Uncontrolled observations and case studies have shown efficacy in the treatment of TN with valproic acid, clonazepam, and pimozide.\textsuperscript{102–105} The efficacy of pimozide is severely limited by its significant side effects which include Parkinsonism, mental retardation, and memory impairment. The anticonvulsant drugs gabapentin and topiramate have been shown to be effective in the treatment of neuropathic pain; however, there are no controlled studies of their effectiveness in the treatment of TN. Small case series report their effectiveness in the treatment of symptomatic TN secondary to MS.\textsuperscript{106–108} In a meta-analysis of effectiveness in TN, overall topiramate results did not differ from CBZ after 2 months of treatment.\textsuperscript{109} A small prospective randomized study and a case report demonstrated relief of TN symptoms with injection of botulinum toxin (16 to 100 units).\textsuperscript{110,111} A six-patient retrospective analysis and an eight-patient prospective trial of intravenous lidocaine, in doses ranging from 2 to 5 mg/kg/hour, resulted in partial or complete relief of TN pain paroxysms provoked by vibratory symptoms.\textsuperscript{47,112}

In summary, the current literature supports CBZ as first-line therapy for TN, although data also supports use of OXC as first-line therapy, particularly in patients refractory to CBZ monotherapy or who have intolerable side effects. Those patients who do not respond to monotherapy of CBZ or OXC may benefit from combination therapy with gabapentin, lamotrigine, levetiracetam, pregabalin, topiramate, or baclofen. Intravenous phenytoin, fosphenytoin, or lidocaine or botulinum toxin injections may be effective in refractory cases of TN for treatment of severe, frequent attacks which may affect the patient’s ability to eat or drink. Infusions should be conducted in a carefully monitored setting with appropriate medical attention and emergency equipment available. Due to reports of spontaneous intermittent or permanent remissions of TN, periodic withdrawal of medications is warranted in patients who have prolonged pain-free periods on oral medications.

**Treatment—Nerve and Neurolytic Blockade**

Local anesthetic injection or infusion has been used for diagnostic purposes and for temporizing treatment in patients with unbearable pain refractory to medical therapy and/or awaiting MVD.\textsuperscript{113} No controlled
studies of nerve blockade for relief of TN have been reported, and controlled studies are needed to validate this approach. Small case series include significant reduction of pain and triggers in five elderly patients for a median of 2 months subsequent to injection of the infraorbital nerve in patients with second division TN using a combination of 4% tetracaine dissolved in 0.5% bupivacaine. Another study looking at relief of pain following injection of the infraorbital nerve reported greater than 3 months of relief with 4% tetracaine and 0.5% bupivacaine (compared to 3 days or less with 0.5% bupivacaine or 1% mepivacaine alone). A combination of ketamine, morphine, and bupivacaine produced similar pain relief and duration as reported following a series of injections of symptomatic peripheral trigeminal nerve branches in patients with TN.

A case report of stimulator-guided mandibular and maxillary division nerve blockade using a combination of lidocaine, bupivacaine, clonidine, and fentanyl at monthly intervals for 1 year in two patients describes prolongation of relief after 3 months and pain-free status with no recurrence at 9-month follow-up. No sensory or motor disturbances were reported. Peripheral injections are of value in elderly patients who have not responded to medical or other surgical therapies. Standard precautions to avoid intravascular injection of drugs should be taken, and care should be taken when performing V2 and V3 blockade as total brainstem anesthesia with respiratory arrest following extraoral trigeminal V2 to V3 blocks has been reported.

Careful aspiration, fluoroscopic guidance when available, utilizing contrast (when no contraindication exists), and digital subtraction can decrease the risk of intravascular or intrathecal injection. As with intravenous infusions, injections should be performed in a monitored setting with appropriate medical attention and readily available emergency equipment.

Alcohol, phenol, or glycerol injection has long been reported in the treatment of TN. Percutaneous gangliolysis using glycerol is discussed under surgical techniques. A retrospective case audit of patients who received peripheral alcohol injections for TN from 1994 to 1999 found a mean duration of effect of 11 months. In a retrospective review of 100 patients with TN who were treated with 1 to 1.5 mL of absolute alcohol
injection, 86% reported pain control. The duration of analgesia varied widely from a period of 2 to 56 months. In a prospective study from South Korea, 98 patients who received mandibular nerve blocks with alcohol had pain relief. At 1 year, 90.4%, at 2 years 69%, at 3 years 53.5%, and at 7 years 33% remained pain-free. Glycerol injections provided a mean of 7 months of pain relief. A retrospective analysis of 157 cases of intractable idiopathic TN treated with peripheral glycerol injections reported an initial 98% success rate with 60 patients having recurrent pain between 25 and 36 months. The study reports complete or near-complete pain relief in 154 patients at 4 years (with inclusion of patients with recurrent pain who were reinjected). Postinjection facial swelling, discomfort, and numbness are reported complications of alcohol injections. More serious complications occurred in 3 of 413 injections over a 20-year period. A small case series of 60 peripheral injections in 18 patients of the infraorbital, supraorbital, and mandibular nerves using 10% phenol in glycerol reported 87% initial marked or total pain relief and a median of 9 months of continued relief. Most patients with recurrent pain requested a repeated procedure rather than surgery or a ganglion nerve block. No serious complications or dysesthetic pain were reported. In patients with facial sensory loss, sensation was recovered within 6 months and was well tolerated. In a randomized control trial of 42 patients with TN, 68% of the subjects who received botulinum toxin type A (BTX-A) in comparison to only 15% of the placebo group subjects, showed significant improvement in pain intensity and frequency after 2 weeks. In an RCT, both 25 and 75 units of BTX-A were better (70.4% and 86.2%) than placebo (32.1%) in the treatment of TN at 8 weeks follow-up. There was no significant difference between two doses of BTX-A.

**Treatment—Surgical**

Surgical therapies are aimed at either damaging or destroying pain transmitting nerve fibers or relieving pressure on the nerve from vascular loops, fibrous bands, or mass lesions. Radiation therapy may relieve pain in patients who are not surgical candidates and who are refractory to medical management of TN.
Microvascular Decompression
MVD is performed under general anesthesia using a microscope to visualize the trigeminal nerve as it leaves the pons via a suboccipital craniectomy. Compression of the nerve by a vein or artery is relieved by repositioning the artery or coagulating the vein. Although MVD is invasive, it is associated with the best long-term outcome and overall mortality and complication rates are low. An analysis of long-term follow-up data of 1,324 patients with TN who underwent MVD between 1976 and 2000 revealed an increase in the postoperative cure rate from 92.9% to 96.7% in patients operated on after 1986. Recurrence rate decreased from 10.2% to 6.5% in the patients operated on between 1986 and 2000 compared to the patients who underwent MVD between 1976 and 1986.128 Barker et al.129 reported results of 1,185 patients who underwent MVD over a 20-year period. It was noted that the rate of complications was significantly reduced, and no deaths occurred after 1980 when intraoperative monitoring of brainstem evoked response was used. Female gender, symptoms lasting more than 8 years, venous compression of the terminal REZ, and the lack of immediate postoperative cessation of pain were significant predictors of eventual recurrence.129 Endoscopic microvascular decompression (E-MVD) was used in 47 patients with TN. In the follow-up period of 15 ± 8 months after the surgery, patients reported overall excellent pain control. One patient had permanent hearing loss as a complication of the surgery. E-MVD was deemed to be safe and effective in the treatment of TN.130 In a comparative study of endoscopic versus traditional microscopic microvascular decompression (M-MVD) for TN, 167 subjects were followed up from 2006 to 2013. Out of 167 patients, 93 patients underwent M-MVD and 74 underwent E-MVD. Overall outcome and complications rates were comparable.131 In a retrospective comparative analysis of 225 patients who underwent MVD and 206 having undergone percutaneous trigeminal radiofrequency rhizotomy, 64% of patients who underwent MVD remained completely pain-free 20 years postoperatively versus 50% risk of recurrence of pain 2 years after radiofrequency rhizotomy.132 Hospital and surgeon volume was found to be a significant factor affecting morbidity in a study conducted from 1996 to 2000 by Kalkanis and associates.133 The overall mortality
rate was 0.3% with volume and mortality not statistically related. The rate of discharge other than to home was 3.8%, with hospitals and/or surgeons who performed the surgeries at low volumes being 5.1% as compared to 1.6% for high volume.\textsuperscript{133} Percutaneous rhizotomy or gangliolysis is useful in treating the elderly or debilitated patient who is refractory or intolerant to medical therapy and for whom surgery is not warranted due to risk factors. Gangliolysis is performed under fluoroscopic guidance by placing a needle percutaneously through the foramen oval and advancing it to the trigeminal cistern.

The three techniques currently used for gangliolysis include percutaneous radiofrequency ablation/thermocoagulation, trigeminal ganglion compression, and retrogasserian glycerol rhizolysis. Percutaneous radiofrequency trigeminal gangliolysis involves the use of radiofrequency to create anatomically distinct lesions in cycles of 45 to 90 seconds at 60° to 90° C. Percutaneous trigeminal ganglion compression is performed under general anesthesia utilizing a Fogarty catheter that is inserted via a 14G catheter into the trigeminal cistern and inflated with radiocontrast to compress the gasserian ganglion. Careful observation of heart rate and blood pressure is required due to the possibility of severe bradycardia and hypotension which may require treatment with atropine and vasopressors. Percutaneous glycerol rhizolysis is performed in a sitting position. After confirmation of needle location with radiocontrast, 0.1 to 0.4 mL of anhydrous glycerol is injected into the cistern of Meckel’s cave.

In a prospective longitudinal study of 48 patients with TN, 31 had pure TN and the remainder presented with atypical facial pain and mixed TN. They were treated with radiofrequency thermocoagulation of the gasserian ganglion with overall favorable outcomes after the treatment. The mean time for reoccurrence of pain was 40 months for the CTN cohort and 36 months for TN patients with atypical facial pain.\textsuperscript{134} An analysis of 100 subjects who underwent percutaneous balloon compression (PBC) of the trigeminal rootlets showed initial pain relief in 90% of patients. Twenty months was the median time to be symptom-free without the help of any medications.\textsuperscript{135} A systematic review of radiofrequency ablation/thermocoagulation techniques for the treatment of TN demonstrated complete pain relief without medication in a median of 88%
in patients undergoing radiofrequency thermocoagulation at 6-month follow-up.\textsuperscript{136} This dropped to 61% at the 3-year follow-up. Retrospective analysis of patients undergoing percutaneous glycerol rhizolysis showed complete pain relief in 84% of patients with or without medication at 6 months following treatment. This dropped to a median of 54% at 3-year follow-up.

Complications with any of the ablative techniques described earlier have been noted to include dysesthetic disturbances in 4% to 10% of patients treated. Up to 30% of patients treated with radiofrequency thermocoagulation experienced significant permanent sensory loss. Other complications included corneal numbness and keratitis, anesthesia dolorosa, transient masseter weakness, cranial nerve deficits, and vascular injuries. The complication rate was highest in patients undergoing radiofrequency thermocoagulation, although most complications were transient.\textsuperscript{136}

Ablative procedures are less invasive than MVD and are generally associated with a high initial response rate. Recurrence is common, however, and the incidence of facial numbness is higher than with MVD. Patients who have a recurrence of TN after an ablative procedure can successfully undergo MVD.\textsuperscript{129}

### Stereotactic Radiosurgery

The first radiosurgical device was developed in the 1950s by Professor Lars Leksell at the Karolinska Institute in Stockholm. This work resulted in the development of the gamma knife which is able to precisely irradiate small intracranial targets with gamma ray photons.

Of 149 patients who received gamma knife stereotactic radiosurgery (GKS) for TN, 76%, 69%, and 60% reported pain control at 1, 2, and 3-year follow-up, respectively. Twenty-seven patients were treated with repeat GKS; 70% and 62% reported freedom from pain at 1 and 2 years.\textsuperscript{137} Pain relief with GKS occurs after a lag time of about 1 month.\textsuperscript{3,138} A systematic review of these data found that approximately 75% of patients report complete relief within 3 months, and 50% of patients can permanently stop drug therapy after surgery. Sensory disturbances (e.g., numbness, paresthesias, and dysesthesias) are the most frequent
complications.\textsuperscript{138}

CyberKnife radiosurgery is a more recently developed system to incorporate a miniature linear accelerator mounted on a flexible, robotic arm. This system offers targeting accuracy without the need for the invasive head frame and is able to treat tumors anywhere in the body. Although GKS has the advantage of over 30 years of clinical use, observational studies using the CyberKnife system for the treatment of TN report a 92.7\% initial success for pain relief at a median latency to pain relief of 7 days. Long-term response rate at 11 months was 78\%.\textsuperscript{139} Larger study groups and longer follow-up is needed to further evaluate long-term pain relief and complications. In an analysis of outcomes in 27 patients who had refractory TN who received CyberKnife radiosurgery, 42.9\% were pain-free within 1 month after the procedure. The time for reoccurrence of pain widely varied.\textsuperscript{140} Although radiosurgery is less effective than MVD, it is an effective, minimally invasive treatment option for patient’s refractory to medical therapy who are not surgical candidates or in whom the risks of surgery are not acceptable. Patients who fail to respond to radiosurgery or who have recurrence of symptoms may respond to repeat treatment.\textsuperscript{141,142}

In a retrospective analysis, 870 patients who received stereotactic radiosurgery for TN (95\% CTN), based on treatment dose, were divided into three groups: 352 patients received the dose of ≤82 Gy, 85 patients received 83 to 86 Gy, and 433 patients ≥90 Gy. In a 4-year follow-up, pain control was 79\%, 82\%, and 92\%, respectively.\textsuperscript{143} In a recent analysis, the stereotactic radiosurgery outcome of 112 patients who had type 1 (TN1) or 2 (TN2) TN (old classification) and treated between 1994 and 2016 was reviewed. At 5, 10, and 15 months, symptom relief was 75\%, 90\%, and 90\% for TN1 and 47\%, 77\%, and 87\% for TN2. In a long-term follow-up at 24 and 36 months, 67\% and 52\% for TN1 and 32\% and 32\% for TN2 reported symptom relief.\textsuperscript{144}

Peripheral Neurectomy
Surgical destruction of the peripheral branches of the trigeminal nerve is indicated for patients who have failed medical therapy, who have failed gangliolysis, or who have severe cardiopulmonary disease and are unable
to tolerate a suboccipital craniectomy and MVD. Duration of good to excellent relief varies from less than 1 year to a range of 2 to 5 years in reported series. In one series, the median pain-free period among 88 patients was 41 months with a mean of 52.5 months. Analysis of 40 patients found excellent to good results in all patients for a period of time ranging from 2 to 5 years.\textsuperscript{145,146} The procedure can be repeated; however, the risk of neuroma is increased as is diminished success. Following neurectomy, dense numbness in the distribution of the eradicated nerve can occur.

Cryoablation of the peripheral branches of the trigeminal nerve can be performed using a 1.4- to 2-mm probe which incorporates a nerve stimulator to test both sensory and motor function as well as a thermistor to identify temperature at the tip of the probe. A 3.5- to 5.5-mm ice ball is produced which results in disruption of the nerve structure with wallerian degeneration while leaving the myelin sheath and endoneurium intact (axonotmesis).\textsuperscript{147} The use of cryotherapy to successfully treat patients with TN has been reported by several authors to provide analgesia for periods ranging from 6 to 13 months. No permanent sensory loss was reported; however, in one review, up to one-third of patients developed atypical facial pain following the procedure.\textsuperscript{148–150}

### Painful Trigeminal Neuropathy

PTN is differentiated from TN through demonstration of a causative lesion other than vascular compression. Sensory impairment and bilaterality may be present as well as lack of a refractory period after a paroxysm.\textsuperscript{2} MS and benign or malignant neoplasms are the most common cause of PTN, although fungal infection and bacterial sinusitis with intracranial extension, scrub typhus, hardened felt from previous MVD surgery, and TN as the first manifestations of mixed connective tissue disorder have also been reported.\textsuperscript{139,151–155}

### MULTIPLE SCLEROSIS

MS is an inflammatory autoimmune systemic disease which is characterized by demyelinating lesions and plaques within the central
nervous system. Widespread neuronal loss with periods of remyelination may be associated with periods of remission.

MS affects women more than men with a cumulative ratio of females to males of 1.77 to 1.0. Median and mean age of onset of MS is 23.5 and 30 years of age, respectively.\(^{156}\) TN occurs in up to 2\% of patients with MS, although this represents only about 0.5\% of patients presenting with TN.\(^{157,158}\) These patients can present with symptoms which mimic CTN but often present with bilateral symptoms and persistent background facial pain.\(^{158}\)

The pathophysiology of TN in MS continues to be debated. Although demyelinating lesions affecting the trigeminal REZ have been found on autopsy and on MRI, 24 MS patients out of a series of 851 studied at one institution were found to have entry zone lesions which were clinically silent.\(^{159,160}\)

Although MVD was once thought to be contraindicated in MS patients with PTN, a report of MVD performed in 35 MS patients with severe neurovascular compression at the REZ resulted in a 39\% excellent and 22\% fair to good long-term pain relief. Seventy-four percent of these patients had demyelinating lesions affecting the brainstem trigeminal pathway on the painful side in addition to neurovascular compression.\(^{161}\) In a series of five patients with TN and MS who were refractory to medical treatment and had undergone multiple unsuccessful percutaneous procedures, those patients undergoing MVD combined with partial sectioning of the nerve did better than those undergoing MVD alone.\(^{162}\) A study reported 43 patients with MS related TN who were treated with GKS, 91\% reported initial symptom relief. The actuarial probability to live pain-free was 87.2\%, 71.8\%, 43.1\%, 38.3\%, and 20.5\%, at 6 months, 1, 3, 5, and 10 years, respectively.\(^{163}\)

In general, patients with PTN secondary to MS respond less favorably to medical and interventional therapies and may require significantly more treatment than their cohorts with CTN.\(^{164}\)

**NEOPLASM**

The presentation of TN does not rule out the presence of a tumor. Some authors advocate advanced imaging of all patients presenting with TN due
to delayed neurologic symptoms in patients with space-occupying lesions.\textsuperscript{154} Among 2,972 patients diagnosed with TN at the Mayo Clinic between 1976 and 1990, tumors were the cause of facial pain in approximately 10% (296 patients). Sex and pain distributions paralleled those in TN; however, patients presenting with tumors were younger than those with TN. Delay in tumor diagnosis averaged 6.3 years. The development of neurologic deficits prompted further imaging and diagnosis of tumor in 47% of these patients. These patients were often successfully treated medically for many years prior to onset of neurologic symptoms.\textsuperscript{53,165}

Meningioma and epidermoid and acoustic neuroma are the most frequent posterior fossa tumors associated with PTN. In a review of 161 and 80 consecutive posterior fossa tumors from 1993 to 1999 and 1979 to 2003 at separate institutions, cranial nerve dysfunction was the most common neurologic sign on admission. Intracranial hypertension and disturbance of gait also presented in up to 44% of these patients.\textsuperscript{166,167} Twenty cases of TN caused by contralateral tumors of the posterior fossa have been reported. Only 4 of these cases symptomatically conformed to CTN. The mechanism of contralateral tumor causing TN is thought to be distortion and displacement of the brainstem and compression of the contralateral Meckel’s cave.\textsuperscript{168,169}

Pain in all three divisions of the trigeminal nerve is the first symptom of a tumor in Meckel’s cave in over 65% of cases. The most common cavernous sinus tumors are trigeminal schwannomas and meningiomas. Tumors in this location make up only 0.5% of all intracranial tumors.\textsuperscript{170} Case reports of metastatic disease to Meckel’s cave presenting as TN include colorectal cancer, esophageal cancer, breast cancer, renal cell carcinoma, and lymphoma.\textsuperscript{170–174} Primary melanoma, adenocarcinoma, and lymphoma involving Meckel’s cave and associated with TN have also been reported.\textsuperscript{175–178} TN with subacute onset of numbness in one or more divisions of the trigeminal nerve is thought to be associated with rapidly expanding tumor in this region.\textsuperscript{174}

Other reported causes of symptomatic TN include platybasia (a skull base deformity),\textsuperscript{179} sarcoid granuloma of the trigeminal nerve, and infarction of the REZ of the trigeminal nerve in the pons.\textsuperscript{180,181} TN has
also been seen in adults and children as the only manifestation of Chiari type I malformations.\textsuperscript{182–184} Patients with hydrocephalus from remote causes such as a lumbar myxopapillary ependymoma and a quadrigeminal arachnoid cyst have also presented with TN.\textsuperscript{185,186} Shunting and relief of hydrocephalus resulted in resolution of symptoms in these cases.

Five percent to 10\% of TN has been reported to be PTN secondary to brain tumors.\textsuperscript{187} Although persistent pain, numbness, palsies, and gait disturbances along with other neurologic signs often differentiate these patients from those with TN, delay in the presentation of neurologic deficits is not infrequent. Expedient workup including advanced imaging is indicated in cases of TN with new onset of neurologic signs such as numbness or palsies.

**HERPES ZOSTER AND POSTHERPETIC NEURALGIA**

HZ and postherpetic neuralgia is classified by ICHD-III as a subgroup of TN under subclassification of PTN caused by HZ infection, whereas the International Association for the Study of Pain (IASP) categorizes it as postherpetic neuralgia.

**Etiology**

Acute HZ results from the reactivation of the varicella zoster virus which is referred to as “chickenpox” in children or “shingles” in adults. The virus remains dormant in the dorsal root ganglia of cranial or spinal nerves after resolution of the original infection. As cellular immunity wanes with disease, chemotherapy, or age, the virus is reactivated and is transported along peripheral nerves producing an acute neuritis. Viral replication results in direct nerve sheath and neuronal injury. Destruction of tissue and inflammation result in excitation of nociceptors and dorsal horn sensitization. The dorsal horns of patients who do not develop postherpetic neuralgia show less tissue damage and more rapid resolution of inflammatory changes.\textsuperscript{188}

**Epidemiology**

The rate of HZ and the rate of HZ-associated complications increase with age, with 68\% of cases occurring in those aged 50 years and older.
Postherpetic neuralgia occurs in 18% of adult patients with HZ and in 33% of those aged 79 years and older.\textsuperscript{189}

In HZ involving the trigeminal nerve, neuronal spread of the virus occurs along the ophthalmic (first) and less frequently the maxillary (second) division of the fifth cranial nerve. Vesicular eruptions usually occur at the terminal points of sensory innervation, causing extreme pain. HZ involving the ophthalmic ganglion of the trigeminal nerve, or zoster ophthalmicus, accounts for as many as 10% to 25% of HZ cases. Nasociliary involvement will most likely cause ocular inflammation. Inflammation of the eye can lead to impairment of vision and in some cases temporary blindness. Such cases are considered emergent, and prompt treatment is required to prevent chronic inflammation or long-term vision loss.

Contiguous spread of the virus may lead to the involvement of other cranial nerves, resulting in optic neuropathy (cranial nerve II) or isolated cranial nerve palsies (cranial nerve III, IV, or VI).

**Symptoms and Signs**

Acute HZ typically presents with a prodrome consisting of hyperesthesia, paresthesias, burning dysesthesias, or pruritus along the affected dermatome(s). This prodrome is usually accompanied by fever and general malaise. It generally lasts 1 to 2 days but may precede the appearance of skin lesions by up to 3 weeks. Manifestation of prodromal symptoms without development of the characteristic rash may occur in some patients. This presentation is known as “zoster sine herpete” and may delay correct diagnosis and treatment.

Following the prodromal period, a vesicular skin rash appears along the affected nerve. Involvement of the trigeminal nerves characteristically respects the vertical midline. The vesicles will discharge fluid and begin to scab over after about 1 week. The pain is extreme during the inflammatory stage. Vesicles at the tip of the nose are known as Hutchinson sign and signal a 75% likelihood of ocular sequelae which may include follicular conjunctivitis; epithelial and/or interstitial keratitis; dendritic keratitis; uveitis; scleritis chorioretinitis; optic neuropathy; and palsy of the third, fourth, or sixth cranial nerves.
Pain that persists beyond healing of the rash but which resolves within 4 months of onset is referred to as subacute herpetic neuralgia. Postherpetic neuralgia refers to pain persisting longer than 4 months from initial onset of rash. Affected patients usually report constant, severe, burning, lancinating pain in the distribution of the affected nerve(s). Patients may also complain of pain in response to nonnoxious stimuli (allodynia). Even the slightest pressure from clothing, bedsheets, or a slight breeze may elicit severe pain.

**Diagnosis**

The diagnosis of acute HZ is essentially clinical, based on the characteristic unilateral appearance of a vesicular rash limited to the distribution of a specific nerve or nerve root. As discussed in the “Symptoms and Signs” section earlier, this is preceded most commonly by a painful prodrome characterized by burning dysesthesias or paresthesias along the affected dermatome. The criterion standard of laboratory diagnosis is polymerase chain reaction testing together with direct identification of varicella zoster virus in culture. Immunocompromised patients may benefit from immunoglobulin (Ig) G- and IgA anti-varicella zoster virus antibodies.

**Treatment**

The goals of treatment of acute HZ include treatment of the acute viral infection, treatment of the severe acute pain associated with HZ infection, and prevention of postherpetic neuralgia.

Acute HZ infection should be treated with antiviral medication within 72 hours of vesicular eruption to reduce the duration and severity of pain associated with the infection. The use of antivirals may produce a moderate reduction in the risk of development of postherpetic neuralgia. Oral steroids may also be beneficial in reducing the severe pain of acute HZ.

Acute treatment of acute HZ with neuropathic analgesics (i.e., anticonvulsants or tricyclic antidepressants) starting within 48 hours of onset of rash may also reduce acute pain and incidence of postherpetic neuralgia. Patients with ocular involvement should have immediate
evaluation and treatment of ophthalmic complications by a specialist.

The varicella zoster vaccine was approved by the FDA in May 2006 and was found to reduce the incidence of shingles by 51% in a randomized double-blind study. Pain was reduced by 61% in those who received the vaccine but still developed the infection, and postherpetic neuralgia was reduced by two-thirds compared with placebo. The FDA recently approved a new shingles vaccine called Shingrix for adults age 50 years and older.

Nutritional counseling may also be indicated in populations at risk for HZ. In a review of 243 HZ cases, it was determined that individuals, particularly those over age 60 years, who ate less than one serving of fruit or vegetables weekly had a threefold greater risk of HZ compared to those who ate more than three servings daily independent of vitamin supplement intake. An association between deficiency of vitamin A (a key immune modulator involved in the synthesis of lymphocytes, neutrophils, cytokines, and immunoglobulins) and increased risk of HZ has also been observed.

Systematic reviews of the literature have concluded that pharmacologic therapies shown to be more effective than placebo for postherpetic neuralgia include tricyclic antidepressants, opioids, gabapentin, pregabalin, tramadol, capsaicin, and lidocaine 5% patch. Intrathecal methylprednisolone was shown to be of benefit in patients refractory to pharmacologic therapies. Safety and tolerability should be considered when selecting pharmacologic treatments. Older patients may have more intolerable side effects at standard doses and thus may require smaller doses and more gradual titration. They may also be on multiple medications for coexisting medical conditions with potential for drug–drug reactions. In a 13-week RCT for the treatment of 370 patients with postherpetic neuralgia, pregabalin showed efficacy from week 1 and continued for 13 weeks. Most common side effects were dizziness (5.8%), somnolence (2.9%), and ataxia (2.5%).

Sympathetic blockade, including stellate ganglion block, has commonly been used to provide pain relief of variable duration in both acute HZ and in postherpetic neuralgia. Although a review of sympathetic blocks in the treatment of acute HZ and postherpetic neuralgia found the evidence to be
inconclusive due to lack of properly controlled studies, it found available
data to suggest that sympathetic blocks may provide considerable pain
relief during acute HZ but appear to provide only short-term relief in
postherpetic neuralgia.188

**Nervus Intermedius Neuralgia**

Nervus intermedius neuralgia is an uncommon disorder affecting the
sensory branch of the facial nerve (cranial nerve VII) (Fig. 66.3). It is
located between the motor component of the facial nerve and the
vestibulocochlear nerve (cranial nerve VIII). Sensory fibers contained in
the nervus intermedius nerve carry afferent sensory input from the skin of
the external auditory meatus; mucous membranes of the nasopharynx and
nose; and taste from the anterior two-thirds of the tongue, floor of the
mouth, and the palate. The geniculate ganglion contains the cell bodies of
the sensory fibers of the nervus intermedius. Compression of the
geniculate ganglion therefore can also result in nervus intermedius
neuralgia.
A,B: Distribution of the facial nerve (cranial nerve VII). The facial nerve emanates from the brainstem between the pons and the medulla. The motor part of the facial nerve arises from the facial nerve nucleus in the pons and divides into five branches after coursing through the petrous temporal bone, the internal auditory meatus, the facial canal, the stylomastoid foramen, and the parotid gland. It is responsible for muscles of facial expression and supplies preganglionic parasympathetic fibers to ganglia of the head and neck. It also supplies taste sensation to the anterior two-thirds of the tongue, partial afferent innervations of the oropharynx, as well as some cutaneous sensation around the auricle. (Reprinted with permission from Moore KL, Dalley AF. Clinically Oriented Anatomy. 6th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2009. Figure 9-10.)
The cell bodies of parasympathetic axons within the nervus intermedius are contained within the superior salivatory nucleus. These axons synapse with neurons which supply parasympathetic innervations to the lachrymal gland as well as the submandibular and sublingual glands.

Nervus intermedius neuralgia involves severe pain deep in the ear which may radiate to the outer ear, mastoid, or eye region. The syndrome was reported as “tic douloureux of the sensory filaments of the facial nerve” by Clark and Taylor in 1909. Rare cases continue to be reported.

**ETIOLOGY**

Vascular compression is suggested as the cause of many cases of nervus intermedius neuralgia. Jannetta described relief of nervus intermedius and other cranial neuralgias following MVD in 1976. He reviewed 14 cases of nervus intermedius neuralgia, which, after failed conservative treatment, went on to MVD. Over 71% experienced an excellent outcome, over 21% experienced partial relief, and 7% had no relief following MVD. Good long-term results were seen in 90% of patients.

In a 1991 review of 18 cases of “primary otalgia” seen over a 15-year period, vascular loops, adhesions, thickened arachnoid, and benign osteoma were among abnormalities involving the nervus intermedius. The authors reported decompression of cranial nerves V, IX, X, the tympanic nerve and the chorda tympani in addition to the nervus intermedius in many of these cases. Nonetheless, the existence of nervus intermedius as a unique entity has been questioned due to the similarity of its presentation to that of glossopharyngeal neuralgia.

**SYMPTOMS AND SIGNS**

The pain of nervus intermedius neuralgia is sharp, lancinating, and paroxysmal. Painful attacks are unilateral and can be triggered by cold, noise, swallowing, or touch. Patients may also experience symptoms such as increased salivation, bitter taste, tinnitus, and vertigo during paroxysms. Patients with nervus intermedius neuralgia may also rarely have pain in the trigeminal distribution. This may be due to cross compression of cranial nerve V in addition to the nervus intermedius (as has been seen on surgical exploration).
DIAGNOSIS
Sensation is supplied to the area of the ear by the cranial nerves V, VII, VIII, IX, and X and the second and third cervical nerves. A thorough history should be taken to ascertain the exact distribution and character of the pain as well as any triggers or precipitating factors. A comprehensive examination should rule out other causes of otalgia before the diagnosis of geniculate ganglion neuralgia can be made. This should include examinations of the nose, paranasal sinuses, mouth, teeth, nasopharynx, pharynx, and larynx to rule out other causes of pain, audiogram, auditory evoked response potentials, and vestibular tests. MRI with gadolinium enhancement of the brain, cerebellopontine angle, and facial nerve and MRA should be performed. As described earlier, vascular compression or other pathology may involve more than one of the cranial nerves in the middle fossa.

As described in the previous section, nervus intermedius neuralgia can be caused by HZ infection. The pain from acute HZ involving the geniculate ganglion is usually constant and burning as opposed to the lancinating paroxysmal pain of nervus intermedius neuralgia. Onset of the pain from acute HZ is generally followed by a vesicular eruption involving the eardrum and external auditory canal.

TREATMENT
Pharmacologic treatment of nervus intermedius neuralgia is similar to that of TN. When conservative management fails, a thorough workup to exclude other causes of pain should be investigated. The nervus intermedius or geniculate ganglion cannot be injected with local anesthetic or other solution; however, blockade of other nerves supplying the area of the ear can be anesthetized to exclude them as causes of the otalgia. Surgical management consists of MVD or section of the nervus intermedius. Excision of the nervus intermedius and geniculate ganglion has also been advocated along with selective retrolabyrinthine V nerve section in extreme cases.208

Glossopharyngeal Neuralgia

3517
Glossopharyngeal neuralgia is a rare neuralgia with a reported relative frequency of 0.75% to 1% compared to TN.\textsuperscript{210,211} It is defined as paroxysmal pain in the areas supplied by cranial nerves IX and X. The glossopharyngeal or ninth cranial nerve exits the upper medulla just rostral to the vagus nerve. Sensory fibers carried in the glossopharyngeal nerve supply the posterior one-third of the tongue, the tonsils, pharynx, the middle ear, and the carotid body. The glossopharyngeal nerve also supplies parasympathetic fibers to the parotid gland via the otic ganglion, motor fibers to the stylopharyngeus muscle, and contributes to the pharyngeal plexus. The symptoms associated with glossopharyngeal neuralgia can be better understood upon review of its branches, which include the tympanic nerve, stylopharyngeal nerve, tonsillar nerve, nerve to the carotid sinus, branches to the posterior third of the tongue, lingual branches, and a communicating branch to the vagus nerve (Fig. 66.4).

\textbf{FIGURE 66.4} Distribution of the glossopharyngeal nerve. \textit{A}: The glossopharyngeal nerve exits the skull via the jugular foramen between the internal jugular vein and internal carotid artery, lateral.
and ventral to the vagus and accessory nerves. It receives general sensory fibers via the tympanic nerve, the nerve to the palatine tonsils, and pharyngeal nerve branches. It receives special sensory fibers (taste) from the posterior one-third of the tongue and visceral sensory fibers from the carotid bodies and carotid sinus. B: The parasympathetic component of the glossopharyngeal nerve supplies the postsynaptic innervations to the parotid gland via the otic ganglion. The glossopharyngeal nerve is responsible for the afferent limb of the gag reflex, and thus, the gag reflex is absent in patients with damage to the glossopharyngeal nerve. The efferent limb of the gag reflex is supplied by the vagus nerve. (Reprinted with permission from Moore KL, Dalley AF. Clinically Oriented Anatomy. 6th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2009. Figure 9-13.)

ETIOLOGY
Similar to TN nomenclature, classical or idiopathic and secondary or symptomatic forms of glossopharyngeal neuralgia exist. Idiopathic glossopharyngeal neuralgia occurs most commonly from vascular compression of cranial nerve IX (often in association with cranial nerve X). Symptomatic causes include tumors, peritonsillar abscess, carotid aneurysm, Chiari type I malformations, and Eagle syndrome (in which cranial nerve IX is compressed against an ossified stylohyoid ligament). The vertebral artery or posterior inferior cerebellar arteries are most often implicated on surgical exploration.

SYMPTOMS AND SIGNS
The character of pain in the patient with glossopharyngeal neuralgia is similar to that of TN. The unbearable, electrical, lancinating pain is located unilaterally in the ear, larynx, tonsillar fossa, or base of the tongue. It is rarely bilateral. It may radiate toward the ear, the angle of the jaw, or the upper and lateral aspect of the neck. Paroxysms of pain are often triggered by swallowing, yawning, coughing, or talking.

DIAGNOSIS
A careful history and physical exam is essential in the evaluation of a patient suspected of suffering from glossopharyngeal neuralgia. MRI/MRA should be performed to rule out a mass lesion or vascular pathology. An ossified stylohyoid ligament (consistent with Eagle syndrome) may be identified on roentgenogram. As in TN, the paroxysms of glossopharyngeal neuralgia may last from seconds to minutes. Dozens of attacks may occur daily with episodes lasting from weeks to months.
followed by periods of remission. The patient is generally free from pain between attacks, although dull background pain may persist. Investigation should also exclude MS in younger patients with bilateral symptoms or neurologic deficits. The branch of the glosopharyngeal nerve to the carotid sinus is involved in maintenance of blood pressure and is thought to play a role in some profound cardiac arrhythmias or even asystole which occur in some patients in association with pain paroxysms. The differential diagnosis includes geniculate or nervus intermedius neuralgia. Rare glosopharyngeal zoster has been reported.\textsuperscript{215}

**TREATMENT**

The pharmacologic treatment of glosopharyngeal neuralgia is similar to TN. When conservative therapy has failed, surgical exploration and vascular decompression has been shown to be highly effective on long-term follow-up with a low complication rate.\textsuperscript{216,217} When a source of neurovascular compression is not found, successful relief of symptoms has been obtained with section of the glosopharyngeal nerve together with the upper fibers of the vagus nerve.\textsuperscript{218,219}

**Vagal Neuralgia**

The two sensory branches of the vagus nerve, the auricular branch and the superior laryngeal nerve, are involved in this rare neuralgia (Fig. 66.5). The auricular branch of the vagus nerve, or Alderman’s nerve, divides into two branches: the posterior auricular nerve and the nerve supplying the auricula and posterior part of the external acoustic meatus. The superior laryngeal nerve descends behind the internal carotid artery and divides into the internal and external laryngeal nerves. The internal laryngeal nerve supplies sensation to the base of the tongue, epiglottis, and the larynx to above the vocal cords. The external laryngeal nerve supplies the cricothyroid muscle and the inferior pharyngeal constrictor and communicates with the superior cardiac nerve behind the common carotid artery.
FIGURE 66.5 Distribution of the vagus nerve (cranial nerve X). The vagus nerve originates in the brainstem and courses through the jugular foramen to extend into the head, neck, thorax, and abdomen where it provides efferent motor parasympathetic innervation to viscera as well as afferent innervation that delivers information about the state of organs to the brain. (Reprinted with permission from Moore KL, Dalley AF. Clinically Oriented Anatomy. 6th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2009. Figure 10-16.)

ETIOLOGY
Idiopathic or classic vagal neuralgia is characterized by lack of a known precipitating lesion or by vascular compression of the upper fibers of the vagus nerve as they leave the brainstem. Secondary or symptomatic vagal neuralgia involving the superior laryngeal branch has been reported to be secondary to multiple causes including deviation of the hyoid bone, lateral pharyngeal diverticulum, and as a complication following carotid endarterectomy.220–222

SYMPTOMS AND SIGNS
Vagal neuralgia is characterized by severe pain paroxysms in the submandibular region, throat, and/or under the ear. Attacks are triggered by swallowing, talking, yawning, coughing, or straining and turning the head. A trigger zone is generally present in the larynx or lateral aspect of the throat overlying the hyoid bone. Compression of the vagus nerve has also reported to be associated with intractable hiccups, coughing, spontaneous gagging, and dysphagia.223,224

**DIAGNOSIS**

The diagnosis of vagal neuralgia is based on a thorough history to define the distinct characteristics and precipitating factors of the patient’s pain. A careful exam of the head and neck should be performed to rule out other pathology. MRI/MRA should be performed to rule out compressive mass lesions or neurovascular compression. Hoarseness of speech and a trigger point superolateral to the thyroid cartilage may be noted on exam of the patient. Differential diagnosis includes glossopharyngeal neuralgia, geniculate neuralgia, and carotidynia.

**TREATMENT**

Pharmacologic therapy of vagal neuralgia is identical to that of TN. Successful treatment of superior laryngeal neuralgia with high concentration lidocaine injections after CBZ treatment failure has been reported.225 Surgical treatment following pharmacologic therapy failure warrants consideration. MVD has been successful when neurovascular compression of the vagus is identified. When no compressive lesion is identified, relief of pain can be obtained following section of the glossopharyngeal nerve and the upper rootlets of the vagus nerves. The medial aspect of the descending trigeminal tract has also been sectioned in refractory cases to produce loss of pain and temperature sensation in the pharynx.226 Kandan et al.227 reported that 21 patients with glossopharyngeal and vagus nerves neuralgias underwent surgery over 19 years, with MVD being the most common procedure. Treatment outcomes were reported as similar to surgical treatments of TN.

**Other Terminal Branch Neuralgias**

3522
Rare neuralgias involving branches of the trigeminal nerve have been reported. These include supraorbital neuralgia, nasociliary neuralgia, infraorbital neuralgia, and nummular headache. Injury or entrapment of other peripheral branches of the trigeminal nerve such as the lingual, alveolar, or mental nerves may result in pain in the area supplied by that branch.

Supraorbital neuralgia is characterized by paroxysmal or constant pain in the region of the supraorbital notch. It is unilateral and radiates to the medial aspect of the forehead in the area supplied by the supraorbital nerve. It can be caused by injury or entrapment of the supraorbital nerve at its outlet. The pain is transiently relieved by injection of a small volume of local anesthetic at the supraorbital notch. Medical treatment is often unsuccessful when entrapment of the nerve is present. Successful treatment with cryoablation and surgical release of the nerve at its outlet has been reported.\textsuperscript{228,229}

Nasociliary neuralgia, or Charlin’s neuralgia, is a rare condition characterized by stabbing pain lasting seconds to hours in one side of the nose. The pain radiates to the medial frontal region and is triggered by touching the lateral aspect of the ipsilateral nostril. Temporary relief from pain following local anesthetic blockade of the nasociliary nerve is diagnostic. Inflammatory cutaneous lesions and chronic sinusitis have been implicated as secondary causes of nasociliary neuralgia.\textsuperscript{230,231} Relief following surgical section of the nasociliary nerve, turbinectomy, and septoplasty has been described.\textsuperscript{232}

Infraorbital neuralgia has been reported most frequently in association with posttraumatic entrapment syndromes.\textsuperscript{233} If pain is not successfully alleviated by reduction of zygomatic fracture and mobilization of surrounding soft tissue and bone, pharmacologic therapy with antiepileptic agents alone or combined with antidepressants such as the tricyclics or serotonin norepinephrine reuptake inhibitors may be effective.

Nummular headache is thought to be neuralgia related to a terminal cutaneous branch of the trigeminal nerve. It has been described as a primary disorder characterized by head pain felt exclusively in a small round area generally 2 to 6 cm in diameter. The pain is not attributed to another disorder, and neurologic and neuroimaging exams are normal by
definition. A constant background pain may be described as well as exacerbations which are spontaneous or triggered by combing the hair or touch in the affected area. A 2013 review found that gabapentin was effective in 60% of subjects, TCAs in about 45% and peripheral nerve block in 42% of the cases.\textsuperscript{234} In patients refractory to pharmacologic therapy, nerve blocks are also effective. Despite small sample size, onabotulinum toxin A was reported to reduce pain for an average of 14 weeks after initial and repeat injections.\textsuperscript{235}

In all cases of idiopathic neuralgia of the terminal branches of the trigeminal nerve, a careful history and physical exam to rule out other causes of facial pain the is imperative. Age less than 40 years and presence of neurologic deficit should prompt further diagnostic radiologic exams to rule out compressive lesions.

**Other Cranial Neuralgia–Related Causes of Pain: Anesthesia Dolorosa**

Anesthesia dolorosa is also known as painful posttraumatic trigeminal neuropathy.

**ETIOLOGY**

Anesthesia dolorosa is defined as perception of pain in an area that is anesthetic. It is a dreaded complication of trigeminal nerve surgery, including partial nerve sections, MVD, percutaneous gangliolysis, neurolytic injections, and stereotactic radiosurgery. It has also been reported after penetrating cranial injury.\textsuperscript{236} The area of persistent and painful anesthesia is in the distribution of the injured nerve.

**SYMPTOMS AND SIGNS**

The patient with anesthesia dolorosa complains of burning, pulling, or stabbing pain which can also include a sharp, stinging, shooting, or electrical component. The pain often increases with cold or with rapid temperature changes.

**DIAGNOSIS**
As it pertains to the head and face, anesthesia dolorosa typically involves the territory of a specific branch or branches of the trigeminal nerve or the occipital nerve. Quantitative sensory testing may be used to confirm lack of sensation.

**TREATMENT**

There are no controlled trials evaluating pharmacologic therapy for anesthesia dolorosa. Empiric treatment of pain by clinical characteristics has led to use of anticonvulsants in patients with lancinating and electrical pain; tricyclic antidepressants, and serotonin norepinephrine reuptake inhibitors in patients with burning pain; and intravenous lidocaine and ketamine infusions in patients unresponsive to other pharmacologic therapy.\textsuperscript{237,238} Motor cortex stimulation was the recommended surgical treatment of choice for facial anesthesia dolorosa according to authors of a review of the literature on central and neuropathic pain over the last 15 years. Motor cortex stimulation may act by replacing nociceptive with nonnociceptive sensory input at the cortical, thalamic, brainstem, and spinal level. It may also interfere with the emotional component of nociceptive perception.\textsuperscript{239} In a prospective study of 10 patients undergoing trial and treatment with motor cortex stimulation, patients with facial weakness and sensory loss regained both strength and discriminative sensation during stimulation.\textsuperscript{240} Raslan et al.\textsuperscript{241} reported positive results of motor cortex stimulation for trigeminal neuropathic or deafferentation pain. Anesthesia dolorosa did not appear to respond to deep brain stimulation according to one 15-year series of 141 patients.\textsuperscript{242}

**Conclusion**

Diagnosis of trigeminal or other cranial neuralgias requires knowledge of the features of neuralgic pain, a thorough understanding of the unique characteristics and specific anatomic distribution of each cranial nerve, and familiarity with the distinctive features of other pain syndromes involving the structures of the head and neck is essential to establishing. Although the cranial neuralgias are rare when compared with other neuropathic pain syndromes, the extreme suffering encountered in patients who present with...
these syndromes, together with the need to distinguish between classical and symptomatic presentations, mandates advanced neuroimaging in all cases to rule out progressive processes such as intracranial tumors, infection, or MS. Pharmacologic, surgical, and percutaneous therapies for the cranial neuralgias have continued to advance with development of new agents and techniques which are associated with fewer side effects and complications. Improved monitoring in the case of surgical and percutaneous therapies have also been instrumental in reducing patient morbidity and mortality.

Facial pain syndromes are common in clinical practice. Many of these syndromes are also unique, given the complex anatomy and specialized sensory innervation of the head, face, and neck. The complexity of the anatomy can pose diagnostic challenges when endeavoring to treat facial pain syndromes.

The common descriptive terms for facial pain complaints are frequently misleading. To avoid confusion, clinicians should be familiar with the International Headache Society’s Diagnostic Classification for Head, Face, and Neck Pain Disorders (Table 67.1).

The aforementioned grouping of diagnose(s) is a rather exhaustive differential diagnosis of facial pain. This includes acute and subacute conditions that affect a vast majority of the structures of the human head. This would include ocular, nasal, sinus, dental, oral, muscular, mucosal, and any other causes specific to the region of the head and face.

Although such a list is good for an all-encompassing reference, it is not necessarily helpful for pain practitioners who deal mostly with chronic pain conditions. In this chapter, the focus is on chronic pain conditions that would present as facial pain. Because the primary differential diagnosis of facial pain is trigeminal neuralgia and the nociceptive pain pathway responsible for facial pain, conditions that present in a similar fashion to trigeminal neuralgia or could be misdiagnosed as such are discussed in detail here.

**Trigeminal and Other Cranial Nerve Neuropathic Conditions**

**TRIGEMINAL NEUROPATHY**

Trigeminal neuropathy is a spectrum, the earliest of which is classically called trigeminal neuralgia. Because the most classic description of trigeminal neuralgia is episodic, sharp shooting pain without any
detectable sensory or motor deficit, there are also other forms of trigeminal neuropathic pain that signify a higher degree of neuropathy. The best description of the spectral nature of trigeminal facial pain is found in the classification offered by Burchiel et al.\textsuperscript{2,3} in 2003 and 2005.

In that classification, pain is classified based on the understanding of the pathophysiology of neuralgia (Table 67.2).

AVM, arteriovenous malformation; ENT, eyes, nose, and throat; MS, multiple sclerosis; TN, trigeminal neuralgia.

