialized surgical, anesthetic, or psychological intervention benefit a significant number of patients. However, the introduction of multiple psychoactive medications can be hazardous, and frequent efforts should be made to eliminate all unnecessary or ineffective medications. The continued growth of the home care industry and hospice and emphasis away from inpatient care has broadened the possibilities of extending basic and sophisticated pain management strategies into the home.

The World Health Organization (WHO) analgesic ladder, as described in the previous chapters on cancer pain management, is practical, easy to implement, and has been taught extensively to health professionals. However, even when the WHO approach is implemented appropriately and aggressively, 10% to 20% of patients do not attain acceptable pain control. Traditionally, it has been this refractory group of patients that has been considered for interventional pain management, but the approach of reserving interventional management as a last resort has been called into question.\(^1\)\(^-\)\(^4\) This is particularly true in relation to intrathecal (IT) therapy, where a multicenter study suggests that early implementation of treatment leads to improved outcomes.\(^5\) Another type of interventional therapy, namely, neurolytic celiac plexus block (NCPB), may be useful as an early intervention in controlling pancreatic cancer pain and other gastrointestinal system pain-producing malignancies.\(^6\) Furthermore, there has been a recent resurgence in interest in neurosurgical techniques in refractory pain due to the precision afforded by recent advances in image-guided surgical approaches. Two interventions, in particular, cordotomy and myelotomy, are being increasingly considered for refractory somatic and visceral pain, respectively.

Impediments to the appropriate use of interventional and neurosurgical techniques include inaccessibility to suitably trained physicians and absence of up-to-date knowledge among cancer care providers of the various techniques available, including indications and timing, benefits, risks, and costs (Table 44.1).

The primary purpose of this chapter is to target this latter group of individuals. It is anticipated that a general understanding of interventional approaches to cancer pain control will lead to more appropriate and timely consideration of all potential therapeutic options.

**Intrathecal Drug Therapy**

IT drug delivery involves drug administration into the cerebrospinal fluid (CSF) through a small catheter. This route allows the medication to circulate in the CSF and adsorb directly onto central nervous system (CNS) effector sites. This direct delivery to the CNS reduces the systemic toxicity of medication administered via enteral, parenteral, or transdermal routes. Opioids, N-type calcium channel blockers, among other pain modulating agents, have been successfully infused intrathecally in the treatment of cancer pain. Effective analgesia using IT opioids is typically obtained using a small fraction (i.e., 1/100th) of the systemic dose. The addition of adjunctive IT agents that have specific activity within the neuraxis, such as local anesthetics and α₂ agonists, may be used to improve overall effectiveness of IT opioid therapy in refractory cases.⁷

**INDICATIONS**
IT therapy is usually indicated in the small proportion of cancer patients for whom comprehensive medical management (CMM) has produced suboptimal pain control or unacceptable, dose-limiting, analgesic-related toxicity. Other factors may make IT therapy an attractive option, including inability to adhere to a more conventional analgesic regimen. Furthermore, cancer pain with a strong neuropathic component (e.g., plexopathy, complex regional pain syndrome) may respond better to IT therapy, particularly when adjunctive agents such as local anesthetics and clonidine are used. In the setting of severe pain and the prospect of a very aggressive chemotherapy regimen, when the oral route will likely be an unreliable means of administering analgesics, strong consideration should be given to adopting an IT approach to pain management.

**INTRATHECAL DRUG DELIVERY SYSTEMS**

**Simple Percutaneous Intrathecal Catheter**
This is a minimally invasive technique that can be done at the bedside for short-term use. It may be implemented as a trial method (i.e., to assess efficacy of IT opioids, with the intent of placing an implantable system if the trial is deemed a success) or it can be used as a definitive method of delivering IT drug when life expectancy is extremely short (i.e., days rather than weeks to months). In the setting of a patient with severe pain and only several days of expected life, this method will allow for rapid control of pain. Because the catheter is not tunneled, infection risk and mechanical failure is higher, markedly reducing successful longer term use.

**Tunneled Intrathecal Catheter**
Tunneled IT catheters are typically placed in the operating room under sterile conditions. A dorsally placed catheter is tunneled subcutaneously for a variable distance and usually exits from the lateral abdominal wall. With appropriate infection control measures, including the use of antimicrobial filters and meticulous exit site care, tunneled IT or epidural catheters can be used for months to years. The catheter is usually not sutured internally, so it can be readily removed in the office if necessary. An advantage of the exteriorized system is that nonpain specialist
palliative care clinicians, including those in-home hospice settings, may become proficient in its management with minimal training. Toward the end of life, when analgesic requirements may be rapidly escalating, hospice registered nurses can easily give IT boluses or increase the infusion rate as indicated and alter the drug(s) used with relative ease. With an implanted system (see the following discussion), drug changes are more complex than intravenous (IV) or oral dosing, and rapid dose titration is not as easily accomplished because of the need for pump reprogramming by trained specialists. Disadvantages of a tunneled system versus a self-contained implanted device are the need for an externalized pump apparatus, increased risk of infection, decreased patient mobility, and the possibility of inadvertent catheter dislodgment or removal.

**Implantable Drug Delivery Systems**
The implanted drug delivery system (IDDS) uses a small, programmable, computerized electronic pump to deliver drug to the IT space through a catheter (Figs. 44.1 and 44.2). The pump is placed subcutaneously in the anterior abdominal wall or buttock and has a reservoir that can be refilled via a port accessed by a specialized needle through the skin. The pump is programmed by an external handheld device that can alter the rate of infusion and deliver boluses and also allows for a patient-controlled analgesia function. The battery life is typically 5 to 7 years, so it is unlikely that a replacement would be necessary during the average lifetime of the cancer patient with advanced disease. Drug refills are office-based and minimally uncomfortable. Refills are needed every 1 to 6 months depending on the drug concentration and infusion rate.
FIGURE 44.1 Schematic of an intrathecal (IT) drug delivery system showing the pump in the anterior abdominal wall and the catheter tunneled to the dorsal spine and into the IT space. (Courtesy of Medtronic, Inc.)
Contraindications to an IDDS are generally related to difficulties forming a suitable subcutaneous pocket for the pump, as would be the case in severe ascites, emaciation, skin infection, or other abdominal wall pathology. Patients with systemic infection, concurrent bleeding diathesis, or clotting abnormalities are poor candidates until these abnormalities are corrected or stabilized. Advantages of this system, compared to an exteriorized system, include increased patient freedom of mobility, low maintenance, and lower infection risk. Disadvantages are the need for an initially more invasive surgery, high upfront costs, and the logistical problems concerning pump refills and programming. See Table 44.2 for a comparison of exteriorized versus implanted pump delivery systems.

IDDS, implantable drug delivery system.

**INTRATHECAL VERSUS EPIDURAL DRUG DELIVERY**

IT drug delivery has largely replaced the epidural route as the preferred neuraxial route of administration for various reasons. With all neuraxial administration of opioids, the target sites are opioid receptors of the dorsal horn of the spinal cord, which requires either direct CSF delivery or absorption of drug from the epidural space. Compared to IT delivery, epidural infusions require a 10-fold greater volume and dose of opioid in order to diffuse passively across the dura and enter the subarachnoid (IT) space. This large difference in infusion volumes and doses has a major impact both on cost and the frequency of drug reservoir changes, which necessitates breaking the system’s sterility more frequently and likely results in a higher infection rate. Furthermore, treatment failure is more frequent with the epidural route due to inadvertent catheter dislodgment and the development of epidural fibrosis which impedes diffusion of drug to the subarachnoid space. Technical complication rates have been shown to be higher with long-term epidural (55%) compared to IT (5%) infusions. Finally, ziconotide, an increasingly used agent in refractory cancer pain, is not approved for epidural use.

Notwithstanding these considerations, there remain some specific indications for epidural analgesia. Pain in a pattern involving specific, consecutive dermatomes may be blocked with local anesthetics with an appropriately positioned epidural catheter. An example of this would be a
thoracic epidural catheter for isolated thoracic pain caused by rib metastases, in the setting of a short life expectancy. This technique may allow for complete analgesia using local anesthetics alone without the use of epidural opioids.

**Implantable or Exteriorized Intrathecal Drug Delivery: Cost Analysis**

With an IDDS, the initial costs are relatively high ($15,000 to $20,000). Over time, the accruing and total care costs may be less in patients with an IDDS compared to those with an exteriorized system due to greater labor-related costs (including managing mechanical failures) with externalized systems. An older study suggested that, compared to an externalized system, an IDDS will be more cost-effective after approximately 3 months of therapy. There are no recent cost comparisons available.

**Outcome Studies**

A 2002 study by Smith et al. randomized 202 patients with advanced cancer to CMM or an IDDS plus CMM. Patients were eligible if they had a Visual Analog Scale (VAS) pain intensity rating of ≥5 at two measurements within a week of randomization, despite 200 mg per day or more of oral morphine or its equivalent. Patients on lower doses of opioids were also permitted entry if opioid side effects refractory to conservative management prohibited further escalation of total opioid dose. All patients were ≥18 years of age, had life expectancy ≥3 months, and were suitable for IDDS (no active infection, obstruction of CSF flow, or mechanical barriers). The primary outcome measure was pain control (VAS improvement ≥20%) combined with an improved toxicity profile, as measured by the National Cancer Institute Common Toxicity Criteria, 4 weeks after randomization. Clinical success was defined as a ≥20% reduction in VAS scores or equal scores with a ≥20% reduction in toxicity.