**Trigeminal Neuralgia Type 1**

This represents the classic description of trigeminal neuralgia in its purest form; it is idiopathic, sharp, shooting, electrical shock-like, episodic pain lasting several seconds, with pain-free intervals between attacks. This diagnosis is fairly straightforward, and most neurosurgeons are familiar with this clinical entity. The condition is caused usually by a vascular compression near the root entry zone because it is the junction of the central and peripheral myelin that renders that zone susceptible to the pathology. Vascular compression leads to demyelination, which in turn leads to ectopic action potential generation that is suspected to allegedly drive the sharp lancinating episodes of facial pain. A full description of the pathophysiology of pain triggering is best described by Devor in 2002 as the ignition hypothesis.\textsuperscript{4,5}

**Trigeminal Neuralgia Type 2**

This is still a variant of the classic idiopathic trigeminal neuralgia;
however, the crucial feature of this condition is the presence of dull aching or background pain for more than 50% of time. This represents a form of trigeminal neuralgia with more evidence of sensory neuropathy compared to type 1. Some of these patients do progress from type 1, and some present as such on initial presentation. Several studies suggest that surgical treatment for trigeminal neuralgia is more successful and durable in patients with trigeminal neuralgia type 1 compared to type 2. It is fairly common to have a normal bedside sensory examination testing in cases of idiopathic trigeminal neuralgia regardless of the type.

**Symptomatic Trigeminal Neuralgia**

In contrast to idiopathic forms of trigeminal neuralgia, this is not an idiopathic form, it is caused by either a diagnosed demyelinating disorder such as multiple sclerosis, a tumor, a vascular malformation, or other structural pathology leading to compression of the trigeminal root entry zone, other than the vascular compression described in idiopathic forms. It is noteworthy that clinically patients may present in either a type 1– or type 2–like presentation; however, constant dull aching pain (type 2 like) is more common in patients with symptomatic trigeminal neuralgia.

**Neuropathic Trigeminal Neuralgia**

In this entity, the degree of trigeminal neuropathy is more advanced compared to idiopathic trigeminal neuralgia; there is an objective sensory loss in the distribution of the trigeminal nerve and it is associated with classic manifestations of neuropathic pain including but not limited to alldynia, hyperalgesia, and burning pain. Neuropathic trigeminal neuralgia is usually caused by either intentional or unintentional injury to the trigeminal nerve. Examples of unintentional injuries would include trauma; postdental injection; postprocedural in maxillofacial surgeries; skull bases surgery; ear, nose, and throat (ENT) surgery; or poststroke. Examples of intentional injuries include trigeminal neuropathy following neurosurgical ablation of the one or more branches of the trigeminal nerve for the purpose of alleviation of pain. Spontaneous neuropathic trigeminal neuralgia had been also described, albeit, a rare condition.
Postherpetic Trigeminal Neuralgia
Postherpetic trigeminal neuralgia is the condition that follows herpes zoster viral infection to the trigeminal ganglion. It is a more severe form of neuropathy manifested by significant allodynia, hyperalgesia, and burning dysesthesia. It commonly affects the first division of the trigeminal nerve.

Deafferentation Trigeminal Neuralgia
Deafferentation trigeminal neuralgia, otherwise known as anesthesia dolorosa, is the most severe form of neuropathy and trigeminal neuralgia. The features of this pathology suggest a marked sensory loss or even corneal anesthesia in severe cases. Unfortunately, this is an iatrogenic condition that is induced by surgical interventions to denervate the trigeminal distribution. It is common with techniques such as rhizotomy or alcohol denervation and less common (or require repeated exposure) after techniques with rather smaller quantifiable ablation such as radiofrequency rhizotomy, glycerol rhizotomy, balloon compression, or radiosurgery.

Atypical Facial Pain
In this particular classification, atypical facial pain refers to somatoform disorder, in which a psychological disorder can be unequivocally diagnosed. Obviously, this is a difficult condition to treat and would be a contraindication to interventional therapies.

Treatment of various forms of trigeminal neuralgia is mentioned elsewhere in this textbook, but the degree of neuropathy determines the possible reversibility and therefore dictates the treatment options. Medical treatments for most of cranial nerve neuropathy–related pain is medical at first with medications such as carbamazepine, gabapentin, and topiramate. Should medical treatment fail, interventional therapies are introduced, and these are introduced based on the degree of neuropathy. As such, early neuropathy such as trigeminal neuralgia type 1 would benefit from a potentially curative option such as microvascular decompression, whereas postherpetic neuralgia requires advanced interventions such as neuromodulation of the central nervous system.

GLOSSOPHARYNGEAL NEURALGIA
Glossopharyngeal neuralgia (GN) is a rare condition in which patients experience paroxysmal episodes of pain along the auricular and pharyngeal branches of both the glossopharyngeal and vagus nerves. Patients will often complain of severe, lancinating pain “attacks” along one side of the throat, with occasional radiation to the ear, that are often precipitated by swallowing, chewing, coughing, or yawning.\(^8\) It can be particularly debilitating when the vagus nerve is involved as patients may experience loss of sympathetic tone that can lead to syncope and seizures in up to 10% of the cases.\(^9\)

GN is most often caused by neurovascular compression at the root entry zone of the brainstem—most often, it is the posterior inferior cerebellar artery that is responsible for the compression, although the anterior inferior cerebellar artery (AICA) has been documented as well.\(^10\) With an incidence of just 1% when compared to its better known counterpart, trigeminal neuralgia, GN is notoriously hard to diagnose.\(^11\) Given this diagnostic dilemma, high-sensitivity, high-specificity magnetic resonance imaging (MRI) is recommended to rule out any other potential causes such as neoplasm or an elongated styloid process.\(^10\)

Treatment is initially medical, as with most cranial neuralgias, and if this fails, surgical decompression or sectioning may be very effective in alleviating pain.\(^12\) Ruling out mimicking conditions such as Eagle syndrome is critical prior to administering an interventional therapy.

**NERVUS INTERMEDIUS NEURALGIA**

Nervus intermedius neuralgia (NIN), also known as geniculate neuralgia, is a rare pain condition characterized by paroxysmal, deep ear pain. Patients commonly describe the pain as “being stabbed in the ear with an icepick.” These attacks can be debilitating and socially isolating. The posterior wall of the auditory canal as well as the superficial ear drum are common trigger zones for the paroxysms, for example, by loud noises or cold wind.\(^13\) Sensory innervation to the skin of the external ear and auditory canal is complex, including contributions from cranial nerves (CN) V, IX, and X; the nervus intermedius (NI); and upper cervical dorsal roots.\(^14\) This complicated innervation leads to confusion about the culprit nerve in primary otalgia and contributes ultimately to confusion in
diagnosis. Medical treatment is the first-line therapy for this condition, and, as with other cranial neuralgia, surgical decompression or section can be effective.\textsuperscript{15}

**Odontogenic and Temporomandibular Joint Disorders**

**ODONTOGENIC PAIN**

Facial pain emanating from an odontogenic source can be a challenge to distinguish from other causes of facial pain. This section guides the clinician to identify potential sources of odontogenic pain, understand the different characteristics of those sources of pain, and ultimately provide for a differential diagnosis. To fully understand the mechanisms to which odontogenic pain arises, a review of dental anatomy and the process of how dental pathology progresses is required.

The normal anatomy of a tooth is characterized by three layers (from the surface to the middle of the tooth): enamel, dentin and dental pulp on the crown of the tooth and cementum, and dentin and dental pulp on the roots of the teeth (Fig. 67.1).
The dental pulp is the generative part of the tooth and is made up of connective tissue and generative cells called odontoblasts. This part of the tooth is also innervated and when insulted causes tooth pain. Dental caries is the typical etiology of dental pain and begins by invading the enamel, progressing to the dentin, and then, if unrestored by a dentist, will progress to invade the pulp, seeding the pulp tissue with harmful bacteria that causes infection and inflammation. This leads to an acute episode of pain and then can lead to abscess formation. As the dental caries progresses through the layers of the tooth, the characteristics of dental pain change, as does the dental or pulpal diagnosis. Once the dental pulp becomes necrotic, the pain may subside, but the necrotic tissue will act as a substrate for pathogenic bacteria that then can cause spread of infection to surrounding tissues.

A second source of odontogenic pain stems from the tissues surrounding
the dentition. Periodontitis is a chronic, periradicular disease characterized by inflammation of the gingiva causing soft tissue attachment loss and bone loss surrounding the tooth. In its early stages, the process may be painless but, if untreated, culminates in mobility of teeth and ultimately tooth loss. The degree of pain associated with periodontal disease in the absence of abscess formation is typically mild and not limited to one particular area of the mouth. It is also important to note that periodontal disease is an inflammatory process that is associated with other systemic, chronic disease such as diabetes.

Pericoronitis is a type of gingival inflammation that typically occurs around an erupting or partially erupted third molar (wisdom tooth). The inflammatory response in acute pericoronitis can be significant causing severe pain and trismus and may lead to severe cellulitis and abscess spreading to the deep spaces of the neck and posterior oropharynx.

Steps for Diagnosis
A good clinical exam begins with a thorough history. The timing, location, and characteristics of the patient’s pain must be investigated. A head and neck exam should include palpation of the neck, facial bones, muscles, and soft tissues. The temporomandibular joint (TMJ) should also be included in the head and neck exam and is discussed in another section in this text. Any asymmetries or swellings should be noted, and in the presence of pain, cellulitis or abscess should be suspected. Tenderness to the muscles of mastication without swelling or dental findings should lead the clinician down the path of myofascial origins. The oral examination should include inspection of the dentition, oral mucosa, tongue, floor of the mouth, and the oropharynx.

Dental Findings
The clinician should look for presence of dental disease including dental caries, fractured teeth, or mobile teeth. Dental caries is characterized by the presence of dark areas of the tooth that have invaded or cavitated the enamel (Fig. 67.2).
Stains may sometimes mimic dental caries but will not exhibit loss of tooth structure. In general, the more tooth structure that is involved, the more invasive the decay and the closer to invasion of the pulp causing pain. The decay may start on the occlusal surface of the tooth, between the teeth, or at the gingival cervical margins. If the decay begins between the teeth, the caries may not be easily identified clinically and may require radiographic evaluation. Teeth with periapical or pulpal inflammation many times will be tender to percussion and will elicit a more painful response then percussion of the surrounding, unaffected teeth. Additionally, the same teeth may elicit painful response to thermal stimulation compared to the surrounding dentition. The degree to which these findings are positive leads to a diagnosis of reversible or irreversible pulpitis (Table 67.3). Mobility of a tooth in the presence of pain may indicate a periapical abscess, or chronic periodontitis. An abscess typically will be limited to one tooth or one area of the mouth, where in chronic periodontitis, multiple teeth usually are affected in several areas of the mouth.

**Oral Soft Tissue Findings**

The oral mucosa, gingiva, tongue, floor of mouth, and oropharynx should be inspected and palpated for any masses, ulcerations, bleeding, suppuration, or swelling. Areas of acute inflammation will typically be painful and characterized by erythema. If the inflammation and pain is in the area of a carious tooth, an acute inflammatory process should be suspected (pulpitis or acute abscess). Any fistulas present on the gingiva indicate chronic periapical abscess and a necrotic tooth. These are not necessarily painful, but at some point, prior to the fistula formation, may have been a source of pain to the patient. Any suppuration emanating from the gingival crevice of a tooth or multiple teeth in the presence of mobility suggests severe, chronic periodontitis. The gingiva, in this instance, may bleed easily when manipulated.

Most dental pain is limited to the general area of the offending tooth. Pericoronitis and pain secondary to third molars may be more precarious and generalized to the face, jaw, and ear on the affected side. When severe, the patient will exhibit trismus and may have signs of cellulitis.

**Radiographic Examination**

Dental radiographs in conjunction with clinical findings are needed for definitive diagnosis in most cases. Dental caries are characterized by radiolucencies within the tooth structure. The depth of invasion of the decay will most likely correlate with the level of reported pain.

Periapical pathology indicating pulpal invasion and necrosis may reveal a widened periodontal ligament (PDL) and possible radiolucency at the apex of the tooth. Bone levels below the cementoenamel junction (CEJ) of the tooth indicate periodontal disease (**Fig. 67.3**).
Evaluating for odontogenic causes of pain should be ruled out when the patient presents with facial pain. Performing a thorough history and clinical exam should lead the clinician to a reasonable suspicion and differential diagnosis; however, a basic understanding of the pathologic process and clinical signs and symptoms of dental disease is helpful in identifying the causes of the odontogenic origin and progression of disease (see Table 67.3).

TEMPOROMANDIBULAR DISORDERS

TMJ disorders are considered the most common musculoskeletal disorders that cause orofacial pain.\textsuperscript{16} These disorders can typically be separated into two entities: myofascial pain disorders and interarticular disorders (internal derangements). Although these two entities can, and many times do coexist, they have very specific pain patterns that characterize each process. It is important for the clinician to understand the differences, as treatment of these two groups may vary widely. Israel\textsuperscript{17} defines internal derangement as a condition in which there are damaged intra-articular tissues leading to disturbances in the biomechanical functioning of the TMJ. Fricton\textsuperscript{18} describes myofascial pain as a regional muscle pain disorder characterized by localized muscle tenderness, limited range of motion, and regional pain.

As with any pain disorder, recognition and diagnosis starts with taking a
thorough history. Elements specific to temporomandibular disorder (TMD) include the following: severity and character of pain, time of onset, factors that exacerbate the pain or factors that decrease pain, history of trauma or other temporal event, progression of the pain over time, history of joint noises, functional impairment, or range of motion issues. Additionally, quality-of-life questions such as work or life stressors, habits such as bruxism, history of depression, chronic pain, anxiety, or other mental health issues should be addressed as these may contribute to the development of myofascial pain/TMD, or may develop as a result of these disorders.\textsuperscript{19}

Clinical exam should begin with inspection of the face to look for jaw relationship discrepancies including asymmetry, retrognathia, or prognathism. Palpation of the facial, cervical, and occipital musculature should be performed, noting any discomfort to palpation and radiation of that pain within a referral zone of the muscle. Additionally, palpation of muscle bands and firm, localized nodules, or “trigger points” should be noted.\textsuperscript{3} Palpation of the lateral poles of the mandibular condyle, just anterior to the tragus of the ear, should be performed. Any pain on palpation should be noted. The clinician should also palpate the condyles while the patient performs mandibular movements (opening and closing, lateral excursive movements, and protrusion of the jaw). During this, the clinician should note any clicking, popping, or grinding sensations. Some would advocate for listening with a stethoscope over the joint as the patient performs the aforementioned movements and documenting any joint noises. Range of motion measurements should be obtained. Normal mandibular opening is typically 40 to 45 mm, measured between the incisal edges of the upper and lower incisor teeth. The clinician should also observe for any deviations upon opening. Deviations on opening and the inability to move the jaw laterally either to the right or left should be noted.

Myofascial pain is typically characterized by pain in the muscles of mastication and may exhibit bands and/or trigger points and typically have a zone of referred pain surrounding the tender point.\textsuperscript{18} The characteristics are summarized in Table 67.4.
**TABLE 67.4 Clinical Characteristics of Myofascial Pain**

- Trigger points in muscle bands
- Tenderness to muscles on palpation
- Consistent points of tenderness
- Pain in zone of referral/reference
- Constant pain
- Dull ache
- Pain fluctuates in intensity.
- Consistent patterns of referral
- Alleviation with extinction of trigger point

The aim of treatment of this disorder is to decrease muscle activity and increase range of motion. This can be accomplished with pharmacotherapy, occlusal splint therapy, and physical therapy.17

Internal derangements can be complex with respect to the pathology and etiology of the disorder. The characteristics of internal derangements are summarized in Table 67.5 but vary widely depending on the type of internal derangement. Common findings include joint capsule tenderness, decreased range of motion, and joint noises.

**TABLE 67.5 Clinical Characteristics of Internal Derangement**

- Localized pain in the preauricular area to palpation
- Localized pain on opening and closing
- Deviation of mandible to affected side on opening
- Minimal lateral excursive movement opposite of the affected side
- Appreciation of joint noises on opening or closing
- Decreased mouth opening (hypomobility of the mandible)

The American Association of Orofacial Pain introduced a taxonomic classification of TMD (Table 67.6).

**TABLE 67.6 Taxonomic Classification for Temporomandibular Disorders**

1. Temporomandibular joint disorders
   1. Joint pain
      A. Arthralgia
      B. Arthritis
   2. Joint disorders
      A. Disk disorders
1. Disk displacement with reduction
2. Disk displacement with reduction with intermittent locking
3. Disk displacement without reduction with limited opening
4. Disk displacement without reduction without limited opening

B. Hypomobility disorders other than disk disorders
   1. Adhesions/adherence
   2. Ankylosis
      a. Fibrous
      b. Osseous

C. Hypermobility disorders
   1. Subluxation
   2. Luxation

3. Joint diseases
   A. Degenerative joint disease
      1. Osteoarthrosis
      2. Osteoarthritis
   B. Systemic arthritides
   C. Condylysis/idiopathic condylar resorption
   D. Osteochondritis dissecans
   E. Osteonecrosis
   F. Neoplasm
   G. Synovial chondromatosis

4. Fractures

5. Congenital/developmental disorders
   A. Aplasia
   B. Hypoplasia
   C. Hyperplasia

Internal derangements can also be classified according to severity of disease. The Wilkes Staging System (Table 67.7) is commonly used by TMJ surgeons to help provide a guide for treatment based on the severity of the damage to the joint. Depending on the physical findings in the clinical exam, imaging may be beneficial for finalizing a diagnosis.

TABLE 67.7 Wilkes Classification of Internal Derangement of the Temporomandibular Joint

<table>
<thead>
<tr>
<th>Stage</th>
<th>Clinical</th>
<th>Radiographic</th>
</tr>
</thead>
<tbody>
<tr>
<td>I. Early</td>
<td>Painless clicking, no limitation on opening</td>
<td>Mild displacement of disk with reduction; normal disk morphology</td>
</tr>
</tbody>
</table>

II. Early/intermediate
Occasional painful clicking, intermittent locking
Anterior disk displacement with reduction

III. Intermediate
Joint tenderness, frequent prolonged locking, restricted motion
Anterior disk displacement with or without reduction; no degenerative changes

IV. Intermediate/late
Chronic pain, no clicking, restricted motion
Anterior disk displacement without reduction; degenerative changes; adhesions

V. Late
Variable pain, painful/reduced function, crepitus
Anterior disk displacement without reduction; advanced degenerative changes; advanced adhesions; gross disk deformity and/or perforation

MRI is typically used when an internal derangement is thought to involve disk displacement, disk perforation, or other soft tissue abnormalities. Computed tomography (CT) imaging can be beneficial to identify degenerative processes, neoplasms, or bony ankylosis of the joint. The treatment of internal derangement is typically aimed at decreasing inflammation and increasing range of motion. Treatment modalities vary widely but most often begin with nonsurgical interventions if possible including pharmacotherapy, occlusal splint therapy, and physical therapy. If symptoms persist, surgical options may then be considered.

Chronic Headache Disorders Causing Facial Pain

PRIMARY HEADACHE CONDITIONS

Migraine Headache
The International Classification of Headache (ICHD) prescribed migraine headache as frequent headaches with a migrainous nature.

The ICHD determined the following criteria for diagnosing migraine headache.

At least five attacks fulfilling the following criteria (1 to 3):  
1. Attacks lasting 4 to 72 hours whether untreated or unsuccessfully treated  
2. The headache has at least two of the following four characteristics:  
   a. Unilateral  
   b. Pulsating in nature  
   c. Moderate to severe in intensity

d. Aggravation by or causing avoidance of routine physical activity

3. Headache is associated with at least one of the following:
   a. Nausea and/or vomiting
   b. Photophobia and phonophobia

Not better accounted for by another ICHD-3 diagnosis

History taking is the most important step in diagnosing migraine headaches. Investigations may be performed to exclude other causes of headache as brain tumors, intracranial hemorrhage, and other physical lesions.

Patients may report certain triggers that initiate their headache. Migraine headache may occur in the following phases:

**Prodrome:** Patients may experience vague affective symptoms as long as 24 hours before the onset of the headache attack.

**Aura:** Some patients will have neurologic symptoms that may last up to 1 hour. Symptoms may be visual, sensory, or brainstem related.

**Resolution:** occurs after the headache resolves and usually characterized by deep sleep

**Migraine hangover:** Some patients may experience malaise, fatigue, and head pain after sudden movement or coughing.

The pathophysiology of migraine is a complex neurobiologic process; several theories have been proposed to explain its pathophysiology including neuronal hyperexcitability, hypersensitivity to stimuli, recurrent activation and sensitization of the trigeminovascular pathway, reduced activation of descending inhibitory pathways, and structural/functional changes in the pain pathways.

Treatment includes the following approaches:

**Lifestyle modifications:** It is very important to recognize if there are any triggers that initiate the headache and work on avoiding those triggers.

**Treatment of acute headache:** Patients may use abortive medication early when headaches start and mild. Some of the medications that can be used include paracetamol, aspirin, ibuprofen, naproxen, and triptans. A combination of triptans and naproxen can also be used. It has been recently suggested that noninvasive stimulation techniques as transcranial magnetic stimulation and vagal stimulation can be used for same purpose.
**Preventive treatment:** Preventive treatment is usually considered when headache frequency and severity increase in a way that interferes with patient’s work and social life. First-line treatment includes β-blockers and tricyclics. Second-line medications include anticonvulsants, onabotulinum toxin A, flunarizine, and supplements as riboflavin and magnesium.27,28

Interventions can be utilized for patients who do not respond to medications. Some of the procedures performed are botulinum toxin type A injection, occipital nerve blocks, occipital nerve stimulator, and deep brain stimulation.29

**Tension Headache**

Tension-type headaches (TTHs) are recurrent episodes of headache that can persist for minutes to weeks. Pain is typically bilateral, described as tightening in nature, and of variable intensity. It may be associated with photophobia and phonophobia, but nausea and vomiting are usually absent.30

It has been proposed that TTH is related to some component of specified stress-related disorders or muscular tension, but large number of clinical trials proposed neurobiologic basis decreasing the belief in psychological diseases as a cause.31–33

Patient history is the main tool of diagnosis. As mentioned earlier, tension headaches are bilateral, tightening in nature, usually not associated with nausea and vomiting but might be associated with photophobia and phonophobia. Patients may report triggering factors as stress, lack of sleep, not eating, alcohol, and menstruation.34

On physical examination, a focus on palpating head and neck muscles is important to identify any tender points.

Although the main pathophysiology remains a matter of debate, some mechanisms have been proposed. Pericranial myofascial mechanisms may explain episodic TTH. Sensitization of central pain pathways due to prolonged nociceptive stimuli from the pericranial myofascial tissues may explain the change from episodic to chronic TTH.32

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstays in the treatment of acute headache. Other medications that can be added in combination with NSAIDs include acetaminophen, caffeine, codeine,
sedatives, and tranquilizers.\textsuperscript{35,36} Preventing an attack can be achieved by avoiding triggers and by using amitriptyline. In addition, nonpharmacologic treatment as relaxation therapy and biofeedback can be equally effective but require skilled personnel to administer.\textsuperscript{37}

For chronic TTH, amitriptyline has been an effective medication. Some studies found modest efficacy of the following medications: citalopram, sertraline, mianserin, fluvoxamine, paroxetine, venlafaxine, sulpiride, and mirtazapine.\textsuperscript{38–43} Muscle relaxants may play a role in the treatment. There is some evidence that tizanidine may be beneficial in treating chronic TTH.\textsuperscript{44} There has been conflicting data on its use in TTH and botulinum toxin type A, and therefore, it is not recommended.

Nonpharmacologic therapy may be used in patients who fail pharmacologic therapy or in conjunction with it; examples include physical therapy, psychological therapy, and nerve blocks.\textsuperscript{45}

**Cluster Headache**

Cluster headache is typically unilateral associated with ipsilateral autonomic symptoms.

It is important to note that cluster headache is more common in men. Diagnostic criteria requires that patients should have at least 5 attacks fulfilling criteria 1 to 4.

1. Severe unilateral orbital, supraorbital, and/or temporal pain lasting 15 to 180 minutes if not treated
2. Headache accompanied by at least one of the following:
   a. Ipsilateral conjunctival injection and/or lacrimation
   b. Ipsilateral nasal congestion and/or rhinorrhea
   c. Ipsilateral eyelid edema
   d. Ipsilateral forehead and facial sweating
   e. Ipsilateral miosis and/or ptosis
3. A sense of restlessness or agitation
4. Attacks have a frequency of 1 every other day to 8 per week.

No other disorder that can explain those symptoms.\textsuperscript{30}

The pathophysiology of cluster headache is still unknown. The hypothalamus as the supraordinate center may be responsible for initiating attacks. The pain in the cranial autonomic nervous system is introduced
and maintained by activation of the parasympathetic and trigeminal nuclei.\textsuperscript{46}

Treatment of acute attack includes inhaling oxygen 8 to 12 L per minute, which is effective in resolving the headache in the majority of patients within 15 minutes.\textsuperscript{47} Serotonin receptor agonists, triptans, have been also shown to be effective and of rapid effect.

Should a patient develop frequent, severe, acute attacks, preventive therapy should be initiated. Calcium channel blockers such as verapamil have been identified as an effective preventive medication. Lithium is an alternative therapy to verapamil but requires closer monitoring for blood levels and side effects. In addition, corticosteroids have been found to be effective and can be used on a temporary basis until verapamil or lithium is started.\textsuperscript{48,49}

Oral ergotamines are alkaloids that have been found to be an effective treatment strategy. However, their serious side effects have limited their use. The sodium channel blocker, topiramate, can be effective if used in high-dosage limits or in combination with other medications.

Interventions can be performed for patients resistant to pharmacotherapy. Some of these interventions include occipital nerve blocks, sphenopalatine ganglion blocks, specified neuromodulation, and rhizotomy.\textsuperscript{50–52}

**Exertional Headache**

Exertional headache is an uncommon, self-limited, and short-lasting headache condition that is precipitated by exertion. The diagnosis of exertional headache can be difficult as it shares symptoms and signs with other headache conditions. Diagnosis is usually made based on clinical grounds, but imaging can be used to exclude other serious conditions such as brain tumors or intracranial hemorrhage.

Exertional headache can be diagnosed based on the following diagnostic criteria\textsuperscript{53–55}:

- Headache is associated with physical activities.
- Bilateral, throbbing, and may develop migrainous features
- Can last 5 minutes to 24 hours
- Avoiding physical exercise prevents the headache.
No other disorders to explain those symptoms. There are several theories proposed to explain the mechanism of exertional headache. Most believe it is vascular in origin. According to one theory, exertion increases cerebral arterial pressure causing pain sensitive venous sinuses at the base of the brain to dilate. The treatment of exertional headache is not well studied. Although several medications have been proposed, indomethacin is the most frequently suggested.

**Hypnic Headache**

It is a primary headache condition occurring exclusively during sleep and mainly in the elderly. Based on ICHD-3 beta version, hypnic headache can be diagnosed based on following criteria:

1. Develops only during sleep
2. Occurs >10 times per month for >3 months
3. Lasts 15 minutes and up to 4 hours after waking
4. No cranial autonomic symptoms or restlessness

Not accounted for by any other condition

Although pathophysiology remains unclear, several mechanisms have been proposed as posterior hypothalamic condition and central sensitization of trigeminal processing but with conflicting results. Several medications were studied for treatment of acute attacks, but results have been controversial. Caffeine-containing analgesics seem to be the most effective.

Preventive medications including lithium, caffeine, indomethacin, and topiramate have been proposed for treatment of chronic hypnic headaches.

**Secondary Headache Conditions**

**MEDICATION OVERUSE HEADACHE**

Medication-overuse headache (MOH) is a headache condition that occurs in patients with previously existing primary headache that occurs on more than or equal to 15 days per month for more than 3 months. It is a headache condition that is caused by overuse of medications used for
treating headache. MOH is diagnosed by fulfilling the following criteria\textsuperscript{1}: headache on $\geq 15$ days per month, preexisting headache disorder, overuse of acute and/or symptomatic headache drugs for $>3$ months, and no other condition can explain those symptoms.

The pathophysiology of MOH is not fully understood, and several theories have been proposed including angiotensin-converting enzyme polymorphism, brain-derived neurotrophic factor polymorphism, catechol-O-methyltransferase polymorphism, and serotonin transporter polymorphism. Additionally, it has been postulated that headache may result from interactions with various neurotransmitter systems, neuronal hyperexcitability, and drug dependence.\textsuperscript{61–66}

Treatment of MOH can be challenging, as medication used for treating the primary headache condition is the cause of the headache. It is important to start the treatment with educating the patient on MOH. Reducing the doses of medications used for treating the primary headache condition should follow dedicated education. Sometimes, detoxification with abrupt withdrawal may be necessary with reinstating the preventive therapy later at lower doses.\textsuperscript{67,68}

Prevention is the best option to avoid MOH. Patients and providers need to work on avoiding very high doses of medications for treating primary headache with close follow-up and monitoring for early detection and treatment.

**SINUS HEADACHES**

Sinus headache, although commonly used, specialists consider it an inaccurate term. It refers to headache or facial pain associated with sinus disease. A more accurate term proposed by specialists is rhinogenic headache.\textsuperscript{69}

The HIS diagnostic criteria for headache attributed to rhinosinusitis include the following\textsuperscript{70}:

1. Presence of clinical, nasal endoscopic, CT and/or MRI, and/or laboratory evidence of acute or acute on top of chronic rhinosinusitis
2. Headache and facial pain that develops simultaneously with onset of
rhinosinusitis
3. Headache and/or facial pain that resolves within 7 days after remission or treatment of acute rhinosinusitis
Management includes treatment of sinusitis, which is essential, migraine-directed therapy, and nasal surgery for mucosal contact point.

HEAD INJURY HEADACHES
Posttraumatic headache (PTHA) is a form of secondary headache that develops within 7 days after a head trauma.

There is no specific pattern for PTHA, as it can share criteria of migraine and tension headaches, but the most important factor is its association with a trauma or traumatic brain injury (TBI). The pathophysiology has been proposed to possibly be related to peripheral or central sensitization mechanisms. Treatment strategies should match the type of headache associated with the trauma. A multidisciplinary approach is highly recommended.

SHORT-LASTING, UNILATERAL, NEURALGIFORM HEADACHE ATTACKS WITH CONJUNCTIVAL INJECTION AND TEARING
Short-lasting, unilateral, neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) syndrome is a unilateral headache/facial pain characterized by brief paroxysmal attacks accompanied by ipsilateral local autonomic signs, usually conjunctival injection and lacrimation.

Diagnostic features include the following:
- Unilateral, mostly described as ocular-related pain but can involve larger area of the head
- Typically does not change sides or cross midline
- Moderate to severe
- Usually stabbing or pulsating in nature
- Pain lasts from 5 to 240 seconds
- Three patterns of attacks are described as follows:
  - Classical single attacks
  - Groups of a number of attacks
  - “Sawtooth” pattern with numerous attacks lasting minutes
The frequency of attacks is from 3 to 200 daily. Additional features include the following: It is accompanied by marked ipsilateral conjunctival injection and lacrimation that appear rapidly with onset of an attack. Whereas nasal stuffiness and rhinorrhea are common, sweating is rare to accompany the attack.

**Pathophysiology:** The mechanism of SUNCT is still unclear, but studies suggested the presence of a relationship between the hypothalamus and the condition. MRI has allowed for recognition of activation within the hypothalamus during an attack. There is a direct connection between the trigeminal nucleus caudalis within the brainstem and the posterior hypothalamus. It is possible that stimulation of the peripheral trigeminal nerve activates the hypothalamus, and the hypothalamus in turn communicates with the trigeminal nucleus caudalis via the release of neurotransmitters. In support of this possible hypothalamic mechanism, elevated levels of prolactin has been associated with SUNCT.\(^79–81\)

SUNCT is refractory to most treatment modalities except for the antiepileptic drug group. Lamotrigine is proposed to be the first-line medication.\(^82,83\) However, intravenously delivered lidocaine and phenytoin have shown some efficacy.

**SHORT-LASTING, UNILATERAL, NEURALGIFORM HEADACHE ATTACKS WITH CRANIAL AUTONOMIC FEATURES**

Short-lasting, unilateral, neuralgiform headache attack with cranial autonomic features (SUNA) is a novel type of headache. It can be difficult to differentiate from SUNCT. One of the main differences is that the attack duration can be extended to 10 minutes with a similar treatment paradigm as SUNCT.

**PAROXYSMAL HEMICRANIAS**

This type of chronic headache is usually continuous with a small percentage of patients who suffer with episodic paroxysmal hemicrania.\(^84\) Clinically, it is usually unilateral; severe orbital or periorbital pain; rarely becomes bilateral; may extend to a larger area in the head; can refer to the shoulder, neck, and arm; lasts 2 to 30 minutes; and sharp in nature.
Additionally, it is accompanied by at least one of these ipsilateral autonomic phenomena/signs: conjunctival injection/lacrimation, nasal congestion, eyelid edema, facial sweating, and miosis/ptosis. Attacks may occur more than five times daily, might be seasonal temporal, periauricular, maxillary, and rarely the occipital region. Referral to the shoulder, neck, and arm is also quite common, and strong pain may cross the midline; the vast majority of attacks do not change sides.

The response to indomethacin is absolute, but the mechanism is not well understood. Other alternatives include calcium channel blockers, naproxen, and carbamazepine.\textsuperscript{84–87}

**CONTACT POINT HEADACHE**

Another headache responsible for facial pain features is the contact point headache. The contact point headache is also called anterior ethmoidal neuralgia, Sluder’s neuralgia, sphenopalatine ganglion neuralgia, and pterygopalatine ganglion neuralgia.

It presents as a persistent stabbing or sharp pain in a single localized area/spot on the face.\textsuperscript{88} It is thought to develop due to nerve compression related to a structural abnormality usually inside the nose, such as a septal spur or a deviated septum.

The nerve affected is usually the anterior ethmoid nerve, a nerve that branches off sphenopalatine ganglion (pterygopalatine ganglion).

Clinically, it presents with a pain syndrome that usually starts after the patient has had an upper respiratory infection and presents as localized pain on one spot and one side of the face; it can be localized to the roof of the mouth and upper teeth. Pain is commonly localized to an area between the eye and cheek but can radiate to other parts of the face.

The only single medication that had shown effectiveness in providing relief of contact point headache is an over-the-counter decongestant. Surgery is the main treatment to cure the condition and relieve the pressure on the nerve.\textsuperscript{89}

47. Cohen AS, Burns B, Goadsby PJ. High-flow oxygen for treatment of cluster headache: a

The unique anatomy of the cervical spine and upper extremity balances the attributes of strength and stability with those of flexibility and range of motion. The biomechanical properties associated with these combined properties allow for a high incidence of degenerative changes. These increase with aging and are often associated with episodic or chronic pain. Although the origin of pain in the neck is often categorized as axial pain versus radicular pain and musculoskeletal pain versus neuropathic pain, the patient presenting for treatment in the clinical setting may not always be representative of these categorical descriptions.

An understanding of the normal anatomy of the neck and upper extremity, pathophysiology of common disorders of the cervical spine, diversity of clinical presentations of neck and arm pain, and the potential contribution of systemic and psychological factors is critical in forming a differential diagnosis, referring the patient for appropriate diagnostic tests and evaluations and instituting timely and appropriate treatment. This chapter focuses on the anatomy of the cervical spine and upper extremity; recent data regarding the epidemiology of neck and arm pain; the critical role of the clinician in performing a thorough and targeted history and physical examination; and finally, a discussion of the etiology and treatment of neck and arm pain.

The common causes of mechanical neck and arm pain, including cervical spondylosis and myelopathy, cervical radiculopathy, cervicogenic headache (CEH), brachial plexopathy, peripheral nerve entrapment syndromes of the upper extremity, and thoracic outlet syndrome (TOS), are discussed in this chapter. Myofascial pain syndromes, fibromyalgia, and acute musculoskeletal disorders can involve the neck and upper extremities and are covered in detail elsewhere in this text. Neck and arm pain may also be secondary to primary or metastatic disease. Cancer pain
Anatomy of the Neck and Arm

CERVICAL SPINE

The anatomy of the cervical spine is complex in order to allow for support of the weight of the cranium, to provide protection and support of the neurovascular elements of the cervical spine, and to simultaneously permit functional mobility in relation to the surrounding structures. It is composed of 7 vertebrae, 5 intervertebral disks, 12 joints of Luschka, and 14 zygapophyseal joints, uniquely bound and connected to numerous ligaments and muscles which both limit and permit varying degrees of motion of the cervical spine.\(^1\)

With the exception of the first two cervical vertebrae, which have unique characteristics, each of the seven cervical vertebrae is composed of a segmental unit, which includes a vertebral body, an intervertebral disk, four uncovertebral joints of Luschka, two pedicles, two lamina, two inferior, and two superior zygapophyseal (articular facet) joints. Between each vertebral segment, a spinal nerve, radicular blood vessels, and the sinuvertebral (recurrent meningeal) nerves pass through neural openings or foramina on each side of the cervical spine (Fig. 68.1).\(^1\)
The upper two segments of the cervical spine have unique anatomic and biomechanical characteristics when compared with the lower five segments of the cervical spine. The atlas, or C1 vertebra, is a ring-shaped vertebra with paired lateral pillars, which function as articulating joints or...
facets. The upper ellipsoid facets articulate superiorly with the occipital condyles to form the atlantooccipital joints, whereas the round and concave inferior facets articulate inferiorly with the axis to form the atlantoaxial joints. The anterior arch of the atlas incorporates an articular surface which contacts the anterior surface of the dens or odontoid process of the axis. The atlas is the widest of the cervical vertebrae, allowing for the spinal cord, dens, and a surrounding cushion of spinal fluid. It has a mean internal, anteroposterior dimension of approximately 31.7 mm and an internal width of 32.2 mm. The atlas is the only cervical vertebra not associated with an intervertebral disk. Its transverse process is longer than the other cervical vertebrae to support the attachments of the muscles that rotate the head, and its transverse foramen contains the vertebral artery, veins, and sympathetic nerves (Fig. 68.2).

![Figure 68.2](image)

**FIGURE 68.2** Anatomy of the atlas and axis. A: Superior view of the atlas. B: The axis viewed from a superior and posteroanterior aspect. C: Lateral view of the axis.

The axis, or C2 vertebra, has a small body anteriorly from which the odontoid process arises and projects upward. Its oval-shaped anterior face articulates with that on the anterior arch of the atlas. The posterior surface of the odontoid process articulates with the transverse ligament. The facets on the upper and lower surfaces of the lateral masses of the axis articulate with the atlas above and the C3 facet joints below. The atlas also has a large palpable bifid spinous process and small transverse processes with transverse openings or foramina through which the vertebral artery, veins, and the vertebral sympathetic plexuses pass. Because both the atlas and the axis lack pedicles and intervertebral foramen, the nerve roots of the first and second spinal nerves pass above and posterior to the articulating lateral masses of each vertebrae. The hypoglossal nerves traverse the
Occipital condyles anterolaterally through the hypoglossal foramen a mean of 12.2 mm from the posterior margin of the occipital condyle (see Fig. 68.2).

The five lower cervical vertebrae share common characteristics in that they are composed of a vertebral body, an intervening intervertebral disk, two pedicles, two laminae, two vertebral arches, and a spinous process. The upper and lower surfaces of the pedicles form the articulating facets of the cervical zygapophyseal joints. The transverse processes are situated anterolaterally to the facet joints. Their trough-shaped surfaces contain the roots of the cervical spinal nerves and a foramen through which the vertebral artery, veins, and vertebral sympathetic nerve pass.

The anterior portions of the C2 through C7 vertebral bodies, like those of the thoracic and lumbar spine, are connected at their upper and lower surfaces by intervertebral disks, which make up the main joints of the spinal column. Each disk is made up of a central nucleus pulposus surrounded by a thick ring of fibrous cartilage called the annulus fibrosis. The disk is connected to the vertebral body above and below by a hyaline cartilage endplate whose fibers interface with the disk and the vertebral body.

The nucleus pulposus contains collagen and elastin fibers embedded in a colloidal proteoglycan gel which is osmotically active in healthy disks with an approximately 80% water content. The annulus is made up of 15 to 25 concentric rings or lamellae made up of collagen fibers oriented in an alternating criss-cross oblique fashion with elastin fibers layered between the lamellae. The annulus attaches around the entire circumference of the upper and lower endplates and, together with the nucleus pulposus, forms a fluid elastic system. These properties allow the disk to absorb and more evenly distribute the mechanical stress of high-impact activity. By the third decade of life, the disk has become avascular and must rely on diffusion of nutrients and water through the endplates and lymph. The properties of the healthy disk permit disk hydration by way of compression and relaxation of the viscoelastic system, similar to the action of squeezing a sponge. With aging, atherosclerosis, and trauma, degenerative changes occur within the disk. A decrease in protein polysaccharide content and thus its water composition leads to loss of its viscoelastic properties.
Degeneration of the disk increases the axial load and shear on the zygapophyseal joints and contributes to simultaneous degenerative changes of these posterior spinal elements (Fig. 68.3).\(^1\)

**FIGURE 68.3** Schematic depiction of the hydraulic mechanism of the intervertebral disk. **A:** Normal disk at rest. The internal pressure is exerted in all directions, and the fibers of the annulus are taut. **B:** When the disk is compressed, the fluid within the nucleus pulposus cannot compress, so the annulus must bulge. **C:** With flexion of the spine, the fluid shifts within the intervertebral disk; the cubic contents remain the same, but the fluid shift causes fibers of the anterior annulus to shorten and those of the posterior annulus to elongate. W, weight. (From Cailliet R. Neck and Arm Pain. 2nd ed. Philadelphia: FA Davis; 1981. Reproduced with permission of F.A. Davis Co., in the format Republish in a book via Copyright Clearance Center.)

The posterior elements of the lower segments of the cervical spine consist of two vertebral arches, a central posterior spinous process, two transverse processes, and a paired articulation. The transverse processes and posterior spinous processes serve as sites for attachment of supporting ligaments and neck muscles. The zygapophyseal facet joints are true joints with cartilaginous surfaces lined with synovium, containing synovial fluid and surrounded with a ligamentous joint capsule. As such, they are subject to the same inflammatory and degenerative diseases found in other synovial joints. The cervical zygapophyseal joints provide a guiding and gliding movement between the adjacent cervical vertebrae. The movements allowed at the atlantooccipital and atlantoaxial joint are much different from those allowed at the C2–C3 through C7–T1 joints. Differences between the cervical and lumbar spine are summarized in Table 68.1 and Figure 68.4.\(^1\)

FIGURE 68.4 Comparative views of the cervical and lumbar functional units. A: Cross-section of the five joints of the cervical spine, which include an intervertebral disk, the paired uncovertebral (Luschka) joints, and the paired posterior articulations. B: Cross-section of the three joints of the lumbar spine, which include an intervertebral disk and the paired posterior articulations. C,D: Lateral views of the same vertebrae shown in A and B. The dashed lines divide the anterior supporting portion from the posterior gliding portion of each functional unit. E,F: Lateral views of the bodies of the vertebrae of the cervical and lumbar spines, depicting particularly the shapes of the intervertebral disks. Note that in the cervical region, the anterior portion of the disk is larger (higher) than the posterior portion, whereas in the lumbar region, the difference between the anterior and posterior portions is much less. (Modified from Cailliet R. Neck and Arm Pain. 2nd ed. Philadelphia: FA Davis; 1981. Reproduced with permission of F.A. Davis Co., in the format Republish in a book via Copyright Clearance Center.)
Ligaments of the Cervical Spine

The ligaments of the cervical spine provide essential protection to the spinal cord and nerves during various stresses which occur owing to a top-heavy and eccentrically balanced head atop a relatively narrow elastic cervical spine. The greatest range and amplitude of movement in the cervical spine occurs between the occiput and the C3 vertebra, whereas nodding in an up and down movement in the sagittal plane occurs between the atlas and the axis.\(^1\)

Atlantooccipital Unit

Flexion and extension at the occiput to C1 level is limited to 23 to 24.5 degrees by impingement of the tip of the dens on the foramen magnum in flexion and the tectorial membrane in extension. The tectorial membrane is a fan-shaped continuation of the posterior longitudinal ligament to the base of the occiput where its fibers connect with the dura mater. Lateral bending is resisted by the anatomy of the occipital-C1 articulation and the alar ligaments and averages 3.4 to 5.5 degrees per side. The alar ligaments are enclosed in a synovial membrane and extend to the margin of the foramen magnum from each side of the odontoid process. Axial rotation is also limited by the atlantooccipital joint and the alar ligament, 2.4 to 7.2 degrees per side. Lateral translation, stretch and compression, and sagittal plane translation are restricted by the tectorial membrane, the alar, and the apical ligaments as well as the occipital-C1 articulation. The apical ligament is a vestigial remnant of the notochord and attaches from the peak of the odontoid process to the anterior foramen magnum. Other ligaments at this level include the posterior atlantooccipital membrane, which forms the connection between the anterior margin of the foramen magnum and the anterior arch of the atlas, and the posterior atlantooccipital membrane, which extends posteriorly over the vertebral artery.\(^1\)

Atlantoaxial Unit

Axial rotation is the primary movement of the C1–C2 segment. The average 23.3 to 38.9 degree per side rotation is limited by the atlantoaxial joints, the transverse ligament of the ipsilateral side, the alar ligaments of the contralateral side, and capsular ligaments. Flexion rotation is 10.1 to 22.4 degrees and is resisted by the transverse ligament during flexion, the
tectorial membrane and joint anatomy. Lateral bending is limited to 6.7 degrees mostly by the alar ligament. Posterior movement or translation at this level is resisted by abutment of the dens on the arch of C1. The transverse ligament extends posteriorly to the odontoid process between the lateral pillars of the atlas. The destabilizing effect of a tear of the transverse ligament is equal to that of a fracture of the odontoid process.\textsuperscript{1,2}

Other Cervical Ligaments
The posterior longitudinal ligament and the anterior longitudinal ligaments limit the degree of flexion, extension, and transverse sliding of the C2 to C7 vertebrae. The anterior longitudinal ligament blends with the annulus as it crosses the disk spaces and adheres to the front of the vertebral bodies. The posterior longitudinal ligament is a double-layered structure which is firmly bound to the posterior surface of the cervical disks and loosely bound to the posterior cervical vertebrae. It reinforces the capsular ligaments and the anterior border of the cervical spinal canal.\textsuperscript{1}

The ligamentum flavum is a paired structure forming the posterior border of the epidural space. Collectively referred to as ligament flava, they extend between the anterior-inferior surface of the lamina above and to the posterior-superior surface of the lamina below. Posterior to the ligamentum flavum, the interspinous ligaments extend between and connect each spinous process. The ligamentum nuchae is the superior continuation of the supraspinous ligaments of the thoracic and lumbar vertebrae. It is a strong fibrous posterior ligament which extends from the base of the skull to the tips of the posterior cervical spinous process and vertebra (Fig. 68.5).\textsuperscript{1}
MUSCULATURE OF THE NECK
The capital movers are the muscles of the neck that flex and extend the head. The capital extensors include the posterior rectus capitis minor and major and the obliquus capitis superior and inferior. The groups of longer muscles that act as capital extensors while working together bilaterally include the longissimus capitis, semispinalis capitis, and splenius capitis. The capital flexors are the short recti and the longus capitis muscles. The most extension and extensor musculature is at the atlantoaxial and C6 through T1 joints. The cervical extensors include the splenius cervicis, longissimus cervicis, and semispinalis cervicis. Maximum flexion of the cervical spine and maximum cervical lordosis occur at C4–C5. The flexors of the cervical spine consist of the scalenus anterior, medius, and posterior. Unilateral rotators of the head include the splenius cervicis, splenius capitis, longissimus capitis, and sternocleidomastoid. The erector muscles of the vertebral column are also involved in movement of the neck (Fig. 68.6).1

THE VERTEBRAL CANAL
A transverse cut through the cervical vertebral canal reveals its triangular shape with the base or anterior wall made of the vertebra, disk, posterior longitudinal ligament, pedicle, and neural foramina. The lateral and dorsolateral aspects of the other two sides of the triangle include the zygapophyseal joints, laminae, and ligament flava. The canal has its largest sagittal diameter, a range of 16 to 30 mm, at the C1–C2 level and its smallest sagittal diameter, a range of 14 to 23 mm, at the C5–C6 level. The cervical canal lengthens and the intervertebral foramina enlarge during flexion, whereas shortening of the cord and a decrease in the size of
the foramen occurs with extension. Lateral flexion or rotation causes the ipsilateral foramina to decrease in size and the contralateral foramina to enlarge. These changes in size of the foramen become significant in the degenerative spine (Fig. 68.7).1

![Image of spinal foramina with movement](image)

**FIGURE 68.7** Changes in the size of the intervertebral foramina with movement of the neck. **A:** With lateral flexion and rotation of the head, the foramina become smaller on the side of the head to which the head flexes laterally or rotates, and they are open on the opposite side. **B:** With forward flexion, the intervertebral foramina become larger, whereas with extension they become smaller. (Modified from Cailliet R. Neck and Arm Pain. 2nd ed. Philadelphia: FA Davis; 1981. Reproduced with permission of F.A. Davis Co., in the format Republish in a book via Copyright Clearance Center.)