At 4 weeks, both groups had an improvement in pain scores and toxicity. Sixty of 71 IDDS patients (84.5%) achieved clinical success compared with 51 of 72 CMM patients (70.8%, P = .05). IDDS patients more often achieved ≥20% reduction in both pain VAS and toxicity (57.7% [41 of 71] vs. 37.5% [27 of 72], P = .02). The mean CMM VAS
score fell from 7.81 to 4.76 (39% reduction); for the IDDS group, the scores fell from 7.57 to 3.67 (52% reduction, \( P = .055 \)). The mean CMM toxicity scores fell from 6.36 to 5.27 (17% reduction); for the IDDS group, the toxicity scores fell from 7.22 to 3.59 (50% reduction, \( P = .004 \)). The IDDS group had significant reductions in fatigue and depressed level of consciousness (\( P < .05 \)). IDDS patients also had improved survival, with 53.9% alive at 6 months compared with 37.2% of the CMM group (\( P = .06 \)). The authors concluded that IT therapy, compared to CMM alone, improved clinical success by reducing drug toxicity, trended toward improving pain reduction, and possibly improved survival. It should be noted that the data were analyzed on an intent-to-treat basis, but that some crossover (five patients) from CMM to the IDDS group did occur. When the data are interpreted on the basis of the actual treatment received, there was a significant difference between the VAS scores between groups, in favor of IT therapy.

In 2005, the same group of authors published a second paper examining the 6-month follow-up of the patients in the aforementioned trial.\(^{14}\) The approach in this paper was to compare outcomes in terms of the actual treatment received (i.e., an IDDS vs. CMM alone) rather than the intent to treat at randomization approach used in the 2002 study. Outcome measures were the same as in the initial study but were also assessed in patients alive at 12 weeks after the initial randomization. At 4 weeks, 88.5% of IDDS patients achieved clinical success compared with 71.4% (\( P = .02 \)) of non-IDDS patients and more often achieved a \( \geq 20\% \) reduction in both pain VAS and toxicity (67.3% vs. 36.3%; \( P = .0003 \)). At 12 weeks, of the 56 patients remaining in the CMM group, 19 had received an IDDS. By 12 weeks, 82.5% of IDDS patients had clinical success compared with 77.8% (\( P = .55 \)) of non-IDDS patients and more often had a \( \geq 20\% \) reduction in both pain VAS and toxicity (57.9 vs. 33.3%; \( P = .01 \)). At 12 weeks, the IDDS VAS pain scores decreased from 7.81 to 3.89 (47% reduction) compared with 7.21 to 4.53 for non-IDDS patients (42% reduction; \( P = .23 \)). The 12-week drug toxicity scores for IDDS patients decreased from 6.68 to 2.30 (66% reduction) and for non-IDDS patients from 6.73 to 4.13 (37% reduction; \( P = .01 \)). All individual drug toxicities improved with IDDS at both 4 and 12 weeks. At 6 months, only 32% of the group
randomized to CMM and who did not crossover to IDDS were alive, compared with 52% to 59% for patients in those groups who received IDDS. This study concluded that an IDDS improved clinical success, reduced pain scores, relieved most toxicity of pain control drugs, and was associated with increased survival for the duration of the 6-month trial.

PATIENT-CONTROLLED INTRATHecal ANALGESIA
A shortcoming of the studies mentioned in the previous section is that patients relied only on basal infusions of morphine, without the ability to self-administer IT boluses.

Consequently, breakthrough medications were continued, and although drug toxicities were much improved, ongoing opioid-related side effects were likely observed. Several years after the completion of the original studies, the technology to self-administer IT opioid (and adjuncts) with a “remote control” device became available. A retrospective analysis of 43 patients with refractory cancer pain treated with intrathecal therapy (ITT) with the ability to self-administer IT boluses showed that, 1 month after implant, 50% stopped all conventional opioids, with the mean oral morphine equivalence decreasing from 796 mg.\textsuperscript{15}

A follow-up prospective observational study of 98 refractory cancer pain patients performed satisfaction and symptom surveys, including a breakthrough pain survey, before and after ITT. Average “worst” pain scores decreased from 8.32 (SD, 1.73) pre-ITT to 4.98 (SD, 2.92) post-ITT ($P < .001$). The prevalence of severe pain (numerical rating score $\geq 7$) decreased from 84% to 35% ($P < .001$). Mean daily morphine equivalent dosing decreased from 805 mg per day to 128 mg per day, with 65.5% of discontinuing all non-IT opioids. The mean M. D. Anderson Symptom Inventory symptom severity score decreased from 4.98 to 3.72 ($P < .0001$) and the symptom interference score from 6.53 to 4.37 ($P < .001$). When assessing breakthrough pain pharmacotherapy, pain intensity reduction was 46.8% with pre-ITT breakthrough medications and 65.2% with patient-controlled intrathecal analgesia (PCIA; $P < .001$). Median time to onset was 30 minutes with pre-ITT breakthrough medications and 10 minutes with PCIA ($P < .001$). Patient satisfaction was also higher with PCIA compared with conventional breakthrough pain medications: “a lot
“better” in 60.7% and “a little better” in 28.6%. Overall pain control satisfaction was also improved, with 78.2% “a lot better” and 10.9% reporting no pain.  

PHARMACOLOGY

Over a dozen different agents have been reported to be used intrathecally in the management of cancer pain, and most of these have never been approved by the U.S. Food and Drug Administration (FDA) for IT use (Table 44.3). Morphine sulphate, one of the few agents the FDA approved for IT use, is the standard first-line drug used in IT pain therapy. Additional agents are usually then added in a stepwise fashion depending on the response to morphine alone; it is not uncommon that one to three adjunctive agents are added to the infused solution. Consensus documents have attempted to standardize the therapeutic approach to IT drug selection and dosing in the cancer patient (see Table 44.3).

**Opioids**

IT $\mu$-opioid agonists directly activate dorsal horn and brainstem opioid receptors. Morphine sulphate is FDA-approved for IT use, and it remains the first-line agent for IT analgesia. Numerous other IT opioids have been used successfully including hydromorphone, fentanyl, sufentanil, meperidine, and methadone. The choice of agent is largely idiosyncratic. Many practitioners purport that hydromorphone causes less nausea than morphine, although there are no comparative trial data to support this view. The comparatively greater lipophilicity of fentanyl and sufentanil leads to relatively rapid absorption into proximate neural structures with less CSF recirculation and migration to the brainstem. This has some theoretical advantages when a more regional analgesic effect is desired, with less risk of opioid activity (respiratory depression) at the brainstem level.

**Ziconotide**

Ziconotide (formally SNX-111) is a novel marine snail peptide that is an
N-type voltage-sensitive calcium channel blocker. Ziconotide can only be given intrathecally and appears to act at the dorsal horn to decrease afferent sensory input by mechanisms different from those of other IT drugs. Ziconotide has emerged as an indispensable tool in the management of advanced cancer pain, either as a first-line agent or as adjunct when IT opioids have failed either due to toxicity or inefficacy. An advantage of ziconotide is the lack of any respiratory depressant effect as well as the absence of any withdrawal phenomenon. A randomized, placebo-controlled trial including cancer patients demonstrated improved mean visual analog scores of 53% in the ziconotide group compared with 18% in the placebo group (P < .001); 53% of patients in the ziconotide group reported moderate to complete pain relief compared with 18% in the placebo group (P < .001).

Ziconotide has a distinct set of side effects that can hamper its use, including ataxia, auditory hallucinations, and psychosis. However, with more measured guidelines, including careful and slow titration, most of these side effects can be limited to mild events and major side effects are now rare.

Local Anesthetics
Local anesthetics, such as bupivacaine and lidocaine, are sodium channel blockers which interrupt neural action potentials along sensory and motor nerves. When given intrathecally, local anesthetics can block incoming sensory nerves and produce complete analgesia. However, this comes at the price of motor blockade resulting in weakness and sympathetic nervous system blockade which may result in hypotension. High doses of local anesthetics may also result in neuro- or cardiotoxicity (seizure or arrhythmia).

Bupivacaine, given in doses less than 30 to 60 mg per day, is an excellent adjunct to IT opioids and generally causes minimal motor block. In the terminally ill patient who is bedbound and does not object to lower extremity weakness, higher doses of local anesthetics may be used to provide profound analgesia with no cognitive side effects. Supportive means to evacuate the bowels and void urine must be anticipated.
**Clonidine**
Clonidine is an α₂-adrenergic agonist that acts at the dorsal horn by modulating the transmission of noxious sensory signals. This modulation is accomplished by mimicking the activation of descending noradrenergic pathways and inhibiting neurotransmitter release.\(^2\) Epidural and IT clonidine has been studied extensively in postoperative pain settings and in obstetric care for labor analgesia, but little data exist from cancer pain treatment studies. It is generally considered a very useful adjunct to opioids and local anesthetics when there is a predominant neuropathic pain component. Dosing is limited by side effects including sedation and hypotension. The consensus guideline by Deer et al.\(^7\) now includes clonidine as a possible second-line adjunct (with an opioid) for both nociceptive and neuropathic pain.