The spinal cord is covered by meninges which consist of the delicate pia matter attached to the cord, the web-like arachnoid membrane, and the strong outer dura mater. The dura mater is attached to the foramen magnum and the dorsal surfaces of the C2 and C3 vertebra. The spinal cord is suspended in and protected by surrounding cerebrospinal fluid and is attached laterally to the dural sheath by the dentate ligaments, which are
thickenings of the pia mater between and anterior and posterior roots. The anterior and posterior rootlets join the anterior and posterior roots, respectively, at the inner aspect of the intervertebral foramina (Fig. 68.8). An enlargement of the cervical cord occurs from the C3–T1 levels. It is larger than the lumbar enlargement as it contains the ascending and descending long tracts for the trunk as well as the upper and lower limbs. The transverse diameter of the cervical spinal cord is greater than its sagittal diameter, and the cervical cord occupies approximately 40% of the canal. With neck extension, the dura relaxes to form a corrugated appearance and the vertebra above approximates the arch of the vertebra below causing encroachment into the cervical canal. These factors, together with shortening of the cord during extension, increase the risk of impingement of the cord during neck extension.¹

**FIGURE 68.8** Transverse sections of the cervical spine. **A:** The spinal cord and anterior and posterior rootlets join to form the spinal nerve. Note the relationship of the nerves to the Luschka and zygapophyseal joints and the two vertebral arteries, which pass through the transverse foramina and are located just anterior to the nerve. **B:** Cross-section of a cervical vertebra showing some details of the relationship of the posterior root to the lateral aspect of the ligamentum flavum, which covers the zygapophyseal joint just posterior to it. The anterior root and its dural covering are close to the lateral part of the posterior longitudinal ligaments and to the capsules of the joint of Luschka. The proximal portion of the dorsal root ganglion is in the outer portion of the intervertebral foramen, whereas the remainder is in the gutter of the transverse process. **C:** Detailed anatomy of a nerve root and its meningeal covering. Note the extent of the root pouch and root sleeve. Just distal to the joining of the anterior and posterior roots is the short spinal nerve covered by epineurium (the continuation of the dura), which promptly divides into the anterior primary division (APD) and posterior primary division (PPD) and gives off a white ramus communicantes (WRC). (A, Modified from Bland JH. Disorders of the Cervical Spine: Diagnosis and Medical Management. 2nd ed. Philadelphia, PA: Saunders; 1987. Copyright © 1987 Elsevier. With permission.; B and C,
VERTEBRAL ARTERIES

The vertebral arteries are the first branches from the subclavian trunk and pass cephalad as they course through the transverse foramina of C6–C2 anterior to the cervical nerves. They are accompanied by the vertebral venous plexus and the vertebral nerve and sympathetic plexus, whose fibers originate from neurons in the stellate and intermediate cervical sympathetic ganglia. Branches from the vertebral artery pass through the intervertebral foramina where they supply ligaments, dura, and bone and communicate with the posterior and anterior spinal arteries, which are also branches of the vertebral arteries. The vertebral arteries are supplied by fibers from the vertebral sympathetic plexus as are the basilar artery, circle of Willis, superior cerebellar, and posterior cerebellar artery (Fig. 68.9).1

FIGURE 68.9 A: Lateral view of the cervical vertebrae depicting the course of the vertebral artery from C6 to C1 through bony ridges of the foramina transversaria. Note the double U turn the artery makes from C2 to C1 in its posterior course around the lateral mass of the atlas. B: The two vertebral arteries join to form the basal arteries. Also shown is the circle of Willis. Note the origin
of the anterior spinal artery and the two posterior spinal arteries from the two vertebral arteries.

**CERVICAL NERVES**

A more detailed discussion of peripheral and spinal pain mechanisms and applied anatomy relevant to pain can be found in earlier chapters of this text. The spinal nerve roots are composed of a dorsal sensory root and a ventral motor root. The posterior root breaks into 12 or more rootlets which attach in series to the dorsolateral sulcus of the cord near Lissauer’s tract and then project into the dorsal and ventral horns. Peripherally, the sensory rootlets converge into the fascicule radiculae which unite to form the dorsal root ganglion. A smaller number of rootlets make up the anterior root which arises from the ventrolateral sulcus of the cord. Each rootlet is covered by pia mater, and as they coalesce to form dorsal and ventral roots, they become separately covered in arachnoid-dural sleeves which are attached to the bony margin of the intervertebral foramen. The anterior roots are in contact with Luschka’s joint, and the disk annulus and the dorsal root approximates the articular process and zygapophyseal joint capsule as they pass through the cervical intervertebral foramen. The dorsal and anterior roots join slightly beyond the dorsal root ganglion to form the composite spinal nerve.\(^1\)

The figure eight-shaped intervertebral foramina are largest at the C2–C3 level and progressively narrow and shorten to the C6–C7 level with an average vertical diameter of 10 mm and transverse diameter of 5 mm. The first and second cervical nerves are unique in that they do not pass through an intervertebral foramen. The first cervical nerve passes between the occiput and C1 lateral to the occipital condyle and the second between C1 and C2 posterior to the lateral pillars.\(^1\)

In addition to the nerve roots, the foramina contain the spinal radicular arteries, intervertebral veins, and venous plexuses together with loose areolar tissue and fat from the adjoining extension of the epidural space. These provide a protective cushion in the healthy spine. Each spinal nerve receives one or more gray rami communicantes from the cervical sympathetic ganglia after exiting the spinal canal. Spinal nerves 1 through 4 receive fibers from the superior cervical sympathetic ganglion, spinal nerves 5 and 6 from the intermediate ganglia, spinal nerves 7 and 8 from the inferior cervical ganglion, and spinal cervical nerve 8 and thoracic 1
from the first thoracic ganglion. The meninges are supplied from a branch of the cervical spinal nerve at each level (Figs. 68.8 and 68.10).1

**FIGURE 68.10** Lateral view showing the course and relation of the cervical nerves and the cervical sympathetic chain.

Lateral to the intervertebral foramen, posterior to the vertebral artery, the spinal nerves separate into posterior and anterior primary divisions with the anterior motor divisions being much larger than the posterior divisions, with the exception of C1. Each spinal nerve supplies muscles (myotomes) and skin (dermatomes) as well as ligamentous and bony structures (sclerotomes). The posterior primary division passes over the posterior portion of the transverse process around the articular pillar and divides into the medial sensory and lateral muscular branches, with the exception of the C1 nerve.1

The first cervical nerve or suboccipital nerve remains as one trunk and supplies the muscles of the suboccipital triangle. Sensory fibers from the C1 nerve supply the periosteum and body of the atlas and occiput, the atlantooccipital and atlantoaxial joints, and ligaments around these joints. It may occasionally supply skin of the scalp and communicate with the
greater and lesser occipital nerves. The posterior primary divisions of the other cervical spinal nerves supply the muscles of the posterior neck (lateral branches) and skin of the neck (medial branches).¹

The greater occipital nerve is the medial or sensory branch of the posterior division of the second cervical nerve. It communicates with the third cervical nerve to supply the scalp over the vertex and top of the head and gives muscular branches to the semispinalis capitis. The third or least occipital nerve arises from the medial sensory branch of the posterior division of the third cervical nerve (Figs. 68.11 and 68.12).¹

FIGURE 68.11  Cross-section of the third cervical segment showing the course and distribution of the posterior primary division, with its medial branch passing posteriorly to supply the skin and subcutaneous structures and the lateral branch supplying the muscles. Also shown is a cross-section of the superior cervical ganglion and its connection to the nerve by the white ramus communicantes. Note the vertebral vessels just anterior to the nerve.
FIGURE 68.12 Cutaneous nerves derived from the cervical plexus (see text for details).

THE CERVICAL AND BRACHIAL PLEXUS
The cervical plexus is made up of the anterior primary divisions of the upper four cervical nerves. The brachial plexus is formed from the lower four cervical nerves, C5 through C8, together with T1 (Fig. 68.13).¹

FIGURE 68.13 Anterior view showing the formation of the cervical and brachial plexuses.

The anterior trunks from cervical nerves two through four divide into
ascending and descending branches which form a series of three loops. These are located lateral to the vertebrae, anterior to the levator scapulae and scalenus medius muscles, and beneath the sternocleidomastoid muscle. The deep branches of the cervical plexus lie beneath the sternocleidomastoid muscle and are divided into the lateral or external group and the medial or internal group. The lateral group of branches supplies muscular branches to the scalenus medius, sternocleidomastoid, trapezius, and levator scapulae. It also sends communicating branches to the spinal accessory nerve. The medial or internal branches send off communicating fibers which join the vagus, hypoglossal and descendens hypoglossi nerves, the superior cervical sympathetic ganglion, and, by means of the ansa hypoglossi, supply the thyrohyoid, geniohyoid, omohyoid, sternothyroid, and sternohyoid muscles. The medial branches also supply the rectus capitis, lateralis, and anticus, the longus capitis and longus colli muscles, as well as the diaphragm by way of the phrenic nerve.¹

The superficial or cutaneous branches of the cervical plexus are often referred to as the superficial cervical plexus and include the lesser occipital nerve, the great auricular nerve, the anterior cutaneous nerve, and the supraclavicular nerve. The lesser occipital nerve joins with the greater occipital and greater auricular nerves to supply the posterior scalp. Its auricular branch supplies the upper and posterior auricula and communicates with the mastoid branch of the great auricular nerve. The great auricular nerve supplies the skin of the face over the parotid gland and communicates with the facial nerve via its anterior or facial branch. Another branch supplies the lobule and lower part of the concha of the ear and communicates with the lesser occipital nerve, the auricular branch of the vagus, and the posterior auricular branch of the facial nerve. The anterior cutaneous nerve supplies the cranial, ventral, and lateral aspects of the neck as far as the sternum.¹

Finally, the supraclavicular nerve supplies the skin and superficial fascia of the clavicular region as well as the periosteum and bone of the clavicle. Via its medial or supraclavicular branches known also as the suprasternal nerves, it supplies the skin of the infraclavicular region medially as far as the midline and laterally to the junction of the medial and middle third of
the clavicle. The intermediate supraclavicular nerve supplies the skin over the pectoralis major as far as the second or third rib and communicates with the cutaneous branches of the second and third intercostals nerves. The lateral supraclavicular nerves or supraacromial nerves supply the skin of the top and dorsal parts of the shoulder (Figs. 68.14 and 68.15).  

**FIGURE 68.14** Origin and composition of the cervical plexus. m., muscle; n., nerve.
The brachial plexus is formed from the primary anterior divisions of the fifth through eighth cervical nerves and the first thoracic nerve with occasional contributing branches from the anterior primary divisions of the fourth cervical and second thoracic nerves. These combine to form three trunks which include (1) the upper trunk, formed from the primary divisions of the fifth and sixth cervical nerves; (2) the middle trunk, formed from the seventh primary division; and (3) the lower trunk, formed from the eighth cervical and first thoracic primary divisions. The upper trunk gives off the suprascapular nerve which supplies the shoulder joint,
the supraspinatus and infraspinatus muscles, and the subclavius nerve, which supplies the subclavius muscle.

The three trunks continue from the interscalenus space in an anterolateral and inferior direction toward the first rib. These further divide into anterior and posterior divisions which pass beneath the midclavicular region to enter the apex of the axilla. Within the axilla, the anterior and posterior divisions form the lateral, medial, and posterior cords. The anterior divisions of the upper and middle trunks, containing fibers from the fifth, sixth, and seventh cervical nerves, form the lateral cord. The anterior division of the lower trunk continues as the medial cord and contains fibers from the eighth cervical and first thoracic nerves. The union of all the posterior divisions makes up the posterior cord, which thus contains fibers from all nerves of the brachial plexus. The three cords divide to give rise to the peripheral nerves of the upper extremity at the lateral border of the pectoralis minor. The lateral aspect of the median nerve and the musculocutaneous nerves derive from the lateral cord. The medial cord divides into the medial head of the median nerve, the ulnar nerve, and the medial antebrachial and brachial cutaneous nerves as well as a branch to the intercostobrachial nerve. The axillary and radial nerves are terminating branches from the posterior cord.\(^1\)

In addition to supplying terminal branches to the upper extremity, the brachial plexus carries postganglionic sympathetic fibers from the cervical and thoracic sympathetic chain to the upper limbs. The brachial plexus also supplies branches to the longus colli muscle and the scalene muscles. The fifth cervical nerve sends fibers to the phrenic nerve, the rhomboid muscles, and the levator scapulae muscles via the dorsal scapular nerve. Fibers from the anterior divisions of the fifth, sixth, and seventh cervical nerves supply the serratus anterior muscle via the long thoracic nerve (Table 68.2 and Figs. 68.16 and 68.17). The segmental and peripheral nerve supply of the neck and arm is summarized in Figures 68.18 and 68.19 as well as Tables 68.3, 68.4, and 68.5. Sympathetic nervous system contributions to the upper extremity from the cervical and thoracic preganglionic neurons are illustrated and described in Figure 68.20. Contributions from the anterolateral and posterolateral subclavian sympathetic nerves, which supply the subclavian artery and its branches
distal to the scalene muscles, contain both sympathetic and sensory fibers.

CN, cranial nerve.

* Only the primary muscle nerves are included.

* Main root is underlined.
FIGURE 68.20  Schematic depiction of the origins and courses of preganglionic sympathetic neurons destined to supply the upper limbs. Note that the axons of the preganglionic neurons, which are located in spinal segments T2–T8 (and occasionally T9), pass through the anterior root as white rami communicantes and from there to the paravertebral sympathetic chain, where they ascend and synapse with postganglionic fibers primarily in the second thoracic, stellate, and intermediate and middle cervical ganglia, and occasionally in the third cervical ganglion (not shown). Some of the postganglionic fibers pass directly to the subclavian artery, but most pass as gray rami communicantes to the roots of the brachial plexus. ICG, inferior cervical ganglion; MG, middle cervical ganglion; SCG, superior cervical ganglion; SG, stellate ganglion.

PECTORAL GIRDLE AND SHOULDER ANATOMY

The differential diagnosis of neck and arm pain includes many disorders of the pectoral girdle and shoulder which can result not only in shoulder pain but also in radiation of pain to the neck and/or arm. Common disorders involving the shoulder and pectoral girdle include rotator cuff tears, tendinitis, impingement syndromes, and arthritis (Figs. 68.21 and 68.22). An understanding of the complex anatomy and biomechanics of pectoral girdle and shoulder is thus essential for the diagnosis and treatment of pain in this region.¹
FIGURE 68.21 Anterior (A) and posterior (B) views of the shoulder identifying the various bones and joints and also the sites of pathologic processes that produce pain and tenderness. (1) Subacromial space, which can be involved with calcific tendinitis, rotator cuff tendinitis and impingement syndrome, and rotator cuff tear; (2) bicipital groove, which can be involved in bicipital tendinitis and biceps tendon subluxation and tear; (3) acromioclavicular joint, which can be involved with degenerative and infectious processes; (4) anterior glenohumeral joint, which can be the site of glenohumeral arthritis, osteonecrosis, glenoid labial tears, and adhesive capsulitis; (5) sternoclavicular joint, which can be the site of pain caused by infection, degenerative changes, or trauma; (6) posterior edge of the acromion, which can contribute to rotator cuff tendinitis, calcific tendinitis, and rotator cuff tear; (7) suprascapular notch, which can be the site of suprascapular nerve entrapment; and (8) quadrilateral space, which can be the site of axillary nerve entrapment.

m., muscle.
FIGURE 68.22 With progressive cuff fiber failure, the head moves upward against the coracoacromial arch. **A:** Normal relationships of the cuff and the coracoacromial arch. **B:** Upward displacement of the head, squeezing the cuff against the acromion and the coracoacromial ligament. **C:** Greater contact and abrasion, giving rise to a traction spur in the coracoacromial ligament. **D:** Still greater upward displacement, resulting in abrasion of the humeral articular cartilage and cuff tear arthropathy. (Reprinted from Matsen FA. Practical Evaluation and Management of the Shoulder. 1st ed. Philadelphia, PA: Saunders; 1994:123. Copyright © 1994 Elsevier. With permission.)

The pectoral girdle is made up of the scapula and clavicle, the sternoclavicular and acromioclavicular joints, and the scapulothoracic and humeroacromial interfaces. Unlike the lower limb, which is built for weight bearing as well as locomotion, the upper limb function is primarily to allow mobility and a wide range of motion for the arm and hand. The girdle does not articulate with the vertebral column, as does the pelvic girdle, but with the thoracic cage at the saddle-shaped sternoclavicular joint. The sternoclavicular joint is divided into two spaces by an articular disk and is surrounded by a strong, lax capsule. In addition to the capsule, the joint is stabilized by the interclavicular ligament superiorly, inferiorly
by the costoclavicular ligament (which limits elevation and rotation of the clavicle and serves as the fulcrum of movements at the sternoclavicular joint), and the posterior sternoclavicular ligament. Dislocation of the costoclavicular joint is rare but tends to occur anteriorly where the joint is weakest when it does occur (Fig. 68.23).

The acromioclavicular joint of the pectoral girdle is surrounded by a weak and lax capsule. It is stabilized by the acromioclavicular ligament superiorly; the fan-shaped coracoclavicular ligament, which serves as a vertical axis for scapular rotation; and the trapezoid ligament, which serves as a hinge for scapular motion about the horizontal axis. A partial or complete disruption of the coracoclavicular ligament, resulting in separation of the acromioclavicular joint, may occur with a fall on the shoulder.

The scapulothoracic interface allows a gliding movement between the ventral surface of the scapula and the thorax overlying the second through the seventh ribs. The scapula is held in close approximation to the thorax by the serratus anterior, the trapezius, and the rhomboid muscles. For full abduction and forward flexion of the shoulder to occur, the scapula must undergo upward rotation. Movements of the pectoral girdle consist of upward-downward rotation, protraction-retraction, and elevation-depression (Table 68.6 and Figs. 68.24 and 68.25).

**FIGURE 68.24** Anatomy of the shoulder joint. 
A: Anterior view of ligaments of the left shoulder. 
B: Coronal section through the head of the left humerus and shoulder joint, anterior half viewed from behind. 
C: Interior of the right shoulder viewed from its lateral aspect. (Adapted with permission from Clement CD. Gray’s Anatomy of the Human Body. 30th ed. Philadelphia, PA: Lea & Febiger; 1985368–372.)
The glenohumeral joint is a synovial joint that consists of the interface of the head of the humerus with the pear-shaped glenoid cavity and ring of fibrocartilage known as the glenoid labrum. These deepen the socket of the scapula and assist with stability of the glenohumeral joint. The supraglenoid and infraglenoid tubercles above and below the glenoid cavity are attachment sites for the long head of the biceps and triceps, respectively. The joint capsule is strong but lax, to allow for mobility, and attaches to the scapula proximally and distally to the articular margins of the head of the humerus superiorly and the surgical neck of the humerus inferiorly. The ligaments of the glenohumeral joint consist of the superior, middle, and inferior glenohumeral ligaments (thickenings of the anterior capsule); the coracohumeral ligament (which attaches to the greater and lesser tuberosities and limits flexion and extension); and the coracoacromial ligament (which extends from the undersurface of the acromion to the coracoid process and acts as an articulating surface for the
head of the humerus). The subacromial and subdeltoid bursae lie between the coracoacromial arch and the rotator cuff tendons and have been implicated in shoulder impingement (see Fig. 68.24).

Movement at the shoulder requires the combined motion of the glenohumeral joint and the pectoral girdle for flexion or abduction greater than 90 degrees. For example, the abduction or elevation of the arm to 180 degrees requires 60 degrees of scapular rotation to alter the angle of the glenoid fossa during its articulation with the head of the humerus (Figs. 68.26 and 68.27). Prime movers of the pectoral girdle and glenohumeral joint are listed in Tables 68.6 and 68.7.1

FIGURE 68.26  Biomechanics of the glenohumeral movements of arm abduction. A: Normal position of the head and shaft of the humerus. The circle in the head of the humerus indicates the center of rotation. B: Humerus (H) abducted 45 degrees and the scapula (S) beginning upward rotation. The upper panel shows that the incongruity of the articulating surface of the head of the humerus and the surface of the glenoid cavity causes the greater tuberosity of the humerus to impinge on the coracoacromial ligament. The upper panel in C shows that to allow the greater tuberosity to pass under the coracoacromial hood during arm abduction, the humeral head is depressed (depicted by downward movement of the center of rotation) and the humeral head rotated (thin arrow). The abduction movement of the arm is accomplished in a smooth coordinated movement during which for each 15 degrees of arm abduction, 10 degrees of motion occurs at the glenohumeral joint, and 5 degrees occurs because of scapular rotation on the thorax. Thus, as noted in C, abduction of the arm to 90 degrees is accomplished by 60 degrees rotation of the humerus and 30 degrees rotation of the scapula. Full abduction of the arm, as shown in D, is accomplished by 120 degrees of rotation at the glenohumeral joint and 60 degrees rotation of the scapula. (Modified from Cailliet R. Shoulder Pain. 2nd ed. Philadelphia: FA Davis; 1981. Reproduced with permission of F.A. Davis Co., in the format Republish in a book via Copyright Clearance Center.)
Epidemiology of Neck and Arm Pain

According to The Global Burden of Disease Study 2013, which evaluated the national disability-adjusted life years (DALYs) for 306 diseases and injuries and healthy life expectancy (HALE) for 188 countries from 1990
to 2013, back and neck pain have risen from the seventh leading cause of
disability in 1990 to the fourth leading cause of disability in 2013,
following ischemic heart disease, cerebrovascular disease, and lower
respiratory infections. The methodology and definition of neck pain
varies significantly in epidemiologic studies of neck and arm pain. An
average prevalence of 15% to 50% with a mean of 37.2% have been
reported in most epidemiologic studies and a recent systematic review.
Associated conditions identified with neck and arm pain include
psychosocial factors such as anxiety, depression, kinesiophobia, poor
coping skills as well as sedentary lifestyle, sleep disorders, smoking, and
genetic risk factors. Associated poor health, as well as musculoskeletal and
psychological health complaints, were prognostic for poor outcome.
Prevalence was found to be overall higher in females with prevalence
peaking in middle age.

Controversy exists regarding the relationship between radiologic
evidence of cervical spine degeneration and neck pain, with some finding
no significant difference in the degree of neck pain in patients with or
without radiographic evidence of cervical spine degenerative changes,
with others correlating neck pain with increasing grade of disk
degeneration. Zapletal et al. showed increasing evidence of neck pain
with increasing prevalence of atlantoaxial degenerative changes.

Up to 78% of asymptomatic subjects have been found to have
degenerative changes on magnetic resonance imaging (MRI) accompanied
by positive findings such as disk bulging and protrusion, foraminal
stenosis, and abnormal spinal cord contour. This evidence suggests that
degenerative findings are common in both asymptomatic and symptomatic
individuals, increase linearly with age, and cannot be assumed to be the
definitive cause of neck pain in symptomatic individuals. One study
comparing cervical spine MRIs of fighter pilots to age-matched controls
showed premature cervical disk degeneration among pilots exposed
frequently to high +Gz forces.

Neck pain following whiplash-associated disorders is common with
more than 300 persons per 100,000 population evaluated for this complaint
each year according to recent data. Increased symptom severity and
presence of neurologic signs is predictive of poor prognosis. Postinjury
feelings of helplessness in controlling the consequences of pain, fear of movement, catastrophizing, and postinjury anxiety have also been found to be associated with higher risk of long-term disability, as has changing the insurance system from a no-fault to a tort system of compensation. Studies from hospital populations report that at an average follow-up of 2 years, 20% to 45% of patients with soft tissue neck injuries following whiplash reported discomfort sufficient enough to interfere with their capacity to work.

Onset of neck and arm pain in the workplace varies widely across various occupations. Highly repetitive work, low job satisfaction, and a high level of fear avoidance are associated with development of neck and arm pain as are jobs which require prolonged bending or flexion of the neck such as computer work. Neck, shoulder, and arm pain associated with generalized pain or pain at other anatomical sites has been associated with greater persistence and disability than more localized neck, shoulder, and arm pain. Neck and arm pain associated with more generalized pain is also more likely to be associated with somatization, poor psychological health, older age, and less correlation with occupation or activity. More localized neck and shoulder pain is more strongly associated with use of keyboards at work and less frequent at older age.

Evaluation of the Patient

HISTORY AND PHYSICAL EXAMINATION

The patient in pain is prompted to seek help not only to alleviate the suffering which accompanies their condition but also to address the accompanying condition of impairment or disability. The psychological, physical, or functional handicap which coexists with pain results in loss of ability to perform normal activities and fulfill roles that are fundamental to personal identity. Ultimately, the goal of a successful evaluation should be the ability to answer the patient’s three fundamental questions: (1) “What’s happening to me?” (2) “What’s going to happen to me?” and (3) “What can be done to improve what happens to me?”

The differential diagnosis of neck and arm pain is broad and encompasses acute pain from work-related injury, motor vehicle trauma
and infection, emerging symptoms from enlarging tumors, vascular abnormalities or infections, manifestations of complex systemic disease processes, and exacerbation of chronic degenerative or inflammatory processes. The initial evaluation should be comprehensive in order to ascertain not only the etiology of physical symptomology but also the impact the patient’s disability has on their psychosocial environment.

**History**
A thorough history of the patient with neck and arm pain is essential to separate acute from chronic, emergent from urgent and routine complaints, and focal and regional injuries and degenerative changes from systemic disorders. Pain in the neck and arm may also be referred from the thorax or abdomen requiring a thorough review of systems. The differential diagnosis is frequently based on the history, which then guides further focus during the physical exam and diagnostic testing.

Immediate consideration must be made regarding the severity and urgency of the complaint. Emergent conditions can often be discerned at the time of phone request for urgent evaluation or by nurses when the patient is screened at check-in. Severe neck pain accompanied by progressive disturbance of gait, progressive motor or sensory deficits, or urinary and fecal incontinence requires prompt physician evaluation. Enlarging tumor, acute infection, and unstable inflammatory spondyloarthropathy can progress to respiratory failure and death if not treated promptly and requires immediate surgical and medical intervention. Acute progressive neurologic and cognitive deficits accompanied by hemodynamic instability may also present with dissecting vertebral and extracranial carotid artery aneurysms. Other red flags include significant head trauma in the presence of a neurologic deficit. Night pain or unrelenting pain with associated weight loss is suggestive of a neoplastic or infectious process.

**Location/Radiation**
Pain in the neck and arm may be skeletal, myofascial, or neuropathic. Neuropathic pain can be further divided into peripheral or segmental nerve pathology versus autonomic and central nervous system pathology or
sensitization. Cohen suggests the diagnostic construct of mechanical versus nonmechanical pain. Mechanical pain is exacerbated by movement and occurs in the essentially well patient. Nonmechanical pain is often related to a medical source such as infection, neoplasm, or an inflammatory process generally seen in patients with systemic manifestations of their disease process.

The purpose of a thorough history with determination of the location, pattern, and distribution of the patient’s pain is to establish an initial differential diagnosis which can subsequently be confirmed or ruled out by physical examination, diagnostic laboratory, radiologic, and electrophysiologic testing. Localized pain is usually caused by disorders of joints and muscles. Segmental pain conforming to dermatomal distributions may implicate lesions of nerve roots. Pain conforming to a peripheral dermatomal and/or myotomal distribution suggests lesions of the cervical or brachial plexus or their branches. Knowledge of dermatomal, myotomal, sclerotomal, and zygapophyseal referral patterns as well as distribution of peripheral nerves of the cervical and brachial plexus are essential for determining a rational differential diagnosis (see Figs. 68.11 through 68.19 and Tables 68.3 through 68.5).

In addition to cervical nerve root inflammation or impingement, cervical and brachial referral patterns may be secondary to myofascial trigger points or referred pain from cervical zygapophyseal joints. Widespread pain may implicate fibromyalgia syndrome, rheumatologic disease such as mild systemic lupus erythematosus, polyarticular osteoarthritis, rheumatoid arthritis, polymyalgia rheumatica, hypermobility syndromes, and even osteomalacia. Nonrheumatologic syndromes must also be considered in patients presenting with widespread pain. These include neoplastic and neurologic diseases, hypothyroidism, and other endocrine disorders, chronic infections, and a variety of psychiatric conditions.

Location of the patient’s pain cannot in isolation lead to a correct diagnosis. All aspects of the history of present illness; past medical and surgical history; family history of hereditary illness; and social, occupational, behavioral, psychological, and demographic information are necessary to identify predisposing factors or mechanisms of injury. A review of systems and detailed physical exam are essential to rule out...
manifestations of systemic disease and presence or absence of significant neurologic deficits. Even then, further diagnostic tests as well as pharmacologic and interventional trials may be required in complex cases to confirm or rule out etiologic hypothesis.

**Onset**

Acute onset of pain may occur after trauma, injury, or following an unaccustomed increase in activity in a deconditioned patient; however, an acute exacerbation of a chronic condition cannot be excluded. More gradual or insidious onset is common in progressive degenerative, inflammatory, or malignant process. It is important to elicit the time at which the pain first occurred, characteristics of the pain during the interval between onset, and evaluation of precipitating events or factors.

**Intensity and Pattern of Severity with Time**

A cardinal principle of diagnosis is assessment of the intensity of pain both at baseline and in response to time, activities, and treatment. Although the visual analogue or numerical rating pain score system is subjective and may be influenced by psychological, social, and occupational factors, it is essential to evaluate the trend of each patient’s pain over time in order to assess the effects of pharmacologic, psychological, behavioral, physical, and interventional therapies. Patterns of pain severity over time are often associated with certain diseases. Chronic unrelenting pain may be due to inflammatory disease or a more centralized pain syndrome. Pain due to cervical spondylosis and stenosis may be severe with activities requiring neck flexion and rotation and absent or significantly reduced when the patient’s neck is held in a neutral position. Patient complaint of night pain or pain of spontaneous onset which is constant and not relieved by rest or modified by movement may raise suspicion for an infectious or neoplastic process.

**Quality**

Electrical, shooting, stabbing, lancinating, burning, tingling, and pins and needles are common terms used to describe neuropathic pain. Dull, aching, cramping, or throbbing pain is more often associated with pain of a musculoskeletal nature. Stiffness is often described in association with
degenerative arthritis or diffuse idiopathic skeletal hyperostosis (DISH). It is not unusual for the patient to include sensory changes (numbness, pins and needles, or burning) as well as cramping and aching pain in their description of cervical radiculopathy. This is most likely due to both the cutaneous or dermatomal and muscular or myotomal distribution of the cervical nerve roots. Burning pain associated with allodynia and thermohyperesthesia suggests complex regional pain syndrome (CRPS). The more chronic the pain condition, the more likely the patient will report a poorly localized, widespread, nondermatomal pain pattern due to changes in central pain processing known to occur following persistent painful peripheral input.\textsuperscript{24}

**Modifying Factors and Drug History**

Asking the patient the question “What makes your pain better or worse?” will assist in further narrowing of the differential diagnosis. Coughing or sneezing and lateral head rotation and extension may cause exacerbation of cervical radicular pain. Chronic inflammatory pain is often worse after a period of inactivity and improves with exercise. Degenerative arthritis is often exacerbated by exercise and improves with rest. In patients with multiple pain complaints, response to medication may help guide diagnosis. In patients who have failed multiple medication trials, it is important to elicit specific reactions to medications, duration of use, dosages reached, and titration schedules implemented. An elderly patient, for example, who gives a history of intolerable sedation with an antiepileptic medication, may have been started at a standard adult dose and subsequently titrated upward using an aggressive titration schedule. This patient may be able to benefit from this same medication if it is titrated more gradually from a low dose.

**Associated Symptoms**

A history of neck and arm pain associated with frequently dropping objects, difficulty with writing, or other fine motor skills is useful in separating motor weakness from guarding secondary to pain. Associated symptoms may help to broaden or further refine the differential diagnosis. A patient with neck and arm pain which occurs with increased activity and
is associated with diaphoresis and shortness of breath may broaden the
differential diagnosis to include coronary artery disease. Indeed, the first
clinical description of cervical radiculopathy by Semmes and Murphy\textsuperscript{25} in
1943 was entitled “The Syndrome of Unilateral Rupture of the Sixth
Cervical Vertebral Disc with Compression of the Seventh Cervical Root:
A Report of Four Cases with Symptoms Simulating Coronary Disease.”
Association of neck and radicular arm pain with positional headaches
accompanied with nausea, photophobia, and blurred vision may lead the
physician to rule out low-pressure headache.\textsuperscript{26}

**Family History**

In addition to more common hereditary arthritides such as rheumatoid
arthritis (more common in females), ankylosing spondylitis
(predominantly seen in males), psoriatic arthritis, and Reiter’s syndrome,
there are also more uncommon hereditary diseases which can involve the
cervical spine. Compression of the cervical cord from cervical root
neurofibromas in patients with neurofibromatosis type 1 has been reported
to present with progressive neurologic deficit.\textsuperscript{27} Tophaceous gout of the
odontoid process and larynx, epidural, mediastinal, and subcutaneous
emphysema in a patient with Marfan’s disease following forceful
coughing, and cervical dystonia in spinocerebellar ataxia type 2 are other
inherited disorders manifesting with neck pain.\textsuperscript{28–31}

**Age and Psychosocial History**

The patient’s age, sex, occupational, and social history is important in
determining risk factors known to be associated with the development of
persistent neck and upper limb pain. Whereas sports or trauma injury and
congenital defects such as Chiari I malformations are common causes of
neck pain in pediatric or adolescent patients, degenerative changes are
common in older patients. Jobs or activities which require repeated lifting
of heavy objects, prolonged bending of the neck, working with arms
at/above shoulder height, and which involve little job control and little
social support are associated with the development of neck pain. Specific
jobs and activities associated with the development of neck pain include
prolonged computer work and bicycling.\textsuperscript{16,17,32} Extensive neck and upper
extremity pain is independently associated with psychological ill health, female sex, unemployed status, and smoking.\textsuperscript{18}

Questions regarding use of pillows at night and bifocals as well as any other activities which put the patient’s neck under prolonged flexion strain should be included in the social and occupational history. In some cases, simple correction of repetitive strain with postural reeducation may result in relief of symptoms.

Depression and anxiety may occur as a reaction to persistent pain and are also independent risk factors for the development of chronic pain. The depressed individual may lack the psychological and social capabilities to cope with the complex physical, emotional, cognitive, and behavioral components of the pain experience.\textsuperscript{33} Patients with coexisting histories of depression and anxiety may benefit from referral to a psychopharmacologist and from psychological consultation for cognitive and behavioral therapies to assist the patient with coping strategies.

**Past Medical History and Review of Systems**
The past medical history, past surgical history, and review of systems may provide essential clues tying the patient’s symptoms to an associated disease process. Table 68.8 lists a few coexisting diseases which may present with neck pain and radiculopathy, whereas Table 68.9 lists a review of systems checklist which may identify systemic involvement or an urgent, rapidly progressing process.

**Surgical History**

A past surgical history of neck fusion may signal risk of pseudoarthrosis or increased risk of recurrent disk disease above or below the level of fusion. Poststernotomy lesions following cardiac surgery with the clinical
appearance of a C8 radiculopathy have been described. The causal mechanism is thought to be related to an occult fracture of the first thoracic rib. These are often mistaken for ulnar neuropathy at the elbow thought to be associated with surgical positioning.34

**Physical Examination**

**General Observations**
Many important observations can be made during the initial interview and even as the patient travels from the waiting area to the exam room. The general health and independence of the patient can be surmised from skin and muscle tone, posture, gait, and use of assistive devices. Cachexia may be a sign of debilitation due to cancer or long-standing depression. Mood, affect, and cognitive state can be ascertained during questioning as well as during the physical exam. Other important general observations include symmetry of the shoulders; abnormal head positions including lateral flexion, rotation, or protrusion; and evidence of muscle wasting or deformity of the neck, shoulders, or upper limbs.

A complete physical exam is paramount in the patient with neck, shoulder, and arm pain. Inspection of the skin for lesions may reveal psoriasis which may be associated with psoriatic arthritis. Vesicles typifying herpes zoster may be found in a patient complaining of radicular symptoms. Lesions typical of erythema nodosum may be indicative of inflammatory disease or cancer, and needle marks (intravenous drug abuse) may raise suspicion for vertebral column infections. Acute pain from viscera sharing the same embryologic segmental derivation as the cervical spine can present as neck, shoulder, or arm pain. These include the submandibular glands, lymph nodes, thyroid, esophagus, heart, lungs, stomach, gallbladder, pancreas, and diaphragm, necessitating a general inspection and palpation of these areas.35 In general, a systematic approach which includes a neurologic exam, inspection and palpation of bony and soft tissue structures followed by range of motion and special tests used in the diagnosis of neck pain should supplement but not replace the full physical examination.

Exam of the Neck
Neurologic Exam. Examination of the neck must include a neurologic exam. Tumors, infections, and carotid dissections which present as neck pain are also associated with cranial nerve palsies and sensory deficits. Delay in recognition of neurologic deficits in these cases can lead to progression of tumor or infection with poor surgical or medical outcome and prognosis.\textsuperscript{36–38} A summary of the motor, sensory, and autonomic functions of the cranial nerves is found in Table 68.10.

</table>
In addition to examination of the cranial nerves, general head, neck, and upper extremity sensory; motor and deep tendon exam; sensory, motor, and deep tendon exam of the lower extremities are essential. Exam findings signaling a possible cervical myelopathy include unilateral or bilateral spastic, ataxic, spastic-ataxic or Trendelenburg gait, hyperreflexia of lower extremity deep tendon reflexes and Babinski sign, and decreased sphincter tone or loss of the anal “wink.”

**Sensory Exam.** The sensory exam is particularly useful in the patient with neuropathic pain. Sensory testing should include brush touch for allodynia; light pressure for tenderness and hyperalgesia; and palpation for painful areas as well as vibration, hot, cold, and sharp versus dull discrimination. Positive sensations, stimulus-evoked hypersensitivities such as allodynia to innocuous stimulation including light touch and cold, and hyperalgesia to noxious stimulation such as pinprick occur focally in mononeuropathies and distally and symmetrically in polyneuropathies. In neuropathic pain syndromes such as CRPS, allodynia, and hyperalgesia may spread outside the area of the original injury or to homologous sites in the opposite limb. These sensory findings are often associated with focal autonomic abnormalities such as sweating, skin temperature and color changes, and edema are also present in CRPS. In central pain and anesthesia dolorosa, allodynia, hyperalgesia, and aftersensation (persistence of pain after the stimulus has ceased) can occur in areas demonstrated to have loss of sensation. In small-fiber neuropathies, loss of thermal, pain, and sometimes touch perception with sparing of large-fiber functions such as muscle strength, deep tendon reflexes, and vibratory and proprioceptive perception is seen. These functions are all compromised in combined large- and small-fiber polyneuropathies. The sensory exam should include evaluation for dermatomal patterns of sensory abnormality and for altered sensation in peripheral nerve distributions in patients with suspected peripheral nerve injury or entrapment syndromes. A “cord” level
of sensory disturbance may be confined to the upper extremities due to “central cord syndrome” with involvement of decussating anterior sensory fibers.\(^{40}\)

**Motor Exam.** Motor exam is tested using the standard muscle strength scale from 0 to 5 (Table 68.11).

</tr>
</tbody>
</table>

In addition to testing of motor function of the cranial nerves, myotomal or segmental nerve root motor supply should be systematically evaluated (Table 68.12).
Deficits consistent with peripheral nerve lesions or injury should also be ruled out (Table 68.13).

Reflex testing should include upper and lower extremities because lesions of the cervical spine may manifest with hypoactive reflexes at the level of the lesion, hyperactive reflexes below the lesion, and pathologic reflexes. Cutaneous reflexes will also be lost below the lesion. Reflexes are tested using the following standard scale:

- 0: absent reflex
- 1+: trace or seen only with reinforcement
- 2+: normal
- 3+: brisk
- 4+: nonsustained clonus (i.e., repetitive vibratory movements)
- 5+: sustained clonus

Using this scale, 1+, 2+, or 3+ reflex is considered normal unless there is a significant difference between sides. In contrast, 0, 4+, and 5+ are considered abnormal.

Upper extremity normal and pathologic reflexes are outlined in Table 3624.

DIP, distal interphalangeal joint.

**Inspection and Palpation.** After observation for abnormal posture such as abnormal loss of cervical lordosis, torticollis, and obvious atrophic musculature of the neck or upper extremity, the patient should be asked to lay supine to relax the musculature of the neck. This allows optimal examination of the bony structures of the neck. While standing at the patient’s side, one hand supports the neck from behind while the other is used to palpate the anterior neck structures.

The most superior bony structure of the anterior neck is the hyoid bone. It is the only bone in the skeletal structure not articulated to any other bone. It supports the root of the tongue and in turn is supported by the...
muscles of the neck and suspended by the stylohyoid ligaments from the styloid processes of the temporal bones. The body of the hyoid bone is palpated in the midline, whereas the lesser and greater cornu are palpated laterally to each side of the body forming a horseshoe-like structure. The hyoid bone lies at the lower level of C3 or at the intervertebral disk between C3 and C4. Although injuries of the hyoid bone are rare outside of strangulation, fractures of the hyoid due to trauma, cardiopulmonary resuscitation, and sports injuries have been reported with complications including carotid pseudoaneurysm, pharyngeal laceration, and airway compromise.\textsuperscript{41–44} Insertion tendonitis of the hyoid bone has also been reported as an unrecognized source of neck pain with recognizable radiologic features.\textsuperscript{45} Below the hyoid bone, at the level of C4 to C5, is the thyroid cartilage. The first cricoid ring forms the upper border of the trachea. It lies at the level of C6. The carotid tubercle, also known as Chassaignac’s tubercle, is the anterior tubercle of the C6 transverse process and can be palpated approximately 3 cm lateral to the first cricoid ring. The carotid arteries overlie the tubercles. Caution should be taken to examine the carotid pulses individually to prevent bradycardia and/or syncope.

Soft tissues of the anterior neck include the H-shaped thyroid gland which extends from the thyroid cartilage cranially to the fourth to sixth tracheal rings inferiorly. This area should be inspected to preclude generalized enlargement of the gland and palpated to exclude thyroid masses. The exam should include inspection for palpable lymph nodes which may be due to infection or metastatic disease. Unknown primary carcinoma presents as painless enlarged cervical lymph nodes and accounts for approximately 5% of all head and neck malignancies. If malignancy is suspected, the patient should be referred for more advanced imaging and diagnostic testing.\textsuperscript{46} By having the patient turn his or her head to the opposite side, the sternocleidomastoid muscle may be examined from the origins on the sternum and clavicle to its insertion on the mastoid process of the temporal bone. The anterior border of this muscle from origin to insertion defines the lateral limit of the anterior triangle of the neck and the posterior border, the anterior limit of the posterior triangle of the neck. The exam should include palpation for painful or painless
masses, trigger points with associated referral patterns, and pain associated with swallowing.

Palpation of the bony landmarks of the posterior cervical spine includes the inion or external occipital protuberance in the midline, which makes the midpoint of the superior nuchal line extending laterally from the inion bilaterally. The occipital nerves run medial to the occipital arteries over the occiput approximately 3 cm from the midline. Tenderness or pain with examination of this area may be seen with occipital neuralgia. Palpation of the cervical spine is performed in a systematic way, starting with the spinous processes, and followed by the zygapophyseal joints. Pain over the midline structures may indicate a structural problem of the cervical spine. The zygapophyseal joints are located 2 to 3 cm from the midline. Palpation of the lateral atlantoaxial joint of C1–C2 is undertaken by rotating the patient’s head to the ipsilateral side. C2, C3, C4, and C5 are usually difficult to palpate because of the normal cervical lordosis but can be easily identified if it is remembered that the C3–C4 joint is at the level of the hyoid bone and the C4–C5 joint is at the superior aspect of the thyroid cartilage. The C6 spinous process can be easily identified as it is usually easily palpable and disappears under the examining finger on extension of the neck. The level of the C6–C7 joint can also be confirmed by its location at the level of the cricoid ring. The largest “fixed” prominence is the spinous process of C7. Referral patterns from the zygapophyseal joints have recently been studied in patients with neck, head, and shoulder pain with the most common referral patterns based on areas in which patients are relieved of pain by controlled blocks are depicted in Figures 68.28 through 68.33.47
FIGURE 68.28  Distribution of pain and pain frequency in each grid area as reported by patients with pain originating from C2 to C3. (From Cooper G, Bailey B, Bogduk N. Examination of the soft tissues of the posterior neck includes palpation of the suboccipital muscles and trapezius which, like the sternocleidomastoid, may be a source of CEH. The trapezius extends from the external occipital protuberance, the medial third of the superior nuchal line of the occipital bone, the ligamentum nuchae, spinous processes of the seventh cervical, and all thoracic vertebrae to the posterior border of the lateral third of the clavicle, the medial margin of the acromion, and the
posterior border of the scapular spine. The scalene muscles should not be neglected in patients with neck ache, arm ache, and headache. Neck pain, occipital headache, extremity paresthesia, pain, and weakness may occur from scarring of the scalene muscles secondary to neck trauma such as whiplash injuries.\(^{48}\) As with examination of the anterior neck, a chain of lymph nodes lies along the anterolateral border of the trapezius. Enlargement or tenderness of these may indicate infection or metastatic disease.

**Special Tests for Neck and Upper Extremity**

**Spurling’s Maneuver.** This maneuver is used to confirm the presence of a cervical radiculopathy. It is performed by extending and rotating the head to the right or left. This narrows the intervertebral foramen by 20% to 30%. It has been shown to have a sensitivity of 30% and a specificity of 93% on 235 individuals referred for electrodiagnosis of upper extremity nerve pain.\(^{49}\) It also increases pressure on the cervical facet joints and may intensify facet mediated pain.

**Valsalva Test.** This test is performed by having the patients place their thumb in their mouth and blow, as if to push the thumb out of their mouth. This maneuver increases the intraspinal pressure and may reveal the presence of space-occupying lesions of the cervical spine such as large intervertebral disk herniations, tumors, and stenosis due to spondylosis or osteophytes. If the mass involves the area of the spine adjacent to nerve roots, radicular pain may be reproduced.

**Distraction Test.** This test reduces pressure on the intervertebral disk and exiting nerve roots and simulates the effect that traction may have on treatment of neck and radicular symptoms. It is performed by placing one hand underneath the jaws, the other beneath the occiput, and applying gentle upward pressure over 30 to 60 seconds. Increased pain with this maneuver may be due to inflammatory or degenerative disease or muscle or ligamentous pathology.

**Jackson’s Compression Test.** As with Spurling’s maneuver, this test places increased pressure on the cervical facet joints and causes narrowing
of the neural foramen. It may reproduce neck pain due to facet arthropathy and/or upper extremity radicular pain due to nerve root compression. To perform this test, the patient is instructed to rotate his or her head first to the right and then to the left. The examiner exerts gentle pressure to the top of the patient’s head after each movement.

**Lhermitte’s Sign.** Lhermitte’s sign is the production of a sensation of lightening-like paresthesias or dysesthesias in the arms or legs upon flexion of the cervical spine. It may be caused by a large disk herniation or bony compression of the anterior cord in patients with a narrowed central canal. It may also occur in patients with rheumatoid arthritis with associated instability or in patients with multiple sclerosis affecting the cervical spinal cord, tumors, and syringomyelia.\(^{50}\)

**Shoulder Depression and Abduction Tests.** The shoulder depression and abduction tests are useful for evaluation of radicular pain. The shoulder depression test is performed by having the patient laterally flex his or her neck while placing downward pressure on the shoulder opposite the direction of flexion. This produces stretch on irritated nerve roots and may accentuate or reproduce radicular symptoms. The shoulder abduction test relieves pressure on the cervical nerve roots and may relieve or reduce cervical radicular symptoms. It is performed by having the patient place the hand from the painful side on the top of their head. This maneuver shortens the distance between the cervical spine and the coracoid process, thus relieving tension on the nerve root.

In vivo studies using kinematic MRI of 21 patients with cervical spine disk herniations or cervical spondylosis demonstrated an increase of foraminal size with flexion, axial rotation to the opposite side of pain, and flexion combined with axial rotation to the opposite side of the pain. Foraminal size decreased at extension combined with axial rotation to the side of the pain. A decrease or no change of foraminal size was observed at either extension or axial rotation to the side of the pain alone. Cervical cord rotation or displacement was noted with axial rotation in 24% of these patients.\(^{51}\) Active versus passive range-of-motion testing is advised in patients with neurologic symptoms or those at risk of instability of the cervical spine (i.e., patients with progressive rheumatoid arthritis involving
the cervical spine). In these patients, limitation of active range of motion due to pain may be protective.

**Adson Maneuver.** This test is used to rule out compression of the subclavian artery by an extra cervical rib or scalene muscle bands, which may result in TOS. It was first described by Alfred Washington Adson in 1927. It is performed by having the patient sit with his or her arms resting on the knees with his or her head extended and rotated toward the affected side. The patient is then instructed to breathe deeply and hold his or her breath while the radial pulse is monitored. The test is considered positive if the radial pulse disappears. More recently, the positioning often includes abduction and external rotation of the arm. Current testing methods include use of Doppler ultrasound to record significant changes in subclavian artery flow characteristics during the earlier mentioned maneuvers. Although the clinical validity of the Adson test has been questioned, a 2006 study showed complete relief of symptoms following surgery in 87% of patients with a positive Adson test using Doppler ultrasound compared to significant relief of pain in only 50% of patients with a negative Doppler-assisted Adson test.

**Halsted Maneuver (Exaggerated Military Position).** The Halsted maneuver is a test of neurovascular compression at the costoclavicular space. The patient assumes a military posture with the shoulders rolled backward and downward so to narrow the costoclavicular space. The radial pulse is monitored. The maneuver is considered positive if the radial pulse disappears.

**Roos Test or Elevated Arm Stress Test.** The Roos or elevated arm stress test (EAST) is a test for TOS during which the patient abducts both arms to 90 degrees with elbows flexed to 90 degrees thus narrowing the scalene triangle. The patient then opens and closes his or her hands for a period of 3 minutes. Patients without TOS will have pain, fatigue, or distress in the forearms only. Patients with TOS will have significant symptomology which replicates their normal TOS symptoms and may not be able to complete the test.

Further diagnostic tests for shoulder pathology are outlined in Table

<th>Maneuver/Description</th>
<th>Diagnosis Suggested by Positive Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Apley scratch test</td>
<td>Patient touches superior and inferior aspects of opposite scapula.</td>
<td>Loss of range of motion of the shoulder: rotator cuff problem</td>
</tr>
<tr>
<td>Neer test</td>
<td>The examiner should stabilize the patient’s scapula with one hand while passively flexing the arm while it is internally rotated. If the patient reports pain in this position, then the result of the test is considered to be positive.</td>
<td>Subacromial impingement syndrome</td>
</tr>
<tr>
<td>Hawkins-Kennedy test</td>
<td>Patient is examined while sitting with shoulder flexed to 90 degrees and their elbow flexed to 90 degrees. Examiner grasps and supports proximal to the wrist and elbow; the examiner and the patient then quickly rotate the arm internally. Pain located below the acromioclavicular joint with internal rotation is considered a positive test result.</td>
<td>Subacromial impingement syndrome</td>
</tr>
<tr>
<td>Drop arm test</td>
<td>Examiner will passively abduct the patient’s shoulder (humerus) to 90 degrees. The patient is then asked to slowly lower or adduct the shoulder to their side. If the patient is unable to perform this motion, the examiner can hold the humerus at 90 degrees of abduction and apply slight pressure to the distal forearm.</td>
<td>Inability to controllably lower the arm can indicate a rotator cuff dysfunction.</td>
</tr>
<tr>
<td>Empty can test</td>
<td>The patient’s arm should be elevated to 90 degrees in the scapular plane, with the elbow extended, full internal rotation, and pronation of the forearm. This results in a thumbs-down position, as if the patient were pouring liquid out of a can. Examiner stabilizes the shoulder while applying a downwardly directed force to the arm; the patient tries to resist this motion. This test is considered positive if the patient experiences pain or weakness with resistance.</td>
<td>Supraspinatus muscle/tendon tear or suprascapular nerve dysfunction</td>
</tr>
<tr>
<td>Lift-off test</td>
<td>Patient stands and places the dorsum of the hand against mid-lumbar spine. The patient then lifts his hand away from the back.</td>
<td>An inability to perform this action indicates a lesion of the subscapularis muscle. Abnormal</td>

<tr>
<td>----------------------</td>
<td>-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
<td>-------------------------------------</td>
</tr>
<tr>
<td>Cross-arm test (scarf test)</td>
<td>With the arm to be tested in 90 degrees of elbow flexion and 90 degrees of shoulder flexion (forward elevation), the patient then cross adducts/horizontally adducts, resting the hand on top of the opposite shoulder. The examiner pushes the arm into further cross/horizontal adduction. The position and movement mimics throwing a “scarf” over the shoulder, hence the name of the test. A positive test is indicated by localized pain over the acromioclavicular joint.</td>
<td>A positive test commonly indicates acromioclavicular joint osteoarthritis or acromioclavicular joint ligament injury.</td>
</tr>
<tr>
<td>O’Brien test (active compression test)</td>
<td>The upper extremity to be tested is placed in 90 degrees of shoulder flexion and 10–15 degrees of horizontal adduction. The patient then fully internally rotates the shoulder and pronates the elbow. The examiner provides a distal stabilizing force as the patient is instructed to apply an upward force. The procedure is then repeated in a neutral shoulder and forearm position. A positive test occurs with pain reproduction or clicking in the shoulder with the first position and reduced/absent with the second position.</td>
<td>Labral (superior labral tear from anterior to posterior or SLAP) lesion or acromioclavicular lesions as cause for shoulder pain</td>
</tr>
<tr>
<td>Apprehension test</td>
<td>Examiner stands either behind or at the involved side, grasps the wrist with one hand, and passively externally rotates the humerus to end range with the shoulder in 90 degrees of abduction. Forward pressure is then applied to the posterior aspect of the humeral head by the examiner or the table (if the patient is in supine). A positive test for anterior instability is if apprehension is presented by the patient or if the patient reports pain.</td>
<td>A positive test indicates a possible torn labrum or anterior instability problem.</td>
</tr>
<tr>
<td>Relocation test</td>
<td>With the patient supine, the examiner pre-positions the shoulder at 90 degrees of abduction and maximal external rotation. The examiner grasps the subject’s wrist and hand with his or her distal hand while applying a posterior force to the humeral head while externally rotating the shoulder. The test is considered positive if the patient is able to be moved into a greater range of external rotation before apprehension is expressed as compared to when there is no posterior pressure exerted by the examiner.</td>
<td>Checks for glenohumeral instability, dislocation, and subluxation This test should be done following the apprehension test especially if anterior instability is suspected.</td>
</tr>
<tr>
<td>Sulcus sign</td>

Examination of the Shoulder and Arm
Detailed anatomy of the neck, shoulder, and upper extremities, including normal range of motion, is covered in the initial part of this chapter and is essential to understanding the anatomic and functional correlates of this
portion of the physical exam. Physical examination of the shoulder, arm, elbow, forearm, wrist, and hand should include the following:

- Blood pressure
- Inspection of position, shape, muscle atrophy, swelling
- Inspection of skin for allodynia, changes in color, temperature, or trophic changes
- Palpation of muscles and tendon for tenderness, pain, trigger points, dysesthesias, and radiation patterns
- Palpation over joints during range of motion testing for crepitus, popping, or locking
- Active and passive range of motion at shoulder: abduction, adduction, internal and external rotation, flexion, and extension at shoulder
- Other tests for shoulder, see Table 68.15
- Range of motion at forearm: flexion, extension, pronation, and supination
- Range of motion at wrist: dorsal flexion, palmar flexion, ulnar flexion, and radial flexion
- Range of motion of fingers: flexion, extension, adduction, abduction, opponens, and grip
- Observation of effect on pain of each movement

**Waddell Signs.** In their study of illness behavior, Waddell et al.\(^54\) described five categories of nonanatomic signs (Table 68.16) and reported that the presence of at least three signs was indicative of significant psychosocial stress. Although the presence of three or more signs is often interpreted as a sign of malingering, no association with malingering or secondary gain has been demonstrated in controlled studies.\(^55\) Fishbain et al.\(^56\) reported that Waddell signs decreased following comprehensive pain management. Pain behaviors are known to be a means for patients to communicate pain and distress. They can be positively reinforced by attention from family members or by being excused from undesirable obligations. Pain behaviors may also be “unlearned” using cognitive and behavioral therapies.\(^57,58\)

1. Superficial and widespread tenderness or nonanatomic tenderness (it is “one” sign)
2. Stimulation tests: axial loading and pain on simulated rotation (it’s another “one” sign)
3. Distracted straight leg raise
4. Nonanatomic sensory changes: regional sensory changes and regional weakness (it’s another “one” sign)
5. Overreaction

LABORATORY EVALUATION

Pain must be seen as a diagnosis of exclusion, for the consequences of treating pain symptomatically in the face of progressive systemic disease can result in a tragic delay of diagnosis and treatment. In general, laboratory testing is guided by the patient’s history of present illness, past medical history, and physical exam. A patient who is systemically ill requires more extensive testing guided by affected organs and systems. For example, patients who are febrile or those with weight loss, anorexia, and other signs suggesting infection or neoplasm would benefit from complete blood count and differential analysis. Those with a history of hepatitis or other risk factors for liver disease would benefit from a liver enzyme panel. Patients with cold intolerance, weight gain, and lethargy should undergo thyroid function test analysis.

Morning stiffness, polyarticular involvement, rigidity, or cutaneous manifestations suggest an inflammatory arthritic component requiring a more extensive rheumatologic evaluation. Patients with a diagnosis of fibromyalgia should undergo testing of both thyroid function and vitamin D levels because hypothyroidism and vitamin D deficiency can both result in diffuse pain syndromes which mimic fibromyalgia.

Laboratory analysis of the erythrocyte sedimentation rate and C-reactive protein may also assist in evaluating inflammatory phenomena such as an autoimmune disease, infection, or neoplasm. These may be significantly elevated with an upward trend in patients who are afebrile, who have a normal white blood cell count, and who culture negative (even in the face of sepsis).\textsuperscript{59,60}

Other laboratory tests which may be useful in ruling out systemic disease in select patients include serum calcium, which among other diagnoses may be elevated in patients with malignancy, and serum alkaline phosphatase, which is elevated in metastatic spine tumors and Paget disease.\textsuperscript{1}
RADIOGRAPHIC STUDIES

Diagnostic and functional imaging is covered in detail in Chapters 18 and 19. In general, imaging of the neck and arm should be performed in patients with a history of trauma, persistent or progressive pain, and in patients with neurologic deficits involving the neck and/or upper extremities in order to confirm or rule out treatable organic causes of pain or neurologic deficits and to guide therapeutic decision making.

Although the clinical usefulness of cervical spine radiographs for evaluation of neck pain has been questioned, cervical spine fractures occur frequently following relatively minor trauma in the elderly patient with a relative risk of up to three times more fractures in elderly versus younger adults evaluated in the emergency room. Although significant cervical spine injury is infrequent in younger patients, diagnosis is often delayed following motor vehicle and sports trauma. In published series, missed cervical spine injuries following trauma have been reported to occur in 4.6% to 33% of patients. C2 and C5–C6 level fractures are the most commonly seen injuries. In a recent report of 100 consecutive patients who underwent operative fixation or halo stabilization for cervical spine injuries, 10% of injuries were missed due to failure to perform plain cervical films versus failure of interpretation or failure to utilize more advanced imaging techniques. A recent prospective, multicenter US study designed to validate clinical criteria developed to evaluate patients with neck pain following blunt trauma confirmed sensitivity of the set of five criteria (Table 68.17) approaching 100% for clinically important injuries.

| No midline cervical tenderness |
| No focal neurologic deficit |
| Normal alertness |
| No intoxication |
| No painful, distracting injury |

NEXUS, National Emergency X-Radiography Utilization Study.

Even fewer injuries were missed in a more recent multicenter study,
when the Canadian C-spine rule was applied (Fig. 68.34). Anteroposterior, neutral lateral, and odontoid plain film views are recommended. A patient with persistent neck pain or tenderness despite normal plain film radiology or suspected ligamentous injury may benefit from flexion-extension views to evaluate for listhesis or instability. These views may also be helpful in determining the amount of motion occurring with flexion and extension in patients with degenerative spondylolisthesis. Prior to flexion-extension imaging, the patient should perform active range of motion in the presence of a physician to confirm that no significant neurologic deficit occurs during these maneuvers.

In patients with chronic neck pain, plain film views can reveal degenerative changes such as loss of disk height, bone spurs, endplate irregularity, and endplate sclerosis. In patients with prior cervical spine fusion, instability secondary to pseudoarthrosis can be appreciated.

Computerized tomography (CT) is recommended for patients with acute or chronic neck pain who have normal plain films and clinically suspected cervical spine pathology or to further define abnormalities seen on plain films. It is also useful for evaluating the size and shape of the spinal canal, facet and uncovertebral joints, and transverse foramina. When possible, patients with neurologic deficits or pain due to suspected neurologic or soft tissue injury or pathology should undergo MRI. According to a systematic analysis and multicenter study comparing CT to MRI for assessment of cervical spine injuries following trauma to the cervical spine, midsagittal T1- and T2-weighted MRI provides an objective, quantifiable, and reliable assessment of spinal cord compression that cannot be adequately assessed by CT alone. MRI and magnetic resonance myelography are comparable to CT myelography in assessing spinal stenosis and spinal nerve roots. Although CT is superior in imaging
canal foraminal osteophytes, MRI is superior to CT in assessment of spinal cord gray matter and nerve root signal changes and well as ligamentous and intervertebral disk changes.\textsuperscript{78} Use of gadolinium-enhanced MRI in symptomatic patients who have undergone surgery of the cervical spine is valuable in identifying changes consistent with postoperative infection in the acute postoperative period and in defining the extent of epidural scar formation versus reherniation of intervertebral disks in patients with recurrent neck and radicular pain.\textsuperscript{79}

If MRI is contraindicated (i.e., due to a pacemaker or spinal cord stimulator), CT using 45-degree oblique reconstruction is superior to sagittal reconstructions oriented at 90 degrees for evaluation of the foramen for bony spurs.\textsuperscript{80}

In regard to imaging of the shoulder, a standard series of shoulder radiographs excludes or confirms arthritis, bursitis, tendonitis, calcification, dislocation, tumor, and old or new fractures.\textsuperscript{81} CT is useful for diagnosing bony lesions, subtle dislocation, labral tears, and full rotator cuff tears. MRI is more expensive, time-consuming, and less readily available in some areas, and certain pathologies such as the glenoid labrum and the surrounding ligaments may be difficult to evaluate with MRI. MRI is able to evaluate partial or full rotator cuff tears and has the advantages of noninvasive nature, lack of contrast exposure, nonionizing radiation, high degree of resolution, and ability to evaluate multiple pathologies.

Ultrasound is used to diagnose rotator cuff tears, is noninvasive, rapid, and relatively inexpensive; however, it has been shown to have more interoperator variability in performance and interpretation of imaging.\textsuperscript{81–85}

Advanced imaging as well as electromyography and nerve conduction velocity testing should be performed as needed for the purpose of guiding treatment decision making. Electrodiagnostic evaluation of acute and chronic pain is discussed in Chapter 16.

Multiple plain radiographic views are often needed to visualize the elbow, forearm, wrist, and hand and can also be used to confirm or rule out fractures, tendonitis, and dislocations. Minimal evaluation of the elbow should include anteroposterior views for the distal humerus and proximal forearm as well as lateral views in maximal flexion and extension. Additional views such as radiocapitellar, cubital tunnel, oblique, and stress
views may be utilized based on history or mechanism of injury and physical exam findings.¹

Common Causes of Neck and Arm Pain

MECHANICAL NECK PAIN AND CERVICOGENIC HEADACHE

Neck pain from similar mechanisms may be axial, associated with radicular pain, headache, and/or symptoms suggesting spinal cord compression. The complex and highly interdependent structures of the neck may preclude identification of a single pain generator in patients with advanced disease. Muscle and ligamentous injury or pain may result from factors related to posture, poor ergonomics, stress, injury, and/or chronic muscle fatigue. Pain may also result from degenerative changes of the cervical facet joints and disks and atlantooccipital and atlantoaxial joints and irritation, inflammation, and mechanical distortion of the cervical nerve roots and spinal cord. These processes may occur independently or concurrently and require a careful history and physical examination together with the judicial use of diagnostic tests to rule out systemic disease and rapidly progressive processes. Recent data reports a 12-month prevalence of 30% to 50% for neck pain and associated disorders in adults.³ A knowledge and application of recent prospective studies, systemic reviews, and meta-analysis proposing guidelines for evaluation and treatment of these patients may assist with assessing the risk versus benefit for effective conservative versus interventional and surgical therapies in this large and heterogeneous population.

Cervical Spondylosis and Radiculopathy

Degenerative changes of the cervical spine reach a prevalence of nearly 95% by age 65 years. These changes are associated with positive changes such as disk protrusion, neural foraminal narrowing, and spinal cord contour changes in up to 78% of asymptomatic individuals.⁷–⁹,⁸⁶ In symptomatic individuals, the risk versus benefit of surgery and other interventional therapy⁸⁷ mandates an understanding of the natural course of symptomatic patients with cervical spondylosis and radiculopathy.
Although the outcome of these patients when treated conservatively versus surgically is controversial, recent investigations reveal clinical and radiographic correlates with outcome in this population, which may be of assistance in timely surgical referral when symptoms continue to progress following conservative treatment. 

Cervical spondylosis was first distinguished from acute cervical disk protrusion by Brain et al. in 1948. The latter occurs more commonly in individuals younger than age 55 years, is often traumatic in origin, and most frequently compresses the nerve roots versus the spinal cord. The former is a chronic degenerative condition of the cervical spine associated with formation of osteophytes. It is a universal finding associated with aging and is associated with compression of the spinal cord in most symptomatic cases. Patients older than age 55 years are more likely to have central canal or neural foraminal stenosis due to spondylosis. In a population-based study conducted from 1976 to 1990 in Rochester, Minnesota, a confirmed disk herniation was found to account for approximately 20% of all cervical radiculopathies and approximately 70% of all spondylosis. The average age-adjusted incidence rate per 100,000 population was 107.3 for males, 63.5 for females, and reached a peak of 202.9 for the age group between ages 50 to 54 years. 

Spondylosis refers to degenerative changes of the spine involving the intervertebral disks, uncovertebral joints of Lushcka, zygapophyseal joints, ligaments, and connective tissue of the cervical vertebrae. Degenerative changes of the cervical spine are seen in approximately 10% of individuals by age 25 years and in 95% by age 65 years. The process is believed to begin with fibrosis and loss of elasticity of the disk which occurs with loss of water, protein, and mucopolysaccharides from the nucleus pulposus. Loss of disk space height initially occurs ventrally and leads to loss of cervical lordosis. This shift of biomechanical forces results in ventral vertebral body compression with resultant pathologic cervical spine kyphosis, dissection of the annulus fibrosus, posterior longitudinal ligament, and Sharpey’s fibers away from the edges of the posterior vertebral body, formation of reactive bone on the edges of exposed dorsal vertebral bodies, and increased axial load bearing by the uncovertebral and zygapophyseal joints, with resultant hypertrophy and osteophytic growth.
formation ventral and posterior to the neural foramen.

Spondylotic spurs may eventually span the width of the vertebral canal in some patients. Because the osteophytes form in response to increased motion or segmental instability, the levels most commonly affected, both by disk herniation and chronic spondylosis are C6–C7 followed by C5–C6 because these are the cervical segments at which the most extension and flexion occur.

The reduction in sagittal spinal canal diameter in cervical spondylosis results from a combination of static and dynamic factors. Static reduction of the sagittal diameter of the spinal canal occurs from disk herniation or bulging; vertebral body osteophyte growth into the anterior spinal canal; and degenerative hypertrophy of the uncovertebral joints, facet joints, and ligamentum flavum combined with calcification of the posterior longitudinal ligament. The addition of dynamic factors such as flexion, extension, or subluxation can further increase the risk for compression and injury to the contents of the spinal canal and neural foramen including the spinal cord, nerve roots, arteries, and veins. These combined pathologic features are thought to be responsible for the production of the wide spectrum of clinical symptoms associated with cervical spondylosis including neck and shoulder pain, occipital pain and headaches, radicular symptoms, and cervical radiculopathies and cervical spondylotic myelopathy (CSM). Compression of the spinal cord may occur from spondylotic bars and calcified posterior longitudinal ligament ventrally or from the hypertrophic ligamentum flavum dorsally. Cumulative repetitive injury to the spinal cord is thought to occur with flexion, due to a “bowstring effect” over the ventral spondylotic bars and kyphotic spine, and compression dorsally by buckling of the ligamentum flavum. MRI flexion and extension studies observed increased cervical stenosis in twice as many patients during extension versus flexion. Risk for compression of the spinal cord is increased in individuals with congenital narrowing of the spinal canal.

CSM refers to clinically evident spinal cord dysfunction with the presence of long-tract signs due to compression of the spinal cord. Weakness or stiffness in the legs with unsteady gait together with weakness or clumsiness of the hands is pathognomonic of CSM.
Progression of weakness may be gradual in some patients or sudden in others following minor trauma. In a prospective study at a UK regional neuroscience center, 23.6% of 585 patients admitted with tetraparesis or paraparesis were found to have CSM. Some patients may complain of hesitancy on urination; however, loss of sphincter control or urinary incontinence is rare and considered a late sign of myelopathy.

Patients with CSM generally present with neck and shoulder pain and stiffness. The patient may also present with pain in the arm, elbow, wrist, or fingers described as combined or isolated sensations of stabbing, dull, or aching pain. Arm pain may be nondermatomal in distribution and accompanied by numbness or tingling in the hands. Pain which conforms to a dermatomal distribution with associated motor and sensory deficits is referred to a radiculopathy rather than myelopathy. Some patients may present with both myelopathy and radiculopathy.

Signs of CSM on physical exam include an electrical sensation radiating down the back to the legs with flexion of the neck (Lhermitte’s sign); atrophy of the intrinsic musculature of the hands; and variable sensory, vibratory, or proprioceptive loss in the extremities. Deep tendon reflexes may be reduced or absent at the level of compression with hyperreflexia below the level of the lesion together with upper motor signs such as clonus, Hoffmann, and Babinski sign.76,93,97,98

There are two commonly used classification systems for CSM. The classification of Crandall and Batzdorf99 divides CSM patients into five groups of spinal cord dysfunction. These include the transverse lesion syndrome, the motor system syndrome, the central cord syndrome, the Brown-Séquard syndrome, and the brachialgia cord syndrome. These are summarized in Table 68.18. Ferguson and Caplan100 categorize CSM into four overlapping syndromes, which are summarized in Table 68.19.

| TABLE 68.18 Crandall and Batzdorf99 Classification of Clinical Syndromes in Cervical Spondylotic Myelopathy |
|--------------------------------------------------|--------------------------------------------------|
| Transverse lesion syndrome                      | Most common lesion. Involves posterior column, spinothalamic and corticospinal tracts, and often anterior horn cells. Posterior column involvement uncommon and late. |
| Motor system syndrome                            | Involves anterior horn cells and corticospinal tracts primarily. Little sensory involvement. Upper and lower extremity weakness, gait disturbance, and spasticity. |
Central cord syndrome  Upper extremities weaker than lower extremities. Profound hand weakness. Posterior column involved often presenting as painful paresthesias of hands.

Brown-Séquard syndrome  Unilateral spinal cord dysfunction. Involvement of corticospinal tract. Posterior column sensory loss (position, vibration) and long tract motor signs (hemiplegia) are found ipsilateral to the lesion, whereas pain and temperature are lost contralaterally. One or two levels below highest level of motor involvement.

Brachialgia cord syndrome  Upper extremity nerve root compression combined with long tract signs (analogous to Ferguson and Caplan’s combined medial and lateral syndrome).

### TABLE 68.19 Ferguson and Caplan Classification of Clinical Syndromes in Cervical Spondylotic Myelopathy

<table>
<thead>
<tr>
<th>Syndrome</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lateral syndrome</td>
<td>Represents a spondylotic radiculopathy. Absence of long tract signs.</td>
</tr>
<tr>

</table>

The differential diagnosis of CSM includes amyotrophic lateral sclerosis, multiple sclerosis, hereditary spastic paraplegia, spinal cord tumors, and subacute combined degeneration of the spinal cord associated with vitamin B$_{12}$ deficiency.

MRI is the imaging technique of choice for evaluating the patient with CSM. T2- and T1-weighted signals on MRI have been found to correlate with various degrees of injury to the spinal cord on histologic studies. Edema is seen as a high-intensity T2-weighted image. Necrotic changes in the gray matter correspond to low signals on T1-weighted studies but high signals on T2-weighted studies. T1-weighted hypointensity is an expression of irreversible damage and, therefore, the worst prognosis.$^{92,101}$ A less favorable surgical outcome is predicted by the presence of a T1-weighted hypointense signal and the presence of clonus or spasticity. A high intramedullary T2-weighted signal without clonus or spasticity is associated with a more favorable surgical outcome with a greater
A recent investigation reported multiple regression analysis of various risk factors associated with surgical outcome. According to this analysis, the most significant prognostic factor was the transverse area of the spinal cord, followed by the duration of symptoms and the presence of multisegmental areas of high-signal intensity on T2-weighted MRI. The latter was associated with upper extremity muscle atrophy and less favorable surgical recovery of neurologic function.

Controversy exists regarding optimal treatment for patients with CSM, and many authors recommend conservative treatment due to significant risks associated with surgery and lack of data supporting long-term improved outcome in patients undergoing surgery versus conservative care. A recent prospective 3-year follow-up study did not show, on average, that the effects of surgery in the treatment of mild and moderate forms of CSM were better than the conservative approach. Nevertheless, there was a slight but statistically significant increase in the number of patients with a negative trend in the score for daily activities in the conservatively treated group. The authors of this study recommend conservative treatment for patients with mild CSM along with careful follow-up evaluation and reassessment 3 months after the start of conservative treatment. Decompression surgery is recommended for patients who experience neurologic deterioration during this period. A prospective, multicenter study with independent clinical review evaluating conservative versus surgical treatment for patients with moderate to severe CSM found that although surgical treatment was not found to improve neurologic outcome, overall pain and functional status improved significantly. When medical and surgical treatments were compared, surgically treated patients appeared to have better outcomes, despite exhibiting a greater number of neurologic and nonneurologic symptoms and greater functional disability before treatment.

Conservative treatment for CSM consists of intermittent cervical immobilization with a soft collar, the use of anti-inflammatory medications, active discouragement of high-risk activities, and avoidance of risky environments involving physical overloading, excess cold, movement on slippery surfaces, manipulation therapies, or vigorous or
prolonged flexion of the head. Additional conservative measures include a rehabilitation program with physiotherapy and referral to a multidisciplinary pain team. Patients with moderate to severe symptoms on presentation and progressive neurologic symptoms should be referred for surgical evaluation. The aim of the surgery in these patients is to stop the progression of neurologic deterioration and prevent sudden deterioration after minor injury or in particular situations such as swimming, cycling, and physical overloading.88,89

Cervicogenic Headache
The term cervicogenic headache (CEH) was coined by Sjaastad et al.107 in 1983. He later organized the Cervicogenic Headache International Study Group (CHISG), and diagnostic criteria for CEH were published by the CHISG in 1990.108 A revision of criteria for CEH was published by the CHISG in 1998.109

CEH was recognized as a unique category of headaches by the International Association for the Study of Pain in 1994, using criteria similar to that published by Sjaastad et al.110 Revised criteria for CEH were published by the International Headache Society (IHS) in 2004.111

Although controversy exists regarding the defining characteristics and prevalence of CEH, there is emerging evidence of valid clinical, diagnostic, and therapeutic criteria which differentiates this syndrome from migraine headache, tension-type headache, hemicrania continua, and chronic paroxysmal hemicrania.112,113

CEH is defined as unilateral head or face pain which starts in the neck and is triggered by neck movement or sustained awkward neck posture. Although pain begins in the neck or occipital region, it may spread to the retroorbital, temporal, and frontal areas of the head and face where maximum pain may be perceived. Pain may occur to a lesser degree on the contralateral side; however, profound unilateral dominance should exist. CEH is typically described as deep and nonthrobbing with intermittent attacks lasting hours to days. In time, headaches may become constant with superimposed attacks of more intense pain. Pain in CEH should be reproducible upon palpation or stimulation of cervical spine or neck structures. It is accompanied by reduced range of motion of the neck and
ipsilateral nonradicular neck, shoulder, or arm pain. Nausea, vomiting, photophobia, dizziness, blurred vision, lacrimation, and conjunctival injection may occur.

The new IHS criteria requires clinical, laboratory, or imaging evidence of a lesion or disorder within the neck or cervical spine known to be associated with the causation of headache. This should be validated by reproducible clinical signs or by controlled diagnostic blockade (Tables 68.20 and 68.21 show comparison of IHS and CHISG criteria for CEH).

Only marginal effect or lack of effect of ergotamine and sumatriptan
Female sex
Not infrequent occurrence of head or indirect neck trauma by history, usually of more than only medium severity

Other Features of Lesser Importance
F. Various attack-related phenomena, only occasionally present and/or moderately expressed when present
   1. Nausea
   2. Phonophobia and photophobia
   3. Dizziness
   4. Ipsilateral “blurred vision”
   5. Difficulties on swallowing
   6. Ipsilateral edema, mostly in the periocular area

The prevalence of CEH in the literature varies widely from 0% to 80%, depending on the population of patients studied, diagnostic criteria, and methodology. A recent Norwegian study reported that 75% of tractor drivers suffered from moderate to severe generalized headache only when working on their tractor because of consecutively turning or twisting their neck for many hours daily. In a series of 100 consecutive patients with neck pain following whiplash, Lord et al. reported a prevalence of associated headache in 88%. Of those patients with headache as the dominant symptom, 54% were found to have neck pain originating from a C2–C3 cervical zygapophyseal joint following diagnostic blocks. This was associated with tenderness over the affected joint on physical examination. In a study of 34 patients with the complaint of headache emanating from the occipital region, tenderness to exam over the tip of the transverse process of C1 and worsening of their usual headache with passive rotation of the C1 vertebra, 60% were found to have complete relief of their pain following diagnostic blockade of the atlantoaxial joint. Pain maps based on regions of the head and neck in which patients were relieved of pain following controlled blocks revealed radiation of pain from the C1–C2 through the C3–C4 facet joints to the suboccipital and occipital regions as well as the vertex, frontal, orbital, and temporoparietal region of the head.

The anatomic basis by which pain from the cervical spine and neck can be perceived in the face and head derives from the convergence of afferents from the trigeminal nerve with those of the first three spinal

3650
nerves in the caudal aspect of the trigeminal nucleus in the brainstem.\textsuperscript{117,118} Musculoskeletal structures innervated by the first three cervical nerves are outlined in Table 68.22. Convergence with the spinal trigeminal nucleus and the extradural convergence of the first three cervical nerves may account for the difficulty encountered in localizing the pain in patients with CEH.

\hline
\end{tabular}
\caption{Musculoskeletal Structures of the Neck Innervated by C1 through C3}
\end{table}

The anatomy of the sinuvertebral nerve may also contribute to the variation of pain patterns among patients and the presence of diffuse neck and head pain in the presence of discrete injuries. The sinuvertebral nerves supply structures within the spinal canal. They arise from the rami communicantes and enter the spinal canal by way of the intervertebral foramina. Branches ascend and descend one or more levels, interconnecting with the sinuvertebral nerves from other levels and innervating the anterior and posterior longitudinal ligaments dura mater and blood vessels as well as sending nociceptive fibers to degenerative intervertebral disks.\textsuperscript{119,120} Neurogenic inflammation from compression ischemia of the cervical nerve and inflammatory response following exposure of spinal tissues to proinflammatory mediators such as phospholipase A2 from extruded nucleus pulposus may also contribute to neck pain and CEH.

In addition to the evidence of atlantoaxial and zygapophyseal joint evidence discussed earlier, there is evidence that CEH may arise from a discogenic origin. Reproduction of patient’s usual headache by cervical provocation discography has been reported, as has relief of headache following decompressive surgery of the upper and lower cervical spine.\textsuperscript{121,122} The mechanisms by which headaches are provoked by levels
below C3 have caused speculation regarding the possibility of convergence of afferents from lower spinal nerves with trigeminal afferents in the spinal trigeminal nucleus. An alternate explanation could lie in the anatomy of the sinuvertebral nerves, which descend from higher levels in the cervical spine to communicate with those at lower levels. An inflammatory response could also be causative with proinflammatory mediators resulting from disk degeneration at lower cervical spinal segments precipitating a nociceptive response at adjacent spinal segments.\textsuperscript{119}

Greater and lesser occipital nerve injections using local anesthetic and/or steroid have been reported as useful for diagnosis and short-term relief of CEH. Many authors consider entrapment of the greater occipital nerve to be one of the major underlying causes of CEH.\textsuperscript{123–125} A recent controlled trial of nerve stimulator-guided greater and lesser occipital nerve blocks with adjuvant agents provided greater than 50% relief versus placebo with significant reduction of associated headache features and medication use in the treatment group.\textsuperscript{126} A case report of pulsed radiofrequency for the treatment of intractable occipital headache reported 70% relief for 4 months followed by an additional 5 months of 70% relief with repeat pulsed radiofrequency.\textsuperscript{127}

Percutaneous radiofrequency cervical medial branch neurotomy has been shown, in a rigorous double-blind controlled trial, to provide relief in 70% of patients diagnosed with cervical zygapophyseal joint pain following whiplash injuries. Other therapies found to have efficacy in the treatment of CEH include the physical therapy modalities of manipulation and/or mobilization in conjunction with exercise and intramuscular lidocaine injections. In chronic neck disorders associated with a radicular component, epidural injection of methylprednisolone and lidocaine improved pain greater than cervical intramuscular injections with the same solution at 1-year follow-up.\textsuperscript{128–130}

**DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS**

DISH is a form of osteoarthritis that is characterized by the calcification and ossification of soft tissues including ligaments and tendons. It may involve both the peripheral joints and the axial skeletal structures in 25%
and 15% of men and women, respectively, who are older than 50 years of age. Its prevalence increases to 35% and 26%, respectively, in individuals older than 70 years. Classical axial involvement results in calcification of the ligamentum flavum in the lumbar spine, the anterior longitudinal ligament in the thoracic spine, and the posterior longitudinal ligament in the cervical spine. It is distinguished from degenerative spondylosis of the spine by earlier onset; sparing of the intervertebral disk; and its association with a number of risk factors including diabetes mellitus, obesity, hyperuricemia, dyslipidemia, hypertension, coronary artery disease, and prolonged use of isoretinal (vitamin A supplementation).

The patient with DISH typically presents with stiffness and decreased range of motion. Older patients with cervical spine involvement may complain of dysphagia due to pharyngeal encroachment from large anterior osteophytes. Other potential sequelae include cervical myelopathy and cervical spine fractures following relatively trivial trauma. The diagnosis of cervical spine fractures is often delayed due to the presence of baseline neck and spine pain.

The diagnosis of DISH is radiographic and is based on the criteria established by Resnick and Niwayama. These include the presence of “flowing” ossification along anterolateral margins of at least four contiguous vertebrae and the absence of changes associated with degenerative spondylosis. Treatment consists of conservative measures similar to cervical degenerative spondylosis. Operative treatment is reserved for those patients who fail to respond to conservative measures.

CERVICAL RADICULOPATHIES
The classical definition and clinical manifestation of cervical radiculopathies is pain, sensory loss, and motor weakness in the distribution of the affected nerve root. Although the cause of radicular symptoms has been presumed to be secondary to compression of the nerve root because of adjacent soft disk herniation or progressive degenerative changes of the cervical spine, the poor correlation between radiologic evidence of degenerative change and incidence of painful symptoms in the cervical spine has been well documented. Other factors thought to
contribute to the pathogenesis of radiculopathic symptoms include vascular insufficiency, venous engorgement, nerve root fibrosis, and inflammation. Type-C cell distortion in dorsal root ganglion of cervical nerve roots has been proposed as a mechanism of accentuated neuropeptide production and increased hypersensitivity in patients with acute and chronic neural foraminal compression or edema. The patient with cervical radiculopathy typically complains of burning, aching, cramping, electrical, or sharp pain which radiates to the neck and head, shoulder, arm, or chest depending on the involved nerve root(s). In acute radiculopathy, pain classically presents in a myotomal distribution versus a distal dermatomal distribution. The pain is generally accompanied by numbness and paresthesias. Motor weakness and diminution or loss of deep tendon reflexes may also be seen. Spurling’s maneuver, Valsalva, coughing, and sneezing will often provoke or aggravate the patient’s symptoms, whereas the shoulder abduction sign (having the patient abduct the shoulder and place their hand on top of their head) will generally relieve their pain.

The C1 nerve passes between the occiput and C1. It is also known as the suboccipital nerve and supplies sensory fibers to the periosteum and body of the atlas, occiput, atlantooccipital joint, and atlantoaxial joint. It is also distributed to the muscles of the suboccipital triangle. The C2 nerve passes between C1 and C2. The medial or sensory branch of C2 is also known as the greater occipital nerve. It supplies the scalp over the vertex and top of the head and supplies muscular branches to the semispinalis.

C3 arises between C2 and C3. The medial sensory branch of the posterior division of the third cervical nerve forms the third or least occipital nerve. The anterior rami of the upper four cervical nerves communicate to form the cervical plexus. Pathologic processes which affect the C1 through C3 nerves cause pain radiating to the head and neck. Pain of the upper cervical spine was covered in more detail in the section on CEHs. The greater auricular nerve and the anterior cutaneous nerve are also derived from the second and third cervical nerves. Processes affecting these nerves can also result in pain involving the mastoid process, the lobule and concha of the ear, the skin of the face over the parotid gland, and the skin of the anterolateral aspect of the neck as far as
the sternum. Via the deep cervical plexus, the second and third cervical nerves also communicate with the vagus, the hypoglossal nerve, the superior cervical sympathetic ganglion, and the diaphragm by way of the phrenic nerve (see Table 68.3).

Radiculopathy of the fourth cervical nerve root results from pathologic changes between the C3 and C4 vertebrae and is more common than a C3 radiculopathy. The supraclavicular nerve arises mainly from the fourth cervical nerve and supplies the skin and superficial fascia of the clavicular region, the periosteum, and bony structure of the clavicle as far as the midline and the skin over the pectoralis major as far as the second or third rib. It additionally communicates with the cutaneous branches of the second and third rib. The lateral supraclavicular nerve supplies the skin of the top and dorsal parts of the shoulder. Involvement of the C3 nerve may be a cause of unexplained pain along the base of the neck that radiates to the superior aspect of the shoulder and posteriorly to the scapula. Pain in the distribution of the supraclavicular nerve may also be a cause of chronic breast pain in women.

The rhomboid, trapezius, and levator scapulae muscles are supplied in part by the fourth cervical nerve root, but a motor deficit may be difficult to detect. A sensory deficit may be present over the anterolateral aspect of the neck, along the distribution of the transverse cervical and supraclavicular nerves. Because the C3, C4, and C5 nerve roots innervate the diaphragm, involvement of these three nerve roots may lead to diaphragmatic weakness.

The brachial plexus is formed by the fifth, sixth, seventh, and eighth cervical nerves together with the first thoracic nerve and frequently contributing branches from the anterior division of the fourth cervical and second thoracic nerve. The variation of brachial plexus and extradural cervical nerve connections may contribute to variations in radicular patterns among patients.

Pathologic changes at the C4–C5 level result in a C5 radiculopathy. The principal motor deficit seen in classical C5 radiculopathy is supraspinatus and deltoid muscle weakness with impaired shoulder abduction. Weakness of the clavicular head of the pectoralis major, biceps, and infraspinatus muscles can also occur. The pectoralis reflex and the biceps reflex, which
are innervated by the fifth and sixth cervical nerve roots, may be decreased or absent. The numbness follows the C5 sensory distribution, which is located over the top of the shoulder along its midportion, and extends laterally to the midportion of the arm. The component fibers of the suprascapular nerve are derived primarily from the fifth and sixth cervical nerves. It supplies sensory, motor, and sympathetic fibers which supply the supraspinatus and infraspinatus muscles, the shoulder joint, and periarticular structures as well as an area of skin at the apex of the shoulder. Patients often present with numbness and localized shoulder pain that can be confused with a pathologic shoulder condition. The absence of pain with a range of motion of the shoulder and the absence of impingement signs at the shoulder help to differentiate radiculopathy of the fifth cervical nerve root from a pathologic shoulder condition.

The sixth cervical nerve root is the second most commonly involved in cervical radiculopathy. Patients with pathology at this level typically present with pain radiating from the neck to the lateral aspect of the biceps, lateral aspect of the forearm, dorsal aspect of the web space between the thumb and index finger, and into the tips of those digits. Numbness occurs in the same distribution. Motor deficits are best elicited in the wrist extensors, but weakness of the biceps, supinator, pronator, teres, and triceps muscles may be present. The brachioradialis and biceps reflexes may be decreased or absent. The pain and paresthesias of C6 radiculopathy may mimic carpal tunnel syndrome (CTS), which is caused by median nerve entrapment at the transverse carpal ligament.

The seventh cervical nerve root is most frequently involved by cervical radiculopathy according to many clinical studies. The patient with C7 radiculopathy complains of pain radiating along the back of the shoulder, often extending into the scapular region, down along the triceps, along the dorsum of the forearm and into the dorsum of the long finger. Motor weakness is most often appreciated in the latissimus dorsi muscle, the triceps, wrist flexors, and finger extensors. The triceps reflex may be lost or diminished. Entrapment of the posterior interosseus nerve may be mistaken for the motor component of seventh cervical radiculopathy and presents with weakness in the extensor digitorum communis, extensor pollicis longus, and extensor carpi ulnaris. With entrapment of the
interosseus nerve, sensory changes are absent and the triceps and wrist flexors show normal strength.

Pathology at the C7–T1 level results in radiculopathy of the eighth cervical nerve root. Patients with a C8 radiculopathy generally present with sensory changes extending over the medial aspect of the arm and forearm and into the medial hand and the fourth and fifth digits. Numbness usually involves both the dorsal and volar aspects of the digits and hand and may extend proximal to the wrist over the medial aspect of the forearm. Weakness may involve the small muscles of the hand, particularly the interossei, and the flexors and extensors of the wrist and fingers (with the exception of the flexor carpi radialis and extensor carpi radialis muscles). This may cause patients to complain of difficulty using their hands for routine tasks such as buttoning shirts and grasping objects. Compression of the C8 nerve root may initially be difficult to differentiate from ulnar entrapment at the elbow. C8 nerve root compression may affect the function of the flexor digitorum profundus in the index and long fingers, the flexor pollicis longus in the thumb, and the pronator quadratus, but these muscles are not affected by entrapment of the ulnar nerve. Also, the short thenar muscles, except for the adductor pollicis, may be involved with C8 or T1 compression but are spared with ulnar nerve involvement. Furthermore, sensory changes seen with ulnar neuropathies include numbness, tingling, and/or pain in the fourth and fifth fingers and the hand just below these fingers but not proximal to the wrist (medial antebrachial cutaneous nerve distribution), as may be seen with C8 radiculopathy. Anterior interosseus nerve entrapment may also mimic C8 or T1 radiculopathy but lacks sensory changes, and thenar muscle involvement is absent.

Although uncommon, occurrence of T1–T2 disk herniations or other pathology at this level may result in a T1 radiculopathy. The T1 nerve is the main contributor to the adductor pollicis, the thenar muscles, the interossei, and the first two lumbricals. Classic T1 radiculopathy results in intrinsic hand weakness. Numbness occurs in the axilla, and Horner syndrome can occur ipsilaterally.¹,⁹⁸,¹⁴²

Epidemiologic data suggest that up to 90% of patients with cervical radiculopathy improve with conservative medical treatment
However, due to lack of standardized diagnostic criteria and comparative randomized controlled trials comparing conservative with surgical treatment, evidence-based guidelines have been difficult to establish.

Conservative therapy in patients with cervical radiculopathy includes activity modification, education, and physical therapy with progressive passive and active modalities. Pharmacologic therapy requires a large armamentarium of medications due to the heterogeneity in this patient population and the various mechanisms involved in the production of neuropathic pain. Options include over-the-counter analgesics, anticonvulsants, tricyclic antidepressants, and selective serotonin norepinephrine reuptake inhibitors, topical anesthetic agents, nonsteroidal anti-inflammatory drugs, antiarrhythmics, muscle relaxants, nonnarcotic analgesics, and opioids. Multiple studies including a recent systematic review support the efficacy of interlaminar cervical epidural steroid injections for the management of cervical radiculitis, discogenic pain without facet joint pain, and postsurgery syndrome. Use of fluoroscopic guidance in interlaminar epidural steroid injections and use of nonparticulate steroid in transforaminal injections may significantly reduce the risk of complications.

Outcome in patients with cervical radiculopathy following medical versus operative treatment was recently reported following a prospective, multicenter study with independent clinical review. Comparison of results of patients undergoing medical versus surgical treatments showed that, although both medically and surgically treated patients reported statistically significant improvement in their overall pain, more improvement was observed in the surgery group. Improvement in worst pain and average pain was also statistically significant in both groups. Surgically treated patients had more neurologic and nonneurologic symptoms and more functional disability before treatment. However, despite high satisfaction in surgically treated patients, a significant number of patients continued to report horrible or excruciating pain, multiple neurologic symptoms, and minimal or no work activity. These results are similar to those in patients with CSM in that the majority of patients improve with conservative therapy, whereas those with persistent severe...
pain and progressive neurologic symptoms are generally referred for operative management, which attempts to improve pain and arrest the progression of neurologic symptoms.\textsuperscript{89,145}

**UPPER EXTREMITY PERIPHERAL NERVE ENTRAPMENT SYNDROMES AND BRACHIAL PLEXUS NEUROPATHY**

Acute trauma with resultant fibrosis and scar tissue, chronic trauma from overuse injuries, or space-occupying lesions can result in entrapment of peripheral nerves. An understanding of peripheral nerve distribution and common entrapment sites is essential for the diagnosis and treatment of peripheral nerve entrapment syndromes. Entrapment typically occurs at sites where a segment of nerve passes through a fibro-osseous tunnel or through an opening in fibrous, tendinous, or muscular bands of tissue. Sustained mechanical compression and ischemia may result in neurapraxia. Peripheral nerve entrapment syndromes typically present with pain at the site of entrapment. Pain can radiate both distally and proximally to this point. Sensory, motor, or sympathetic changes can occur in the nerve distribution distal to the site of entrapment.