**Other Drugs**
A diverse group of drugs have been reported to be useful IT adjuncts, including baclofen, ketamine, neostigmine, midazolam, ketorolac, and droperidol.

**CONTRAINDICATIONS AND RISK MANAGEMENT**
Absolute contraindications to IT analgesia are rare. Skin infection over the intended catheter site, bacteremia/sepsis, and uncorrectable coagulopathy represent absolute contraindications to IT catheter placement, given the respective risks of CNS infection and spinal hematoma. Coumadin needs to be held until the international normalized ratio is 1.5 or less. If indicated, a low molecular weight heparin (LMWH) may be used, provided it is held for 24 hours before the catheter placement. Given the plethora of novel anticoagulants on the market, specific guidelines have been created.\(^7\) Hematologic relative contraindications include a lowered white cell count ≤2 × 10⁹/L, an absolute neutrophil count ≤1,000/µL, or a platelet count ≤20 × 10³/µL.\(^1\) Depending on the patient circumstances, thrombocytopenia may be treated with a platelet transfusion prior to implantation. Special consideration must be given to the feasibility of implanting available pump devices in the anterior abdominal wall, particularly in emaciated patients or children. A smaller 20-mL capacity...
pump is available and may be more practical in these instances.

**COMPLICATIONS AND SIDE EFFECTS**

In general, most of the commonly reported drug-related adverse effects are well tolerated or readily managed with palliative or supportive interventions. The usual IT-opioid side effects are similar to those experienced with the oral or transdermal route but usually much less pronounced and include sedation, nausea, pruritus, and urinary retention. The serious complication of respiratory depression is rare, especially in opioid-tolerant patients. Local anesthetics may cause lower extremity weakness, hypotension, and bowel or bladder dysfunction. Clonidine may cause hypotension and sedation.

Meningitis is the most feared complication of IT drug delivery, but it occurs infrequently when standard infection control measures are followed. Localized skin infection is more common and can usually be managed by oral antibiotics and close observation.

Occasionally, catheter or pump explantation will be necessary. Guidelines about the prevention and treatment of IT drug delivery system infection have been published. Typical surgical complications may develop, including seroma formation and pump pocket hematoma. These are usually self-limiting, but ongoing assessment for infection is required, and they may add to postimplant discomfort. The best prophylaxis is an appropriately sized surgical pocket with fastidious hemostasis, and this is achieved through experience.

Catheter tip inflammatory masses (granuloma) are now a well-recognized complication of IT drug delivery. These granulomatous masses can present with new onset lower extremity neurologic symptoms and are associated with high doses and high concentrations of opioid infusate. Clinicians must have a high index of suspicion for this complication; to ignore it may result in permanent neurologic damage, whereas with early recognition and minimally invasive treatment, there are seldom any long-term sequelae.

Postdural puncture headache can result from persistent CSF leak around the catheter. This uncomfortable and often distressing experience is usually self-limiting, resolving spontaneously over days to weeks.
Conservative management includes rest, fluids, additional analgesia, and caffeine. A headache that persists may be treated with a fluoroscopically guided epidural blood patch, provided that there are no contraindications related to bleeding risk or leukopenia.

**INTRATHECAL THERAPY AND ONGOING ONCOLOGIC CARE**

The initiation or continuation of IT therapy need not interfere with chemotherapy or radiotherapy regimens. The superior symptom control offered by IT therapy may in fact allow patients to tolerate aggressive treatment more comfortably and increase the efficiency of the oncology suite by decreasing the amount of time spent managing complicated cancer-related symptoms. Particularly aggressive chemotherapy protocols may require that the implantation of an IT drug delivery system be strategically timed to avoid a white cell count or platelet count nadir. Radiation therapy may affect the battery life of IDDS and may result in electrical failure. The pump may be protected by lead shielding and, if possible, radiation field avoidance.

**Spinal Chemoneurolysis**

Spinal chemoneurolysis involves the destruction of nerve root axons or other spinal cord elements by chemical means, using alcohol or phenol. The destruction of selected nerve roots interrupts nociceptive pathways and can potentially create excellent analgesia in a relatively selective body area. Alcohol or phenol ablation of central neural structures has largely fallen out of favor in recent decades, mostly because of advances in the pharmacologic treatment of pain, including via the IT route as previously described.

Nevertheless, it remains a useful and effective technique in developing countries with limited opioid access and where a rapidly effective therapy, requiring little or no follow-up, is required. Like other interventional pain management techniques, intraspinal neurolysis offers the advantage of localized pain control while minimizing the burden of systemic side effects. However, the potential adverse effects of the procedure are
significant, including motor nerve root dysfunction, bowel or bladder dysfunction, and dysesthesias in the denervated dermatomes. In experienced hands, these adverse effects may be minimized, but the potentially high morbidity of these problems has generally placed intraspinal neurolysis toward the end of the treatment spectrum in modern day practice.

**SPINAL CHEMONEUROLYSIS TECHNIQUE**

Spinal chemoneurolysis, or simply neurolysis, notwithstanding its value in appropriately selected patients, is rapidly becoming a forgotten technique, and therefore, physicians with experience with this treatment modality, and the ability to teach it to trainees, are becoming relatively scarce. Neurolysis is targeted at the sensory nerve root and dorsal root ganglion within the subarachnoid space while attempting to spare the more anteriorly located motor nerve roots. Neurolysis may be performed at the cervical, thoracic, or lumbosacral levels, with the last being the most common site of intervention. Neurolysis in the epidural space has also been described but is less favored because of pain on injection and disappointing outcomes. Knowledge of the chemical properties of alcohol and phenol is essential to the safe and effective use of each agent. The disposition of alcohol and phenol are distinctly different when deposited in the IT space (Figs. 44.3 and 44.4). Alcohol is hypobaric relative to CSF and therefore will “float” upward, whereas phenol is hyperbaric and will “sink” within the subarachnoid space relative to the position of the needle tip. These properties allow for reasonably selective targeting of nerve roots using careful patient positioning and needle placement. The patient is placed in the lateral decubitus position, with the painful side uppermost for alcohol neurolysis, and dependent for phenol neurolysis. Because it is most common for patients to be intolerant of having the painful side down (dependent), alcohol ablation is the preferred technique. For alcohol neurolysis, the patient is rolled 45 degrees away from the operator who is on the dorsal side of the patient, so that the hypobaric alcohol preferentially floats to the dorsolateral subarachnoid space where the sensory dorsal roots reside. To treat this same anatomic location with phenol, the patient needs to be rolled toward the operator. A
small-bore spinal needle is advanced into the IT space at the appropriate nerve root level for the affected pain site to be treated. Recall that nerve roots and their respective dermatomal, myotomal, and sclerotomal levels do not necessarily line up anatomically.

Very small aliquots (0.1 to 0.2 mL) of the neurolytic agent are then injected incrementally with careful monitoring of sensory changes and dermatomal spread until the desired region is blocked. A detailed description of spinal neurolysis technique is contained within the text Neural Blockade in Clinical Anesthesia and Management of Pain.\textsuperscript{25}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure44.3.png}
\caption{Lateral supine position used for injection of intrathecal phenol, with the hyperbaric solution falling toward the sensory dorsal roots.}
\end{figure}
Lumbosacral Neurolysis

Lumbosacral spinal neurolysis can provide excellent pain relief of the pelvis, perineum, rectum, and genital area in patients who have been refractory or intolerant of aggressive conventional management. Patients, who are confined to bed due to their symptom burden or who have already had urinary and bowel diversion procedures, can expect good pain relief with an acceptable risk of complication. Prior to proceeding with lumbosacral subarachnoid neurolysis, consideration should be given instead to performing a superior hypogastric plexus block (SHPB) because this procedure may be equally effective yet considerably safer.

Cervical and Thoracic Neurolysis

Cervical neurolysis is seldom performed due to the technical difficulty of subarachnoid access at this level, the compactness of anatomy in this region making selective neurolysis more difficult, as well as the inherent risk of causing injury to the cervical spinal cord with consequent neurologic deficits and adverse symptoms (including pain). Thoracic
neurolysis for thoracic wall pain is also technically difficult, but the consequences of motor root dysfunction are less pronounced, in that the loss of several levels of intercostal muscle function is usually well tolerated. Thoracic neurolysis does have the advantage of not placing the innervation of the bowel, bladder, and lower extremities at risk and consequently has less risk of significant morbidity.

ADVERSE EFFECTS
Studies reporting on bladder and bowel dysfunction after lumbosacral neurolysis report that about one quarter of patients develop urinary incontinence, with most resolving within 10 days. Bowel dysfunction and lower extremity weakness was relatively less frequent. Yet, it should be noted that some of these patients may already have had urinary and bowel diversion for surgical reasons, making the decision to proceed with neurolysis somewhat easier. Other adverse effects of IT neurolysis include deafferentation pain and headache. Rare complications include infection, spinal cord damage, and posterior spinal artery thrombosis causing paraplegia.

CONTRAINDICATIONS
IT neurolysis is contraindicated when (1) the patient has spinal cord tumor or tumor obliteration of the subarachnoid space at the selected level; (2) skin infection is present at the needle puncture site; (3) the patient is unable to tolerate appropriate positioning; and (4) there is a primary pain source, such as a bone metastasis or fracture, that is amenable to more definitive procedural treatment.

Celiac Plexus Block
Chemical neurolysis of the components of the celiac plexus can be a highly effective treatment for visceral pain of the upper abdomen and is the most commonly performed interventional cancer pain technique.

INDICATIONS
NCPB is typically performed for cancer-related visceral pain originating in the upper abdomen. Pain originating from the somatic nerve fibers
emanating from the upper abdominal wall will not be blocked by NCPB, and therefore, it is very important to distinguish between visceral versus somatic pain before contemplating this procedure. The celiac plexus carries afferent fibers from the upper abdominal organs from the stomach to the mid transverse colon, including pancreas and gallbladder. Deep visceral pain related to pancreatic adenocarcinoma and cholangiocarcinoma are typical indications for NCPB. As will be discussed later, this is a highly efficacious and safe procedure, so it should be considered early in the treatment of upper abdominal cancer pain.\textsuperscript{32}

**ANATOMY OF THE CELIAC PLEXUS**

Understanding the path of the needle and the position of its tip in relation to the local anatomy is crucial to the safe and effective performance of any interventional procedure. The celiac plexus is a complex grouping of one to five ganglia of various sizes interconnected by a dense network of neural fibers. The plexus is located in the upper abdomen typically anterolateral to the aorta at the L1 vertebral level, just caudal to the takeoff of the celiac artery; however, some variability has been noted, and the plexus can be found anywhere from the level of T12–L1 disk space to the level of the L2 vertebral body.\textsuperscript{33} Just lateral to the celiac plexus are the adrenal glands and inferiorly are the renal arteries. The celiac plexus is formed by the convergence of sympathetic preganglionic and afferent fibers from the greater (originating from the T5–T10 spinal level), lesser (T10–T11), and least (T12) splanchnic nerves. The splanchnic nerves are composed of preganglionic autonomic efferent fibers to the upper abdominal viscera that synapse in the celiac ganglia and ascending afferent fibers capable of carrying nociceptive signals from abdominal viscera including the distal portion of the stomach; pancreas; gallbladder; and other hepatobiliary structures, the duodenum, the small intestine, and the large intestine, as far distal as the transverse colon. The splanchnic nerves travel from the spine in the posterior mediastinum, anterolateral to the thoracic vertebral bodies, and pierce the diaphragmatic crus to enter the retroperitoneal abdominal cavity. Parasympathetic preganglionic and afferent fibers originating from the vagus nerves also contribute to the celiac plexus.
GENERAL CONSIDERATIONS
Preparation of patients should include counseling regarding the potential adverse effects and complications of the procedure. Anticoagulants should be discontinued long enough to allow normalization of coagulation profiles. IV access is mandatory so that sedation may be administered, adverse effects can be treated, and prehydration can be accomplished. The latter point is important because celiac plexus blockade will cause splanchnic vasodilation potentially leading to systemic hypotension, particularly in the cancer patient who may already be dehydrated and hypovolemic. An important factor to consider is whether the patient will be able to tolerate lying in the prone position; a patient with gross ascites, even with sedation, will be unable to assume the appropriate position and may be a better candidate for an anterior or endoscopic approach.

Tumor location within the pancreas and the degree of local tumor burden has been shown to impact NCPB outcome, with pain related to head of pancreas lesions having a more favorable outcome compared to lesions of the body and tail of the pancreas.\(^{34}\) Computed tomography (CT)-guided celiac plexus studies using a radiopaque injectate have shown that outcome may also be affected by local anatomic distortion caused by tumor infiltration.\(^{35,36}\)

ADVERSE EFFECTS
NCPB is a relatively safe and well-tolerated procedure. Serious complications include transient or permanent spinal cord damage and paraplegia due to spread of the lytic injectate to the nerve roots, epidural, or IT space. Neurologic damage may also ensue after damage to an anterior spinal artery, such as the artery of Adamkiewicz, disrupting the vulnerable arterial supply of the spinal cord.\(^{37,38}\) Fortunately, serious neurologic complications are very rare, with an incidence of less than 0.2\% in one series of 2,730 NCPBs.\(^{39}\) Side effects are common and generally mild and well tolerated. NCPB will predictably cause a disruption of the sympathetic nervous supply to the proximal bowel resulting in unopposed parasympathetic (vagal) tone. This excessive parasympathetic tone will typically result in transient gastrointestinal hypermotility and diarrhea in approximately 44\% of patients, side effects...
that are seldom considered a problem by the patient who has been constipated due to opioid consumption and debilitation. The loss of sympathetic tone also results in splanchnic vasodilation, intravascular fluid shift to the bowel, and hypotension in approximately 38% of patients. This should be anticipated and prevented with preprocedural volume enhancement and sufficient means to monitor and treat hypotension.

**CELIAC PLEXUS BLOCK TECHNIQUES**

Numerous approaches to the celiac plexus have been described, ranging from traditional blind landmark techniques, sophisticated CT-guided methods, and endoscopic ultrasound (EUS) techniques. A 1992 study by Ischia et al. compared the outcomes of the retrocrural technique, a transaortic approach, and neurolysis of the splanchnic nerves at the T12 level. No statistically significant differences ($P > .05$) were found among the three techniques in terms of either immediate or up-to-death results. Procedure mortality was zero with the three techniques and morbidity negligible. NCPB provided excellent pain relief in 70% to 80% of patients immediately after the block and in 60% to 75% until death. Celiac plexus neurolysis may also be achieved intraoperatively at the time of diagnostic or therapeutic laparotomy, with reported good success.

**Posterior Approach to the Splanchnic Nerves and Celiac Plexus**

The most common celiac plexus block technique is the posterior approach using a needle on either side of midline. This was first described as a blind technique but is now performed with the help of fluoroscopy or CT. The L1 vertebral body is identified with fluoroscopy and then the C-arm is rotated obliquely so that a skin puncture site 6 to 8 cm (6 cm for smaller, cachectic individuals; more toward 8 cm for obese patients) lateral to the midline will allow for coaxial needle advancement to the anterolateral aspect of the upper half of L1 vertebral body. A 15 cm or longer 20-gauge needle is then advanced toward the anterolateral shadow of the L1 vertebral body. The intention is to just miss contact with the vertebral body because this can be quite uncomfortable for the patient. Care should be taken not to touch the L1 transverse process because this can be mistaken
for the vertebral body, giving an incorrect, and potentially dangerous, estimate of depth. This author typically performs the left side first, so if an inadvertent aortic puncture is obtained, a transaortic approach can be completed, assuring good placement anterior to the aorta and avoiding the need for a second needle placement (the transaortic approach has been advocated as a safe, alternative technique and involves intentionally piercing the aorta in order to provide direct chemoneurolysis to the celiac ganglia anterior to the aorta). The second needle is placed in identical manner from the right side, aiming for the space anterolateral to the right side of the L1 vertebral body. Final needle advancements should be done under lateral fluoroscopic guidance: The left needle tip should be advanced 0.5 cm ventral to the anterior edge of the L1 vertebral body (further advancement may result in aortic puncture); the right needle tip is advanced 1 cm beyond the anterior edge of the vertebral body (Fig. 44.5). As the aorta is approached, transmitted arterial pulsations may be appreciable at the needle hub, but this is unreliable. The anatomic location of these needle tips is likely to be retrocrural and in good position to block the splanchnic nerves as they pierce the diaphragm. Note that the celiac plexus itself is not the primary target when using the retrocrural technique, but this appears to be of little clinical significance.

**FIGURE 44.5** Fluoroscopic images of a retrocrural celiac plexus block. **A:** Anteroposterior view with the needle tips anterolateral to the L1 vertebral body. Contrast has been injected through the left needle with spread cephalad along the course of the splanchnic nerves. **B:** Lateral fluoroscopic view showing the needle tips advanced anterior to the anterior shadow of the L1 vertebral body and contrast spreading in the retrocrural fascial plane.
If an anterocrural needle position is desired, with direct lysis of the celiac plexus itself, the needles need to be further advanced through the crus of the diaphragm. The final anatomic position of the needle can only be determined by injecting several milliliters of a radiopaque contrast agent through each needle in an anteroposterior (AP) and lateral projection. Retrocrural contrast will spread cephalad along the anterolateral aspect of the T12 and L1 vertebral bodies, whereas anterocrural spread will be noted in a more anterior and caudal plane. In either case, spread toward the midline should be present. While injecting the radiopaque contrast, meticulous attention should also be given to avoid (1) vascular uptake which might result in neurolytic being delivered to the spinal cord or other organs; (2) posterior spread toward the neuroforamina, the nerve roots, and the epidural space; and (3) contrast uptake into the intima of the aorta (this is seen, under real-time fluoroscopy, as a pulsating “streaking” outlining the assumed position of the aorta). Once the needles are in a radiographically satisfactory position, 5 to 10 mL of lidocaine 2% is injected through each needle after attempting aspiration of blood, CSF, or urine and confirming proper needle placement. After several minutes, the patient is questioned about the presence of any unwanted lower extremity weakness or other neurologic symptoms. A reduction in abdominal pain should also be noted, although this may be unreliable if the patient has received IV analgesics or sedatives.

Finally, neurolysis is achieved by injecting 10 to 12 mL of ethyl alcohol (60% or higher concentration) or phenol (6% or higher concentration) through each needle.