The diagnosis of nerve compression or nerve entrapment is based on a careful history of the mechanism of injury or repetitive use and a thorough physical exam together with neurologic and electrodiagnostic examinations. MRI is helpful in identifying the cause of the neuropathy, identifying the site of entrapment based on muscle denervation patterns, and detecting unsuspected space-occupying lesions.\textsuperscript{152,153} Nerve entrapment and radiculopathies may infrequently exist simultaneously. In a retrospective analysis of 12,736 cases of CTS and ulnar neuropathy at the elbow, 435 (3.4\%) of these cases were found to have a coexisting cervical root lesion. However, lesions were on the same nerve in only 98 (0.8\%) of these cases.\textsuperscript{154} Upper extremity nerve entrapment syndromes are characterized in Table 68.23. Two most common nerve entrapment syndromes of the upper extremity, CTS and cubital tunnel syndrome (CuTS), are discussed in the following text in greater detail.

Carpal Tunnel Syndrome

CTS is the most common upper extremity entrapment syndrome estimated to affect 3% to 6% of adults in the United States. Risk factors for the development of CTS include age, smoking, obesity, rheumatoid arthritis, diabetes, lupus, hypothyroidism, acromegaly, flexor tenosynovitis, ganglion, pregnancy, multiple sclerosis, work with vibrating tools, and repetitive hand and wrist tasks. CTS is more common in women, with higher risk in those taking birth control pills and those going through menopause. The incidence of CTS is also high in wheel chair athletes, cyclists, wrestlers, and football athletes (from blocking technique).

It is useful to review the anatomy of the carpal tunnel, the fibro-osseous outlet which lies between the flexor retinaculum, and the carpal bones. Its contents include the tightly packed median nerve and nine extrinsic flexor tendons of the thumb and fingers. Pressure within the carpal tunnel averages 2 to 31 mm Hg in healthy individuals and as high as 32 to 110 mm Hg in patients with CTS. Carpal tunnel pressure increases up to 8-fold with wrist flexion and 10-fold with wrist extension.

The clinical diagnosis of CTS includes a history of paresthesia affecting
the median nerve distribution (generally the thumb and first two and a half fingers although some patients complain of paresthesias radiating up the arm to the shoulder), often bilaterally but initially in the dominant hand in most patients. Other signs and symptoms may include brachialgia paraesthetica nocturna, thenar atrophy, loss of two-point sensory discrimination, and reduced manual dexterity. Clinical diagnosis includes a positive Phalen test (sustained wrist flexion for 60 seconds [78% to 80% sensitivity and 73% to 83% specificity]), Tinel sign (reproduction of paresthesias in median nerve distribution with percussion over the carpal tunnel at the wrist [20% to 50% sensitivity and 76% to 77% specificity]), and Durkan or carpal compression test (87% sensitivity and 90% specificity). Electrodiagnostic studies (EDS) have a 49% to 84% sensitivity and a 95% to 99% specificity. Although EDS are often used to confirm clinical diagnosis, other more expensive imaging modalities may be indicated in complex cases to rule out additional suspected etiologies of patient symptomology.

In regard to treatment of CTS, although patients with mild to moderate symptoms may respond to conservative treatment, with splinting and steroid injections having the best evidence of nonoperative treatments, several high-quality studies have demonstrated superior outcome with operative versus nonoperative treatment of CTS.\textsuperscript{155,156}

**Cubital Tunnel Syndrome**

Second only to CTS, CuTS is the second most common nerve entrapment syndrome in both the general population and due to sports. CuTS occurs slightly more in males versus females, increases with age and is seen more frequently in occupations with frequent elbow flexion such as carpenters, musicians, and painters. It is seen in athletes from sports such as baseball, wrestling, and football. Risk factors also include prolonged pressure over the forearm with the elbows in a flexed position such as when resting forearms on a hard surface.

The cubital tunnel consists of the medial epicondyle medially, the olecranon laterally, the elbow capsule at the posterior aspect of the ulnar collateral ligament which forms the floor of the cubital tunnel, and the deep forearm fascia of the flexor carpi ulnaris and the arcuate ligament of
Osborne or cubital tunnel retinaculum which forms the roof. The ulnar nerve is most commonly compressed beneath Osborne’s ligament, although it may also be compressed proximately at the arcade of Struthers and distally by the deep pronator aponeurosis. Intraneural pressure sharply increases with elbow flexion greater than 90 degrees.

Clinical signs and symptoms in patients with CuTS include pain localized to the elbow or radiating to medial forearm and wrist, atrophy of intrinsic hand muscles, flexion weakness of the fourth and fifth fingers, and sensory deficit in fourth and fifth fingers. Weakness of the interossei may result in Wartenberg sign (inability to fully adduct the small finger with finger held abducted and extended). Weakness of the adductor pollicis may result in Froment sign (positive Froment sign consists of flexion of interphalangeal [IP] joint of the thumb as compensation for weakness of adductor pollicis by using the flexor pollicis longus when asked to perform a pinch). Weakness of the ulnar lumbrical muscles may result in claw hand deformity. Routine provocative testing also includes ulnar nerve percussion at the retrocondylar groove and the elbow flexion test. In more severe CuTS, severe weakness, atrophy of intrinsic hand musculature, and loss of two-point sensory discrimination may also be seen. Electrodiagnostic and nerve conduction studies may be helpful in localizing the site of compression.153

Conservative or nonoperative treatment is recommended in patients with mild CuTS as up to 88% of patients with mild symptoms reported relief of paresthesia with nonsurgical management. A 2012 Cochrane review of treatment for ulnar neuropathy at the elbow found that giving information on avoiding prolonged movements or positions causing traction and compression on the cubital tunnel (avoid full flexion and direct pressure) was effective for mild to moderate symptoms. Nonoperative therapies which are commonly prescribed include discontinuing triceps strengthening exercises, avoidance of direct pressure to the medial aspect of the elbow on firm surfaces, maintaining a resting elbow position of 45 to 50 degree of flexion, and using a nighttime elbow towel orthosis to prevent elbow flexion beyond 50 degrees. In regard to surgical treatment, the 2012 Cochrane review found no difference between simple decompression and transposition of the ulnar nerve but higher rates of
infections in the transposition cases.\textsuperscript{153}

Early recognition is essential for timely diagnosis and treatment of nerve entrapment syndromes involving the upper extremity as they are thought to affect the function of many individuals, including musicians, athletes, and as many as one in four office workers.\textsuperscript{155} Most patients respond to conservative treatment including rest splints, rehabilitative exercises, passive physical therapy modalities, relative rest, and correction of training and equipment use errors. Other measures may include anti-inflammatory medications, protective padding or bracing, and injections with local anesthetic and steroids. In patients with severe or progressive neurologic deficit or intractable pain, surgical decompression may be necessary.\textsuperscript{156}

\section*{Lesions of the Brachial Plexus}

Injury to the brachial plexus resulting in functional impairment of the upper extremity can occur secondary to penetrating or blunt trauma, severe traction, or acceleration-deceleration injuries. Other etiologies include congenital, developmental or exogenous compression, vascular or infectious disease, and neoplastic disease. The relative incidence of these lesions of the brachial plexus is presented in Table 68.24.

\begin{table}[h]
\centering
\begin{tabular}{|c|p{10cm}|c|}
\hline
\textbf{Cause} & \textbf{Example(s)} & \textbf{Incidence (% of cases)} \\
\hline
Trauma & Penetrating injuries (e.g., gunshot, knife); closed injuries: obstetric (newborn), mechanical distortion & 70 \\
Compression & Exogenous (knapsack paralysis); congenital abnormality; developmental abnormality & 10 \\
Vascular & Local disease of major vessels; generalized vasculopathy (lupus erythematosus, arteritis); secondary to radiation therapy & 5 \\
Infectious Neoplastic & Viral; bacterial (local sepsis, abscess, or cellulitis) & 3 \\
& Primary tumors of brachial plexus; secondary involvement of plexus by tumors of surrounding tissues (Pancoast’s tumor) & 10 \\
Miscellaneous causes & Electric shock; parainfectious; following serum therapy; unknown & 2 \\
\hline
\end{tabular}
\caption{Causes of Brachial Plexus Lesions}
\end{table}

Brachial plexus injury (BPI) can be classified into preganglionic lesions,
postganglionic lesions, and a combination of preganglionic and postganglionic lesions. In a preganglionic lesion, the nerve root is avulsed. A postganglionic lesion involves the nerve distal to the sensory ganglion and is further divided into nerve ruptures or lesions in continuity.

Clinical exam and electrodiagnostic and imaging studies may help in determining the location and severity of injury, which is essential in therapeutic decisions regarding these injuries. CT myelography is considered most reliable in detecting avulsion injuries. MRI, as well as new techniques such as MR myelography, diffusion-weighted neurography, and Bezier surface reformation, provides additional useful data in the evaluation and management of BPI.\textsuperscript{157,158}

Treatment of traumatic BPI is conservative versus surgical and is based on various factors such as the degree of damage, the site and type of injury, the time interval between injury and surgery, and the patient’s age and occupation. Surgical treatment includes neurolysis, nerve grafting, nerve transfer, and other reconstructive procedures.\textsuperscript{159–161} Physical therapy and pain control is essential for recovery of function following operative cases and for optimization of function and palliation of pain in nonoperative cases. In addition to pharmacologic treatment options, successful treatment of pain related to brachial plexus lesions has been reported following implantation of spinal cord and deep brain stimulator systems.\textsuperscript{162,163}

**Acute Brachial Plexus Neuritis**

Acute brachial plexus neuritis is an uncommon disorder of unknown etiology that is commonly misdiagnosed as cervical spondylosis or cervical radiculopathy. It was first described by Spillane\textsuperscript{164} in 1943 and is also known as Parsonage-Turner syndrome or neuralgic amyotrophy due to the case series of this condition by Parsonage and Turner\textsuperscript{165} in 1948. Other names by which it is referred include brachial plexus neuropathy, paralytic neuritis, and acute shoulder neuritis.

The classical presentation of the patient with acute brachial plexus neuritis is the acute onset of severe burning pain in the neck, shoulder, and upper arm not associated with a precipitating injury or trauma. The pain may or may not be associated with sensory deficit and generally subsides.
over the following days to weeks. It is followed by a profound weakness, sometimes to the extent of flaccidity, involving the supraspinatus, infraspinatus, and deltoid and/or biceps muscles. Involvement of the sternomastoid or diaphragm has also been described, as has isolated or single nerve involvement. Bilateral brachial plexus involvement is not uncommon. Gradual recovery of muscle strength over 3 to 4 months is the usual course of brachial neuritis; however, some patients may experience several years of permanent muscle weakness. Chronic scapulocostal pain syndromes may occur due to dysfunctional mechanics following profound weakness.

Although a viral etiology has been proposed, various infections have been reported as preceding the onset of this disorder in up to 25% of cases. Onset following influenza, hepatitis B, or other vaccinations in up to 15% of cases suggests an immunologic etiology. Familial and recurrent cases are encountered. Other reported precipitating factors include childbirth, trauma, and surgery. Pathologic studies favor an immune-mediated demyelinating pathogenesis over an axon-loss mechanism.\textsuperscript{166,167}

The annual incidence of acute brachial plexus neuritis is reported to be 1.64 cases per 100,000, although this figure is presumed to be low because of misdiagnosis. It occurs most often between age 20 and 60 years with a reported male predominance of 2:1 to 11.5:1.\textsuperscript{166}

Diagnosis of brachial neuritis requires a high level of suspicion. A case series report of electrodiagnostic results reports no evidence of prolongation of F latencies and no reduction of conduction velocity or conduction block in conventional peripheral ulnar and median nerve motor studies. Proximal nerve stimulation of the cervical roots and brachial plexus revealed axonal degeneration in most cases as well as evidence of proximal conduction block consistent with demyelination. MRI is useful in evaluating muscle denervation, muscle signal intensity changes, and muscle volume loss.\textsuperscript{168}

Treatment of brachial neuritis is primarily supportive with use of analgesic medications followed by range-of-motion exercises. An arm sling may be helpful in preventing injury and strain from the weight of the arm distracting the humeral head from the glenoid fossa.\textsuperscript{59} Full functional recovery is expected in 80% to 90% of patients, although the course may
be protracted. Ten percent to 20% of patients may continue to have significant residual muscle weakness. In cases of profound and early weakness, intravenous immunoglobulin treatment has been proposed due to its usefulness in treating other focal demyelinating peripheral nerve diseases.\textsuperscript{169,170} Acupuncture may also be effective in treating pain and improving function.\textsuperscript{171,172}

**Thoracic Outlet Syndrome**

The definition, diagnosis, and treatment of TOS are among the most disputed of any clinical entity. The syndrome generally refers to a variety of symptoms in the upper extremity due to compression of the brachial plexus, subclavian artery, and subclavian vein. Compression of the neurovascular bundle can occur as it passes through the interscalene triangle, the costoclavicular triangle, and subcoracoid space during its passage from the base of the neck to the proximal aspect of the arm. Structural compressive etiologies include fibrous bands, scar tissue, hypertrophied or fibrous muscles, anomalous soft tissue, and cervical ribs. Previous to the coining of the term TOS in 1956 by Peet,\textsuperscript{173} the name of this syndrome was assigned according to the etiologies of compression including scalenus anticus syndrome, costoclavicular syndrome, hyperabduction, cervical rib syndrome, or first rib syndrome. The lower trunk of the brachial plexus (C8 and T1) is most often affected. Other factors associated with the development of TOS include repetitive trauma to the brachial plexus, median sternotomy, or traumatic events such as motor vehicle accidents.\textsuperscript{174}

TOS is variably divided into arterial, venous, or neurogenic. Alternatively, it has been classified as vascular, neurogenic, and nonspecific. The latter classification system reflects both diagnostic criteria and therapeutic recommendations and outcome.

Vascular TOS occurs in only 2% to 5% of thoracic outlet cases and is described most frequently in young individuals following vigorous arm activity or strenuous work. Patients with subclavian artery compression frequently present with pallor, pulselessness, and coolness of the affected upper extremity; transient ischemic attack; or infarcts of the hand and fingers. Decreased blood pressure in the affected arm when compared with
the opposite arm of more than 20 mm Hg may also be present. Claudication may occur only with arm hyperabduction in some patients. Injury may include thrombosis, aneurysm, and/or stenosis.

Subclavian vein compression typically presents with edema and cyanosis of the upper limb with hyperabduction of the upper extremity. Thrombosis of the axillary-subclavian vein (also known as Paget-von Schröetter syndrome), occurs in association with vigorous shoulder activity.

Doppler and duplex ultrasonography, magnetic resonance arteriography, CT angiography, and arteriography are used to confirm the diagnosis of vascular TOS. Decompression procedures or vessel reconstruction may be indicated in urgent cases and in cases not responsive to conservative therapy.\textsuperscript{174–177}

Neurogenic and nonspecific categories of TOS comprise 95% to 98% of cases. A syndrome of painless atrophy of the hand primarily involving the abductor pollicis brevis with lesser atrophy of the interossei and hypothenar muscles known as Gilliatt-Sumner hand is the classic presentation of the true neurogenic type of TOS. This is associated with positive neurologic and electrodiagnostic findings. Sensory loss typically involves the ulnar aspect of the forearm and hand consistent with lower trunk compression, although upper trunk compression has also been reported. Pain is not the primary symptom of true neurogenic TOS; however, the patient may complain of diffuse, dull pain in the neck, shoulder, axillary region, and arm which may worsen with overhead activities and repetitive use of the arm.

The most common form of TOS is the nonspecific type. Patients generally present with the primary complaint of pain, often following a motor vehicle– or work-related injury. EAST, upper limb tension test, and Adson tests may be positive, but specificity is limited as they have been shown to be positive in many asymptomatic individuals. The specificity of Adson test and EAST tests was 76% and 30%, respectively, and 82% when combined. Physical examination findings are often inconclusive and nonspecific, although physical exam may guide further diagnostic electrophysiologic and imaging studies and subsequent treatment decisions.\textsuperscript{177–179} The differential diagnosis of TOS includes cervical
radiculopathy or myelopathy, acute brachial neuritis, Reynaud’s disease, multiple sclerosis, ulnar or median nerve entrapment syndromes, acute coronary syndrome, and CRPS.

The diagnosis of nonspecific TOS requires a detailed history and physical exam to rule out other causes of neck and upper extremity pain. Electrodiagnostic testing may help localize and quantify a brachial plexus lesion in true neurogenic TOS and rule out other segmental or systemic neuropathies.\textsuperscript{180,181} Radiographic studies used in evaluation with the patient with suspected TOS include cervical spine and chest radiographs to rule out bony abnormalities and MRI and CT to evaluate the cervical spine for soft tissue anomalies, tumors, or degenerative disease of the cervical spine.\textsuperscript{182}

Conservative treatment of TOS is indicated in the majority of cases and consists of activity modification education with instructions to avoid provocative positions and activities. Physical therapy programs to restore normal posture and strengthen the muscles of the pectoral girdle have also been successful in alleviating symptoms in greater than 50\% of cases.\textsuperscript{183} Surgical approaches to treatment are undertaken in intractable or urgent cases. Surgery in the nonspecific type of TOS is associated with the least favorable outcome and is generally discouraged due to the significant risks associated with surgeries in this region. New minimally invasive techniques are now being investigated and may offer reduced risk of complications.\textsuperscript{184,185}

CHAPTER 69

Chest Wall Pain

NARASIMHA R. GUNDAMRAJ and STEVEN H. RICHEIMER

General Considerations

The chest wall is a common site of pain encountered in clinical practice. The origin of pain can be from various structures of the chest wall. These include pain from skeletal components including the spine, muscles, and nerves or pain that is referred from outside the chest wall (Table 69.1). For instance, visceral pain from the chest can be perceived as chest wall pain. It is important to distinguish the origin of pain as arising from the chest wall or from the viscera inside. Focusing on some key points in the history and physical examination can assist in diagnosing the origin of pain. A thorough knowledge of the anatomy and physiology of the chest wall and its relationship to the vital organs enclosed inside is essential for any clinician involved in treatment of chest wall pain.

   E. Deep axillary abscess
   F. Adiposis dolorosa
   G. Phlebitis of the anterolateral chest
   H. Other dermatologic painful disorders

IV. Chest pain caused by extrathoracic diseases
   A. Disorders of the cervical spine and shoulder
      1. Intervertebral disk disease
      2. Thoracic outlet syndromes
   B. Abdominal diseases
      1. Gas entrapment syndromes
      2. Disorders of the gastrointestinal tract
      3. Disease of the biliary tract
      4. Disease of the pancreas
      5. Other abdominal visceral disease
   C. Diseases of the diaphragm
      1. Acute primary diaphragmatitis
      2. Subphrenic abscess
      3. Diaphragmatic flutter

V. Chest pain primarily of psychological origin
   A. Abnormal emotional reactions to visceral disease
   B. Anxiety syndrome
   C. Depression syndrome
   D. Conversion reaction
   E. Hypochondriasis
   F. Psychiatric syndromes

---

**Anatomy of the Chest Wall**

The chest wall is made up of skeletal structures, muscular elements, and neurovascular components. The skeletal structures of the chest wall include the ribs, vertebrae, and the sternum. From a functional standpoint, the skeletal components of the chest wall provide protection for the specialized organs that support the vital functions of the human body.

**SKELETAL STRUCTURES OF THE CHEST WALL**

The chest wall is made up of the vertebrae posteriorly, ribs and costal cartilages laterally, and the sternum anteriorly. The superior boundary of the thorax includes the T1 vertebra posteriorly, 1st rib laterally, and superior margin of the sternum (Fig. 69.1). Inferiorly, the thorax is
bounded by the T12 vertebra and the 12th rib posteriorly, 7th to 10th ribs and their cartilages laterally joining anteriorly to the xiphisternum.\textsuperscript{1,2} The anteroposterior and lateral diameter of the thorax is smaller at the top compared to the inferior portion. A compromise in the space at the thoracic inlet due to pathology of the skeletal structures or thoracic viscera can compromise the neurovascular structures and also result in chest wall pain.\textsuperscript{3,4}

\textbf{Thoracic Spine}

The thoracic spine is made up of 12 thoracic vertebrae (Fig. 69.2). Each thoracic vertebra is heart-shaped with long and inclined spinous processes (Fig. 69.3). Costal facets are present laterally on either side of the body for articulation with the ribs. Costal facets are also present on the transverse processes (except T11 and T12) for articulation with the tubercles of the ribs.

FIGURE 69.3 Thoracic vertebra. A: Superior surface. B: Lateral surface. (Reprinted with permission from Snell RS. Clinical Anatomy by Regions. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2011. Figure 2-3.)
Ribs
There are 12 pairs of ribs attached posteriorly to the spine. The upper 7 pairs of ribs are attached anteriorly to the sternum by costal cartilages and are called true ribs (Fig. 69.4). The 8th, 9th, and 10th ribs are attached to each other, and the 7th rib by their costal cartilages forming small synovial joints. These ribs are called false ribs. The 11th and 12th ribs have no anterior attachments and are called floating ribs. A typical rib is a long, curved, flat bone. The superior border is smooth and rounded. The inferior border is sharp and thin, and it overhangs the costal groove, which encloses the intercostals vessels and the nerves. The head of the rib has two facets for articulation with the corresponding vertebral body and the one above it. The neck is a constricted portion of the rib after the head. A prominence on the outer surface of the rib at the junction of the shaft and the neck is called the tubercle. It also has a facet for articulation with the transverse process of the corresponding vertebra. A cervical rib arising from the transverse process of the 7th cervical vertebra is seen in 0.5% of humans. It can cause pressure on the adjacent neurovascular structures—the brachial plexus and the subclavian artery.

FIGURE 69.4 Fifth rib as it articulates with the vertebral column posteriorly and the sternum anteriorly. (Reprinted with permission from Snell RS. Clinical Anatomy by Regions. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2011. Figures 2-4 and 2-5.)

Sternum
The sternum is a flat bone in the middle of the anterior chest wall. It is divided into three parts: manubrium, body, and xiphoid process. The manubrium is the upper portion of the sternum that articulates with the body of the sternum at the manubriosternal joint. It also articulates at the
clavicles, the first costal cartilage, and the upper portion of the second costal cartilage. The body of the sternum on each side articulates with the second to seventh costal cartilages. The xiphoid process is a roughly triangular cartilaginous structure that becomes ossified in adulthood. The angle of Louis or sternal angle is the junction between the manubrium and the body of the sternum. This useful anatomic landmark is palpated by feeling for a transverse ridge on the anterior aspect of the sternum. It correlates to the second costal cartilage anteriorly and the intervertebral disk between the fourth and fifth thoracic vertebrae posteriorly.

**JOINTS OF THE CHEST WALL**

The chest wall includes many joints. The manubriosternal joint and xiphisternal joints are fixed joints. The costochondral connections of ribs with costal cartilages are also nonsynovial joints. These costochondral joints can become the source of painful irritation. The costal cartilages often calcify with age, reducing the flexibility of the chest wall. The joints of the heads of the ribs with the vertebral bodies, and the joints of the tubercles with the transverse processes of the ribs, are synovial joints that allow for the expansion movements of the chest wall. The joints of the costal cartilages with the sternum are synovial (with the exception of the first rib), but these joints allow for only slight motion and they tend to disappear with age.

**INTERCOSTAL SPACES**

The intercostal space between the ribs is covered with three muscles: the external intercostals, internal intercostals, and the innermost intercostals muscle (Fig. 69.5). The innermost intercostal muscle is lined by the endothoracic fascia, which in turn covers the parietal pleura. The intercostal nerves and blood vessels run between the internal and the innermost intercostals muscles in the intercostals groove. The intercostal muscles play an important role in the mechanics of respiration. They are supplied by the corresponding intercostal nerves. The neurovascular structures in the intercostal groove are arranged from above downward as vein, artery, and nerve.
INTERCOSTAL NERVES

The anterior rami of the first 11 thoracic spinal nerves form the intercostals nerves. The anterior ramus of the 12th nerve lies in the abdominal wall as the subcostal nerve. The rami communicantes connect the intercostals nerve to the sympathetic trunk. The collateral branch runs forward inferiorly to the intercostal nerve on the upper border of the rib below. The lateral cutaneous branch runs in the skin on the side of the chest and divides in to the anterior and posterior branches. The anterior cutaneous branch is the terminal portion of the intercostal nerves and reaches the skin near the midline anteriorly (Fig. 69.6). Muscular branches are given out to the intercostals muscles. Pleural sensory branches go to the pleura. Peritoneal sensory branches from the 7th to 11th intercostal nerves run to the parietal peritoneum. The 1st intercostal nerve has a branch joining the brachial plexus. The second intercostal nerve joins the medial cutaneous nerve of the arm by the intercostobrachial nerve. In coronary artery disease, referred pain to the arm might be through this nerve.\(^5\)
Neoplastic Chest Wall Pain

A thorough history and physical examination is necessary to rule out pain caused by neoplasms of the thorax. Associated symptoms of cough, dyspnea, brachial plexopathy, and hoarseness due to recurrent laryngeal nerve involvement or Horner syndrome should arouse the suspicion of possible neoplastic disease. Diagnostic radiologic tests can confirm the diagnosis and the extent of involvement. If there is a high level of suspicion for neoplastic disease in a patient presenting with chest wall pain, diagnosis of the condition should be undertaken prior to any interventional procedures. Pain due to neoplastic disease is treated with a comprehensive or multimodal approach with opioid and nonopioid analgesics, physical therapy, interventional treatment with intercostal nerve blocks or epidural injections, and psychotherapy. In patients with refractory cancer pain, neuraxial delivery of opioid and local anesthetics...
by continuous infusion pumps or neurolytic ablation may be necessary for pain control.

Lung and breast cancers account for the majority of the thoracic neoplasms. Other neoplasms include metastatic lesions of the lung and the skeletal structures. Neoplasms of the lung present with symptoms of cough, dyspnea, hemoptysis, or obstructive symptoms due to compression of the neurovascular structures. Pain is not a common symptom with lung cancers except when there is pleural involvement. Nociceptive pain is usually localized, constant, or associated with chest wall movement and is caused by the invasion of the pleura, vertebrae, or other soft tissues of the chest wall. Deafferentation or neuropathic pain is caused by compression, infiltration, or damage to the involved spinal nerves and produces allodynia, hyperalgesia, dysesthesis, or hyperesthesia in a segmental fashion. Involvement of the superior pulmonary sulcus produces Pancoast syndrome. It is characterized by pain in the shoulder and arm, motor weakness and wasting of muscles of the hand, as well as Horner syndrome. A mass in the superior sulcus of the lung can cause compression of the lower trunk of the brachial plexus. Pain and motor symptoms are most commonly seen in the distribution of the ulnar nerve. Brachial plexopathy can also result from other causes such as metastatic tumors, radiation, or thoracic surgery.

**EPIDURAL SPINAL CORD COMPRESSION**

Epidural spinal cord compression is the second most common central neurologic complication of systemic cancer. Pain is the initial symptom before the development of other neurologic signs and symptoms. The pain can be misdiagnosed as musculoskeletal in origin. Appropriate imaging studies can aid in the diagnosis. Treatment includes corticosteroids and radiation. Surgical decompression with laminectomy or vertebral body resection is recommended in patients who are relatively healthy.

**SUPERIOR VENA CAVA SYNDROME**

Obstruction of the blood flow through the superior vena cava results in superior vena cava syndrome. The obstruction can be due to external compression from pathology of the lung, lymph nodes, or mediastinum. It
can also result from internal obstruction due to thrombus formation. Chest wall pain, cough, dyspnea along with collateral venous engorgement of the chest wall and neck, and facial edema are the common signs and symptoms. Dyspnea is the most common symptom. Lung cancer is the most common cause followed by lymphoma. Malignancy accounts for 60% to 85% of all cases of superior vena cava syndrome with small-cell lung cancer serving as the most common type of lung malignancy causing this syndrome. Non-Hodgkin lymphoma is the most common type of lymphoma resulting in obstruction of the superior vena cava. The widespread use of central venous catheters, ports, pacemakers, and defibrillators has increased the incidence of benign superior vena cava syndrome (SVCS) due to endovascular obstruction. Diagnosis is made based on clinical symptoms and the findings of abnormal lesions in the chest radiograph. Confirmatory studies include contrast-enhanced computed tomography (CT) scan and venous angiography. Current treatment strategies include chemotherapy, radiation, or endovascular stenting. Surgical treatment is performed with spiral saphenous interposition graft or other grafts. Radiation treatment is indicated for emergency relief of airway obstruction.

**COSTOPLEURAL SYNDROME**

Tumor invasion of the pleura, ribs, and soft tissues of the chest wall with or without involvement of the intercostals nerves can result in sharp, aching, or burning pain (Fig. 69.7). Pain is exacerbated by movements of the chest wall, deep breathing, and coughing. Lesions of the pleura closer to the diaphragm can cause localized pain in the shoulder region or referred dull aching pain in the back or upper abdomen. Mediastinal pleural involvement causes pain deep in the central portion of the chest or the shoulder region. This type of pain is often potently responsive to steroidal or nonsteroidal anti-inflammatory analgesics.
Nonneoplastic Chest Wall Pain

Chest wall pain from other than neoplasms and visceral pain is discussed in this section. This section includes a discussion of chest wall pain due to neuropathy including neuraxial pain, myofascial, skeletal, and joint pain.

NEUROPATHIC PAIN

Pain due to neuropathy can arise anywhere along the nervous system supplying the chest wall. The pain can be neuraxial involving the spinal cord and nerve roots or related to peripheral nerves (Table 69.2).

Neuropathic Pain of Central Origin

Thoracic myelopathy can cause chest wall pain, back pain, or abdominal pain. Lesions can be present within the spinal cord or extramedullary or epidural spaces. Thoracic disk herniation can also result in chest wall pain (Fig. 69.8). Pain is usually the initial symptom before other neurologic symptoms. Pain is worsened in the recumbent position. If pain is the only symptom, it is often confused as myofascial or skeletal pain. Prompt diagnosis is important in light of potentially evolving cord compression.
Pain that is progressive and not relieved by conventional therapy for musculoskeletal pain requires prompt attention to rule out neoplasm. Acute neurologic symptoms are initially treated with corticosteroids and radiation therapy. Surgical decompression with laminectomy may be necessary if the symptoms are not relieved by nonsurgical methods. Lower cervical disk herniation can also present as neuropathic chest wall pain. A relatively rare cause of thoracic neuropathic pain is seen in the form of an extramedullary granuloma in patients with neuraxial infusion pumps. Stopping the implanted infusion pump and radiographic exam with contrast through the catheter, CT myelography, or magnetic resonance imaging (MRI) can help make the diagnosis. Stopping the infusion may decrease the size of the mass. Consensus guidelines to improve safety and mitigate risk of granulomas are available and updated every few years. Surgical removal of the symptomatic granuloma is rarely necessary.

**FIGURE 69.8** Sagittal T2-weighted magnetic resonance imaging showing a central thoracic disk herniation at T11–T12 (arrow). The cord is displaced posteriorly. The arrowhead shows a Schmorl nodule. Figure 23-37B.)

**Peripheral Neuropathic Chest Wall Pain**

3691
Herpes Zoster and Postherpetic Neuralgia

Acute herpes zoster, also called shingles, is caused by the DNA virus, varicella zoster virus (VZV). The incidence of herpes zoster is higher in older and immunocompromised patients. Factors that decrease immune function such as chronic corticosteroid use, human immunodeficiency virus infection, cancer, and chemotherapy can increase the risk of developing herpes zoster. Following a primary VZV infection, the virus remains dormant in the dorsal root ganglia. Acute herpes zoster is characterized by the reactivation of the latent virus in the dorsal root ganglion. It typically presents as a mononeuropathy involving the intercostal nerves. Clinically, the presentation begins with burning pain, hyperesthesia, or tingling followed by the characteristic vesicular rash. The prodromal sensory symptoms may be present for 1 to 2 weeks prior to the appearance of the rash. The characteristic rash is initially maculopapular and progresses into vesicles with erythematous bases. The rash of herpes zoster is commonly seen involving one or two contiguous thoracic dermatomes, almost always unilateral. T5 and T6 dermatomes are most commonly affected. Pain is sharp, burning, and superficial in nature. Pain can be worsened with ulceration and secondary infection of the vesicles. Associated muscle spasms can worsen the pain.

Diagnosis of the condition is made by the clinical presentation of the characteristic rash.

The main goal of treatment of acute herpes zoster infection is not only to treat the acute condition but also to prevent central sensitization and postherpetic neuralgia. Treatment of the acute condition is initially pharmacologic. Elderly patients are more susceptible to developing postherpetic neuralgia; therefore, more aggressive treatment with additional interventional modalities is recommended. Pharmacologic therapy involves initiating treatment with oral antiviral agents as soon as the diagnosis has been made. Studies have shown efficacy of antiviral agents if started within 72 hours. Interventional treatments include segmental epidural blockade with dilute local anesthetic solutions, intercostal nerve blocks, and sympathetic blockade of the cervicothoracic chain with stellate ganglion blocks are recommended. For an elderly patient suffering with a very painful bout of acute zoster, aggressive
interventional treatment can reduce the severity of pain and may reduce the risk of severe pain of postherpetic neuralgia. The number of interventional treatments can range anywhere from three to four in a 2-week period. Continuous segmental epidural blockade with thoracic epidural catheter is also recommended; however, it may require hospitalization of the patient. Continuous blockade of the intercostal nerves can be achieved by placing a catheter in the intercostal space connected to an isomeric infusion pump. Such therapy can be used effectively on an outpatient basis. Use of dilute local anesthetics with less toxicity can reduce complications due to local anesthetic toxicity in older patients.

Postherpetic neuralgia presents with persistence of severe sharp, burning pain in the affected dermatomes after the disappearance of the acute rash. About 20% of elderly patients with herpes zoster develop postherpetic neuralgia. The pain may persist for months to years without treatment. Hyperalgesia and allodynia of the effected dermatome is seen. The chronicity of the pain can result in behavioral changes affecting sleep and mood. Psychosocial symptoms and depression can worsen the pain. Treatment of postherpetic neuralgia includes symptomatic treatment of pain with medications and interventions. Medical management involves the use of neuropathic analgesics which are discussed extensively elsewhere in this text. These may include tricyclic antidepressants, duloxetine, and anticonvulsants.\textsuperscript{23–25} Systemic corticosteroids are ineffective in preventing postherpetic neuralgia. However, their use during the acute phase has not been associated to worsening of the disease.\textsuperscript{26,27} Topical treatment with local anesthetic patches, local anesthetic ointments, preparations with capsaicin, and compounded creams can be used to achieve symptomatic treatment of the condition.\textsuperscript{28–30} Transcutaneous electrical nerve stimulation (TENS) can also be helpful.\textsuperscript{31} Interventional treatment with intercostal nerve blocks or epidural injections may be required. Permanent implants like dorsal column spinal cord stimulators and peripheral intercostal nerve stimulators offer a novel approach to pain control in patients who require repeated interventional treatments. A trial of such a stimulator is recommended before permanent implantation. Along with the interventional treatments, aggressive behavioral therapy is
highly recommended. Chronic opioid therapy may be needed. A comprehensive approach using pharmacologic, interventional, rehabilitative, and behavioral treatments will help achieve pain relief and improve functional capacity of the patient.

Intercostal and Peripheral Neuropathy
Chronic intercostal neuralgia can result from trauma or compression of the intercostals nerves. Due to the proximity of the nerves to the inferior aspect of the ribs, any abnormalities of the ribs such as fractures and metastatic lesions can result in intercostal neuralgia. Prior thoracic or breast surgery and surgical lesion of the nerves can result in chronic intercostal neuralgia. Other causes include trauma or infection. Pain is characterized as sharp, superficial, burning, or lancinating in the distribution of the affected nerve. Pain is worsened by respirations and movements of the chest wall similar to the clinical presentation of pleuritic lesions. Localized tenderness to palpation may be appreciated in the intercostal space. A thorough history looking for previous trauma or surgeries can assist in the diagnosis.

Medical management of intercostal neuralgia consists of treatment with nonsteroidal anti-inflammatory agents, tricyclic antidepressants, and anticonvulsants. Intercostal nerve blocks with long-acting local anesthetics and corticosteroids can be effective (Fig. 69.9). Cryoablation or radiofrequency neurolysis of the intercostal nerves can provide longer pain relief. Ultrasound guidance can provide accuracy in identification of the nerves for radiofrequency neurolysis. We avoid chemolysis of the intercostals nerves because of concerns of postlysis neuralgia and neuritis. Dorsal root ganglion radiofrequency ablation has been described for treatment of intercostal neuralgia. Long-term relief can also be achieved by implantable dorsal column or peripheral nerve stimulators.
CHEST WALL PAIN OF SKELETAL ORIGIN

Skeletal chest wall pain can originate from the thoracic spine, ribs, costal cartilages, or sternum.

Abnormalities of the Thoracic Spine

Localized pain in the back can result from abnormalities of the thoracic spine. Pain is caused by stimulation of nociceptive fibers in the periosteum, joints, and ligaments. Reflex muscle spasms of the paraspinal muscles are also associated with pain. Deep palpation of the thoracic spinous processes, the paravertebral region, and movement of the spine can elicit pain.

Congenital abnormalities of the spinal curvature resulting in scoliosis can cause chest wall pain as the patient ages. Structural changes in the thoracic spine due to postural kyphosis, trauma, or disease can result in pain. Correction of lateral scoliosis with surgical or nonsurgical interventions can help alleviate the pain. Posture training with strengthening exercises and relief of muscle spasms is helpful.

Vertebral Fractures

Fractures of the vertebral body can be very painful. The pain can be particularly severe and may radiate into the chest wall. Vertebral fractures are the result of trauma, metastatic disease, or osteoporosis. Compression fractures in younger patients are mostly due to trauma. However,
corticosteroid use can also result in compression fractures in younger patients. Osteoporosis is a major public health concern in the modern world. It is estimated that by the eighth decade, 50% of all women will develop vertebral fractures. There is significant impact on the patient with an osteoporotic vertebral fracture resulting in pain, deformity, dependence, and fear of falling. More than 200,000 people per year with osteoporotic fractures require opioid pain medications. Radiologic diagnosis with plain films, CT scan, or MRI can assist in the diagnosis of a patient who presents with acute onset posterior axial pain with or without radicular symptoms (Fig. 69.10).

Physical examination may reveal deformity of the spine. A prominent spinous process can sometimes be palpated above or below the level of the compression fracture. Pain may not be present initially, and about 50% of the patients present at a later time with the onset of pain. Most of the fractures are due to a combination of flexion with axial compression resulting in collapse of the anterior portions of the vertebral body. With osteoporosis, as the load-bearing capacity of the vertebral bodies...
decreases, minor movements such as bending or lifting can result in a fracture in older patients. Crushed fracture of the anterior and middle columns of the vertebral body, the so-called burst fractures, can result in neurologic compromise. The main goal of therapy is prevention. Treatment options for pain due to vertebral compression fractures include analgesics, bracing, and interventional treatments. Surgical treatment is indicated if there is neurologic compromise. However, surgery can be invasive and result in failure of fixation in the osteoporotic spine.

Vertebral body augmentations with vertebroplasty or balloon kyphoplasty have had promising results. It involves mechanical augmentation of the compressed vertebral body by injecting acrylic bone cement material. Use of polymethylmethacrylate for vertebral compression fractures was reported in France in 1991 with good results of pain relief. Polymethylmethacrylate is injected into the vertebral body via a posterolateral approach. The posterior cortex of the vertebral body must be intact prior to injection. Studies have recognized the best timing of interventional procedures to be within 6 weeks of the fracture. No differences in pain were reported when vertebroplasty is compared to balloon kyphoplasty. Both techniques have their own advantages and disadvantages. Medial branch nerve blockade and radiofrequency ablation is an emerging option with lower risk than other interventional approaches described earlier, albeit without an extensive evidentiary basis.

Ankylosing Spondylitis
Ankylosing spondylitis results in a stiff spine due to arthritic changes in the intervertebral joints including the costovertebral, costotransverse, and apophyseal joints. The sternoclavicular joints can also be involved. Patients can typically present with mild to moderate pain in the posterior chest wall. Anterior chest wall pain has also been reported in patients with ankylosing spondylitis. Physical examination demonstrates limited movements of the spine with contracted tender paraspinal muscles. Diagnosis is made by plain films that show characteristic fused spine or “bamboo spine.” Occasionally, involvement of the nerve roots due to arthritic changes in the joints can result in radicular pain. Secondary
contracture of the paraspinal muscles can worsen the pain. Effective treatment involves physical therapy, trigger point muscle injections, and muscle relaxants. Progression of the arthropathy should be addressed with the expertise of a rheumatologist. Paravertebral blocks can provide relief from radicular pain. Thoracic facet joint injections with corticosteroid and local anesthetics can provide significant relief of pain. If good results are encountered with facet joint injections, longer term relief of pain can be obtained with radiofrequency ablation of the nerve supply of the facet joint. The radiofrequency technique is generally considered to be safer than chemical ablation because there are additional risks associated with the potential unwanted spread of the chemolysis agent.

Costovertebral Arthritis
Arthritis of the costovertebral and costotransverse joints can cause posterior chest wall pain. Pain is localized, aching, and deep in character. Pain can be increased with deep breathing, coughing, or lateral compression of the chest. Physical examination may reveal localized deep tenderness that may be hard to distinguish from thoracic facet syndrome. Characteristics of pain and radiologic examination can delineate the pathology. Treatment is provided with nonsteroidal anti-inflammatory agents and physical therapy. Interventional treatment with injection of the joints with local anesthetic, corticosteroid mixture with fluoroscopic confirmation can alleviate the pain. It can also be diagnostic. Low-dose opioid medications may be needed for treatment of chronic pain from the arthritis. Rarely, resection of the joints is considered for refractory pain from isolated costovertebral joint arthritis.

Diffuse Idiopathic Skeletal Hyperostosis
Another cause of posterior chest wall pain in elderly patients can be due to diffuse idiopathic skeletal hyperostosis (DISH), also called Forestier disease. Patients present with dull aching thoracic back pain, posterior chest wall pain, dysphagia, myelopathy due to involvement of the posterior longitudinal ligaments, fractures, subluxation, and, rarely, intercostal neuralgia. Physical findings include slight increase in dorsal kyphosis, minimal reduction in motion, and localized tenderness. Diagnosis is confirmed with radiologic exams with plain films and CT scans showing
spinal hyperostosis resulting in linear ossification and bridging osteophytosis along the anterior and anterolateral aspects of the vertebral bodies. DISH most commonly affects the thoracic spine. Absence of sacroiliitis, true syndesmophytes, and ankylosing apophyseal joints distinguishes this syndrome from ankylosing spondylitis.52,53 The syndrome of synovitis, acne, pustulosis, hyperostosis, and osteitis (SAPHO syndrome) can also be a cause of anterior chest wall hyperostosis.54 Treatment is symptomatic with nonsteroidal anti-inflammatory drugs (NSAIDs) and physical therapy.

Thoracic Facet Syndrome
Thoracic facet syndrome results from abnormal locking or binding of the facet joints. Sudden or rapid turning movements of the trunk, working with hands over the head, or lifting with the trunk in a twisted position can result in this syndrome. Symptoms include moderate to severe pain on the side of the spine or anterolateral chest wall.55,56 The pain is worsened with extension of the spine and relieved with flexion. Localized deep tenderness can be elicited to deep palpation over the facet joint. Tenderness and spasms of the erector spinae muscles can exacerbate the pain. It can mimic the pain from costovertebral arthropathy. Injection of the joint can assist in making the correct diagnosis. Treatment includes NSAIDs, physical therapy, and injection of the facet joints and medial branches with corticosteroid and local anesthetics. Radiofrequency denervation offers long-term pain relief but for unknown reasons may be associated with higher rates of postlytic neuritis than comparable radiofrequency denervation of medial branch nerves in the lumbar or cervical regions.57–59

Chest Wall Pain Arising from the Ribs
Rib fractures account for one of the most common causes of acute chest wall pain of skeletal origin. Blunt trauma to the ribs is the usual cause of fractures. Other causes include severe paroxysmal coughing (tussive fracture), metastatic disease, osteoporosis, osteomalacia, and Paget disease of the bone (Fig. 69.11). Elder or child abuse should be sought in unexplained rib fractures after all other etiologies are eliminated.
Fractures may involve several ribs or multiple fractures of the same rib. Acute pain from rib fractures is usually aching, sharp, and worsened with respirations. Pain from multiple fractures can restrict breathing leading to additional pulmonary complications. Acute pain from rib fractures is treated with NSAIDs, low-dose opioids, or continuous intercostal nerve blocks. Chest wall pain from multiple rib fractures in trauma patients, in which serious consequences might occur from hypoventilation due to pain-related splinting, are candidates for a thoracic epidural catheter with a continuous epidural infusion. Multiple studies in selected trauma patients have shown better outcomes of pain relief and reduction in pulmonary complications with thoracic epidural infusion compared to systemic opioids or intrapleural catheters.

Ultrasound-guided serratus plane blocks have been used recently for pain control after multiple rib fractures.

Occasionally, rib trauma without radiographically apparent fracture can cause localized pain and swelling with point tenderness in the area. If these are related to hypoventilation due to splinting from pain, they may be
considered the same as rib fractures potentially requiring neuroaxial analgesia. Local injections with local anesthetics, intercostals nerve blocks, and NSAIDs can help relieve the pain. Topical local anesthetic patches with 5% lidocaine may be helpful for some with pain from single rib fractures or rib injuries without a fracture. Metastatic disease from the breast, lungs, and prostate can cause isolated rib tenderness. Plain radiographs and nuclear medicine bone scans can aid in the diagnosis.

Slipping Rib Syndrome
Slipping rib syndrome was described first in 1922 by Davies-Colley. It is characterized by chest wall or abdominal pain due to irritation of the intercostal nerves. The etiology is thought to be due to trauma. There is increased mobility of the costal cartilages of 8th to 10th ribs near the sternum. The syndrome is also referred to as clicking rib, gliding rib, or displaced ribs. It is also seen in children. The cause for pain is due to anatomic variation of the 8th to 10th ribs, which, instead of articulating directly with the sternum, articulate with the costal cartilages of the upper rib. As such, the sternal ends of these ribs are more prone to trauma. Injury can cause separation of the cartilages causing slipping movements of the ribs with respiration. A characteristic click can be felt with the movement of the ribs over the border of the upper cartilage. Diagnosis of the condition can be accomplished by the “hooking maneuver.” The examiner’s curled fingers are placed over the inferior border of the rib and the rib is pulled up anteriorly. A positive test produces a clicking noise and increases the pain. Slipping rib syndrome is treated conservatively with reassurance and nonopioid analgesics. Injection of the painful site (between the detached cartilage and the rib) with local anesthetic steroid combination medications may relieve pain for a longer period. Surgical excision of the involved rib and costal cartilages has also been suggested for refractory cases.

Tietze Syndrome
Tietze syndrome is characterized by a benign, nonsuppurative, painful swelling of the second or third costal cartilages. It was first described in 1921 by Tietze. Straining, severe cough, heavy manual work, nutritional deficiencies, and arthritic conditions have all been implicated as the
possible causes. In 80% of the patients, the condition is unilateral. Pain is usually localized but occasionally can radiate over the anterior chest wall to the shoulder or neck. Pain is characterized as heaviness, tightness, or soreness. Pain is exacerbated by coughing and deep breathing. There is localized tenderness and swelling over the involved cartilage. The overlying skin is normal. Radiologic diagnosis by bone scans is nonspecific. Treatment includes use of nonopioid anti-inflammatory medications. The condition usually is self-limited with occasional exacerbations and remissions.

Costochondritis
Costochondritis is one of the most common causes of anterior chest wall pain often confusing or coexisting with the pain due to coronary artery disease. Pain is characterized as aching, sharp, or tightness in the anterior chest wall. Unlike Tietze syndrome, it involves multiple sites. No swelling is palpated. There is localized tenderness involving multiple costochondral regions of the anterior chest wall. Second to fifth costal cartilages are frequently involved. Pain is aggravated with movement of the chest. Pain can radiate anteriorly or to the back. In adolescents, it can cause chest wall or abdominal pain. Firm steady pressure applied over the sternum, intercostal spaces, costochondral junctions, and the ribs can reproduce the pain. The horizontal flexion test consists of having the arm flexed across the anterior chest wall and applying steady traction in a horizontal direction while the patient’s head is rotated toward the ipsilateral shoulder. The crowing rooster maneuver involves having the patient extend the neck as much as possible by looking toward the ceiling while the clinician, standing behind the patient, exerts traction on the posteriorly extended arms.