**Anterior Approaches**

Numerous anterior approaches to the celiac plexus have been described with efficacy and safety profiles comparable to those of the posterior approaches. A single needle may be placed through the anterior abdominal wall under CT guidance, potentially traversing the bowel, stomach, and pancreas, to the preaortic region where the celiac plexus elements reside.\(^{35,43}\) An increasingly popular approach to the celiac plexus is via EUS endoscopy. A needle is advanced through the endoscope under ultrasound guidance through the posterior wall of the stomach into the
preaortic area in the vicinity of the celiac plexus. This technique requires that the patient can tolerate esophagogastroscopey and typically require deeper sedation or general anesthesia. However, if a patient is having EUS for diagnostic purposes, it is very expedient to complete a celiac neurolysis simultaneously.

**OUTCOME STUDIES**

Numerous case reports, uncontrolled case series, and several randomized controlled trials report a preponderance of favorable outcomes with NCPB. A 1995 meta-analysis by Eisenberg et al. revealed 24 papers (with 1,145 patients) suitable for inclusion. Included were 2 randomized controlled trials, 1 prospective case series, and 21 uncontrolled retrospective case series. When analyzed, good to excellent pain relief was reported in 89% during the first 2 weeks after NCPB. This effect persisted after 2 weeks, with partial or complete pain relief reported in 90% of living patients at 3 months and in 70% to 80% until death. The most frequent indication was unresectable pancreatic cancer (63%), with the balance being a variety of nonpancreatic pain sites including the stomach and esophagus. The pancreatic and nonpancreatic cases did not appear to have a significantly different outcome. The bilateral posterior approach with 15 to 50 mL of 50% to 100% ethyl alcohol was the most common technique used. No procedure-related mortality was reported, and adverse effects were minimal. The most common adverse effects reported were transient hypotension, diarrhea, and transient pain at the site of injection.

A controlled trial by Wong et al. randomized 100 patients with unresectable pancreatic adenocarcinoma to either NCPB or systemic analgesia therapy (SAT) and a sham injection. A blinded observer recorded patient pain intensity, quality of life (QOL) measures, opioid consumption and related side effects, and survival time for 1 year.

Baseline pain scores were relatively low, but comparable, in both groups (VAS 4.4 ± 1.7 vs. 4.1 ± 1.8, respectively). The first week after randomization, pain intensity and QOL scores were improved (pain intensity, \( P \leq .01 \) for both groups; QOL, \( P < .001 \) for both groups), with a more significant decrease in pain for the NCPB group (\( P = .005 \)). Using repeated measures analysis, pain was found to be lower for NCPB over
time \((P = .01)\). However, opioid consumption \((P = .93)\), frequency of opioid adverse effects (all \(P > .10\)), and QOL \((P = .46)\) were not significantly different between groups.

In the first 6 weeks, fewer NCPB patients reported moderate or severe pain (pain intensity rating of \(\geq 5/10\)) compared to opioid-only patients (14% vs. 40%, \(P = .005\)). At 1 year, 16% of NCPB patients and 6% of opioid-only patients were alive, but this was not a statistically significant difference.

Although the previous study did not show a difference in life expectancy, a randomized, placebo-controlled study by Lillemoe et al.\(^{41}\) in patients with abdominal pain and unresectable pancreatic cancer demonstrated longer survival when an intraoperative chemical splanchnicectomy was performed compared to patients who received saline. A subsequent study by Staats et al.\(^{49}\) involved additional follow-up and analysis of this same group of patients. Data on visual analog pain scores, mood, and interference with activity were collected preoperatively and every 2 months postoperatively until death. Univariate and multivariate analyses of variance showed that neurolysis, compared to the medical management, had a significant positive effect on mood scores, pain interference with activity, and had an associated increase in life expectancy \((9.15 \pm 9.04\) vs. \(6.75 \pm 4.65\) months, \(P < .05)\).

**Superior Hypogastric Plexus Block**

Pelvic pain is common in advanced cervical, uterine, ovarian, bladder, rectal, and prostate cancers. When pain is primarily visceral in origin, the use of SHPB can be a safe and effective treatment to reduce pain and opioid needs.

**INDICATIONS**

The primary indication for superior hypogastric plexus nerve block is visceral pelvic pain that has been refractory to medical management. A local anesthetic block is sometimes performed first; however, in the setting of severe pain and advanced cancer, proceeding directly to neurolytic block may be preferred.
ANATOMY OF THE SUPERIOR HYPOGASTRIC PLEXUS
The superior hypogastric plexus spans the anterior surfaces of the lower L4 and L5 vertebral bodies and upper sacrum, posterior to the psoas fascia and peritoneum, and bounded laterally by the iliac vessels. This plexus innervates the pelvic viscera through the hypogastric nerves and inferior hypogastric plexus.

GENERAL CONSIDERATIONS
Prior to SHPB, normal coagulation studies should be confirmed, and anticoagulants should be discontinued for a period of time sufficient to allow normal coagulation. A discussion of the potential risks and benefits of SHPB should be undertaken and IV access obtained prior to the procedure to allow appropriate sedation and to allow the patient to comfortably lay in the prone position during the procedure. In the setting of severe ascites that precludes the prone position, the patient may be better treated with an anterior ultrasound or CT-guided approach. Of note, in contrast to celiac plexus neurolysis, there are no hemodynamic effects associated with SHPB.

ADVERSE EFFECTS
There have not been any reports of serious complication related to superior hypogastric plexus diagnostic block or neurolytic procedure. Given its location, potential adverse effects include neuraxial injection of neurolytic substance with resulting damage to the cauda equina, discitis, bladder injury, iliac vessel injury, intravascular injection, and retroperitoneal hematoma.

TECHNIQUES
SHPB is most commonly performed using fluoroscopy and a bilateral posterior approach, with appropriate needle placement confirmed with radiographic contrast (Figs. 44.6 and 44.7). A single needle technique, traversing the L5–S1 intervertebral disk, has also been described in patients with difficult anatomy compromising the bilateral approach, with good outcomes and a favorable safety profile in a case series of eight
patients.\textsuperscript{50} Additionally, CT-guided and ultrasound-guided approaches have also been reported that has success using radiofrequency ablation rather than chemical neurolysis.\textsuperscript{51–53}

\textbf{FIGURE 44.6} Fluoroscopic anteroposterior image of superior hypogastric plexus neurolysis.

\textbf{FIGURE 44.7} Fluoroscopic lateral image of superior hypogastric plexus neurolysis.

\textbf{OUTCOME STUDIES}

Evidence supporting the use of superior hypogastric plexus neurolysis is
limited to case reports, several prospective case series, and one randomized controlled trial. These studies have consistently demonstrated good to excellent pain relief in a majority of patients, reduced opioid consumption, and no significant adverse effects or complications.\textsuperscript{32,54–58}

The largest study was published in 1997 by Plancarte and colleagues and reported on 227 patients with gynecologic, colorectal, or genitourinary cancer and cancer-related pelvic pain with poor pain control despite the use of oral opioids. All patients reported a VAS pain score of 7/10 or greater before a diagnostic block with 0.25% bupivacaine was performed. A positive response to the diagnostic block was obtained in 79% of patients, and these patients then went on to receive a neurolytic SHPB utilizing a bilateral percutaneous approach with 10% phenol. A second neurolytic block was offered in the event of suboptimal response to initial neurolytic block. SHPB reduced the VAS to <4/10 in 72% of patients, and the remaining 28% of patients had moderate reduction of VAS to 4 to 7/10. Oral opioid therapy was reduced 43% following neurolysis, no complications related to the procedure were reported, and no additional neurolytic blocks were required during the 3-month follow-up period.\textsuperscript{56}

In the randomized controlled trial by Mishra et al.\textsuperscript{57} 50 patients were randomized to anterior ultrasound-guided neurolytic SHPB plus oral morphine or oral morphine alone for severe pelvic pain associated with gynecologic malignancy. Patients treated with SHPB had a greater reduction in pain, lower total morphine consumption, greater patient satisfaction, and no increased incidence of adverse effects.\textsuperscript{57}

A 2008 review of the literature applied evidence grades to 10 articles, including 4 case reports and 5 case series which received a grade of 1c and 1 prospective, randomized trial which received a grade of 1b in support of SHPB.\textsuperscript{59} The European Association for Palliative Care (EAPC) conducted a systematic review in 2015 which lead to a weak recommendation for superior hypogastric plexus neurolysis for cancer-associated pelvic pain.\textsuperscript{60}

**Ganglion of Impar Block**

The ganglion of impar, also known as the ganglion of Walther, is the terminal sympathetic ganglion in the body and neurolytic blockade of this
ganglion that can aid in pain relief from visceral perineal pain as a result of neoplastic disease.

**INDICATIONS**
Ganglion of impar neurolysis is indicated for the treatment of visceral perineal pain as a result of primary or metastatic lesions of the distal rectum, anus, vulva, or perineum.

**ANATOMY OF THE GANGLION OF IMPAR**
The ganglion of impar is a solitary sympathetic ganglion located on the anterior inferior surface of the sacrum near the sacrococcygeal junction and supplies visceral innervation to the perineum and distal rectum/anus.

**GENERAL CONSIDERATIONS**
Normal coagulation profile should be confirmed and a discussion of the risks and benefits of ganglion impar neurolysis undertaken prior to the procedure. There are no hemodynamic effects of ganglion impar neurolysis, and the procedure often does not require sedation.

**ADVERSE EFFECTS**
Ganglion of impar neurolysis is a safe and technically straightforward procedure to perform. Reports in the literature of complications are rare. Given its location in close approximation to the rectum, care should be taken to avoid rectal perforation. Other potential risks include local infection or bleeding as well as intravascular injection.

**TECHNIQUE**
Neurolytic block of the ganglion of impar is most commonly performed using a percutaneous transcoccygeal approach with fluoroscopic guidance (Fig. 44.8). A lateral view of the sacrum is obtained, and a needle inserted midline through the sacrococcygeal ligament until the tip lies just anterior to the sacrum, taking care to avoid perforating the rectum. Appropriate position is confirmed with contrast and a small amount of local anesthetic is administered, followed by phenol or alcohol as a neurolytic agent. Approaching the ganglion of impar using an
anococcygeal approach has also been described as having CT-guided approaches.\textsuperscript{62}

\textbf{FIGURE 44.8} Fluoroscopic lateral view of ganglion of impar neurolysis.

Data regarding the efficacy of neurolytic ganglion of impar block for cancer-associated perineal pain are limited to case reports and case series. However, these studies consistently report significantly improved pain with no significant adverse effects.\textsuperscript{59,61–64} In its 2017 Clinical Practice Guidelines in Oncology for Adult Cancer Pain, the National Comprehensive Cancer Network (NCCN) recommends consideration of ganglion impar block in the setting of cancer-associated rectal or perineal pain.\textsuperscript{65}

\textbf{Intercostal Nerve Block}

Chest wall pain is a common symptom accompanying many cancers due to local tumor invasion as well as metastatic lesions to the area. Breast, lung, melanoma, and renal cell carcinomas are often associated with chest wall involvement and associated pain.

Oncologic chest wall pain often has both somatic and neuropathic
components, making it potentially difficult to treat with conventional medications. Intercostal nerve block (ICNB) can be a useful adjunct in this setting.

**INDICATIONS**
ICNB is indicated in patients with cancer-associated chest wall pain recalcitrant to conservative medical treatment and palliative therapies such as radiation therapy.

**ANATOMY OF THE INTERCOSTAL NERVES**
The intercostal nerves and branches innervate the thoracic chest wall and parietal pleura. They arise from the ventral primary rami of T1–T12, which traverse the paravertebral space and then divide into anterior and posterior branches. The anterior branch forms the intercostal nerve and is initially located deep to the innermost intercostal muscle and superficial to the pleura. At approximately the midscapular line, the nerve pierces the innermost intercostal muscle and travels in a facial plane between the innermost intercostal and inner intercostal muscles until it terminates at the sternum. The intercostal nerve is reliably accessed at each level at the inferior aspect of the rib in close approximation but inferior to the intercostal artery and intercostal vein.

**GENERAL CONSIDERATIONS**
ICNB can be conducted as a diagnostic block with local anesthetic only or with therapeutic intention using either local anesthetic plus steroid or neurolytic agent. In many cases, a diagnostic block is first performed and if this provides short-term pain relief, neurolysis is then performed. Phenol is most commonly used; however, successful use of alcohol has also been described. Neurolysis will result in denervation of the associated intercostal muscles; however, this is rarely clinically significant unless multiple levels and/or bilateral blockade are performed in a patient with significantly compromised pulmonary function.

**ADVERSE EFFECTS**
There is a noteworthy risk of pneumothorax with ICNB due to the nerve’s
location in relation to the pleura. The ability to directly visualize the pleura and its relationship to the needle tip increasingly favors the use of ultrasound guidance with ICNB. Bleeding from intercostal vein or artery puncture can be a dangerous complication in patients who are anticoagulated.

As a result of the communication between the fascial planes of the intercostal muscles and the paravertebral space, there is also risk for neuraxial spread of medication. A 2016 study by Matchett\textsuperscript{66} reported paravertebral extension of contrast dye in 11/11 patients, and epidural extension in 1/11 patient, who underwent diagnostic ICNB. In the setting of local anesthetic, this results in a temporary unilateral paravertebral block or thoracic epidural block; however, there are two published case reports of permanent spinal cord injury resulting from intercostal neurolysis with phenol.\textsuperscript{67,68} There is also a risk of deafferentation pain with neurolytic procedures using phenol or alcohol. Nevertheless, intercostal neurolysis is generally a safe and well-tolerated procedure with few reports of complications in the literature.

**TECHNIQUE**

Prior to the procedure, any available imaging should be reviewed to ensure correlation between the chest wall pathology and the patient’s reported symptoms, with identification of the most likely rib level(s) affected. ICNB can be accomplished using either fluoroscopic or ultrasound guidance. In the case of fluoroscopic guidance, the appropriate rib is identified, and at a point 8 to 12 cm lateral to midline, the needle is inserted and advanced to contact bone, at which point it is carefully “walked off” the inferior aspect of the rib and advanced several millimeters. Contrast is then used to confirm spread along the inferior rib and rule out vascular uptake or neuraxial spread. Next, 2 to 3 mL of local anesthetic, local anesthetic plus steroid, or neurolytic substance is then injected slowly (Fig. 44.9).
For ultrasound-guided procedures, the appropriate level is identified, often by counting up from the 12th rib. The needle is inserted in an out-of-plane or in-plane approach, and hydrodissection is used to visualize the needle tip advancing into the fascial plane between the internal intercostal and innermost intercostal muscles, pushing pleura downward with medication administration, taking care to remain superficial to the pleura at all times (Fig. 44.10).

**FIGURE 44.9** Fluoroscopic view of intercostal neurolysis with the needle tip inferior to the rib.
In addition to intercostal chemical neurolysis, a 2017 report detailed the successful use of thermal radiofrequency ablation of the intercostal nerves in 25 patients with uncontrolled cancer-related breakthrough pain arising from rib metastasis. More than half of patients experienced a 50% reduction in intensity and frequency of breakthrough pain episodes with minimal adverse effects.\textsuperscript{69}

\section*{OUTCOME STUDIES}
Published reports are limited to case reports and case series.\textsuperscript{70} A 2007 publication detailed 25 patients with metastatic rib lesions who underwent neurolytic intercostal block. Optimal local pain control was reported in 80\% of patients, and 56\% reduced their analgesic use after the procedure.\textsuperscript{71}

In 2015, Gulati et al.\textsuperscript{72} reported on their experience with thoracic chest wall pain in the oncologic population between 2004 and 2014. Among 146 patients who underwent a diagnostic ICNB with local anesthetic and steroid, 79\% had improvement in pain (defined as a reduction in VAS >1 point). Interestingly, 22\% of patients had prolonged improvement in pain with an average duration of 21.5 days. However, only 32\% of patients overall who responded to diagnostic blockade chose to undergo neurolytic ICNB with alcohol ablation, with a success rate of 62\%. Additionally, the
authors present an interventional treatment paradigm based on their review and clinical experience to guide the appropriate interventional modality for oncologic chest wall pain. In patients with peripheral tumor or anterior chest wall pain, they recommend diagnostic ICNB followed by neurolysis with good response to the diagnostic injection. However, with a more central location of tumor in the paravertebral area and posterior chest wall pain, they advocate for diagnostic paravertebral nerve block followed by paravertebral neurolysis as indicated if the tumor is not encroaching the thoracic nerve root and pulsed radiofrequency ablation of the thoracic nerve root in the setting of tumor encroachment on the neuroforamen (Fig. 44.11).

Blocks of the Head and Neck

Head and neck cancers have among the highest rates of cancer-associated pain, and these patients rate pain control just behind treatment outcome and life expectancy among their priorities after diagnosis. Interventional targets for managing cancer-associated head and neck pain most commonly include the trigeminal ganglion and its branches; however, the autonomic sphenopalatine and stellate ganglia have also been successfully targeted.

Nerve Blocks of the Trigeminal Nerve and Its Branches

INDICATIONS

The trigeminal nerve is the fifth cranial nerve and has both motor and sensory function. In addition to innervating the muscles of mastication, it is responsible for sensation over most of the face. Neurolytic blockade of the trigeminal ganglion and its branches is indicated for patients with primary or metastatic head and neck cancer and associated severe pain. In the setting of cancer-associated pain, neurolytic blocks are most common, although local anesthetic block with indwelling catheter, thermal and pulsed radiofrequency ablation, and cryoablative techniques have all been described.