It is important to distinguish pain due to costochondritis (especially left-sided) from that of coronary artery disease or abdominal pathology. Pain due to costochondritis is usually located to the lateral side of the sternum unlike substernal cardiac pain. Pain can radiate to the left arm or shoulder. The patient gives a history of pain with movement and postural changes. Localized concordant tenderness can be palpated. Pain usually lasts for a few minutes to hours, distinguishing it from pain of acute
cardiac origin. Intercostal nerve blocks and injection of the tender costochondral areas with local anesthetic have been used for diagnostic purposes. Rarely, emergency room physicians experience a patient with both costochondritis and coronary artery disease. Careful history and physical exam along with treatment with sublingual nitroglycerin can aid in prompt diagnosis of the cardiac pain, which is relieved with the nitroglycerin.

Treatment of costochondritis is initiated with NSAIDs, physical therapy, heat application, and less commonly with low-dose opioids. Once the diagnosis has been made, reassuring the patient about the benign nature of the condition can prevent patient anxiety and avoid unnecessary expensive diagnostic workup. Localized injection of the costochondral junction with local anesthetics and corticosteroids can help relieve the pain.

Costochondral Dislocation
Costochondral dislocation is commonly seen after trauma in young patients.\textsuperscript{83} It is also encountered after thoracic surgery with rib retraction. The pain is typically dull, aching, or burning and is usually continuous. Localized tenderness is present. Sometimes, a mass is felt due to cartilaginous excess from the injury. Treatment is similar to other conditions as described earlier with oral analgesics and intercostal nerve blocks. Manipulation and reduction of the dislocation after adequate analgesia can correct the condition.

Chest Wall Pain of Sternal Origin
Sternoclavicular joint arthritis can be caused due to various arthritic conditions (osteoarthritis, rheumatoid arthritis, psoriatic) and rarely infections due to central venous catheters.\textsuperscript{84–86} Infections are also seen in intravenous drug users. Traumatic subluxation and dislocation can also cause pain.\textsuperscript{87} Apart from trauma, such conditions are also seen after cardiac surgery when the sternum is retracted. Pain is localized to the affected joint. Localized tenderness of the joint is seen with palpation along with pain from shrugging the shoulders. Treatment consists of oral NSAIDs and injection of the joints with local anesthetic and corticosteroid. Such intervention must be avoided in infectious joints which are treated
with antibiotics and analgesics.

Blunt injuries to the sternum can cause subluxation of the manubriosternal joint. Manubriosternal arthritis can occur due to various arthritic conditions. Septic arthritis of the joint is also seen. Pain is localized to the anterior sternum or angle of Louis with occasional radiation parasternally. Pain is characterized as sharp aggravated with deep breathing, coughing, or yawning. Pain may mimic anginal pain. Diagnosis is made by physical examination. Bone scans can be positive. Treatment consists of systemic analgesics, topical lidocaine patches, heat, infiltration of the joint with local anesthetics, and corticosteroids. Rarely, surgical intervention to correct the manubriosternal displacement is necessary.

Xiphoidalgia (Painful Xiphoid Syndrome, Xiphoid Cartilage Syndrome, Hypersensitive Xiphoid)
Intermittent, inferior substernal, or epigastric pain associated with tenderness of the xiphoid to palpation is characteristic of xiphoidalgia. Pain is spontaneous without any obvious precipitating cause. It is sometimes seen along with coronary artery disease, intestinal disease, and metabolic disorders. Movements of the xiphoid with bending, stooping, or turning precipitates or exacerbates the pain more commonly after a full meal. Along with NSAIDs, local injection of the xiphisternal joint with local anesthetic and corticosteroid can alleviate the pain.

Chest Wall Pain of Myofascial Origin
Myofascial strain can be caused by excessive muscular activity. Repeated stress due to exercise, coughing, straining, or repetitive movements (chopping wood, painting a ceiling) can result in generalized tenderness over the anterior chest wall. Pain in the intercostals or accessory thoracic muscles is usually due to trauma. Pain from the pectoralis muscles can be exacerbated with adduction movements of the shoulder. Pain between the scapula and spine from an injured rhomboid is increased with bracing of the shoulders backward. Treatment consists of reassurance, local heat or cold, NSAIDs, topical lidocaine patches, physical therapy, and avoiding precipitating activities. Infiltration of the muscle with local anesthetic can be undertaken if there is localized tenderness. Caution regarding the risk of
Pneumothorax is necessary for all chest wall injections.

Precordial Catch Syndrome (Chest Wall Twinge Syndrome)
This is characterized by episodes of sudden, brief, sharp precordial or periapical pain. This is a benign, self-limited condition.\textsuperscript{96,97} Sharp pains, stitches, or catches are felt in the chest wall in the left parasternal on or near the cardiac apex. Some patients report pain from assuming a slouching or bent position. Pain may last for a few seconds to up to 3 minutes. Deep breathing exacerbates the pain, whereas shallow breathing relieves it. There is no localized tenderness. The cause is unknown. Intercostal muscle spasms and pain from the pleura have been postulated as possible causes. Treatment consists of reassurance and correction of posture. Due to the unpredictability and the benign short duration of pain, analgesics are not necessary.

Epidemic Myalgia (Bornholm Disease, Epidemic Pleurodynia, Devil’s Grip)
This condition is characterized by paroxysms of intense sharp chest wall and upper abdominal pain due to viral infection with coxsackie or echoviruses.\textsuperscript{98} The paroxysms of pain are separated by pain-free intervals. Frequently, there is associated fever, headache, and pharyngitis. The condition is self-limited.

**Breast Pain**
Pain arising from the breast is a common and nonspecific symptom in women.\textsuperscript{99,100} Usual causes include benign cysts, fibrocystic change, or cyclical pain due to hormonal cycle changes of the menstrual cycle. Other causes of breast pain include malignancy, mastitis, ductal ectasia, breast abscess, hormone replacement therapy, or large breasts. Careful clinical evaluation and mammography to rule out malignancy should be undertaken. Pain due to malignant breast lesions does not usually present until the tumor is large (greater than 2 cm in diameter). Axillary lymph node involvement can present as either localized or sharp pain in the arm with involvement of the intercostobrachial nerves. Extramammary sources of breast pain should be evaluated if no other etiology is suggestive. Causes include skeletal and myofascial pain from the chest wall, radicular
pain, or pain from peripheral nerves.

Chronic severe breast pain that persists for years without any obvious cause characterizes idiopathic mastalgia. Pain can be unilateral or bilateral, cyclical or noncyclical, which is usually seen in the third or early fourth decades of life. Without any organic diagnosis, the etiology is often misdiagnosed as psychologic. 100 Cyclical mastalgia responds to danazol, bromocriptine, or tamoxifen. Hormonal events such as pregnancy, menopause, or use of oral contraceptives may lead to relief. 101–103

Breast pain is often treated with NSAIDs and acetaminophen. Warm compresses, ice packs, or gentle massage can also help relieve pain. Pain arising from the cervical or thoracic spine requires appropriate treatment of the cause as discussed elsewhere in this book. Peripheral myofascial and skeletal pain, also discussed elsewhere in this book, can be treated with injection of local anesthetic and corticosteroid. 104,105

Adiposis Dolorosa (Dercum Disease)
This syndrome is characterized by painful subcutaneous fatty tumors in various parts of the body, including the breast. 106 This can result in chronic pain in the breast. Treatment with intravenous lidocaine and resection of the fatty lesions is helpful.

Mondor Disease
Thrombosis of the superficial veins of the thoracic wall can cause pain in the anterolateral chest wall. 107 This is seen occasionally in patients who abuse intravenous drugs. 108 The disease is mostly seen in middle-aged women with pendulous breasts and can cause pain in the breast. 109 Presence of a palpable tender cord is characteristic. The disease can cause anxiety in the patient. Mondor disease is self-limited. Treatment involves management of pain with NSAIDs.

**Postsurgical Chest Wall Pain**
Pain can persist for several months to years after surgery. It is often additively perplexing for the patient to live with pain after the original pathology has been corrected with surgery. Chronic postsurgical pain is most commonly seen after thoracotomy, mastectomy, and cardiac surgery. Other rare causes of chronic postsurgical chest wall pain include video-
assisted thoracoscopy, mediastinoscopy, breast reconstruction, and surgery of the cervical or thoracic spine.

Postsurgical Breast Pain and Postmastectomy Pain Syndrome
Persistent pain in the anterior chest wall, axilla, and the arm can be seen in a few patients after mastectomy.\textsuperscript{110–112} It can also occur after minor breast surgeries, such as lumpectomy. Breast reconstruction or other cosmetic breast surgeries can be also associated with such pain. Submuscular implants and capsule formation around the implant can cause injury or impinge on the thoracodorsal, long thoracic, lateral, or medial pectoral nerves. Postsurgical complications such as wound infection, fluid or hematoma retention, and reexploration can frequently result in pain. Although previous studies describe pain in less than 10% of patients, more recent studies report pain, paresthesias, and phantom sensations in about half of the patients.\textsuperscript{113,114} In about half of the cases pain resolves with time. Pain is described as burning, sharp, or tight constriction of the axilla. Pain can be associated with surgical scar sensitivity. There can be associated dysesthesia or hyperesthesia of the anterior chest wall. It is presumed that injury to the intercostobrachial nerves and, rarely, the intercostal nerves is the cause. However, pain management interventions have included intercostal nerve blocks and not blockade of the intercostobrachial nerves,\textsuperscript{115} but it should be noted that the intercostobrachial nerves are branches of the second and third intercostal nerves, so blocks of the second and third intercostal nerves will also block the intercostobrachial nerves. Patients are at risk for developing upper extremity problems due to restricted movement of the arm secondary to pain. Treatment consists of analgesic and neuropathic medications, physical therapy, reassurance, intercostal or paravertebral nerve blocks, or epidural analgesia.\textsuperscript{116,117} Intraoperative infiltration of botulinum toxin into the chest wall musculature has also been suggested.\textsuperscript{118} Ultrasound-guided pectoral blocks have demonstrated pain control similar to thoracic paravertebral blocks.\textsuperscript{119} Persistent pain should arouse suspicion for recurrent breast disease.

Phantom breast syndrome has been a common occurrence after a mastectomy in the past.\textsuperscript{120–122} The incidence has decreased with adequate
psychosocial supportive therapy.\textsuperscript{123,124} It can present as painful or nonpainful sensations in the region of the missing breast as if it is still present. It can develop within 3 months after the surgery. Risk factors for development of the syndrome include psychosocial factors, damaged body image, and impaired sexual function. Affected women are usually younger, premenopausal with children. Predisposing factors for phantom breast pain are similar to phantom limb syndrome and include pain in the involved breast prior to surgery.\textsuperscript{125} Preoperative analgesia may be effective in preventing this syndrome; however, it has not been significantly studied.

**Postthoracotomy Pain**

Chronic chest wall pain after thoracotomy can be disabiling to the patient.\textsuperscript{126,127} Characteristics of postthoracotomy pain can be burning, aching, hyperesthesia, or allodynia along the surgical incision and the involved dermatome. Women experience more pain than men after major thoracotomy.\textsuperscript{128} No difference has been seen in the incidence of acute or chronic pain with different types of thoracotomy incisions.\textsuperscript{129} Prospective studies have predicted that adequate management of acute postsurgical pain can prevent the chronicity of pain.\textsuperscript{130,131} Preoperative psychosocial factors were not associated with development of chronic pain after thoracic surgery. There was no difference in the incidence and severity of chronic pain after thoracotomy versus thoracoscopy.\textsuperscript{132}

Management of acute pain with thoracic epidural placed prior to surgery has been shown to decrease the severity of perioperative pain and decrease the incidence of chronic pain. Other causes of radicular chest wall pain and recurrent cancer have to be excluded, especially in postthoracotomy patients who experience onset of severe pain several months after the thoracotomy. Management is similar to treatment for intercostal neuralgia.\textsuperscript{133,134} Thoracic paravertebral blocks are also helpful to control acute and chronic pain.\textsuperscript{135,136} Pulsed radio frequency of dorsal root ganglia or intercostal nerves is recommended for refractory pain.\textsuperscript{137} Prior to any injections of the surgical scar site, a careful examination is necessary to avoid injury to herniated lung tissue in rare cases.\textsuperscript{138,139} A multimodal approach to pain management provides higher success in controlling
chronic postthoracotomy pain.

Postcardiac Surgery Pain
Persistent anterior chest wall pain has been reported in about 28% of patients after cardiac surgery.\cite{140,141} Myocardial ischemia, infection, sternal or costosternal instability, sternal wires, and intercostal neuralgia (especially after dissection of the internal mammary artery from the chest wall) can be possible causes.\cite{142} Pain can persist up to 2 years postoperatively. Initial attempts at treatment should be focused on eliminating obvious serious causes. Treatment consists of analgesic and neuropathic medications, costosternal joint injections, and surgical removal of sternal wires.\cite{143}

CHEST PAIN AND PSYCHOLOGICAL FACTORS
Patients with sudden acute chest pain, regardless of the cause, experience varying degrees of anxiety, apprehension, and fear, depending on their interpretation of the cause of pain. Those who believe they are experiencing a heart attack become extremely frightened of possible impending death. Patients with persistent angina develop reactive depression, which, if untreated, produces progressive physical and psychological deterioration.\cite{144} Musculoskeletal chest pain can cause a great deal of anxiety and apprehension until the patients are reassured about the benign nature of the condition.\cite{145,146} Adolescents can often present with chest pain that is mostly myofascial or psychogenic in origin.

Chest pain can also result from psychological mechanisms. Because of the potential seriousness of a physical cause of chest pain, thorough history, physical examination, and diagnostic workup is essential. Some of the features of psychological chest pain include pain at the apex of the heart, patients describing the character of pain dramatically, development of pain unrelated to physiologic events, and possible presence of an emotional precipitating event prior to the pain. Once the diagnosis of psychological chest pain has been made, reassurance, relaxation techniques, anxiolytic drugs, sedatives, tranquilizers, and time can reduce the anxiety.

Patients with chronic anxiety can present with chest pain and other
symptoms. This syndrome has been called Da Costa syndrome, neurocirculatory asthenia, vasoregulatory asthenia, effort syndrome, and soldier’s heart. Patients can present with symptoms of apical chest pain, shortness of breath, nervousness, anxiety, fatigue, generalized weakness, and low energy level. Treatment consists of reassurance, behavioral therapy, and treatment of underlying psychiatric disorders, if any. Other psychiatric disorders, such as depression, conversion reactions, hypochondriasis, and learned behavior, can manifest as chest pain.

CHEST WALL PAIN OF CARDIAC ORIGIN
In any patient who presents with chest pain, the differential diagnosis must include chest pain of cardiac origin. Angina presents as substernal chest pain or tightness. However, atypical presentations of chest pain or gastric symptoms can be seen from cardiac disease. Evaluation of risk factors may help assist in making the diagnosis in atypical presentations. Chronic refractory angina pectoris is a condition where patients present with chronic and disabling chest pain despite optimal medical treatment. In such patients who are not candidates for invasive cardiac procedures, spinal cord stimulation (SCS) offers adequate pain control and improvement in the quality of life. SCS is also mentioned as an available adjunct by the task force on the management of stable angina pectoris of the European Society of Cardiology. Angina due to acute myocardial infarction is not masked by SCS.

Conclusion
Chest wall pain can result from lesions within the chest wall or referred pain from the thoracic viscera (Figs. 69.12 and 69.13). A comprehensive assessment and examination is needed to differentiate these and to further determine if the lesion involves skeletal, muscular, or neurologic components of the chest wall or thoracic and abdominal viscera (Table 69.3).

|                         |     | Dyspnea occurs because of marked increase in pain with normal respiration; triphasic pericardial friction rub occurs with atrial
H. Diseases of the thoracic aorta

1. Dissecting aneurysm

- Sudden, severe excruciating pain with maximal intensity at its onset; location of pain helps to localize dissection: ascending aortic dissection produces anterior chest pain in 65% of patients and posterior chest pain in 50%; dissection in descending thoracic aorta produces back pain in nearly all patients; radiation to the neck, throat, jaw, and abdomen in a small percentage of patients

- Nausea, vomiting, diaphoresis, bradycardia, and hypotension or tachycardia and hypertension; loss of one or more arterial pulses; sense of impending death, apprehension

2. Nondissecting aneurysm

- Mild to severe continuous burning, aching pain with bouts of lancinating pain; radiation to the chest, shoulder, and back caused by mechanical compression or

- Dyspnea, cough, dysphagia, hoarseness; Horner syndrome; pulsating mass; radiographic evidence
### II. Diseases of the respiratory system

#### A. Diseases of the tracheobronchial tree

<table>
<thead>
<tr>
<th>Description</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acute tracheobronchitis</td>
<td>Mild to moderate burning, aching pain in the retrosternal and parasternal regions; pain severe with thermal injury; associated with sore throat.</td>
</tr>
<tr>
<td>Bronchiectasis</td>
<td>Mild to moderate aching pain in retrosternal and parasternal regions.</td>
</tr>
</tbody>
</table>

Preceded by upper respiratory infection: coryza, malaise, chilliness, slight fever, back and muscle pain; with bronchitis, initially dry and nonproductive cough but later mucoid or mucopurulent, dyspnea might be present.

### B. Diseases of the pulmonary circulation

<table>
<thead>
<tr>
<th>Description</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acute pulmonary hypertension</td>
<td>Severe crushing, gripping pain in the center of the chest simulating that of acute myocardial infarction, but does</td>
</tr>
</tbody>
</table>

Usually decrease in arterial PO$_2$ can have dyspnea, cyanosis, sweating.
2. Chronic pulmonary hypertension (primary, secondary)

- Pain in anterior chest, primarily retrosternal; radiation to neck; some patients have typical angina pectoris complicated by myocardial ischemia

Primary hypertension usually in female subjects; dyspnea, easy fatigue, less frequently syncope; right ventricular hypertrophy can progress to failure

3. Pulmonary embolism

- With large embolus, pain is sudden, severe, crushing, and of a visceral central type; simulates pain of myocardial infarction but does not radiate to the jaw or arms; lasts for minutes to several hours; small embolus produces localized severe pleuritic pain that is persistent and lasts a week or longer; aggravated by deep breathing or coughing

Feeling of impending death (angor animi), pressure on throat, desire to defecate; history of thrombi in leg, pelvis, occasionally in upper extremity; rarely, embolic fluid or fat emboli; initially the large embolus usually produces pulmonary hypertension from increased pulmonary vascular resistance, leading to decreased cardiac output, hypotension that can progress to shock, with sweating, tachypnea, dyspnea, arterial hypoxemia; hemoptysis,
C. Diseases of the lungs

1. Pneumonia  
   - With lobar pneumonia, patient develops pleuritis with moderate to severe pain in lateral chest or shoulder aggravated by deep breathing and coughing (because of involvement of central diaphragmatic pleura); little or no pain with bronchopneumonia
   - Systemic symptoms and signs of infection: fever, cough, occasionally nausea, vomiting, malaise, and muscle pain; blood-streaked sputum, occasionally hemoptysis; rhonchi; percussion reveals dullness; radiographic evidence

2. Lung abscess  
   - Typical pleuritic chest pain if abscess produces pleuritis; characteristics similar to those of lobar pneumonia (see earlier)
   - Malaise, anorexia, sputum-producing cough, sweats, severe prostration, and fever; putrid odor (anaerobic infection); fine moist rales

3. Atelectasis  
   - Rapid occlusion with massive lung collapse causes moderate to severe pain on the affected side
   - Rapid collapse causes dyspnea, cyanosis, hypotension, tachycardia, fever, and shock; percussion, dullness, or flatness; diminished or absent breath sounds; decreased chest excursion of

undifferentiated small or large cell adenocarcinoma, bronchoalveolar carcinoma) carcinoma: sternal and parasternal pain
Intrapulmonary carcinoma: vague central (visceral) pain
Pleural spread: sharp, stabbing, chest wall pain markedly aggravated by breathing, coughing, movement
Mediastinal spread: neuropathy with segmental pain
Pancoast syndrome (brachial plexopathy): pain in shoulder, scapula, medial arm

Cough, hemoptysis Hypoxia, dyspnea, atelectasis
Signs and symptoms of pleuritis (see earlier)
Compression of superior vena cava Ø superior vena cava syndrome
Horner syndrome, hoarseness, weakness of all muscles supplied by the ulnar nerve

III. Diseases of the esophagus
A. Esophagitis
1. Gastroesophageal reflux disease
   - Retrosternal pain extends from suprasternal notch to xiphoid process; radiation to epigastrium, neck and back, and, rarely, arms; simulates pain of myocardial ischemia; lasts seconds to many hours; aggravated by stooping or lifting, recumbency, citrus juices, exercise, heavy meal, coffee, alcohol, aspirin, tobacco, and obesity; relieved by antacids
   - Dysphagia, odynophagia, regurgitation, and occasionally aspiration; diagnosis helped by pH monitoring, acid perfusion test, and esophagoscopy

2. Acute and chronic
   - Corrosive agents:
     - Infection: signs and
<table>
<thead>
<tr>
<th>Condition</th>
<th>Symptoms</th>
</tr>
</thead>
<tbody>
<tr>
<td>Esophagitis caused by infection or chemical agents</td>
<td>immediate, severe, burning pain in throat and behind the whole length of the sternum down to epigastrium, pain is constant with periodic increases in intensity produced by esophageal spasm; infection: pain appears gradually over a period of hours or days and is constant, mild to moderate, and burning in character; both are markedly aggravated by swallowing (odynophagia) and by citrus juices and other factors listed previously for gastroesophageal reflux disease</td>
</tr>
<tr>
<td>Symptoms of inflammation (e.g., fever, chills); chemical esophagitis: pharyngeal erythema; moniliasis; typical soft white patches in tongue, tonsil, and buccal mucosa; other associated symptoms as earlier (e.g., dysphagia, odynophagia)</td>
<td></td>
</tr>
<tr>
<td>B. Esophageal motor disorders (achalasia; diffuse spasm unclassified motor disorders)</td>
<td>Moderate to severe retrosternal pain; radiation to epigastrium and back, neck, jaw, teeth, left arm, or both arms; aggravated by cold liquids, solids, and emotional stress; partially relieved by nitroglycerin; lasts seconds to many hours and can awaken patient from sleep; simulates pain of myocardial infarction</td>
</tr>
<tr>
<td>C. Esophageal laceration and rupture (Mallory-Weiss syndrome, Boerhaave syndrome)</td>
<td>Mallory-Weiss syndrome: laceration of distal esophagus and proximal stomach during retching, vomiting, or hiccups causes pain in lower sternum and epigastrium; Boerhaave syndrome: spontaneous rupture occurs during intense vomiting following a large meal and causes sudden, severe, excruciating crushing or tearing pain in lower retrosternal region and epigastrium, with radiation to the back.</td>
</tr>
<tr>
<td>---</td>
<td>---</td>
</tr>
<tr>
<td>D. Carcinoma</td>
<td>Moderate to severe retrosternal pain; radiation to epigastrium with lower lesions and to upper sternum with upper lesions; radiation to neck, interscapular region; pain continuous and aggravated by food ingestion.</td>
</tr>
<tr>
<td>E. Paraesophageal hiatal hernia</td>
<td>Generally asymptomatic; might be feeling of epigastric fullness and lower retrosternal discomfort; with incarceration and strangulation.</td>
</tr>
</tbody>
</table>
### IV. Diseases of the mediastinum and diaphragm

#### A. Mediastinal disorders

1. **Spontaneous mediastinal emphysema**
   - **Symptoms:** Severe, excruciating epigastric and retrosternal pain
   - **Signs of emphysema:**
     - Crunching sound in area of pain
     - Decreased or obliterated cardiac dullness
     - Pneumothorax, subcutaneous emphysema (crepitus)
     - Radiographic evidence

2. **Acute or chronic mediastinitis**
   - **Symptoms:** Continuous; mild to moderate; retrosternal, central; oppressive or burning, aching sensation; can be severe
   - **Systemic signs of infection:**
     - History of esophageal rupture or other trauma

3. **Neoplasms (anterior compartment, superior compartment, middle compartment, posterior compartment)**
   - **Symptoms:** One-third of patients asymptomatic: remainder have chest pain, cough, dyspnea, and symptoms caused by compression or invasion of structures in mediastinum
   - **Middle compartment:**
     - Dysphagia, hoarseness
     - Anterior compartment:
     - Superior compartment:
     - Retrosternal and suprasternal discomfort, local chest pain from pressure on sternum
     - Posterior compartment:
     - Neurogenic tumors, vague chest pain, cough, radicular pain from
B. Diseases of the diaphragm

1. Diaphragmatic pleuritis

   - Sharp, stabbing pleuritic pain along the nape and shoulder or in the posterior and lateral parts of the lower chest and upper abdomen, or both; aggravated by diaphragmatic motion
   - Signs and symptoms of pneumonitis or infectious processes with inflammation of diaphragmatic pleura

2. Acute primary diaphragmatitis (Hedblom syndrome)

   - Moderate to severe pain in lower chest, upper abdomen, and shoulder
   - Chills and fever, muscle spasm of abdomen; decreased lung expansion on inspiration; radiographic evidence of flattened diaphragm

3. Diaphragmatic spasm

   - Precordial pain; radiation to shoulder
   - Dyspnea during sustained spasm of the diaphragm can cause occlusion of esophagus; some patients develop progressive dyspnea, pallor, sweating, hypotension, and angor animi simulating that of acute myocardial infarction; occlusion of the esophagus causes dysphagia and odynophagia

4. Diaphragmatic flutter

   - Lower chest pain felt along the
V. Pain of neuropathic origin
   A. Lesions or diseases of the spinal cord (myelopathy)

1. Intramedullary lesion (tumor, syringomyelia, trauma, multiple sclerosis, abscess, hemorrhage)
   - **I-6**
   - Spontaneous, burning, diffuse, poorly localized pain; bouts of explosive pain; later radicular pain involving several segments, depending on the size of the lesion
   - Dissociation of sensation, loss of pain and temperature sensation but little effect on proprioception; sensory changes often “spotty”; lower motor neuron signs; with multiple sclerosis spotty paresthesia, pain, symptoms and signs of other involved parts of CNS

2. Extramedullary lesion (primary or metastatic tumor; abscess; hemorrhage)
   - **I-6**
   - Initially localized back pain but subsequently pain is radicular; aggravated by increase in CSF pressure, such as that caused by straining, sneezing, coughing
   - Paravertebral tenderness, paresthesia, followed by sensory loss, muscular weakness; lower motor neuron signs at level of lesion; increased deep reflexes; CSF changes early and marked; spinal cord compression with large lesion

3. Epidural spinal cord
   - Localized back pain
   - Back tenderness on
<table>

with unrelieved postherpetic neuralgia
History of syphilis; CSF evidence; other symptoms of CNS syphilis
Hyperalgesia, hyperesthesia, hypesthesia, dysesthesia; radiographic evidence of pathology
Paravertebral tenderness and segmental hyperalgnesia, hyperesthesia, hypesthesia; radiographic evidence (CT scan)
adenopathy)

3. Primary neurogenic tumors (neurofibroma, schwannoma, ganglioneuroma, neuroblastoma)
   - Possibly localized back pain and tenderness but usually continuous burning, aching pain; associated with lancinating pain in distribution of affected nerve
   - Sensory deficit (hypesthesia), paresthesia, dysesthesia; CT scan and radiographic evidence

4. Other neuropathies (systemic infection, alcoholism, avitaminosis, diabetes, metals)
   - Continuous or intermittent mild to moderate burning pain; associated with paroxysms of stabbing pain in one or more dermatomes
   - History of infection, alcoholism, nutrition deficiency, exposure to ingestion of metals; hyperesthesia, hyperalgesia, hypesthesia, paresthesia, dysesthesia; other signs and symptoms of primary disorder

D. Lesion or disease of the intercostal nerves—intercostal neuropathy (compression or irritation secondary to rib fracture; trauma; primary or metastatic tumor of ribs; pleuritis)
   - Superficial continuous burning pain in distribution of affected intercostal nerve; also, local pain with rib fracture or tumor, pleuritic pain with pleuritis
   - History of trauma or infection; paresthesia, hyperesthesia, hypalgesia, hypesthesia; superficial and deep tenderness; radiographic evidence; palpable tumor or fracture

VI. Pain of musculoskeletal origin
   A. Lesions of the thoracic spine
      1. Fracture (trauma, neoplasm, osteoporosis, subluxation, dislocation)
         - Initially localized dull, aching pain, often referred to anterior part of chest; aggravated
         - History of trauma; radiographic evidence; localized tenderness
<table>

actinomycosis,
tuberculosis,
syphilis,
subperiosteal hematoma)

severe; aggravated by pressure, often worse at night

inflammation; localized tenderness paravertebrally and over spinous process

Tenderness
### C. Disorders of the costal cartilages

| 1. Costochondritis (anterior chest wall syndrome) | Unilateral or bilateral aching pain in lower anterior chest wall usually in region of cartilages of third, sixth, and seventh ribs; aggravated by deep breathing, coughing, palpation | No swelling of costochondral region; more frequent in younger than older people; development of anxiety and concern about heart disease if pain is on left side |
| 2. Tietze syndrome | Localized moderate dull, aching pain in upper anterior chest in region of second and perhaps third costochondral junction; aggravated by palpation, movement of chest wall, coughing, respiratory infection; worse when lying down; recurs between intervals of remission | Palpable tender tumorlike swelling at site of costochondral joint; occurs mostly in people older than 50 y; radiography not diagnostic; development of anxiety, fatigue, concern about heart disease |
| 3. Slipping rib syndrome (rib tip syndrome, slipped cartilage) | Unilateral lower chest and upper abdominal localized aching or sharp pain; aggravated by hyperextension and raising of arms; | Palpation produces tenderness and reveals upward curling of loosened end of cartilages of 8th, 9th, and 10th ribs; hooking |

3. Other bone diseases (osteitis deformans, acromegaly, Paget disease, osteoporosis, hyperostosis)

- Relatively localized but can also produce intercostal neuralgia
- Localized continuous aching pain; intercostal neuralgia if lesion irritates nerve
- Evidence of disease elsewhere; tenderness on palpation; radiographic evidence
<table>
<thead>
<tr>
<th>Fracture of cartilage or dislocation of costochondral joint</th>

</tr>
</thead>
<tbody>
<tr>
<td>Pressure on xiphoid process produces spontaneous pain that can radiate deep retrosternally and to the precordium, epigastrum, and across shoulder and back; persists for weeks or months but usually.</td>
<td></td>
</tr>
</tbody>
</table>
4. Arthritis of sternoclavicular joint

E. Muscle disorders
1. Myofascial pain syndromes with trigger points
   a. Anterior chest (major and minor, pectoralis; scaleni; sternalis; intercostals)
   b. Lateral chest (serratus anterior; intercostals)

and by increase in intragastric pressure caused by a large meal; can be constant or recurs several times a day; lasts for minutes to several hours; disappears spontaneously

Localized sharp or aching pain in region of joint; radiation to shoulder and upper chest

Joint swollen, tender on palpation; radiographic evidence

Frequent cause of pain in anterior chest; pain is deep and aching; aggravated by activity; sternalis and pectoralis pain can simulate pain of angina pectoris; pain relieved by injection of trigger points with local anesthetic

History of severe strain by heavy lifting; local tenderness, trigger points present; unaffected body activity

Deep aching pain on the lateral aspect of the chest extending from the lower axilla to about the seventh to the sixth ribs; pain also in area near the inferior angle of the scapula; with intercostal syndrome site of pain varies with site of trigger points; relief with trigger point

Localized tenderness and trigger point about the level of the sixth rib; pressure on trigger points produces spontaneous pain
<table>
<thead>
<tr>
<th>c. Posterior chest (rhomboidei, latissimus dorsi multifidi, serratus posterior superior, iliocostalis thoracis)</th>

   A. Disorders of the cervical spine that cause neuropathy
      1. Posterolateral

---

esophageal lesions

(See Chapter 31 for detailed discussion)

Rare condition manifested by thrombosis of superficial vein of thoracic wall that produces palpable painful cord within the skin; usually sharp and persistent; intensified by deep inspiration or flexion of the trunk

Presence of painful, tender, subcutaneous cord running obliquely across thorax in distribution of one or more superficial veins; lesion indolent after several weeks

Early breast cancer not painful; in far advanced disease, skin nodule eventually breaks down and formation also causes localized breast pain; metastasis to the pleura produces pleuritic pain; metastasis to the ribs causes localized pain and can be associated with segmental neuralgia; metastasis to the spine produces back pain and later can cause epidural spinal cord compression or plexopathy

Early: retracted nipple, bleeding, distorted areola or breast contour, skin dimpling (peau d’orange); later: axillary supraclavicular adenopathy; metastatic lesion demonstrated by radiography and CT scan

---

Pain in the neck, Paravertebral and
protrusion of intervertebral disk (C7, C8)

shoulder, medial aspect of the arm, and pectoral region of the chest; with left-sided lesion, pain can simulate that of myocardial ischemia but is differentiated by aggravation by lateral flexion and the Spurling test (see Chapter 54); unaffected by activity if neck and arms not moved

pectoral muscle tenderness; hyperalgesia, hyperesthesia, and paresthesia of the arm; decrease in reflexes and some muscle weakness in the upper limbs

2. Arthritis, osteophyte, fracture or other lesion that compresses root or nerve

3. Thoracic inlet syndromes (scalenus anticus syndrome; cervical rib or abnormal first rib; costoclavicular compression)

Pain most prominent in the shoulder and upper limbs; radiation to the upper pectoral region; aggravated by severe arm abduction and walking with swinging arms; unaffected by activity if arms not moved

Supraclavicular (scaleni) tenderness and fullness; neurovascular signs and symptoms in the upper extremities; radiographic evidence of abnormal cervical rib

4. Pancoast syndrome

Pain in shoulder, scapula, medial aspect of arm, and superior anterior chest; aggravated by extreme abduction of the arm and paravertebral pressure; unaffected by activity if neck and limbs are not moved

Signs and symptoms of plexopathy with paresthesia, dysesthesia, numbness in the medial aspects of the forearm and fourth and fifth fingers, also medial aspect of arm; marked weakness of muscles supplied
B. Diseases of the abdominal viscera

1. Gas entrapment syndromes (e.g., caused by aerophagia, excess production of gas in bowel)

   - Bloated sensation associated with pain in the epigastrium and central lower chest; if diaphragm irritated, pain also in shoulder; dull, aching pain worsens as day progresses; transiently relieved by belching; gas entrapment in hepatic flexure of colon produces discomfort in right upper quadrant and lower part of right chest, gas in splenic flexure causes pain in left upper quadrant and left lower chest

2. Peptic ulcer disease

   - Ulcer in cardia of stomach produces pain in the epigastrium and central lower anterior chest, ulcer in other locations not associated with chest pain; duodenal ulcer causes pain that radiates to xiphoid process but not higher

3. Perforated ulcer

   - Sudden severe epigastric pain that

Our growing treatment armamentarium includes analgesic and neuropathic medications, nerve blocks and ablations, joint injections, implanted pumps, and transcutaneous or implanted peripheral or dorsal column stimulators as well as behavioral medicine approaches. In recent years, portable ultrasound has become an easily accessible, user-friendly tool in diagnosis and interventional treatment of chest wall pain. In most cases of chest wall pain, conservative, multidisciplinary approaches are initially preferred, saving invasive treatments for the more refractory cases.

112. Vecht CJ, Vande Brand HJ, Wajer OJ. Post-axillary dissection pain in breast cancer due to a

The information in this chapter is presented in three major sections detailing (1) specific causes of lumbosacral plexopathy, (2) specific lower extremity peripheral nerve lesions, and (3) specific causes of foot pain.

**Lumbosacral Plexopathy**

Although the lumbar and sacral plexuses are separate structures, they are often referred to as a single structure—the lumbosacral plexus—that provides motor and sensory innervation to the pelvis and leg (Fig. 70.1). The lumbar plexus, which is made up of the ventral rami of the T12–L3 and a portion of the L4 nerve roots, is contained within the psoas muscle and lies anterior to the L2–L5 vertebral bodies.\(^1\)\(^-\)\(^3\) The anterior and posterior divisions of the ventral rami form the terminal branches of the lumbar plexus and include the iliohypogastric (T12, L1), ilioinguinal (L1), genitofemoral (L1, L2), lateral femoral cutaneous (L2, L3), obturator nerves (L2, L3, L4), and femoral (L2, L3, L4) nerves.\(^3\) The saphenous nerve is a branch of the femoral nerve.
The sacral plexus (Fig. 70.2), which is made up of the ventral rami of the S1–S5 nerve roots, connects with the lumbar plexus via the lumbosacral trunk. It is made up of the ventral rami of the L4–L5 nerve roots and lies just anterior to the piriformis muscle, posterior to the internal iliac vessels, and in close proximity to the hypogastric arteries and veins, lateral rectum, pelvic colon, and ureters. Similar to the lumbar plexus, terminal branches arise from the anterior and posterior divisions of the ventral rami of the sacral plexus. The tibial nerve (made up of the anterior divisions of the ventral rami) and the common fibular (peroneal) nerve
(made up of the posterior divisions) form the terminal branches of the sciatic nerve on bifurcating from their common epineural sheath. Additional terminal branches of the sacral plexus include the superior gluteal (L4, L5, S1), inferior gluteal (L5, S1, S2), posterior femoral cutaneous (S1, S2, S3), and pudendal (S2, S3, S4) nerves.

There are multiple causes of lumbosacral plexopathy. These include space-occupying masses (invasive neoplasm, compression by retroperitoneal or pelvic mass), vascular/metabolic diseases (diabetes, chronic idiopathic peripheral polyneuropathy, vasculitis, aneurysmal dilation), trauma (pelvic fractures, complications from surgery or radiation therapy), and idiopathic causes. Nontraumatic lesions are the most common, as evidenced by one report of 86 cases revealing a neoplastic etiology in more than 50% and trauma in only 6%. Patellar reflex impairment along with hip flexion, knee extension, and/or dorsiflexion

**FIGURE 70.2** Oblique sagittal view of the sacral plexus.
weakness suggests lumbar plexopathy, whereas ankle reflex impairment along with hip extension, knee flexion, and/or plantarflexion weakness suggests sacral plexopathy.

Depending on the cause, diagnostic workup for plexopathy can include plain film x-ray imaging, detailed neuroimaging (computed tomography [CT] and magnetic resonance imaging [MRI]), angiography, ultrasonography, electrodiagnostic studies (electromyography [EMG] and nerve conduction study [NCS]), and laboratory studies. Diagnostic studies in isolation of the patient’s medical history and physical exam findings, however, have limitations. For example, neuroimaging may not be able to differentiate between benign tumor versus malignant tumor versus radiation-induced plexopathy. Likewise, electrodiagnostic studies may not be able to differentiate between peripheral neuropathy versus plexopathy. Electrodiagnostic studies, however, may be able to provide information on the extent of motor axon loss or on the presence of muscle denervation when clinical assessment is limited by the cause of injury.

Treatment options depend on the cause, location, symptom severity, physical exam findings, and duration of the plexopathy. In certain situations, surgery may be the initial treatment of choice, whereas in other circumstances, observation and symptom management may be the preferred approach. Conservative therapy for symptomatic relief includes medications (corticosteroids, acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs], anticonvulsants, tricyclic antidepressants, opioids, topical analgesics, and lidocaine patch) and injections. Spinal cord stimulation or intrathecal therapies may be considered for those who have a suboptimal response to the aforementioned and/or those who are not surgical candidates. Physical therapy is important for those with evidence of motor weakness in order to minimize muscle atrophy, prevent muscle contractures, and maintain ambulatory status. Assessment for orthotic devices (e.g., ankle-foot orthosis [AFO]) and gait assistive devices (e.g., crutches, cane, walker) also may be necessary in order to prevent falls.

**NEOPLASMS**

In comparison to neoplastic involvement of the lumbosacral spinal nerves, cauda equina, or conus medullaris, lumbosacral plexus involvement is
relatively uncommon and has a reported incidence of 0.71%. Neoplastic plexopathies can involve the sacral plexus (50%), lumbar plexus (33%), or lumbosacral plexus (17%). Most are of malignant origin, with 75% occurring by direct extension (most commonly from gastrointestinal tumors, genitourinary tumors lymphomas, sarcomas), or metastasis. Breast cancer is the most common primary source, and rarely is the diagnosis of neoplastic plexopathy made before discovery of the primary neoplasm.

Neoplastic plexus involvement portends a poor prognosis, with death often occurring within 6 months of diagnosis. Insidious onset of low back pain (lumbar plexus) and/or leg pain (sacral plexus) are often the primary heralding features and can precede other neurologic symptoms. At initial onset, unilateral leg pain is present in 90% of patients and tends to be more prominent than low back pain. The pain can have both nociceptive and neuropathic features and is worse with recumbency, movement, and Valsalva maneuvers. Lumbar plexus involvement, also known as malignant psoas syndrome, is suggested by localization of pain over the costovertebral angle, anterior abdominal wall, groin, or thigh and by painful fixed flexion of the hip worsened by passive or active hip. Within 13 months of pain onset, many patients develop additional neurologic symptoms: weakness (86%), gait dysfunction, sensory loss (73%), reflex impairment (64%), and paroxysmal or continuous paresthesias or dysesthesias. Additional physical exam findings may include (1) lower extremity edema (seen in 50%), (2) warm and dry foot (seen with sympathetic nerve involvement), (3) palpable rectal mass and perineal pain (seen in more than one-third with sacral involvement), (4) incontinence and impotence (seen in 10%, usually implying extensive sacral involvement with bilateral sacral plexopathy), and (5) abdominal and pelvic pain. The differential diagnosis, however, must also include radiation-induced plexopathy, peripheral neuropathy, radiculopathy, cauda equina syndrome, retroperitoneal hematoma, and vertebral compression fracture.

Tumors can be broadly classified as intrinsic or extrinsic. Intrinsic tumors can be benign (e.g., neurofibromas and plexiform lesions) or malignant (e.g., schwannomas or neurogenic sarcomas). Neurofibromas,
which are common in patients with neurofibromatosis type 1, are commonly seen in the paraspinal, sacral plexus, sciatic notch, and perirectal regions. Patients may or may not have symptoms with benign or malignant tumors, and an MRI alone may be insufficient to differentiate one from the other. Symptomatic relief with analgesic medications may be necessary until the tumor can be excised.

Extrinsic tumors are malignant. Lymphoma can cause a plexopathy due to enlarged lymph nodes (most common), extranodal disease in the muscle (e.g., psoas, iliacus, piriformis, and gluteal muscles) or subcutaneous fat, or direct sciatic nerve involvement (rare). Carcinomas (colorectal, genitourinary, breast, lung, and prostate) and retroperitoneal sarcomas can cause a plexopathy by encasement of the plexus by the primary tumor itself, metastasis into the surrounding soft and bony tissue, or metastasis into the plexus itself. Sacral chordomas, which can cause constipation, urinary frequency, and sciatica, are the most common primary malignant sacral tumors. Imaging with MRI, CT, or positron emission tomography computed tomography (PET-CT) may help with the workup of these extrinsic tumors. Chemotherapy, radiation therapy, and/or surgical resection of the tumor is usually indicated.

**RADIATION-INDUCED PLEXOPATHY**

Pelvic radiation therapy to treat urologic cancers, gynecologic cancers, and lymphomas can result in radiation-induced lumbar, sacral, or lumbosacral plexopathy. Unlike neoplastic plexopathy, which is often associated with significant pain and weakness, radiation plexopathy is primarily associated with weakness, with significant pain being present in fewer than 25% of patients. Weakness is noted predominantly in the distal L5–S1 innervated muscles and may be accompanied by reflex and sensory impairment, skin changes, and lymphedema; bowel or bladder disturbance is rare. The mean duration of symptom onset is 5 years but can vary from a few months to more than three decades. Skin changes and lymphedema are commonly seen. Because of obvious therapeutic implications, neuroimaging studies are critically important in order to discriminate between tumor recurrence, radiation fibrosis, and surgical scar tissue. Electrodiagnostic studies should be included to help establish the diagnosis.
when neuroimaging findings are nonspecific. Characteristic electrodiagnostic findings include demyelinating conduction block and myokymia. If electrodiagnostic findings are also nonspecific, the diagnosis usually needs to be confirmed by biopsy or surgical exploration. For those with only radiation-induced plexopathy, treatment is nonsurgical and involves symptom management.

**DIABETIC AND NONDIABETIC LUMBOSACRAL RADICULOPLEXUS**

Diabetic lumbosacral radiculoplexus (diabetic amyotrophy) involves microvasculitic ischemic nerve injury. It most commonly occurs in elderly patients with chronic type 2 diabetes mellitus and does not occur in isolation of diabetic peripheral polyneuropathy. Patients usually report weight loss and low back and/or leg pain that is worse at night. These symptoms are often followed by signs of weakness, atrophy, and sensory deficits involving the anterior thigh along with an absent patellar reflex. Electrodiagnostic findings include axonal loss, demyelination, and denervation changes in muscles innervated by the obturator and femoral nerves. Neuroimaging is necessary to rule out other potential causes of lumbosacral plexopathy. Because the plexopathy is due to ischemic nerve injury, treatment focuses on symptom management, physical therapy, and assessment for a gait assistive device.

Nondiabetic lumbosacral radiculoplexus is an underappreciated cause of lumbosacral plexopathy. Similar to diabetic lumbosacral radiculoplexus, nondiabetic lumbosacral radiculoplexus involves microvasculitic (motor, sensory, and autonomic) nerve injury; initially involves the legs; and is associated with pain, weight loss, prolonged morbidity and mortality, and incomplete recovery. Both nondiabetic and diabetic lumbosacral radiculoplexus also share similar electrodiagnostic findings and treatment strategies. Unlike diabetic lumbosacral radiculoplexus, however, nondiabetic lumbosacral radiculoplexus is not associated with hyperglycemia and is probably due to an autoimmune phenomenon.

**ABSCESS**

Psoas, gluteal, and pelvic abscesses can present acutely or insidiously with
painful fixed flexion of the hip or pain in the abdominal, pelvic, or gluteal regions. In their retrospective analysis of 23 retroperitoneal collections related to the psoas muscle, Paley et al. confirmed 5 were hematomas and 18 were abscesses, and of the abscesses, 3 were caused by primary infections and the remainder by infections of spinal, renal, or gastrointestinal origin. Because their appearance on MRI and CT can be confused with lymphoma or tumor deposits, image-guided percutaneous drainage can be of diagnostic and therapeutic value.

RETROPERITONEAL HEMATOMA
Retroperitoneal hematomas can occur from anticoagulant therapy, hemophilia, ruptured aortic aneurysms, idiopathically, or iatrogenically (e.g., cardiac catheterization). The degree of neurologic deficit depends on the size of the hematoma: (1) A small hematoma compresses the intrapelvic portion of the femoral nerve within the iliacus muscle; (2) a large hematoma compresses the lumbar plexus within the psoas muscle, affecting both the obturator and femoral nerves; and (3) a widespread hematoma affects the lumbosacral plexus. Signs and symptoms may include ecchymosis (flank, low back, and/or thigh) and acute or subacute onset of lower abdominal or groin pain radiating to the anterior thigh. Neuroimaging facilitates the diagnosis. EMG and NCS findings include abnormalities in the adductor muscle and axonal loss in the distribution of the femoral nerve or lumbar plexus (although involvement of the lumbosacral plexus can also occur). Even though retroperitoneal hematomas are considered compartment syndromes, treatment is nonsurgical.

ANEURYSMS
Aneurysms of the distal aorta, iliac arteries, intrapelvic arteries, and hypogastric arteries and arteriovenous malformations can injure the lumbosacral plexus via direct compression or ischemia from embolism of feeding vessels. Symptoms may include low back pain with or without radicular symptoms, sensory loss, and weakness. The initial diagnostic workup includes an abdominal and pelvic ultrasound, followed by neuroimaging and angiography. The electrodiagnostic finding includes
axonal loss, but pinpointing the location is often challenging. Treatment involves surgical repair of the aneurysm.