ANATOMY OF THE TRIGEMINAL NERVE AND ITS BRANCHES

The trigeminal, or gasserian, ganglion arises from the brainstem and divides into its three primary branches, the ophthalmic nerve (V1), maxillary nerve (V2), and mandibular nerve (V3), just prior to exiting the skull via the superior orbital fissure, foramen rotundum, and foramen ovale respectively (Fig. 44.12).
The ophthalmic nerve supplies sensory innervation to the skin of the scalp, forehead, upper eyelid, and tip of the nose via its terminal branches, the supraorbital and supratrochlear nerves. The maxillary nerve innervates the skin of the cheek, lower eyelid, nares, upper lip, upper teeth and gums, palate and roof, and the pharynx via its infraorbital and superior alveolar branches. In addition to supplying motor function to the muscles of mastication, the mandibular nerve innervates the skin of the chin, jaw, lower lip, external ear, and lower teeth and gums via its branches, the auriculotemporal, lingual, buccal, and inferior alveolar and mental nerves, all of which may be affected by direct tissue invasion, anatomic distortion, or metastatic lesions.\textsuperscript{78}
GENERAL CONSIDERATIONS
Nerve blocks in the setting of head and neck cancer may present technical challenges owing to significant anatomic distortion from direct tumor invasion as well as prior surgical intervention. Both fluoroscopic and CT-guided approaches have been described for neurolytic blocks of the head and neck. The most common trigeminal nerve targets are summarized in Table 44.4.

ADVERSE EFFECTS
The trigeminal ganglion lies in close proximity to both the dura as well as the middle meningeal and carotid arteries, and care must be taken to avoid dural puncture, intrathecal injection, bleeding, or intravascular injection. Neuritis or deafferentation pain is a possible complication of neurolysis of the trigeminal ganglion or its branches. In the case of the ophthalmic (V1) branch, neurolysis can result in impaired corneal reflex and corneal anesthesia, whereas neurolysis of the mandibular branch may denervate the ipsilateral muscles of mastication. However, this is typically not clinically significant unless bilateral neurolysis blockade is performed, which can result in significant difficulties in chewing and swallowing.

TECHNIQUES
The trigeminal ganglion is most commonly accessed via the foramen ovale. A submental fluoroscopic view is used to identify the foramen and a
needle is inserted 2.5 cm lateral to the corner of mouth. The needle is advanced in a trajectory in line with the ipsilateral pupil and an AP plane bisecting an imaginary line bisecting the angle between the external auditory meatus and the lateral canthus of the eye. Needle advancement should be discontinued when a lateral view shows appropriate placement in the foramen ovale, directly inferior to the sella turcica (Figs. 44.13 and 44.14). Iodinated contrast 0.1 to 0.5 mL is used to verify correct placement of the needle followed by neurolysis with 0.3 to 0.5 mL of neurolytic agent, mostly commonly phenol.

FIGURE 44.13  Fluoroscopic view of foramen ovale with needle in place—anteroposterior view.
To access the maxillary or mandibular nerve selectively, the coronoid notch is palpated just anterior to the external auditory meatus and inferior to the zygomatic arch, with the patient in a “slack jaw” position. Lateral fluoroscopy is used to identify the pterygopalatine fossa as a V-shaped structure superior to the upper molars and inferior to the orbit. The needle is inserted and directed in a plane perpendicular to the skull toward to pterygopalatine fossa. Once the lateral pterygopalatine plate is encountered, the needle is then be redirected anteriorly and superiorly for the maxillary nerve, or posteriorly and inferiorly for the mandibular nerve, and advanced approximately 0.5 to 1 cm to enter the pterygopalatine fossa. The position is confirmed with AP fluoroscopic view showing the needle tip lateral to the middle nasal turbinate as well as with appropriate contrast spread (Figs. 44.15 and 44.16). In this location, chemical neurolysis has been reported anecdotally using phenol or alcohol, but no case reports or studies have been published. More commonly, local anesthetic and steroid or pulsed radiofrequency ablation is utilized.
FIGURE 44.15  Lateral view of maxillary nerve block with needle in the superior anterior part of the pterygopalatine fossa.

FIGURE 44.16  Anteroposterior view of maxillary nerve block.

The terminal branches of the maxillary and mandibular nerves are also
interventional targets for cancer-related facial pain. Given their more superficial positions, chemical neurolysis is used infrequently, and local anesthetic and steroid as well as pulsed radiofrequency ablation are preferred.

The supraorbital nerve, innervating the skin of the ipsilateral forehead, is accessed by identifying the supraorbital foramen using fluoroscopy or palpating the supraorbital notch above the pupil along the orbital rim. The needle is then advanced toward the notch in a slight medial direction, taking care not to enter the foramen itself. The supratrochlear nerve, innervating the medial aspect of the forehead, is found by palpating the supratrochlear notch along the medial aspect of the supraorbital ridge just lateral to the junction of the supraorbital ridge and the bridge of the nose. The needle is advanced toward the notch until bone is contacted and then withdrawn slightly.

In the case of the infraorbital nerve, which innervates the lower eyelid, medial cheek, and lateral nares and upper lip, the infraorbital notch is identified using AP fluoroscopy and a needle is inserted 1 cm inferior and lateral to this. The needle is in an upward lateral trajectory toward the foramen. Finally, the mental nerve can be found by identifying the mental foramen using fluoroscopy or with palpation slightly superior to the mandible approximately 1 cm medial to the angle of the lip. A needle is directed toward the foramen in a slightly medial direction until bone is contacted.

OUTCOME STUDIES

Most published reports on trigeminal nerve interventions address its use for trigeminal neuralgia, with a reported success rate of 80% to 90%. The literature in cancer pain is limited to case reports. However, given the high burden of pain in the head and neck cancer population, the use of interventional treatment targeting the trigeminal ganglion and its distal branches should be considered for pain refractory to conservative treatment.

OTHER HEAD AND NECK INTERVENTIONAL TARGETS
The sphenopalatine ganglion (SPG) is a mixed parasympathetic and sympathetic ganglion that lies in close approximation to the maxillary nerve in the pterygopalatine fossa and has multiple connections to trigeminal and facial nerve fibers. It has been implicated in many facial pain and headache conditions and can be targeted in a similar fashion to the maxillary nerve block detailed previously, with the needle positioned slightly more inferiorly in the pterygopalatine fossa. Varghese and Koshy, in 2001, reported good results with endoscopic neurolytic block of the SPG with phenol, but data on percutaneous approaches has been limited. In 2017, Sanghavi et al. published a report of 33 patients with severe pain related to advanced head and neck cancer who underwent thermal radiofrequency ablation of the SPG following successful diagnostic block. Pain was reduced from an average VAS 8.4 to 1.4 after the procedure, and morphine consumption decreased to one-third the preprocedural level, with relief persisting for an average of 18 weeks. Similarly, Rana published a report of 20 patients with cancer-related orofacial pain, half of whom underwent pulsed radiofrequency ablation of the SPG and half who underwent SPG neurolytic block with alcohol. The authors did not report their technique for the procedures, but both groups experienced improved pain, with the radiofrequency ablation group having slightly better pain control at 1 month.

Similar to SPG, the stellate ganglion is a sympathetic ganglion implicated in headache and neuropathic facial pain syndromes. It is formed from fusion of the inferior cervical first thoracic ganglia and overlies the anterolateral T1 and T2 vertebral bodies. It can be accessed under fluoroscopic or ultrasound guidance at Chassaignac tubercle at the C6 level. Ghai et al. reported in 2016 on the use of stellate ganglion block with phenol and corticosteroid for intractable cancer-related facial pain and edema not amenable to trigeminal or sphenopalatine approaches due to anatomic distortion.

**Spinal Cord Stimulation**

The need for frequent magnetic resonance imaging (MRI) studies in cancer patients has previously limited the use of spinal cord stimulation in
treating cancer-related pain. However, there are now multiple spinal cord stimulator systems that have MRI-conditional labeling, indicating these devices pose no known hazards in the specified MRI environment under specified conditions.

The use of spinal cord stimulation for cancer pain has expanded in recent years with this change, although data are limited to case reports and small case series. Spinal cord stimulation has been used successfully for multiple types and locations of cancer pain, including pain directly resulting from anal cancer, metastatic colon cancer, testicular cancer, and angiosarcoma.\(^{85-88}\) There are also reports of its use for pain related to cancer treatment, including chronic chest wall pain following thoracotomy and radiation, chemotherapy-induced peripheral neuropathy, phantom limb pain following amputation, and failed back surgery syndrome related to resection of spinal tumors.\(^{85,89,90}\)

**Vertebral Augmentation**

The percutaneous treatment of painful vertebral collapse secondary to metastatic tumor has emerged as a very promising therapy in recent years. Metastatic spread to the skeleton is common, and 30% to 80% of bony metastases involve the vertebrae (see Chapter 46).\(^91\) Vertebroplasty is a minimally invasive outpatient procedure whereby painful vertebral compression fractures are stabilized by the injection of the bone cement polymethyl methacrylate (PMMA). Access to the vertebral body is typically achieved by passing a specialized needle under fluoroscopic guidance through the pedicles bilaterally.

Kyphoplasty differs in that the injection of cement is preceded by the creation of a cavity with a percutaneously placed intravertebral balloon, as demonstrated in Figure 44.17. Traditionally, the balloon inflation was intended to restore vertebral height loss, but this often requires very high pressures which may have been responsible for morbidity.
Vertebral height restoration is now considered less important, and the emphasis is now on creating a cavity so the cement injection can be performed under lower hydrostatic pressures with more predictable filling of the fractured vertebrae. A meta-analysis comparing vertebroplasty and kyphoplasty studies showed that vertebroplasty produced more significant pain relief but had a higher risk of cement extravasation into the spinal canal.\textsuperscript{92}

**INDICATIONS**
Vertebroplasty or kyphoplasty are indicated in an acute or subacute (<6...
months) painful vertebral body pathologic (secondary to osteoporosis or tumor) fracture without the involvement of the spinal canal and its elements.\textsuperscript{92,93} Careful clinical correlation between the pain symptoms and the radiographic findings should be established because not all radiographically evident fractures are symptomatic. If there is doubt about the significance of a fracture, or in the presence of fractures at multiple levels, clinical correlation is often best achieved by examining the spine with the aid of fluoroscopy while palpating or percussing the spinous process of the vertebrae in question to see if concordant pain can be elicited. In the case of a fracture involving the spinal canal, actual or impending neurologic deficits are best treated by a surgical approach with decompression and probable spinal fusion.

**CONTRAINDICATIONS**

Absolute contraindications to vertebroplasty and kyphoplasty include asymptomatic stable fractures, clinically effective medical therapy, osteomyelitis of target vertebra, uncorrected coagulation disorders, allergy to any required component, and local or systemic infection. Relative contraindications include radicular pain or radiculopathy caused by a compressive syndrome unrelated to vertebral body collapse, a retropulsed fragment with >20% spinal canal compromise, tumor extension into epidural space, and severe vertebral body collapse (vertebra plana). The need for subsequent radiation to the area is not a contraindication because PMMA has been shown to be resilient to radiation at therapeutic doses.

**OUTCOMES**

Both vertebroplasty and kyphoplasty have consistently shown a significant improvement in postprocedure pain scores. In a meta-analysis by Eck et al.,\textsuperscript{92} 168 eligible studies on vertebroplasty and kyphoplasty were assessed for their comparative analgesic efficacy and rates of complication. The mean pre- and postoperative VAS scores for vertebroplasty were 8.36 and 2.68, respectively, with a mean change of 5.68 (\(P < .001\)). The mean pre- and postoperative VAS scores for kyphoplasty were 8.06 and 3.46, respectively, with a mean change of 4.60 (\(P < .001\)). The pain reduction for vertebroplasty was noted to be statistically greater (\(P < .001\)) compared
with kyphoplasty. However, the risk of new vertebral fracture was 17.9% with vertebroplasty versus 14.1% with kyphoplasty (P < .01), and the risk of cement leak was 19.7% with vertebroplasty versus 7.0% with kyphoplasty (P < .001).

An important 2011 study by Berenson et al.\textsuperscript{94} looked at balloon kyphoplasty versus conservative management in cancer-related vertebral compression fractures. There were 134 patients randomly assigned to either group, with the primary follow-up at 1 month. The kyphoplasty group, compared to conservative management group, demonstrated improved function relating to back pain as measured by the Roland-Morris Disability Questionnaire (RDQ), with the mean score in the kyphoplasty group changing from 17.6 at baseline to 9.1 (mean change −8.3 points, 95% CI −6.4 to −10.2; P < .0001) and the mean score in the control group changing from 18.2 to 18.0 (mean change 0.1 points; 95% CI −0.8 to 1.0; P = .83). At 1 month, the kyphoplasty treatment effect for RDQ was −8.4 points (95% CI −7.6 to −9.2; P < .0001). The most common adverse events were back pain (4 of 70 in the kyphoplasty group and 5 of 64 in the control group) and symptomatic vertebral fracture (two and three, respectively). One patient in the kyphoplasty group had an intraoperative non–Q-wave myocardial infarction, which was not directly related to the procedure.

A possible, emerging adjunct to vertebral augmentation for cancer of the spine is radiofrequency ablation followed by cementoplasty, although there is presently no data to support this therapy over vertebral augmentation alone.\textsuperscript{95}

**Spinal Cord Ablation**

Spinal ablation remains a relevant and important technique for the treatment of medically refractory cancer pain. Interruption of the spinothalamic tract (cordotomy) or the dorsal column’s visceral pain pathway (myelotomy) can be achieved either through open surgical techniques including laminectomy or percutaneously. Advantages of these techniques as compared with IT drug delivery include immediate onset pain relief, no ongoing medical visits for maintenance of therapy, and cost-effectiveness.
**Cordotomy**

**INDICATIONS**
Cordotomy, a lesion of the spinothalamic tract, is highly effective for the treatment nociceptive pain due to cancer. Cordotomy is safest when performed unilaterally, so as to avoid the well-documented complication of inducing sleep apnea by disrupting the bilateral interruption of reticulospinal fibers.\textsuperscript{96,97} Due to the decussation of spinothalamic fibers, cordotomy is effective for pain arising two to five segments below the targeted spinal level. Because cordotomy is usually performed percutaneously at the C1–C2 level, it can usually have an effect on pain arising from the C5 or C6 dermatomes and below (Fig. 44.18).

![Cordotomy diagram](image)

**FIGURE 44.18** Cordotomy. Axial section of the cervical spine showing the spinothalamic tract ascending in the anterolateral quadrant of the spinal cord. A radiofrequency electrode is used to create a thermal lesion.

**SURGICAL TECHNIQUES**
Although fluoroscopy can be used as the primary imaging modality for cordotomy, the additional safety and accuracy afforded by intraoperative CT imaging has improved outcomes for this procedure. Cordotomy may be performed either in an operating room equipped with a CT scanner or in the diagnostic radiology suite.

On the day of the procedure, the patient is transported to the diagnostic
CT scanning area. A lumbar puncture is performed and IT contrast is administered to obtain an adequate cervical myelogram. The patient is placed in the Trendelenburg position for 15 to 20 minutes to allow adequate dispersion of the contrast. IV sedation is provided, and local anesthetic is infiltrated in the skin approximately 1 cm inferior and posterior to the tip of the mastoid. A CT scan of the cervical spine is obtained, focusing on the C1–C2 region. A disposable percutaneous cordotomy electrode (LCED; Cosman Medical, Burlington, Massachusetts) kit may be used for this procedure. A 20-gauge spinal needle is advanced toward the C1–C2 interspace, and intermittent short-segment CT scans spanning 15 mm are used to direct the needle toward the dura. For lower extremity pain, the target for the spinal needle is just anterior to the AP midpoint of the spinal cord; for pain in the chest or upper extremities, the target is 1 to 2 mm more anterior to this. The tip of the spinal needle is advanced further until it is adjacent to the spinal cord. At this point the stylet was replaced with the electrode.

Electrical impedance measurement along with tactile feedback is used to determine the location of the electrode. When the electrode is in CSF, the impedance will measure a few hundred ohms (<300 Ω). As the electrode abuts and presses into the pia of the spinal cord, the impedance will increase significantly into the range of several hundred ohms (300 to 500 Ω). Entrance of the electrode into the spinal cord is met with a clear popping sensation, and the impedance will increase dramatically to greater than 700 Ω. At this point, another CT scan is obtained to confirm the position of the radiofrequency electrode.

Intraoperative physiologic testing is then performed to test for both sensory and motor effects. Sensory testing is performed at 100 hertz (Hz) and a 0.1-msec pulse width, whereas motor testing is performed at 2 Hz. At this point in the procedure, the patient’s cooperation is needed, and hence, the sedation is adjusted until the patient can intelligibly answer questions. Sensory testing is performed to physiologically confirm the electrode tip’s presence within the spinothalamic tract. Testing for motor contractions is also performed up to 1 V stimulation, indicating a safe distance from the corticospinal tract.

When the radiofrequency electrode is in the appropriate radiologic and
physiologic location, lesioning is performed using increasing levels of temperature starting at 60° C for 60 seconds and proceeding up to 80° C for 60 seconds. Because lesioning the spinothalamic tract is not painful, additional sedation is not required for the ablation. Between lesions, testing for the development of hyperesthesia is helpful, because an additional lesion may be required if the patient has no decreased pinprick sensation. The goal of the cordotomy is to create a moderate hypoalgesia.

OUTCOMES
Two important neurosurgical series of CT-guided cordotomy have been published. In a prospective study of 41 patients who underwent cordotomy, 80% of patients had no pain postoperatively and for 1 month postprocedure. At 6 months postprocedure, 32% of patients had no pain, and another 48% of patients had partially satisfactory pain relief. Similarly, in Kanpolat et al.’s series of 207 cordotomies, a significant improvement in the pain intensity from a mean of 7.6/10 preoperatively to a mean of 1.3/10 postoperatively was achieved. When Kanpolat reported his subset of 108 patients with lung cancer, 89% of patients had no pain postoperatively.

COMPLICATIONS
Cordotomy has become a much safer procedure in the era of CT guidance. The risk associated with spinal needle insertion and penetration of the radiofrequency electrode into the pia of the spinal cord appears to be negligible. The radiofrequency ablation itself can be a source of complication for cordotomy. Hence, the art of cordotomy is determining the appropriate balance between an aggressive lesion to optimize a durable pain outcome and a safe lesion to avoid undesired side effects.

In 2008, Raslan reported his series of 41 patients who underwent cordotomy, and no patients were found to have new neurologic deficits. In Kanpolat et al.’s series of 207 cordotomies, 5 patients (2.4%) developed temporary weakness and 5 patients (2.4%) developed temporary ataxia. These symptoms resolved within 3 weeks after the procedure. In the 251 CT-guided cordotomies reported in the literature, four patients (1.6%) had dysesthetic pains. Respiratory complications or serious neurologic injury
has not been reported using a CT-guided approach.

**Myelotomy**

**INDICATIONS**