TRAUMA
Traumatic injuries to the lumbosacral plexus, in comparison to the brachial plexus, occur infrequently because the neural structures are (1) relatively distant to highly mobile structures and (2) well protected by muscle and bone. Therefore, trauma-induced lumbosacral plexopathy typically results from penetrating or violent injuries—gunshot blast, high-speed motor vehicle or motorcycle accident, pedestrian versus motor vehicle accident, or fall from a tall height—and is often associated with pelvic bony fractures. Isolated fractures involving the non–weight-bearing anterior one-third of the pelvic ring are often stable and do not result in neurovascular injury. Conversely, because the posterolateral two-thirds of the pelvic ring is involved with weight bearing and lays in close proximity to neurovascular structures, fractures in this area lead to instability and neurovascular compromise. Symptoms can include variable degrees of pain, sensory and reflex impairment, muscle weakness, atrophy, and gait abnormality. Treatment involves identifying the extent of neurovascular injury. Because most nerve traumatic injuries spontaneously improve (to a certain degree) and surgical repair can be technically challenging, surgery is not recommend as the initial treatment of choice. Of those who do require surgery, outcomes are relatively better with repair of the lumbar instead of sacral plexus. Neuropathic pain persisting beyond the anticipated healing process suggests the presence of a neuroma or scar tissue. Treatment may involve additional surgery to remove the neuroma or scar tissue, medication management, or implantation of a spinal cord or peripheral nerve stimulator.

OBSTETRIC-RELATED PLEXOPATHY
Compression of the lumbosacral plexus between the pelvic rim and fetal head can occur during the latter stages of pregnancy or during delivery (Fig. 70.3). Katirji et al. described seven patients with intrapartum maternal lumbosacral plexopathy who shared common features: short maternal stature, prolonged labor, pain and demyelination in an L5 nerve
root distribution, foot drop, and complete resolution of symptoms within 5 months. A large fetal head or the use of forceps can also cause compression of the lumbosacral plexus. Neuroimaging may be of limited benefit when the fetus is present. EMG and NCS abnormalities include abnormalities in muscles innervated by the L5 nerve root and a demyelinating conduction block of nerves supplying the muscles of the anterolateral leg. Aside from delivery of the fetus, treatment is nonsurgical.

![Image of nerve compression](https://example.com/image)

### Specific Nerve Entrapment Syndromes

#### LATERAL FEMORAL CUTANEOUS NERVE ENTRAPMENT
The lateral femoral cutaneous nerve (LFCN), a purely sensory nerve,
originates from the lumbar plexus and conveys fibers from posterior divisions of the ventral rami of the L2 and L3 nerve roots (Fig. 70.4). Near the anterior superior iliac spine (ASIS), the LFCN divides into anterior and posterior branches and conveys sensory information from the anterolateral and lateral surfaces of the thigh, respectively. Compression of the LFCN most commonly occurs as the nerve exits the pelvis and pierces or crosses the inguinal ligament and attaches to the ASIS. Entrapment of the LFCN, also known as lateral femoral cutaneous neuralgia, was first characterized by Bernhard in 1878. In 1895, Roth coined the name meralgia paresthetica (MP), which is derived from the Greek words meros (meaning thigh) and algos (meaning pain).18,19

![FIGURE 70.4](image)

**FIGURE 70.4** Cutaneous branches of the lateral femoral cutaneous nerve. Anterior (A) view and posterior (B) view.

Although MP is not rare, its exact prevalence remains unknown. It can occur at any age but is most commonly seen in patients 30 to 60 years of age.19,20 After looking at the relationship between comorbidity (e.g., carpal tunnel syndrome, pregnancy, hip osteoarthritis, obesity, symptoms of the pubic bone, thrombosis of the leg, diabetes mellitus, and the use of corticosteroids) and the occurrence of MP, van Slobbe et al.20 concluded the incidence rate of MP is 4.3 per 10,000 person-years. Although probably underdiagnosed in children, it has been seen in as many as one-third of those treated for ostoid osteoma.19 Whether there is a true gender predilection remains unknown, as results vary depending on the study referenced.17,20–23
Etiology
Causes of MP have been categorized as spontaneous or iatrogenic. Spontaneous causes result from entrapment due to intrapelvic (pregnancy, pelvic or abdominal tumors, uterine fibroids, degenerative pubic symphysis, diverticulitis, and appendicitis), extrapelvic (seatbelt trauma, tight garments or belts, and obesity), or mechanical (prolonged sitting, prolonged standing, and leg length discrepancy) factors or from metabolic derangements (diabetes mellitus, hypothyroidism, alcoholism, and lead poisoning). The greatest risk factor is obesity. Mondelli et al. noted that obese patients (body mass index \( \geq 30 \text{ kg/m}^2 \)), but not overweight patients (body mass index 25 to 29.9 kg/m\(^2\)), showed twofold greater risk for developing MP. Interestingly, some have even reported cases of MP in patients who have lost weight. Postulated mechanisms may include the presence of other compressive factors, lack of nutritional factors, or underlying systemic disease. Iatrogenic causes of MP result from orthopedic procedures (pelvic osteotomy, iliac crest bone graft harvest, spine surgery, and total hip replacement) and nonorthopedic procedures (gastric bypass surgery, laparoscopic inguinal herniorrhaphy, laparoscopic cholecystectomy, laparoscopic myomectomy, coronary artery bypass grafting, aortic valve surgery, and renal transplant).

Symptoms and Signs
Although the majority of patients usually complain of unilateral sensory loss, paresthesias, or dysesthesias, the incidence of bilateral symptoms can be as high as 20%. The symptoms rarely radiate proximally toward the spine. Hair loss over the anterolateral thigh due to constant rubbing may be present. Prolonged standing, walking, or hip extension may worsen the symptoms. Hip flexion may alleviate or worsen the symptoms. A Tinel sign (paresthesias radiating to the anterolateral thigh) sometimes can be elicited by percussing medial to the ASIS. For those patients in whom inguinal ligament LFCN entrapment is suspected, the pelvic compression test should be performed (Fig. 70.5). With the patient lying in a lateral decubitus position on the unaffected limb, the examiner maintains downward pressure on the pelvis for 45 seconds. Transient improvement of symptoms is considered a positive result. Nouraei et al. showed this
test had a sensitivity of 95% and a specificity of 93.3% in those with electrodiagnostically proven MP.

Symptoms extending beyond the territory of the nerve, reflex changes, muscle weakness, or muscle atrophy suggest an alternate diagnosis, such as a lumbar plexopathy, high lumbar radiculopathy, or other peripheral neuropathy.

**Diagnosis**

Imaging and laboratory studies should be considered when a clear cause cannot be identified: radiograph or neuroimaging of the pelvis to rule out pelvic tumor or fracture and neuroimaging of the lumbosacral spine to rule out disk herniation.\(^\text{19}\) Although electrodiagnostic studies can play a role in the diagnosis of MP, some argue its utility may be hampered by inherent technical difficulty, challenges in obtaining a response in obese patients, and small recordable sensory responses (absent in 71% and prolonged in 24%).\(^\text{24}\) Furthermore, in order to obtain the best recordings one must use needle electrodes instead of surface electrodes. Others, however, claim that electrodiagnostics should play a central role in diagnosing MP. Instead of strictly looking at the absolute value of the sensory nerve action potential (SNAP) amplitude, Seror and Seror\(^\text{22}\) demonstrated a specificity of 98.75% in their study of 120 patients when the side-to-side amplitude ratio was greater than 2.3 and the amplitude was less than 3 microvolts. Because the nerve is purely sensory, EMG testing of muscles should be normal. The value of somatosensory-evoked potentials (SSEPs) in making the
diagnosis is debatable. Ultimately, the greatest benefit of performing an electrodiagnostic is to rule out other entities—high lumbar radiculopathy, lumbar plexopathy, or other peripheral neuropathy—that can cause similar symptoms.

**Treatment**

Nonsurgical treatment for MP is typically successful, as symptoms are often mild and self-limited. In their study of 277 patients, Williams and Trzil reported conservative management was successful in 91% of patients. Initial recommendations include advising patients to avoid wearing tight-fitting garments or belts, advising obese patients to lose weight, and correcting leg-length discrepancies. If symptoms persist, other treatment options include ice, transcutaneous electrical nerve stimulation (TENS) unit, and analgesic medications and injections. Because no controlled studies have been performed, the long-term efficacy of a local anesthetic LFCN block (with or without corticosteroids) is unclear. Furthermore, whether temporary relief of symptoms alters the long-term prognosis is unknown. Using a standard treatment algorithm in 79 patients, Haim et al. showed symptomatic improvement in 21 patients requiring conservative therapy and medical management, 48 patients requiring LFCN blocks using corticosteroid and local anesthetic, and 10 patients requiring surgery. At 1-year follow-up, the authors reported none of the patients had recurrence of MP symptoms.

Traditionally, the target site of injection is identified based on anatomic landmarks (1 cm medial and 1 cm inferior to the ASIS), with a large volume of medication being injected using a fanning technique. Although large volumes may increase the success rate of blocking the LFCN to obtain useful diagnostic information, it can also come at the risk of inadvertently blocking the femoral and/or obturator nerves. However, absence of immediate analgesia does not necessarily rule out the diagnosis of MP given the LCFN’s anatomic variability and given failure rate of this technique being as high as 60%. In a prospective, randomized, crossover study involving 20 patients, the same authors demonstrated a 100% versus 40% success rate with blocking the LFCN using a stimulating needle versus a fanning technique, respectively. Ultrasound guidance can also
improve the success rate of identifying the correct nerve. In their study of 20 patients, Tagliafico et al.\textsuperscript{30} described a technically successful LFCN block in 100\% of the patients and no short-term or long-term complications. Similarly, Hurdle et al.\textsuperscript{31} reported a technically successful LFCN block in their study of 10 patients, 5 of whom were obese. The advantages to using ultrasound-guidance include real-time visualization of the needle position and the adjacent structures, use of lower volumes of injectate, and avoidance of blockage of the femoral and/or obturator nerves.\textsuperscript{30,31}

For those who do not obtain long-term benefit from corticosteroid injections, other treatments that have been tried include cryoanalgesia, pulsed or continuous radiofrequency (RF), alcohol neurolysis, peripheral nerve stimulation, and spinal cord stimulation. The successful outcomes reported in some of these studies need to be interpreted with caution, though, as they tend to be case reports, case series, or retrospective studies.\textsuperscript{32–35} For those patients whose symptoms are refractory to analgesic medications, LFCN blocks, and neurostimulation, operative interventions may include transecting the LFCN at the level of the inguinal ligament (neurectomy) or incising the inguinal ligament to decompress the LFCN (neurolysis).\textsuperscript{28} Based on their systematic review of the literature, Payne et al.\textsuperscript{36} could not identify one treatment as being superior to the other due to the lack of high-quality studies. As with any neurodestructive procedure, there is a risk of nerve injury or neuroma formation.

**FEMORAL NERVE ENTRAPMENT**

The femoral nerve is a sensory (Fig. 70.6) and motor nerve and is the largest nerve of the lumbar plexus. It originates within the psoas muscle and arises from the posterior divisions of the ventral rami of the L2, L3, and L4 nerve roots (see Fig. 70.1A).\textsuperscript{37} (The anterior divisions of the same nerve roots form the obturator nerve.) In the abdomen, the femoral nerve gives off branches to the iliacus and psoas muscles, and as it passes under the inguinal ligament, it gives off a branch to the pectineus muscle. The nerve then enters the femoral triangle lateral to the femoral artery, and upon exiting the triangle, it splits into an anterior and posterior division. The anterior division provides motor innervation to the sartorius muscle.
and sensory innervation (via the medial and intermediate femoral cutaneous nerves) to the anterior thigh as far distally as the knee. The posterior division provides motor innervation to the quadriceps muscles (rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis) and sensory innervation (via the saphenous nerve) to the anteromedial aspect of the knee, medial calf, medial malleolus, and part of the medial arch of the foot and great toe.  

Isolated femoral neuropathy, originally known as anterior crural neuritis, was first reported in 1822 in a thesis by Descot. Although most lesions are unilateral, bilateral involvement has been observed. Because an isolated unilateral femoral neuropathy is uncommon, its true incidence remains unknown. Kuntzer et al. reported that of 7,252 electrodiagnostic examinations performed at their institution between 1988 and 1994,
femoral neuropathy accounted for the diagnosis is only 32 patients (0.5%). Femoral neuropathies can cause either motor and sensory disturbances or sensory disturbances only. The latter occurs when the saphenous nerve, which is the distal sensory continuation of the femoral nerve, is involved.

**Etiology**

The causes of femoral neuropathy may be divided into the following categories: (1) direct nerve trauma (gunshot or knife wound, hip or pelvic fracture, hip replacement, hip prosthesis displacement, thermal energy from methyl methacrylate, inguinal herniorrhaphy, or femoral nerve block), (2) nerve ischemia due to interrupted vascularization at the intrapelvic level (common iliac artery occlusion, vascular or aortic surgery, or renal transplant with graft in the iliac fossa), (3) nerve compression (femoral artery injury in the femoral triangle, retroperitoneal hematoma, retroperitoneal mass, lithotomy positioning, prolonged hyperextension of the hip, or entrapment under the inguinal ligament with hip flexion), (4) metabolic (diabetes or pelvic radiation therapy), and (5) idiopathic.\(^{37,39–41}\)

Because of a somewhat differential blood supply, the left femoral nerve is more susceptible to ischemic injury than the right.\(^{42}\) The most vulnerable site of injury is located 4 to 6 cm above the inguinal ligament, which is where the nerve exits from the psoas muscle.\(^{26}\) Because most pelvic surgical maneuvers occur proximal to the psoas muscle and out of the direct path of the nerve, neuropathy due to a compressive injury from retractors is more likely than that due to nerve transection and is independent of the type of incision (horizontal, midline, or lateral).

Most surgery-related causes of femoral neuropathy are preventable as long as retractors are used with care and positional factors are taken into account.\(^{41}\) In their analysis of 32 patients with electrodiagnostically confirmed femoral neuropathy, Kuntzer et al.\(^{39}\) identified an iatrogenic cause in 65% of the cases, and of these, 87% were related the hip surgeries. The incidence of femoral neuropathy after total hip arthroplasty is estimated to be as high as 3%.\(^{42}\) A significant number of cases of femoral neuropathy occur with gynecologic, urologic, orthopedic, and vascular surgeries.\(^{26,39,42}\) The incidence of neuropathy after abdominal
hysterectomy, for example, ranges from 7% to 12%. Based on their prospective study looking at femoral neuropathy subsequent to abdominal hysterectomy, Goldman et al. reported the incidence of femoral neuropathy decreased from 7.45% to 0.7% when self-retaining retractors were eliminated. The compression is often indirect, as the nerve becomes entrapped between the pelvic wall and the psoas muscle on which the retractor rests. In those instances where a compressive neuropathy has occurred, direct ischemia of vasa nervorum due to deficient vascularization is the most likely mechanism of action. Urologic procedures (renal transplant, radical cystectomy, transurethral resection of the bladder with exploration and biopsy of a tumor mass, percutaneous nephrolithotomy of a pelvic kidney, radical cystoprostatectomy and continent urinary diversion, and psoas hitch vesicopexy) can also be a cause of femoral nerve injury. For patients undergoing renal transplant with graft in the iliac fossa, the occurrence of femoral neuropathy ranges from 0.5% to 2.2%. Possible explanations for the cause include nerve compression combined with potential hematoma in the iliac space and prolonged vascular anastomosis or arterial clamping time.

**Symptoms and Signs**

Unilateral sensory loss, paresthesias, or dysesthesias in the distribution of the femoral nerve and its branches, an impaired patellar reflex, and/or hip flexion and knee extension weakness may be present. Quadriceps atrophy may be noted in chronic and severe cases. Patients with hip flexion and knee extension weakness describe frequent buckling of the knee and/or falls while ambulating. Navigating stairs is often difficult, requiring patients to ascend by leading with the unaffected leg and to descend by leading with the affected leg. Kuntzer et al. reported weakness and dysesthesias in 88% and 44%, respectively. Pain, if present, can be at the site of the causative lesion (iliac fossa and inguinal region) or in the distribution of the nerve itself (anterior thigh or medial calf). Inguinal pain suggests a retroperitoneal mass. Pain may be exacerbated by hip extension and partially relieved with hip flexion and external rotation.

**Diagnosis**
If femoral neuropathy is noted in the immediate postoperative period, appropriate neuroimaging and radiographic studies should be ordered to determine the cause. Because motor weakness and reflex changes can also be seen with lumbar plexopathies or radiculopathies, these diagnoses must be included in the differential. Electrodiagnostic testing can help isolate the location and extent of nerve injury. Although the presence of EMG abnormalities in the vastus medialis muscle was not predictive of prognosis, the presence of NCS abnormalities, especially percentage of axonal loss, was predictive of prognosis.\(^{44}\) Axonal loss, which is indicative of axonotmesis, portends a slower and possibly incomplete recovery. Kuntzer et al.\(^ {39}\) concluded that all patients with less than 50% axonal loss showed improvement within 1 year, whereas less than half the patients with greater than 50% axonal loss improved with conservative management alone. Irrespective of cause of injury, no improvement occurs after 2 years. Prognosis of recovery is greater if testing reveals only demyelinating abnormalities.\(^ {41}\) However, if abnormal EMG findings are found in the lumbar paraspinal muscles, this suggests a lumbar radiculopathy or plexopathy and not a peripheral neuropathy.

**Treatment**

If imaging studies identify a treatable cause, then the appropriate surgery should be performed as soon as possible to minimize the extent of neurologic deficit. Based on their retrospective series (1967 to 2000) of 119 surgically treated patients with intrapelvic or thigh-level femoral nerve lesions (89 traumatic injuries and 30 tumors), Kim et al.\(^ {45}\) recommended surgery in the absence of improvement at 3 to 4 months: neurolysis if intraoperative nerve action potentials across the nerve lesion are present and resection with grafting if intraoperative nerve action potentials are absent.\(^ {45}\) Although fewer patients underwent neurolysis compared to resection with grafting, the extent of recovery was greater in the former group, consistent with the severity of nerve injury. If there is no evidence of clinical or electrodiagnostic improvement after 3 to 6 months in those with iatrogenic or idiopathic femoral neuropathy, then surgical exploration with neurolysis should be considered.\(^ {41}\)

Assuming the femoral neuropathy is not due to traumatic injury or mass
effect that necessitates surgery, recovery is typically the rule, and conservative treatment is usually sufficient. In their retrospective analysis of 2,175 patients undergoing a combined sciatic-femoral nerve block, Fanelli et al. found 45 patients (2%) experienced transient neurologic dysfunction and all, but 1, improved within 4 to 12 weeks. Extent of recovery (none, partial, or complete) and time to recovery after abdominal surgery is much more variable, the latter ranging from 2 weeks to 1 year. Nonoperative treatment options include rest, analgesic medications, injections, and physical therapy. Whether temporary relief of symptoms with medications or injections alters the long-term prognosis is unknown, as the extent of recovery depends on the causative factor, extent of nerve damage, and location of injury. Longer recovery times should be anticipated when nerve damage is extensive and/or more proximal. Recovery is excellent if the etiology is due to lithotomy positioning, but it is less than satisfactory when due to hip surgery or inguinal procedures. Kuntzer et al., however, reported no association between etiology and outcome. Physical therapy is important for those with evidence of motor weakness in order to prevent muscle contractures, minimize muscle atrophy, and maintain ambulatory status. For those with significant quadriceps weakness and knee instability, orthotic and/or gait assistive devices should be considered.

SAPHENOUS NERVE ENTRAPMENT
The saphenous nerve is the terminal sensory branch of the posterior division of the femoral nerve and is the longest cutaneous branch of the femoral nerve (Fig. 70.7). It originates near the inguinal ligament and descends within the quadriceps muscles in the subsartorial (Hunter’s) canal and emerges from the canal to become subcutaneous approximately 10 cm proximal to the medial femoral condyle. The canal, which is located in the middle third of the medial thigh, also contains the femoral artery and vein. The saphenous nerve along with its two main divisions, the sartorial and infrapatellar nerves, supplies cutaneous sensation from the anteromedial aspect of the knee, medial calf, medial malleolus, and part of the medial arch of the foot.
Etiology
Saphenous nerve injury can occur anywhere along the course of the nerve. Most saphenous neuropathies are iatrogenic or related to surgical procedures, although spontaneous neuropathies with unidentified causes can also occur.\textsuperscript{37,48} Saphenous nerve trauma during femoral vascular surgeries and from saphenous vein harvesting for coronary artery bypass graft surgery can result in saphenous neuropathy.\textsuperscript{49–55} After undergoing vascular reconstructions below the inguinal ligament, Adar et al.\textsuperscript{49} reported variable degrees of saphenous neuropathy in 27 of 55 (49\%) of patients, which were unrelated to surgical technical flaws. Inadvertent transection of the infrapatellar or sartorial nerves, such as during knee surgery (medial arthrotomy, medial meniscectomy, patellar realignment, total knee arthroplasty, and secondary repair for medial instability with pes transfer) can occur.\textsuperscript{38,48,56,57} Schwabegger et al.\textsuperscript{58} reported how a retained hemostatic clip on the infrapatellar nerve after a gracilis muscle flap resulted in neuralgia due to neuroma formation and moderate fibrosis within the subsartorial (Hunter’s) canal. Resection of the neuroma resolved the pain, but sensory impairment remained. Another case report describes nerve damage resulting following a medial knee joint injection.\textsuperscript{59}

Saphenous nerve entrapment can occur as it travels through the
subsartorial (Hunter’s) canal. One case report documents distal tibial pain mimicking a tibial stress fracture from entrapment of the saphenous nerve caused by pes anserine bursitis. Compression or thrombosis of the superficial femoral artery within the adductor canal can cause claudication pain in the lower leg. Neural compression from the femoral vessels and adductor magnus tendons, which is more proximal to the subsartorial (Hunter’s) canal, has also been reported. Other case reports describe compression of the nerve due to an osteochondroma and from sitting astride and gripping a surfboard between the knees.

**Symptoms and Signs**

Knee pain is the main complaint, occurring in 90% of patients in one study, and tends to be worst with walking or any exercise involving active knee extension. In another study involving 15 cases of saphenous nerve entrapment, patients most commonly reported medial knee and leg pain after prolonged walking (87%) and standing (47%). Additional symptoms reported by these same patients included hypoesthesia (47%), no change in sensation (47%), and hyperesthesia (6%). Point tenderness over the subsartorial canal may be elicited in some of those with a suspected entrapment neuropathy but it is unlikely to be present in those with a traumatic nerve injury. Because it is a purely sensory nerve, motor strength is unaffected. Therefore, sensory abnormalities or pain beyond the territory of the nerve, reflex changes, muscle atrophy, or muscle weakness suggests a lumbar plexopathy, lumbar radiculopathy, or other peripheral neuropathy.

**Diagnosis**

Electrodiagnostic studies can be helpful, but performing a saphenous NCS can be challenging. Instead of strictly looking at the absolute value of the SNAP amplitude or latency in the affected limb, it is more important to compare the side-to-side SNAP amplitudes. A SNAP amplitude of less than 50% of the unaffected limb suggests the lesion is at or distal to the dorsal root ganglion. Because the nerve is purely sensory, the EMG result should be normal. The clinical utility of saphenous nerve SSEPs is low. A pelvic MRI or CT should be considered if one suspects a mass
lesion in the subsartorial canal.

**Treatment**

Nonsurgical treatment options include rest, analgesic medications, and injections. For those with a suspected entrapment neuropathy, a saphenous nerve block (with or without corticosteroid) over the subsartorial or transsartorial canal can be tried. Both of these approaches have been described as part of the anesthetic plan for lower extremity surgery.\(^{64,65}\) Although the long-term efficacy of doing a saphenous nerve block in the setting of saphenous neuralgia remains unclear, the nerve block might yield a diagnostic answer. A local anesthetic saphenous nerve block provided relief in 12 of 32 (38%) cases described by Mozes et al.,\(^{66}\) but they did not provide lasting relief in any of the 15 cases described by Worth et al.\(^{48}\) With corticosteroid added to the local anesthetic in 30 patients undergoing a series of saphenous nerve blocks, Romanoff et al.\(^{53}\) reported favorable outcomes (80%), no change (13%), and increased pain (7%). Whether temporary relief of symptoms alters the long-term prognosis is unknown. An ultrasound-guided saphenous nerve block can improve chances of obtaining a successful block.\(^{67}\) Of 39 patients undergoing an ultrasound-guided subsartorial saphenous nerve block, Tsai et al.\(^{64}\) reported a 77% success rate. For those with unremitting symptoms, neurolysis or neurectomy may be indicated, although which surgical approach offers the best outcome with the fewest complications is debatable.\(^{48,66}\)

**OBTURATOR NERVE ENTRAPMENT**

The obturator nerve, which is a sensory and motor nerve, originates from the anterior divisions of the ventral rami of the L2, L3, and L4 nerve roots (Fig. 70.8; see Fig. 70.1A). (The posterior divisions of the same nerve roots form the femoral nerve.) The obturator nerve emerges from the medial surface of the psoas major muscle at the pelvic brim and descends along the lateral pelvic wall where it passes through the fibroosseous obturator foramen. Within the foramen, the obturator nerve splits into an anterior and posterior branch, finally emerging through the obturator foramen and entering the thigh. At the point of origin, the anterior branch
supplies an articular branch to the hip joint followed by motor branches to the adductor longus and brevis, gracilis, and pectineus muscles. The sensory fibers of the anterior branch convey cutaneous information from the distal two-thirds of the medial thigh. The posterior branch supplies motor branches to the obturator externus and adductor magnus muscles and sensory branches to the articular capsule, cruciate ligaments, and synovial membrane of the knee joint. A normal variant in approximately 8% to 13% of the population, the accessory obturator nerve supplies the pectineal muscles and hip joint.

![FIGURE 70.8](image.png) Cutaneous branches of the obturator nerve. Anterior (A) view and posterior (B) view.

**Etiology**

An isolated obturator neuropathy is uncommon because the nerve is well protected within the pelvis and medial thigh. Causes of obturator neuropathy include entrapment (obturator hernia or local infection), compression (pelvic trauma, pelvic hematoma, pelvic tumor, retroperitoneal mass, fetal head or forceps in the pelvic canal during delivery, trauma or hematoma caused by cesarean section, acetabular labral cyst, extrapelvic synovial cyst, prolonged tourniquet use, or myositis ossificans), surgery (orthopedic, gynecologic, or pelvic laparoscopy), lithotomy positioning, and diabetes. Of 22 patients with
electrodiagnostic evidence of obturator neuropathy, Sorenson et al.\textsuperscript{69} found perioperative complications or pelvic trauma were the most common causes. Because laparoscopic pelvic procedures could result in inadvertent electrocautery of the wrong nerve, careful visualization of the adjacent neurovascular structures should be undertaken.\textsuperscript{37,70} The mechanism of entrapment is unclear, but Bradshaw et al.\textsuperscript{68} concluded from their study of 32 athletes that electrodiagnostic and surgical findings (nerve entrapment by fascia and vessels over the obturator externus and adductor brevis muscles) suggest entrapment occurs at the level of the obturator foramen and proximal thigh, instead of within the obturator tunnel. Gender differences in the bony pelvic anatomy also play a role. Higher iliac bones, a smaller transverse pelvic inlet diameter, and a narrower subpubic angle, which all contribute to a greater bend in the obturator nerve within the obturator canal, probably accounts for the higher incidence of obturator neuropathy in men.\textsuperscript{68}

**Symptoms and Signs**

Symptoms of obturator neuropathy include weakness, paresthesias, sensory loss, and/or pain along the medial thigh with extension as far distally as the knee. Sorenson et al.\textsuperscript{69} reported that patients most commonly complained of medial thigh or groin pain (73%) followed by muscle weakness (27%) and sensory impairment (27%). Unfortunately, the complaints of pain can make it challenging to differentiate whether it is due to obturator neuropathy versus a traumatic or surgical procedure. Similar to Sorenson et al.,\textsuperscript{69} Bradshaw et al.\textsuperscript{68} found that self-reports of numbness or paresthesia among their 32 athletes were uncommon except in those with chronic obturator neuropathy. Additional symptoms included referred pain to the ASIS, exercise-induced exacerbation of pain with radiation from the medial thigh to knee, resolution of pain with rest, exercise-induced adductor muscle weakness and spasm, and wide-based gait. Because the femoral and sciatic nerves provide partial innervation to the adductor longus and magnus, respectively, muscle weakness may be difficult to appreciate on physical exam. With chronic and severe obturator neuropathy, though, medial thigh atrophy may occur. The adductor tendon reflex may even be diminished, but because this reflex can be absent in
those without neuropathy, it must be obtainable in the unaffected limb. A positive Howship-Romberg’s sign—pain provocation along the medial thigh to the knee with passive abduction and extension of the affected hip or passive internal rotation of the hip—suggests the diagnosis. This neural tension maneuver is felt to be pathognomonic of an obturator hernia, occurring in 15% to 50% of cases.

**Diagnosis**
Because motor weakness and reflex changes can also be seen with lumbar plexopathies or radiculopathies, these diagnoses must be included in the differential. When the physical exam is nonspecific, sensory and motor findings can be confirmed with electrodiagnostic testing. Sorenson et al. were able to diagnose a different disorder in 15 of 38 (39%) of patients who carried a presumptive diagnosis of obturator neuropathy. Radiographs of the pelvis are typically normal, unless osteitis pubis is present, and bone scans may show increased uptake in the pubic ramus on the affected side that presumably represents an inflammatory reaction that tracks along the fascia to entrap the nerve. Alternatively, the periosteal changes may represent adductor insertion avulsion syndrome (“thigh splints”). If an intrapelvic or extrapelvic lesion is suspected, neuroimaging should be obtained.

**Treatment**
Recovery after sustaining an obturator nerve insult appears good in those with an acute neuropathy and poor in those with a chronic neuropathy. Conservative treatment measures include rest, physical therapy to stretch the groin muscles and to strengthen the adductor and pelvic muscles, soft tissue massage, and analgesic medications. Physical therapy is important for those with evidence of motor weakness in order to prevent muscle contractures, minimize muscle atrophy, and maintain ambulatory status. Among patient with an acute obturator neuropathy, Sorenson et al. found that 93% of patients improved with conservative treatment or surgical exploration, indicating conservative management is the preferred course of care. Conversely, a chronic obturator neuropathy portends a poor prognosis as none of the patients with this diagnosis improved.
Controversy exists as to whether severity of nerve injury affects long-term prognosis. Bradshaw et al.\textsuperscript{68} noted failure with conservative treatment in those with electrodiagnostic evidence of denervation, instead preferring definitive surgical neurolysis. Conversely, Sorenson et al.\textsuperscript{69} found three of four patients with electrodiagnostic evidence of a complete lesion improved without surgical exploration. For those who have limited benefit with noninjection therapies, a fluoroscopically guided obturator nerve block at the obturator foramen can be attempted.\textsuperscript{68} Successful treatment of groin pain, medial and lateral thigh pain, and hip joint pain with continuous RF and pulsed RF of the articular branches of the obturator and femoral nerves has also been described in various case reports.\textsuperscript{79–81} For those with persistent symptoms or severe injuries (pelvic trauma, intraoperative nerve laceration, or tumor), surgery is recommended.\textsuperscript{37}

**SCIATIC NERVE ENTRAPMENT**

The sciatic nerve arises from the lumbosacral plexus and is composed of the L4, L5, S1, S2, and S3 nerve roots (Fig. 70.9). It enters the lower extremity by exiting the pelvis through the sciatic notch. Variability exists, however, in the course the sciatic nerve takes as it exits the pelvis through the greater sciatic notch near the piriformis muscle. Beaton and Anson\textsuperscript{82} found that among 1,510 cadaveric extremities, in 88%, the sciatic nerve exited below the piriformis muscle; in 11%, the piriformis muscle was divided in two parts such that the fibular division of the sciatic nerve passed in between both parts of the piriformis muscle and the tibial division passed below the bottom-most part of the muscle; in 0.86%, the fibular and tibial division of the nerve either passed above and below the muscle, respectively; and in 0.13%, the entire sciatic nerve pierced an undivided piriformis muscle (Fig. 70.10). The two anatomic variations where the sciatic nerve or its divisions pass in between the nerves lead to the nontraumatic variant of piriformis syndrome. Upon leaving the gluteal region, the sciatic nerve travels posterior and medial to the hip joint.
Commonly perceived of as a single nerve, the sciatic nerve is composed of lateral (fibular division) and medial (tibial division) trunks that actually lay adjacent to each other. Around the middle to distal aspect of the posterior thigh, the divisions diverge to form the common fibular and tibial...
nerves. Prior to diverging, the fibular division innervates the short head of the biceps femoris muscle, with tibial nerve branches innervating the remaining hamstring (semitendinosus, semimembranosus, and long head of the biceps femoris) muscles. With the exception of the saphenous nerve, branches of the sciatic nerve supply the sensory innervation below the knee, and branches of the sciatic nerve supply the entire motor innervation below the knee.

**Etiology**

After fibular neuropathy, sciatic neuropathy is the second most common lower extremity peripheral neuropathy.\(^8^3\) Injury can occur anywhere along the course of the nerve from the gluteal region to the posterior thigh. Causes of sciatic neuropathy include compression (hematoma, abscess, piriformis syndrome, benign or malignant tumor, myositis ossificans, endometriosis, prolonged sitting or supine positioning without adequate pressure relief, lithotomy position, vaginal delivery due to nerve compression from the fetus’s head, or pneumatic thigh tourniquet), contusion (fall from a height without fracture or dislocation), trauma (gunshot wound, laceration, femur fracture, intramuscular injection of medication into the gluteal region), stretch injury (hip arthroplasty, hip dislocation, hip or femur fracture), nerve ischemia (vasculitis, arterial thrombosis, arterial bypass surgery, diabetes mellitus, postradiation therapy), and idiopathic.\(^4^4,^8^4–^8^6\) Based on 492 reported cases of sciatic neuropathy in the English literature from 1967 to 1997, Plewnia et al.\(^8^6\) found that the five most common causes were hip arthroplasty (34%), intramuscular injection of medication into the gluteal region (28%), hip fracture or dislocation (9%), benign or malignant tumor (8%), and external compression (8%).

Sciatic nerve injury is the most common neurologic complication of total hip arthroplasty—with an estimated incidence of 0.6% to 6.7% of all arthroplasties—and can be caused by stretch injury, direct trauma from retractors or fixation screws, infarction, intraneural hemorrhage, hip dislocation, thermal injury from methyl methacrylate extravasation, or compression from the prosthesis or a bony prominence.\(^8^4\) In their study of 100 patients with electrodiagnostically confirmed sciatic neuropathy, Yuen
et al.\textsuperscript{83} reported that hip arthroplasty occurred in 22\% and accounted for the most common cause of sciatic nerve injury. Kline et al.\textsuperscript{84} however, discovered that of 380 patients seen from 1967 to 1991, hip arthroplasty only accounted for a minority (3\%) of cases and that injection injury from intramuscular drug administration accounted for the majority (36\%) of cases. Although most cases of hip arthroplasty–related sciatic neuropathy occur in the perioperative setting, delayed onset can also be seen.\textsuperscript{85}

Sciatic nerve entrapment by the piriformis muscle, also known as piriformis syndrome, can be another cause of sciatica. Although its diagnosis remains controversial, it is reported to occur with a 6:1 female-to-male predominance.\textsuperscript{87} It is less commonly due to sciatic nerve entrapment by the piriformis muscle and instead is more commonly associated with direct trauma to the sciatic notch and the gluteal regions; prolonged sitting; prolonged combined hip flexion, adduction, and internal rotation; and certain athletes (cyclists who ride for prolonged periods of time, tennis players who constantly internally rotate their hip with an overhead serve, and ballet dancers who constantly externally rotate their hip while dancing).\textsuperscript{82,88–91} Although the mechanism of injury may be postulated, the etiology of the signs and symptoms remains less clear. Traumatic injury to the piriformis muscle may generate inflammatory and edematous changes to the muscle and surrounding fascia, subsequently compressing the sciatic nerve against the wall of the pelvis and leading to a compression neuropathy.\textsuperscript{90} The trauma itself may induce focal hyperirritability in the piriformis muscle, which can be further exacerbated by muscle spasm or hypertrophy.

**Symptoms and Signs**

Signs and symptoms of sciatic neuropathy include weakness, impaired ankle reflex, paresthesias, sensory loss, and/or pain in the distribution of the nerve. Weakness of toe extension and flexion, ankle dorsiflexion and plantarflexion, and ankle eversion and inversion are the most prominent signs.\textsuperscript{85} Clinically, absence of complete weakness of ankle dorsiflexion and plantarflexion predicts earlier or better recovery.\textsuperscript{92} Of the two nerve trunks, weakness more commonly affects fibular-innervated versus tibial-innervated muscles.\textsuperscript{85,93} This is especially true in sciatic neuropathy after
Although it is not entirely understood why the fibular division is more selectively injured compared to the tibial division, various reasons have been postulated: (1) superficial and lateral position, thereby placing the fibular division in closer proximity to the hip joint and exposing it to injury from hip joint trauma or surgery; (2) smaller blood supply; (3) fewer and larger fascicles; (4) less supportive endoneurium and perineurium between fascicles; and (5) relative tethering of the nerve at the sciatic notch and fibular head, thereby making it vulnerable to stretch injuries. The exception to this rule appears to be femur fractures or gunshot wounds to the thigh, in which case the tibial division can be involved to an equal or greater extent. Because of preferential fibular involvement, knee flexion weakness is commonly insignificant, and isolated injury to the fibular division can masquerade as a fibular neuropathy at the knee or fibular head.

The most common presenting symptoms with piriformis syndrome are a deep, aching buttock pain that is often associated with a limp and sitting intolerance on the affected side. Squatting, climbing stairs, walking, and prolonged sitting (especially on hard surfaces) typically worsen the pain. In addition, the piriformis muscle’s compression of the pudendal nerve and blood vessels may cause labial pain and dyspareunia in females and scrotal pain and impotence in males. Painful bowel movements have also been reported, presumably due to the close proximity of the piriformis muscle and the rectum. The two most consistent physical exam findings are tenderness to palpation in the greater sciatic notch and reproduction of pain with maximum flexion, adduction, and internal rotation of the hip. Various physical exam maneuvers can be tried in an attempt to reproduce these findings: Freiberg sign (buttock pain with passive, forced internal rotation of the hip), Lasègue’s sign (pain and tenderness to palpation in the greater sciatic notch with the hip passively flexed to 90 degrees and the knee passively extended 180 degrees), Pace’s maneuver (buttock pain with resisted abduction of the affected leg while in the seated position), and Beatty’s maneuver (while lying in a lateral decubitus position on the unaffected side, buttock pain is elicited in the affected extremity when the patient actively abducts the affected hip and holds the knee several inches off the table).
Diagnosis
Because the differential diagnosis can include radiculopathy, plexopathy, or fibular neuropathy, neuroimaging of the pelvis and/or lumbosacral spine may be necessary to help establish the cause of nerve damage based on the mechanism of injury. Electrodiagnostic testing can be performed to confirm the location of the lesion and to offer prognostic information based on the chronicity and severity of nerve damage. Because muscles innervated by the nerve roots are uninvolved, the lumbar paraspinal muscles are unaffected. In their retrospective analysis of 100 patients, Yuen et al.\(^8\) noted greater severity of injury of the fibular division (64%), significant axonal loss (93%), tibialis anterior muscle EMG abnormality (92%), and low or absent extensor digitorum brevis (EDB) compound muscle action potential (CMAP) amplitude (80%). A more favorable prognosis—earlier or better recovery—was noted in those with a recordable EDB, CMAP, and presence of demyelination instead of axonal loss.\(^8\) Because normal sural and superficial fibular SNAP amplitudes were obtained in 29% and 9% of patients, respectively, the authors concluded that sparing of the tibial division does not necessarily exclude the diagnosis of sciatic neuropathy.

To diagnose piriformis syndrome, the symptoms and clinical exam findings must be correlated with neuroimaging of the pelvis (asymmetry of the piriformis muscle, mass effect, or anatomic variation consistent with entrapment) and electrodiagnostic studies (evidence consistent with extrapelvic compression of the sciatic nerve at the level of the piriformis muscle).\(^95,98,99\)

Treatment
Conservative therapy for symptomatic relief includes analgesic medications, injections, and physical therapy. Physical therapy is important for those with evidence of motor weakness in order to prevent muscle contractures, minimize muscle atrophy, and maintain ambulatory status. An AFO should be considered for those with significant ankle dorsiflexion and plantarflexion weakness. Spinal cord stimulation or intrathecal therapies should be considered for those who have a suboptimal response to the aforementioned and/or those who are not surgical...
candidates.

Surgical treatment of sciatic neuropathy is directed at identifying the cause of nerve injury. Surgery should be considered for cases of compression due to obvious mass effect or traumatic neuropathy that fails to improve with time. Surgical exploration for trauma-induced injuries, however, requires careful deliberation. Kline et al. found that medical management in those patients with a partial deficit and/or improvement in function and pain resulted in an 80% and 60% chance of useful return of function in the tibial and fibular divisions, respectively. In those patients in whom surgery (neurolysis, suture repair, or nerve graft) was performed because of evidence of a nerve action potential distal to the lesion, good-to-excellent outcomes were common for the tibial division but less common for the fibular division. Kline et al. suggested that the paucity of successful functional outcomes with fibular division surgeries may be related to uncoordinated muscle reinnervation (as opposed to insufficient nerve regeneration), further calling into question the practicality of fibular division surgery.

If the diagnosis of piriformis syndrome is confirmed and conservative management with physical therapy and medication fails to adequately relieve symptoms, an intramuscular piriformis injection of corticosteroid and local anesthetic can be undertaken with image guidance (fluoroscopy, CT, or ultrasound) alone or in combination with EMG guidance or nerve stimulation. Comparing ultrasound guidance versus fluoroscopic guidance, Finnoff et al. found the accuracy of needle placement was 95% versus 30%, respectively. Because the duration of analgesia with corticosteroid can be short-lived, some have even advocated the use of botulinum toxin for prolonged analgesia in those that at least respond diagnostically to the local anesthetic. The use of botulinum toxin for this diagnosis, though, is an off-label use of the medication. Surgical consultation for evaluation of piriformis tendon release and sciatic neurolysis should be considered as a last resort.

FIBULAR (PERONEAL) NERVE ENTRAPMENT
The fibular nerve is derived from the L4, L5, S1, and S2 nerve roots as a part of the sciatic nerve (Fig. 70.11). The fibular nerve, along with the
tibial nerve, is a division of the sciatic nerve. Approximately 8 cm proximal to the popliteal fossa, the fibular nerve separates from the tibial nerve and forms the common fibular nerve. As it descends into the popliteal fossa, it innervates the short head of the biceps femoris muscle. Proximal to the fibular head, the common fibular nerve gives off two branches: the sural communicating branch and the lateral cutaneous branch. The sural communicating branch becomes part of the sural nerve after receiving a branch from the tibial nerve. The lateral cutaneous branch conveys sensory information from the proximal and lateral aspect of the leg. As it winds around the fibular head, covered only by skin and a thin layer of subcutaneous tissue, the common fibular nerve is most vulnerable to injury. Approximately 1 to 2 cm distal to the fibular head, the common fibular nerve dives into the fibular tunnel which is made up of the aponeurosis of the soleus muscle and a wide, thick, and inflexible fibrous arch. Distal to the fibular tunnel, the common fibular nerve separates into the superficial and deep fibular nerves. The superficial fibular nerve innervates the ankle evertors and plantar flexors (peroneus longus and brevis muscles), after which it divides into the medial and intermediate dorsal cutaneous nerves to provide sensory innervation to most of the dorsal aspect of the foot, with the exception of the web space between the first and second toes. (Ankle inversion is unaffected because the tibial nerve innervates the tibialis posterior muscle.) The deep fibular nerve innervates the ankle and toe dorsiflexors (tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peroneus tertius muscles). Distal to the ankle mortise, the deep fibular nerve gives off lateral and medial branches. The former innervates the EDB and extensor hallucis brevis, and the latter supplies cutaneous sensation to the web space between the first and second toes.
Etiology

Fibular neuropathy is the most common lower extremity mononeuropathy, but its exact gender or age prevalence is unknown. In a retrospective analysis looking at 5,777 trauma patients, Noble et al. noted 79 lower extremity peripheral nerve injuries involving the fibular (39), sciatic (28), tibial (8), and femoral (4) nerves. Although fibular nerve trauma most commonly occurs at the fibular head where it is superficially protected only by the skin and thin underlying fascia, injury to the fibular nerve and its branches can occur anywhere along the course of the nerve. Aprile et al. demonstrated that most (83%) causes of fibular neuropathy are identifiable, with the majority (31%) being due to perioperative issues. Various causes of fibular nerve injury include entrapment, compression (improperly applied casts or braces, tight stockings, vascular abnormality, osteophytes, and intraneural or extraneural tumor), traction (leg-crossing, prolonged squatting or kneeling, prolonged ankle plantarflexion, surgical positioning, high-heeled shoes), trauma (fracture of the proximal fibular head, knee dislocation, ankle sprain or fracture, nerve laceration, and gunshot injury), metabolic (rapid weight-loss, hyperthyroidism, diabetes mellitus, vasculitic disorders, and leprosy), surgery (orthopedic surgery, vascular surgery, and plastic surgery), or idiopathic. In their study of 146 fibular nerve injuries requiring surgery, Piton et al. classified the causes as fibular tunnel syndrome (62), external compression (16), trauma (33), iatrogenic injury (16), tumor (9), wound injury (7),
contusion (2), and burn injury (1). In a larger and more recent study involving 318 fibular nerve injuries requiring surgery, Kim et al.\textsuperscript{130} classified the causes as stretch or contusion without fracture or dislocation (141), tumor (40), laceration (39), entrapment (30), stretch or contusion with fracture or dislocation (22), external compression (21), iatrogenic (13), and gunshot (12). Looking at 60 patients who only had entrapment, Fabre et al.\textsuperscript{111} classified the causes as idiopathic (53), postural (5), and dynamic (2). True entrapment can be classified as postural (which is associated with kneeling, crouching, squatting, or ankle plantarflexion) or dynamic (which is associated with activities such as running).\textsuperscript{24,131–133} For those with entrapment, it is postulated that chronic nerve irritation within the fibrous arch of the fibular tunnel causes edema, which subsequently causes scar tissue formation as the nerve glides in the narrow tunnel during knee flexion and extension.\textsuperscript{111}

Superficial fibular nerve entrapment is relatively uncommon and usually is due to compression of the nerve as it exits the anterolateral compartment 10 cm proximal to the ankle.\textsuperscript{134–136} Although deep fibular nerve entrapment can occur anywhere along its course, it is known as “anterior tarsal tunnel syndrome” when it becomes compressed beneath the inferior extensor retinaculum.\textsuperscript{136–138} Postural causes of deep fibular entrapment include prolonged plantarflexion, such as with wearing high-heeled shoes.\textsuperscript{24}

**Symptoms and Signs**

Symptoms of fibular neuropathy may include weakness, paresthesias, sensory loss, and/or pain in the distribution of the fibular nerve and its various branches. Patients with dynamic entrapment report activity-related leg pain with or without sensory impairment.\textsuperscript{24} The degree and extent of neuromuscular deficit and atrophy depends on the location (common vs. superficial vs. deep fibular), severity, and chronicity of nerve injury. Common fibular injury typically causes dorsiflexion (ankle and toes) and eversion (ankle) weakness, leading to tripping due to dragging of toes, excessive hip and knee flexion in an attempt to clear the foot (steppage gait), and foot slap.\textsuperscript{136} When the injury is proximal to the knee, knee flexion weakness also occurs because the biceps femoris muscle is
affected. A positive Tinel sign at the fibular head, 10 cm proximal to the ankle, or over the dorsal aspect of the ankle suggests a common fibular, superficial fibular, or deep fibular neuropathy, respectively. Fabre et al.\(^{111}\) noted a positive Tinel sign at the fibular head in 60 of the 62 (97\%) cases of common fibular entrapment. Sensory abnormalities, motor weakness, or pain beyond the territory of the nerve suggest an alternate diagnosis, such as a lumbar plexopathy, a lumbar radiculopathy, or other peripheral neuropathy.

**Diagnosis**
Electrodiagnostic studies can be performed to confirm the diagnosis, location, and extent of fibular neuropathy. Without axonal loss, the NCS reveals slowing of the nerve conduction velocity. However, when long-standing compression or direct nerve injury results in axonal loss, a decreased SNAP amplitude, a decreased compound muscle action potential amplitude, and a conduction block can be seen on NCS. The EMG portion of the study not only helps confirm axonal loss but the extent of muscle involvement can also aid in determining whether the lesion involves the common fibular, superficial fibular, or deep fibular nerve. For those with exercise-induced (dynamic) fibular neuropathy, electrodiagnostic studies may need to be done before and after exercising.\(^{24}\) Once a fibular neuropathy has been confirmed electrodiagnostically, additional imaging (radiograph, CT, and MRI) or laboratory studies may be needed to isolate the cause of nerve injury.

**Treatment**
Nonsurgical treatment options include rest, modification of footwear or garments, analgesic medications, injections, and physical therapy. Physical therapy is important for those with evidence of motor weakness in order to prevent muscle contractures, minimize muscle atrophy, and maintain ambulatory status. Whether temporary relief of symptoms with medications or injections alters the long-term prognosis is unknown, as the extent of recovery depends on the causative factor, extent of nerve damage, and location of injury. The degree of pain relief after doing a fibular nerve block at the fibular head can provide diagnostic information.
Significant fibular nerve damage resulting in ankle and foot weakness may necessitate an AFO and customized orthopedic shoes to correct any gait disturbance.

Depending on the etiology of fibular nerve injury, surgery is advocated within 2 to 4 months if there is lack of clinical and electrophysiologic improvement.\textsuperscript{111,129,130} In their retrospective analysis of 318 patients with preoperatively confirmed EMG evidence of knee-level common fibular nerve lesions, Kim et al.\textsuperscript{130} reported recovery of useful function in 88\% and 84\% of those undergoing neurolysis and end-to-end suture repair, respectively; recovery of useful function in 75\%, 38\%, and 16\% for those requiring nerve grafting less than 6 cm, 6 to 12 cm, and 13 to 24 cm, respectively; and preservation of preoperative clinical function in 80\% of those requiring tumor resection.\textsuperscript{130} For patients with idiopathic entrapment, surgical decompression is recommended when symptoms fail to resolve within 3 to 4 months because the time needed for recovery is shorter than that associated with conservative management.\textsuperscript{111}

**Foot Pain**

**PES PLANUS**

**Etiology**

Pes planus, a condition also known as flatfoot, refers to the loss of the normal longitudinal arch of the medial foot (Fig. 70.12). The most common cause of pes planus is insufficiency or dysfunction of the posterior tibial tendon.\textsuperscript{139} Congenital flatfoot is used to describe a flatfoot present since birth. Trauma, such as Lisfranc joint injuries and calcaneal fractures, can also lead to pes planus due to joint subluxation. Degenerative changes secondary to arthritis can also lead to pes planus. Tarsal coalition—a congenital fibrous union or fusion between the bones of the hindfoot and midfoot—has also been implicated as a cause of flatfoot.\textsuperscript{140}
Symptoms and Signs
Symptoms of pes planus can vary among patients with different forms of anatomic pathology and biomechanics leading to the condition. Examination of the feet should begin with the patient in standing position. Typically, the longitudinal arch flattens upon standing and appears when the foot is not bearing weight. Heel eversion often accompanies pes planus. Severe pes planus may result in significant pain, particularly along the course of the posterior tibial tendon, which may be tender upon palpation.\textsuperscript{141}

Diagnosis and Treatment
Radiographic imaging should be performed of the foot and ankle in three weight-bearing views—anteroposterior, oblique, and lateral. Loss of the longitudinal arch is best visualized on the weight-bearing lateral radiographs.\textsuperscript{142} MRI can also be useful in assessing this condition, particularly in evaluation of the posterior tibial tendon. Treatment is often conservative through the use of arch supports and plantar inserts. Surgical treatment may involve posterior tibial advancement, subtalar fusion, or osteotomies, depending on the initial cause of the condition.

PES CAVUS
Etiology
Cavus foot deformity is an abnormal elevation of the longitudinal arch (Fig. 70.13). This results in increased stress forces on the metatarsal heads and decreased weight bearing by the plantar region of the foot.\textsuperscript{143} Causes
Symptomatology varies based on the extent of the deformity. Lateral foot pain can develop as a result of increased weight bearing by the lateral foot. Metatarsalgia is frequently associated with pes cavus. Intractable plantar keratosis is often seen as well. Clawing of the toes—hyperextension at the metatarsophalangeal joints and flexion of the proximal and distal interphalangeal joints—may also be present. Patients may experience generalized stiffness of the joint, leading to disuse of the affected foot.

Diagnosis and Treatment

Physical examination should elucidate if the deformity is flexible or rigid. This can be determined by performance of the Coleman block test. A 1-in wood block is placed beneath the heel and lateral foot while the first, second, and third metatarsals are allowed to hang freely into plantarflexion and pronation. If heel varus corrects in this stance, the deformity is flexible. If the hindfoot does not correct, the deformity is rigid. Weight-bearing radiographs of the ankle and foot aid in the diagnosis through demonstration of hindfoot varus. MRI of the spine may be necessary to
evaluate for possible spinal tumor presence if the deformity is unilateral and no inciting traumatic event is noted. In addition, a neurologic consultation and an EMG/NCS can be obtained to evaluate for polio, Charcot-Marie-Tooth disease, and other neurologic causes of pes cavus. Conservative therapy for pes cavus includes the use of orthotic shoe inserts to offset increased weight-bearing forces on the metatarsal heads. Surgical intervention is warranted if the condition is severe and is aimed at construction of a plantigrade foot. This may be accomplished through tendon transfers, osteotomies, and arthrodesis.\textsuperscript{142}

**PLANTAR FASCIITIS**

**Etiology**
Plantar fasciitis is a painful inflammatory condition involving the insertion of the plantar fascia on the medial process of the calcaneal tuberosity. Pes planus, pes cavus, leg-length discrepancy, overpronation, and running all involve increased stress forces placed on the plantar fascia and thus can lead to plantar fasciitis.\textsuperscript{144}

**Symptoms and Signs**
Patients typically complain of intense sharp heel pain after the first few steps in the morning or after a period of rest. The pain is usually located along the anterior portion of the heel, with radiation into the sole of the foot.\textsuperscript{145} The pain is exacerbated by weight-bearing activities and relieved by rest. Patients may also experience generalized stiffness of the foot and swelling of the heel.

**Diagnosis and Treatment**
Pain can be reproduced on palpation of the anteromedial aspect of the calcaneus as well as the proximal plantar fascia. Passive dorsiflexion of the toes and toe walking can also reproduce pain secondary to plantar fasciitis.\textsuperscript{145} Radiographic imaging can reveal soft tissue calcifications in the heel and may be more useful to investigate for bony tumor or fractures as an underlying cause. Ultrasound may reveal a thicker heel aponeurosis, which can be associated with plantar fasciitis. MRI can demonstrate thickening of the plantar fascia. Because of the poor sensitivity and
specificity of these imaging techniques, diagnosis of plantar fasciitis is usually made through the history and physical examination. Conservative treatment involves the use of medial arch support inserts in footwear, shoe modifications, stretching exercises focusing on the plantar fascia, ice therapy, and NSAIDs.\textsuperscript{145,146} Night splints can be worn to allow the plantar fascia to heal in an elongated position as opposed to the natural plantarflexed position of the foot during sleep. Some studies have demonstrated that corticosteroid injections, botulinum toxin injections, and autologous platelet-rich plasma therapy can also be useful in treating plantar fasciitis.\textsuperscript{147,148} It should be noted that injection of botulinum toxin for plantar fasciitis is considered an off-label use of the medication. The injection of either corticosteroid or botulinum toxin is performed with a medial or lateral approach into the site of maximal tenderness. Complications of corticosteroid injections include plantar fascia rupture and fat pad atrophy.\textsuperscript{149} When these treatment modalities are unsuccessful, surgical release of the plantar fascia may be indicated. However, extracorporeal shockwave therapy (ESWT) could be an alternative to a surgical remedy that also happens to be noninvasive and safe. In their systematic review of ESWT (2005 to 2016), Roerdink et al.\textsuperscript{146} found no complications at 1-year follow-up.

**HEEL PAD DEFICIENCY**

**Etiology**
The fat pad of the heel is made of individual fibrous septa containing fat and elastic fibrous tissue. The fat pad absorbs shock and distributes mechanical forces to the calcaneus. The fat pad atrophies with age, multiple glucocorticoid injections, and trauma.\textsuperscript{150}

**Symptoms and Signs**
Patients typically experience deep, diffuse plantar heel pain that is exacerbated upon standing and walking/running on hard surfaces. Direct palpation of this area reproduces this pain. There is palpable atrophy of the heel pad, and underlying bone may be palpated. Scar tissue and calcification can be observed.
Diagnosis and Treatment
Diagnosis is usually made through history and physical examination. NSAIDs can provide significant analgesia. Long-acting local anesthetics, such as bupivacaine, can be infiltrated into the affected area for severe, painful crises. Corticosteroids are contraindicated, as they can worsen the condition. Shock-absorbing footwear inserts can be helpful by providing cushion and absorbing shock.

TARSAL TUNNEL SYNDROME
Anatomy
The tarsal tunnel is bounded by the flexor retinaculum, a strong fibrous band that extends from the medial malleolus to the margin of the calcaneus, and the medial surfaces of both the calcaneus and talus. The posterior tibial nerve courses beneath the flexor retinaculum through this tunnel and divides into the medial and lateral plantar nerves, which innervate the small muscles of the foot and the skin on the plantar aspect of the foot and toes (Fig. 70.14).

Etiology
Compression of the posterior tibial nerve as it passes behind the medial malleolus in the tarsal tunnel may lead to tarsal tunnel syndrome, a painful
condition of the ankle and plantar aspect of the foot. The branches of the posterior tibial nerve are vulnerable to compressive injury (restrictive footwear), entrapment from space-occupying lesions (i.e., ganglion cysts, osteophytes, and tumors), direct trauma, overuse injuries, and inflammation within the tarsal tunnel. Hindfoot valgus deformities can further exacerbate tarsal tunnel syndrome symptoms due to increased neural tension that is secondary to an increase in eversion and dorsiflexion foot positioning. All of these conditions can lead to edema and scar tissue formation, which further limit the vascular supply and cause increased traction of the nerve between joint movements. This ultimately can result in axonal and wallerian degeneration.

**Symptoms and Signs**
Pain or paresthesias in the heel, medial malleolus, or plantar surface of the foot may occur, depending on which nerve branch is compressed and the severity of the compression. When both plantar nerves are affected, symptoms extend from the posterior malleolus to the plantar aspect of the foot and dorsal surfaces of the distal aspect of the toes. Pain can be experienced in both the standing and reclining positions and may be worse at night. Simultaneous dorsiflexion and eversion of the ankle exacerbates the pain due to increased nerve tension. Advanced disease leads to weakness of the intrinsic muscles of the foot and of the toe plantar flexor muscles. Physical examination typically reveals tenderness to palpation of the tibial nerve. Percussion at the medial malleolus (Tinel sign) causes radiation of pain and paresthesias along the path of the posterior tibial nerve and its branches. In addition, symptoms may be reproduced through continuous compression of the nerve for 30 seconds (Phalen’s sign). Sensory deficits are uncommon but can affect the sole of the foot if present.

**Diagnosis**
An EMG/NCS often reveals prolonged motor terminal latency of the medial or plantar nerves to the abductor hallucis and abductor digiti quinti muscles, absent nerve potentials, or slow nerve conduction velocities. Although electrodiagnostic testing can aid in the diagnosis of tibial
neuropathy, neuroimaging may still be necessary to demonstrate whether a space-occupying lesion within the tarsal tunnel is the source of the symptoms. An MRI demonstrates the anatomy of the tarsal tunnel and its contents and can prove useful in planning for surgical decompression.

**Treatment**
The initial treatment includes nonsurgical measures such as avoidance of exacerbating activities, medications (corticosteroids, acetaminophen, NSAIDs, antiseizure medications, opioids, tricyclic antidepressants, topical analgesics, lidocaine patch), TENS, physical therapy, shoe inserts, and night splints with the foot in plantarflexion. An injection of local anesthetic and corticosteroid into the tarsal tunnel may provide analgesia. Surgical decompression with release of the flexor retinaculum, is employed if nonoperative measures fail. If present, space-occupying lesions of the tarsal tunnel, such as varicose veins and ganglions, are removed along with release of the flexor retinaculum. Decompression may also be accomplished through division of the proximal ridge of the abductor hallucis. Surgical complications primarily involve incomplete release of the flexor retinaculum, resulting in persistent pain.

**LISFRANC JOINT INSTABILITY**
**Etiology**
The Lisfranc joint (tarsometatarsal joint or metatarsal cuneiform joint) is a six-bone complex that connects the forefoot and the midfoot. It is made up of the articulation of the bases of the first three metatarsals with the cuneiforms and the fourth and fifth metatarsals with the cuboid. The joint aids in pronation and supination of the foot. The great majority of Lisfranc joint injuries are associated with fractures, especially the metatarsals. Although injury to the joint is generally associated with high-energy mechanisms (e.g., falls or motor vehicle collisions), resulting in severe inversion or plantarflexion, low-impact mechanisms (e.g., direct trauma in sports-related injuries) are also known to cause injury. The Lisfranc injury may be classified by the direction of the dislocation.
Symptoms and Signs
Lisfranc joint instability is characterized by severe midfoot pain and the inability to bear weight. Point tenderness over the midfoot is noted on exam. Bruising on the plantar surface of the midfoot represents an occult sign of an injury. Depending on the mechanism of injury, there may be soft tissue damage, such as edema, a wound, or vascular impairment. Pain or edema that persists after soft tissue healing is expected to have occurred should raise the index of suspicion for a Lisfranc joint injury.\textsuperscript{155}

Diagnosis
Conventional radiography is the initial imaging modality of choice. Radiographs will reveal fractures of the joint and displacement of the metatarsals. Because sprains are more difficult to detect, weight-bearing plain radiographs and stress radiographs taken with the foot plantarflexed and inverted have been suggested to establish the diagnosis.\textsuperscript{156} Advanced imaging, however, should be considered in the following circumstances: (1) CT for identifying occult fractures or subtle subluxations and (2) MRI for soft tissue and ligamentous injuries.\textsuperscript{157}

Treatment
Treatment depends on the type and severity of the injury as well as the length of time between injury and diagnosis. Ligamentous injury can benefit from casting or a fitted boot. If these conservative treatments fail, surgical open reduction or joint fusion may be required.

POSTERIOR TIBIAL TENDON INSUFFICIENCY
Etiology
Posterior tibial tendon insufficiency is the most common cause of acquired adult flatfoot deformity.\textsuperscript{158} Flatfoot deformities result from flattening of the medial longitudinal arch of the foot with failing of the supporting soft tissue structures of the ankle and hindfoot. The posterior tibial tendon is the principle supporting mechanism of this arch, although ligament involvement is extensive.\textsuperscript{139} Dysfunction of the posterior tibial tendon leads to the collapse of the arch and the formation of a pes planovalgus deformity. Arthritis may develop secondary to the foot deformity.
Insufficiency of the posterior tibial tendon may result from a variety of insults, including trauma and arthritic damage. Patients are most often middle-aged females and are often obese.\textsuperscript{159}

**Symptoms and Signs**
Initially, patients report pain along the medial aspect of the foot and ankle due to stretching of medial ligaments and soft tissues. On physical exam, erythema, edema, and tenderness to palpation along the course of the posterior tibial tendon can be appreciated. Later, as the arch begins to collapse, the ankle starts to roll inward, resulting in pain along the lateral aspect of the foot.\textsuperscript{159} There may be difficulty in performing a single leg heel rise. Persistent dull aching pain due to destruction of the midfoot may culminate in difficulty with standing and ambulation.

**Diagnosis**
Radiographic imaging should include weight-bearing anteroposterior and lateral radiographs of the foot to evaluate the biomechanical relationships and detect secondary arthritic changes.\textsuperscript{159} MRI is utilized to assess the integrity of the posterior tibial tendon.

**Treatment**
Initial treatment is supportive and involves immobilization, analgesic medications, and orthotic devices to correct pronation. Steroid injections have not been proven to be efficacious and remain controversial. When supportive measures fail, treatment consists of surgical augmentation of the posterior tibial tendon alone or in combination with osteotomy or arthrodesis.\textsuperscript{159}

**DORSAL FOOT GANGLIA**

**Etiology**
The etiology of dorsal foot ganglia is uncertain. However, they are the most common nodules found in the foot, with women accounting for up to 85\% of the cases.\textsuperscript{160}

**Symptoms and Signs**
Ganglia are generally asymptomatic. However, pain can occur as a result of inflammatory pressure points created while walking or from wearing tight-fitting footwear.\textsuperscript{160}

**Diagnosis and Treatment**
Ganglia are fluid-filled nodules that typically arise from a joint or tendon sheath and are most commonly located over the dorsum of the midfoot, forefoot, and toes.\textsuperscript{160} Upon palpation, they are firm and well-circumscribed. Nonsurgical treatment options include use of footpads, compression of the ganglion with an arch strap, or fine needle aspiration of the ganglion. Recurrence of the ganglion after aspiration is not uncommon. When conservative measures fail, surgical excision of the ganglion and stalk from its origin on the ligament or joint capsule and capsular excision should be performed.

**METATARSALGIA**

**Etiology**
Metatarsalgia refers to pain involving one or more of the metatarsal heads and distal metatarsal shafts secondary to chronically elevated stress forces as the total body weight is transferred to the forefoot during the midstance and push-off phases of walking and running.\textsuperscript{161} Abnormal biomechanics resulting from excessive pronation, cavus deformities, foot surgeries (e.g., osteotomies), and high-heeled shoes can further increase the weight distribution on the metatarsal heads.\textsuperscript{162} The increased prevalence of metatarsalgia among women is likely due to wearing high-heeled shoes. Other causes of metatarsalgia include intermetatarsal bursitis/neuritis, metatarsal stress fracture, metatarsophalangeal joint stress syndrome, sesamoiditis, inflammatory arthritis, interdigital neuroma, and aseptic necrosis of the second metatarsal head (Freiberg disease).\textsuperscript{162}

**Symptoms and Signs**
Pain severity is gradual in nature and is aggravated with walking and running activities. Over time, calluses can form over the second and third metatarsal heads and can further increase weight bearing on the metatarsal heads. On physical examination, palpable point tenderness is elicited at the
distal end of the plantar metatarsal fat pad and also can be reproduced by squeezing the metatarsal head between the thumb and index finger. Interdigital neuromas can lead to metatarsalgia and should be considered when pain is present in the interdigital web spaces. Over time, the pain may progress to diffuse forefoot and midfoot pain.

**Diagnosis**
Laboratory and imaging studies are not performed to confirm the diagnosis of metatarsalgia but instead are performed to rule out other diagnoses that may have a similar presentation. Radiographic imaging (weight-bearing anteroposterior, lateral, and oblique views) of the affected foot should be obtained to exclude metatarsal stress fractures, which may also lead to forefoot pain. Ultrasound and MRI may be necessary if a neuroma, cyst, bursitis, or other soft tissue anomaly is suspected. A serum C-reactive protein, uric acid level, and erythrocyte sedimentation rate should be obtained to exclude gout, which often presents as metatarsal pain at the base of the great toe.

**Treatment**
Conservative treatment includes the use of analgesic medications and semirigid orthotic inserts to reduce pressure on the metatarsal heads. Kang et al. showed that the use of metatarsal pads resulted in decreased maximal peak pressures and pressure time intervals during exercise, which translated to improved function and analgesia. Athletes can achieve significant pain reduction through the use of metatarsal bar appliances that can be placed in footwear. Surgical procedures are aimed at equalizing weight-bearing forces on the metatarsal heads and may include metatarsal shaft osteotomy or metatarsal head condyle excision.

**HALLUX VALGUS**

**Etiology**
Hallux valgus, also known as bunion deformity, is the most common deformity of the metatarsophalangeal joint. Subluxation results in lateral deviation of the proximal phalanx of the great toe and the formation of a medial prominence by the first metatarsal head (Fig. 70.15). The
deformity can be congenital or can result from biomechanical instability. Use of improper footwear, such as high-heeled shoes with tight-fitting and small toe boxes, may explain the higher prevalence hallux valgus among women.\textsuperscript{165}

![FIGURE 70.15](image) Hallux valgus. See text for details.

**Symptoms and Signs**

Pain occurs in the first metatarsophalangeal joint and can be described as deep, aching, and/or lancinating. Pain is worsened with ambulation and relieved upon shoe removal. Physical examination reveals a prominence on the medial aspect of the first metatarsal head and valgus deformity of the great toe. Adventitial bursa formation over the prominent medial metatarsal head can also be observed.\textsuperscript{166} Bursitis and overlying skin inflammation may be present. Osteoarthritic changes that occur over time may result in significant reduction in joint range of motion associated with pain.

**Diagnosis**

Radiographic imaging (weight-bearing anteroposterior, lateral, and oblique views) should be obtained in order to measure the angular degree of deformity, which provides diagnostic and prognostic information.\textsuperscript{166}
**Treatment**

Conservative treatment involves wearing footwear with wide toe boxes and placing pads in the first web space and over the median prominence to relieve pressure-induced pain. Oral analgesic medications and corticosteroid injections into the first metatarsophalangeal joint can be used to address acute, painful inflammatory states. Surgical treatment is indicated for intractable pain associated with significant functional impairment. Surgical options include osteotomy, exostectomy, resectional arthroplasty, resectional arthroplasty with implant, capsulotendon balancing, first metatarsophalangeal joint arthrodesis, and first metatarsocuneiform joint arthrodesis. A majority of these techniques involve excision of the medial prominence of the metatarsal head (bunionectomy), adductor hallucis tendon release, and occasional excision of the lateral sesamoid bone. Major surgical complications include overcorrection and recurrence.

**HALLUX RIGIDUS**

**Etiology**

Hallux rigidus is osteoarthritis of the first metatarsophalangeal joint and is associated with restricted range of motion and pain (Fig. 70.16). This results from cartilage degeneration, altered joint mechanics, and osteophyte formation. Impingement of the dorsal osteophytes results in inflammation and pressure point pain. Athletic activities involving running have been associated with development of hallux rigidus.

Symptoms and Signs
Patients describe a dull, aching pain on the dorsal surface of the first metatarsophalangeal joint that occurs during weight-bearing activities involving the forefoot and often results in an antalgic gait. Unlike hallux valgus, pain from hallux rigidus is associated with or without wearing shoes. Neuropathic pain can result from first dorsal digital nerve entrapment. Physical examination reveals an osteophyte formation on the dorsal surface of the first metatarsophalangeal joint and extremely limited range of motion.

Diagnosis
Radiographic imaging reveals degenerative changes of the first metatarsophalangeal joint. Early changes include dorsal and marginal osteophyte formation. Severe changes that can be visualized include joint space narrowing, sclerosis, joint irregularities, and sesamoid and cystic degeneration. Coughlin and Shurnas\textsuperscript{168} proposed a grade 0 to 4 classification system based on range of motion, physical exam findings, and radiographic results.

Treatment
Conservative treatment includes rest, customized foot orthotics, and wearing low-heeled, rigid rocker bottom soled shoes with soft surfaces lining the dorsum of the foot. Corticosteroids can be injected into the first metatarsal interspace lateral to the joint, along with local anesthetic application in the region of the first dorsal digital nerve.\textsuperscript{167} Several surgical treatments can be attempted to correct the condition. The least invasive, a cheilectomy, involves the excision of all irregular bony spurs contributing to decreased range of motion. This can provide significant pain relief and gain in function, although a successful outcome is inversely proportional to the degree of arthritic changes. A resection arthroplasty (Keller procedure), which involves excision of the base of the proximal phalanx, is usually reserved for patients with low functional demands.\textsuperscript{167} A proximal phalanx and metatarsal osteotomy can also be performed. Complications, such as flaccidity and motor weakness of the hallux, are quite high.\textsuperscript{167} Although a joint arthrodesis can provide analgesia, it results
in loss of joint motion. Despite this, patients can continue to remain physically active.

**INTRACTABLE KERATOSIS**

**Etiology**
Intractable keratosis is characterized by hard callus formation that develops underneath the metatarsal heads due to plantar flexion. Callus formation results in point pressure on the plantar fat pad.

**Symptoms and Signs**
Intractable keratosis presents as a painful discrete lesion that is aggravated by weight-bearing activities and causes an antalgic gait. Physical examination reveals a 1-cm focal, white-colored lesion with circumferential erythema found on the plantar aspect of the forefoot.

**Diagnosis**
Radiographic imaging should be performed to exclude other pathology, including fractures and metatarsal avascular necrosis.

**Treatment**
Conservative treatment involves wearing shoes with wide toe boxes and placing a pad underneath the uninvolved metatarsal heads in order to off-load weight from the involved metatarsal head. Pumice stones and prescription creams containing lactic acid can be used to reduce the mass of the keratosis and thereby provide symptomatic relief. Analgesic medications can provide minor relief. Corticosteroid injections are controversial as they can create fat-pad atrophy and further exacerbate the condition. Surgical options can include callus tissue reduction and core removal, a variety of distal metatarsal osteotomies, and segmental resection of the proximal metatarsal.

**SESAMOIDITIS**

**Etiology and Pathophysiology**
Sesamoiditis refers to inflammation of the two sesamoid bones on the plantar of the first metatarsophalangeal joint. This state of inflammation
can occur as a result of increased stress forces on the sesamoid bones from repetitive trauma due to increased activity, ill-fitting foot wear, anatomic variations, infection, osteoarthritis, or inflammatory arthropathies. Postural abnormalities may also contribute to this condition.

**Symptoms and Signs**
Pain is localized on the plantar aspect of the foot and is aggravated by weight-bearing activities. Physical examination reveals pain with direct palpation of the sesamoid bone and on dorsiflexion of the metatarsophalangeal joint.\(^{172}\)

**Diagnosis**
Radiographic studies should be performed to exclude fractures and other anatomic abnormalities. If plain film radiographs are nondiagnostic, a bone scan, CT, or MRI can prove useful.\(^{172}\)

**Treatment**
The initial treatment includes reducing loading forces on the sesamoid bones, immobilization with rocker bottom shoes or orthoses, activity modification, and NSAIDs.\(^{172}\) If conservative management fails, then surgical options should be considered.\(^{172}\)

**GOUT**
**Etiology**
Elevated systemic uric acid levels—due to increased uric acid production, decreased renal excretion of uric acid, or both—cause gout.\(^{173}\) When serum uric acid concentrations exceed 7.0 mg/dL, precipitation of uric acid crystal occurs.\(^{174}\) Gout typically manifests in men with a peak age of onset in the fifth decade of life and in women in the sixth decade of life.\(^{174}\)

**Symptoms and Signs**
The natural history of gout can be divided into three distinct stages: asymptomatic hyperuricemia, acute and intermittent gout, and chronic tophaceous gout.\(^{173}\) Asymptomatic hyperuricemia can last for 10 to 30 years before an acute gouty arthritis event occurs. This event is
characterized by severe pain in conjunction with edema, erythema, and rubor of the affected joint, after which resolution occurs within 1 to 2 weeks. Gout typically involves only one joint in the early course of the disease, and it is usually the first metatarsophalangeal joint. The acute and intermittent phase involves asymptomatic periods interrupted by acute attacks. These intervals can vary from months to years, but over time, the frequency and duration of attacks and number of joints involved increases. Although it remains uncertain, the attacks may be associated with rapid fluctuations of serum uric acid levels. Chronic gouty arthritis typically develops after more than 10 years of acute intermittent gout. There are no pain-free intervals in this stage.

**Diagnosis**
Patients report multiple painful, stiff, edematous joints, particularly in the toes, ankles, and knees. Although elevated serum uric acid levels (greater than 7.0 mg/dL) are commonly seen in gout, there may be periods of time when serum uric acid levels are normal.\(^{173}\) In addition to hyperuricemia, leukocytosis, elevated erythrocyte sedimentation rates, and elevated C-reactive protein levels may be present in acute attacks. The criterion standard of diagnosis, however, remains aspiration and examination of synovial fluid from an actively affected joint. Under polarized microscopy, monosodium uric acid crystals are seen as negatively birefringent needle-like structures engulfed by polymorphonuclear neutrophils.

**Treatment**
Treatment of acute gouty arthritis focuses on decreasing the inflammation within the joints.\(^{175}\) This is best accomplished through NSAIDs. In patients who cannot take NSAIDs, corticosteroids can be given via the oral, intravenous, or intra-articular routes. If taken within the first 12 hours of an acute gouty attack, oral colchicine can have an anti-inflammatory effect and can prevent uric acid crystal deposition. Although colchicine does not lower the uric acid levels, in low doses, it can be used to prevent or reduce the severity of future attacks. Patients, however, may not be able to tolerate the side effects of nausea, vomiting, and diarrhea. Chronic therapy to prevent recurrence of gouty arthritic attacks is aimed at
normalizing serum uric acid levels. Uricosuric agents, such as probenecid, work by increasing uric acid secretion into the urine. Xanthine oxidase inhibitors, such as allopurinol, work by inhibiting uric acid synthesis. Surgical resection of large nodular deposits of uric acid crystals, also known as tophi, can offer improvement in terms of mechanical function.176

INTERDIGITAL (MORTON’S) NEUROMA

Etiology
An interdigital neuroma is characterized by a well-localized area of pain on the plantar aspect of the forefoot that radiates into the web space. It typically involves the third interspace of the foot. Although this condition is termed interdigital neuroma, it is not a true neuroma. The histopathologic changes include the degeneration of nerve fibers associated with deposition of amorphous eosinophilic material that is more congruent with neuropathy secondary to an entrapment phenomenon.177 What causes an interdigital neuroma is unclear, although it has been hypothesized that it arises from constant traction of nerve fibers against the transverse metatarsal ligament during dorsiflexion of the toes.178 Interdigital neuromas occur approximately 10 times more frequently in women than men. This may be explained by the state of continuous dorsiflexion of the feet when wearing high-heeled shoes.178

Symptoms and Signs
Patients typically complain of localized pain in the region of the metatarsal head. The third interspace is more frequently involved than the second interspace, but it rarely involves the first or fourth interspace.179 The pain is aggravated by wearing tight-fitting shoes and walking and is alleviated by rest and removal of shoes. Upon palpation of the involved interspace, patients report a sharp pain that radiates into the toes. Often, a mass located in the interspace can be palpated. Palpating the affected interspace with one hand and squeezing the entire foot at the same time with the other hand, resulting in narrowing of the intermetatarsal space and compression of the mass can often reproduce symptoms. This can elicit an audible click, known as Mulder’s sign.170 The differential diagnosis of interdigital
neuroma should include stress fracture, tendon sheath ganglion, foreign-body reaction, nerve sheath tumor, strain of the plantar capsule, and capsulitis or bursitis at the level of the plantar metatarsophalangeal joint. In many of these conditions, inflammation of the adjacent nerve also may be present, causing the neuritic sensation of an interdigital neuroma, thus complicating proper diagnosis. It is also important to distinguish interdigital pain from metatarsalgia, which gives rise to a host of other possible pathologies including avascular necrosis, synovial cysts, and tarsal tunnel compression.

**Diagnosis**

Although interdigital neuromas are often diagnosed based solely on clinical findings, MRI, CT, and ultrasound have all been utilized for diagnostic purposes as well. MRI has emerged as the preferred imaging modality due to superior contrast resolution and precision. Interdigital neuromas are best visualized on short-axis (transverse) T1-weighted images through the metatarsal heads. Due to their highly vascular nature, intravenous contrast agents typically result in visual enhancement. They appear as bulbous masses arising between the metatarsal heads (Fig. 70.17). Although radiographs may reveal pathology at the metatarsophalangeal joint, they are not useful in the diagnosis of interdigital neuromas.
Conservative management of interdigital neuromas includes wearing shoes with wider toe boxes, adequate cushioning, and heels no higher than 1 in. Neuroma pads—soft support inserts that are placed proximal to the affected metatarsal head—are designed to separate the metatarsal heads and prevent rubbing or irritating the affected neuroma when stepping down. Oral NSAIDs and corticosteroid injections into the affected interspace can be tried. However, corticosteroids can result in local fat atrophy and metatarsalgia. Phenol neurolysis of the common interdigital nerve has also been reported to be effective. When conservative management fails, surgical intervention may be indicated. This involves a dorsal incision in the midline of the affected interdigital space in order to release the transverse metatarsal ligament, as the nerve typically lies beneath this ligament. Postoperative recovery includes a compression dressing worn for several weeks after wound closure. Ambulation is permitted in a postoperative boot. It is important to note that patients may experience decreased sensation in the interdigital web space.
HAMMERTOES

Etiology
Hammertoe deformities are primarily flexible or fixed plantarflexion deformities of the proximal interphalangeal (PIP) joint, with hyperextension of the metatarsophalangeal joint and extension deformities of the distal interphalangeal joint (Fig. 70.18). This results in a dorsal prominence on the PIP, which can cause pain secondary to compression and inflammation from footwear. Physical examination must include determining if the deformity is fixed or flexible. Other deformities may be present, such as hallux valgus or cavus foot deformities. Examination of the extensor surface of the PIP joint may reveal callus or ulcer formation. Intractable keratosis can develop underneath the metatarsal head of the involved toe.

![Site of pressure](image)

FIGURE 70.18  Hammertoe deformity, a typical small toe deformity, often causes corns and calluses with standard footwear. Extra deep shoes avoid these problems.

Diagnosis
Radiographic imaging should include weight-bearing anteroposterior and lateral radiographs of the involved foot.

Treatment
Conservative management involves the use of metatarsal pads and shoes with wide toe boxes. Surgical treatment involves metatarsophalangeal joint correction, but the type of surgery is influenced by whether the deformity is fixed or flexible. Fixed hammertoe deformities are corrected through resection arthroplasty of the PIP joint, with the aim of reducing soft tissue contraction forces through toe shortening. Additional procedures such as flexor/extensor tenotomies, metatarsophalangeal joint release, or arthroplasty may be necessary. Weil osteotomies, which primarily involve metatarsal shortening, have also been used to correct the deformity.
Flexible hammertoe deformities are surgically corrected with a Girdlestone flexor tendon transfer. This involves harvesting the long flexor tendon from the plantar aspect of the foot and surgically affixing this into the extensor hood. Thus, the tendon functions as both an extensor of the interphalangeal joints and a flexor the metatarsophalangeal joint. The major complication of Girdlestone flexor tendon transfer is a failure to identify a contracture of the flexor digitorum longus tendon during surgery, resulting in inadequate correction.

CLAW TOE DEFORMITY
Etiology
Claw toe deformity results from dorsiflexion of the proximal phalanx on the lesser metatarsophalangeal joint and concurrent flexion of the PIP and distal interphalangeal joints (Fig. 70.19). Pain results from friction between the interphalangeal joints and the shoe. In addition, patients experience pain underneath the metatarsal heads from being in plantarflexion. As with hammertoes, claw toe deformities may be flexible or fixed. They typically involve all four of the lesser toes. The clinical evaluation is similar to that of hammertoe deformities, including inspection for possible callus and ulcer formation along the extensor surface of the PIP joints.

Diagnosis
Radiographic imaging should include weight-bearing anteroposterior and lateral radiographs of the involved foot.

Treatment
Conservative management includes wearing shoes that have increased
depth to reduce pressure on the lesser toes and placement of arch supports underneath the metatarsal heads. Shoe inserts can be positioned proximal to the metatarsophalangeal joints in flexible deformities that are mild. The flexible deformity is corrected with a Girdlestone flexor tendon transfer. The fixed deformity requires a DuVries proximal phalangeal condylectomy in conjunction with the Girdlestone tendon transfer procedure.\textsuperscript{179} As with hammertoe surgical correction, the major complication is inadequate correction and subsequent recurrence of the deformity.\textsuperscript{183}

**HARD CORN (CLAVUS DURUM)**

Corns are painful, hyperkeratotic skin lesions located over bony prominences that result from excessive pressure on the skin. Histologic specimens reveal hyperplasia of the epidermis, especially proliferation of the stratum corneum.\textsuperscript{185} Hard corns are notable for their dry, horny appearance that develops over the dorsal and lateral surfaces of the fifth toe, on the lateral condyle of the proximal phalanx.

**Treatment**

Conservative treatment is aimed at reducing pressure on the bony prominences by wearing shoes with large toe boxes. Surgical correction involves débridement of the lesion and, occasionally, necessitates removal of the distal portion of the proximal phalanx. The most common complication of the latter surgical procedure is excessive bone removal, resulting in a flaccid fifth toe.\textsuperscript{186}

**SOFT CORN (CLAVUS MOLLUM)**

Soft corns are macerated lesions that frequently occur in the fourth web space between the base of the proximal of the fourth toe and the medial condyle of the head of the proximal phalanx of the fifth toe.\textsuperscript{179} These typically develop as a result of small bony protrusion anomalies that cause pressure points, which can then result in ulceration.\textsuperscript{186}

**Treatment**

As with hard corns, management first focuses on reducing pressure on the
bony prominences through utilization of footwear with large toe boxes. Other treatment modalities include the use of keratolytics such as salicylic acid.\textsuperscript{187} Surgical treatment involves removal of the bony protrusion.

**INGROWN TOENAIL (ONYCHOCRYPTOSIS)**

An ingrown toenail is a painful condition resulting from nail plate penetration on the medial or lateral nail fold epithelium (Fig. 70.20). This typically involves the great toe. It is associated with trauma, tight-fitting footwear, improperly trimming the nails at the nail margins, and aberrant nail curvature.\textsuperscript{188}

![FIGURE 70.20](image)

*FIGURE 70.20* Ingrown toenail is often caused by improper nail cutting techniques or by wearing ill-fitting footwear that creates pressure against the lateral nail fold producing exquisite pain and tenderness.

**Treatment**

If no infection is present, initial treatment includes elevation of the nail by placing cotton between the nail plate and the skin. This can be aided by daily foot soaks and removal of any pressure points on the nail. Additional treatment involves trimming an oblique portion of the affected nail toward the posterior nail fold under a digital block.\textsuperscript{188} The nail groove is then débrided and dressed. If infection or granulation occurs, treatment is focused on partial removal of the nail plate. This involves performing a digital nerve block, followed by a longitudinal incision from the base to the tip of the affected region of the nail plate, including the nail beneath the cuticle. The nail is then grasped with a hemostat and removed from the nail groove using a rocking motion. The nail groove is then débrided and
dressed.188

Definition

In its taxonomy, the International Association for the Study of Pain (IASP) defined neck pain to be pain arising from the cervical spine. It defined cervical spinal pain from a posterior perspective as pain anywhere in a region bounded superiorly by the superior nuchal line, laterally by the margins of the neck, and inferiorly by an imaginary transverse line through the T1 spinous process (Fig. 71.1). The definition allowed for the identification of upper and lower cervical spinal pain, for pain located in the respective halves of this region.

FIGURE 71.1 Neck pain is defined as pain perceived within a region bounded superiorly by the superior nuchal line, laterally by the margins of the neck, and inferiorly by an imaginary transverse line through the T1 spinous process.

Neck pain was defined in this way primarily because patients with neck
pain typically indicate the location of their pain as behind the cervical spine. A supplementary reason was to distinguish neck pain of spinal origin from pain arising from the viscera of the neck, which lie anterior to the cervical spine.¹

## Referred Pain

Numerous experiments in human volunteers²–⁷ have shown that pain from various somatic structures, such as the posterior neck muscles, cervical synovial joints, and cervical intervertebral disks, can be referred to various extents in various directions, depending on the segmental location of the source of pain. This type of pain is known as somatic referred pain and is different and distinct from cervical radicular pain. It does not involve irritation of nerve roots. It arises because of convergence of primary afferents on common neurones in the spinal cord.¹ Thus, pain that is mediated by a particular nerve, and relayed to a particular spinal cord segment, may be perceived in the territory subtended by other nerves that relay to that spinal cord segment. Characteristically, somatic referred pain is dull and aching in quality, in contrast to the lancinating quality of radicular pain. Furthermore, somatic referred pain tends to be sessile; it occupies a particular region and may expand slowly, in contrast to radicular pain which tends to shoot or travel in a linear pattern.¹

From upper cervical segments (C1, C2, C3), pain can be referred into the occipital region, across the parietal region of the skull, and into the frontal region or orbit (Fig. 71.2). From lower cervical segments (C5, C6, C7), pain can be referred across the shoulder or shoulder girdle (see Fig. 71.2).
Older studies, using injections of hypertonic saline into the interspinous spaces of the neck, reported patterns of referred pain extending into the arm, forearm, and hand, but these observations have not been corroborated using modern techniques. Although some physicians have reported anecdotally that they have encountered such distant patterns of somatic referred pain, these patterns have not been formally documented in the modern literature. That literature indicates that the common patterns of somatic referred pain from the cervical spine are more proximal in distribution.

Patterns of referred pain are not dependent on the structure that is the source of pain. The pattern is dictated by which segmental nerves innervate the source. Consequently, for example, the cervical zygapophysial joints and cervical intervertebral disks in the same vertebral segments have similar patterns of referred pain because they share a similar segmental nerve supply (Fig. 71.3).
These patterns of referred pain, evoked by noxious stimuli in volunteers, have been corroborated and elaborated by studies of patients whose neck pain has been abolished temporarily by controlled diagnostic blocks of the cervical zygapophysial joints and lateral atlantoaxial joints.\(^8\)

Pain from the C3–C4 segment may extend into the occipital region but largely tends to lie topographically over the levator scapulae muscle. Pain from C4–C5 tends to nestle into the angle between the neck and the top of the shoulder.

Pain from the C5–C6 segments tends to radiate over the deltoid region of the shoulder. Pain from C6–C7 segments tends to spread more posteriorly, over the shoulder girdle, but there can be considerable overlap between the distributions of referred pain from C5–C6 and C6–C7.

Pain from C1–C2 and C2–C3 structures radiates into the occipital region but can extend across or through the head into the forehead or orbit. Although there is considerable overlap between the pain patterns of C1–C2 and C2–C3, pain from C1–C2 tends to spread somewhat more rostrally across the vertex and into the forehead rather than across the parietal region and into the orbit.\(^8\)

**CERVICOGENIC HEADACHE**

In some patients with neck pain referred to the head, headache is their dominant complaint. Consequently, they seek the attention of neurologists.
or other specialists in headache. In those circles, this type of headache is referred to as cervicogenic headache, if and once the cervical origin of pain is established.9–11

**Pursuing Diagnosis**

The rubric “neck pain” is not a diagnosis; it is simply a restatement of the patient’s presenting complaint. A diagnosis requires a statement of the source of pain, if not also its cause. However, because a diagnosis is not often possible, most practitioners avoid pursuing a diagnosis and manage neck pain as a symptom rather than a diagnosis.

Neck pain does not include neurologic symptoms or signs. If a patient exhibits features of radiculopathy or myelopathy, those features take precedence. The pursuit of diagnosis converts from a pursuit of neck pain to a pursuit of the neurologic disorder.

Traditional means of pursuing a diagnosis are history, examination, and imaging. To these have been added minimally invasive tests. These approaches or tools have different utility depending on the category of neck pain established by history.

Very few causes of neck pain can be diagnosed from history alone, but history does provide cues that define different categories of neck pain. The five useful categories are trauma, acute, chronic, whiplash, and cervicogenic headache. These categories differ in terms of the nature, volume, and quality of evidence that apply to each, both for diagnosis and subsequent treatment.

Although physical examination may provide an assessment of the patient’s disability to move his or her neck, it does not contribute to diagnosis. Features such as range of movement, aggravation of pain, and tenderness are nonspecific; they can be affected or produced by virtually any cause of neck pain. Moreover, most signs elicited by physical examination of the neck lack either reliability or validity or both.12 Therefore, they cannot be relied on to make a diagnosis.

Medical imaging can detect fractures, tumors, and infections, but these are rare causes of neck pain. For most patients, imaging provides no diagnostic information. Medical imaging, therefore, has no role in the
routine screening of patients with acute neck pain. In order to be efficient, and not wasteful, its use should be predicated by particular features in the patient's history or presentation.

Minimally invasive tests have no established or proven role in the investigation of acute neck pain. Their role lies in the pursuit of the causes of chronic neck pain.

**TRAUMA**

Serious injuries to the neck can arise from motor vehicle accidents, falls, or a blow to the head. This etiology will be evident from the history.

The lesions of concern are fractures to the cervical spine, particularly fractures that threaten the integrity of the spinal cord, for these may require specialist management by immobilization or urgent surgery. However, fractures are not common, even among patients with a history of significant injury. A review of studies in departments of emergency medicine found that only $3.5\% \pm 0.5\%$ of patients suspected of possibly having a fracture proved to have a fracture on imaging.\(^{13}\)

Studies looking for predictors of fractures have shown that the alerting features are loss of consciousness, neurologic signs, and immediate onset of pain.\(^ {14}\) These features have been captured in the Canadian C-Spine Rules,\(^ {15}\) which are validated guidelines for the use of imaging in the pursuit of fractures (Fig. 71.4). Given the low pretest likelihood of fractures, even in patients at risk, these rules serve to eliminate unnecessary imaging in patients in whom the likelihood of fractures is essentially zero and in whom any missed fractures are unlikely to be of practical consequence.
ACUTE NECK PAIN

Technically, the definition of acute neck pain is pain that has been present for less than 3 months. However, in practice, acute neck pain would be pain of recent onset, measured in hours or days. Whereas other considerations will apply later, the prime imperative of assessment of acute neck pain is the recognition of conditions that involve a serious cause of pain, or systemic conditions in which involvement of the neck is only part of the problem (Table 71.1).

**Serious Conditions**

Serious causes of acute neck pain are rare. Two population studies of plain radiography of the cervical spine, each involving over 1,000 patients, both reported not detecting any serious disorder that was not otherwise suspected from the patient’s history.\(^{16,17}\) By inference, this zero prevalence of undiagnosed fractures, tumors, or infections has an upper 95% confidence limit of 0.4%. Thus, it can be deduced that serious causes of neck pain have a prevalence substantially less than 0.4%. This rarity argues against wanton application of medical imaging to screen for conditions that are extremely unlikely to be present.

Screening for suspected fractures should be governed by the Canadian C-Spine Rules (see Fig. 71.4). For tumors and infections, no guidelines have been validated for the cervical spine, but in principle, those for the lumbar spine would seem applicable.\(^{18}\) For tumors, the indications for imaging would be a past history of cancer or persistence of pain and failure to improve on treatment. For infections, the indications would be a history of possible inoculation, an evident source for infection, immunosuppression, systemic features of infection, or failure to improve. Meningitis is readily suspected on clinical grounds (fever, neck stiffness, Kernig’s sign).

Epidural hematoma is a serious condition because it threatens the spinal
cord. Once neurologic signs appear, the window of opportunity for successful neurosurgical decompression is only a matter of hours.\textsuperscript{19} However, the initial presenting feature may simply be neck pain,\textsuperscript{20,21} but motor and sensory deficits develop usually within hours of the onset of pain.\textsuperscript{20,22–24} Patients presenting with neck pain should be warned to report immediately the onset of any new clinical features, at which time the instigation of investigations can be considered.

Aneurysms most commonly present with headache, but neck pain alone can be the sentinel feature of dissections of the internal carotid artery, the vertebral artery, or the aorta.\textsuperscript{25–29} The alerting features to these conditions are a history of cardiovascular risk factors, direct trauma to the neck, and the onset of cerebrovascular features.

A case report records two patients in whom neck pain was the presenting feature of intracranial lesions: one a subarachnoid hemorrhage and the other a glioblastoma multiforme.\textsuperscript{30} The mechanism of pain was neither determined nor discussed but possibly involves irritation of the dura mater of the posterior cranial fossa, which is innervated by cervical nerves. The rarity of such cases, however, excuses intracranial lesions from the differential diagnosis of acute neck pain in the first instance, but physicians should remain alert to this possibility in patients with persistent, unresponsive neck pain.

**Inflammatory Disorders**

Neck pain can be, or can become, an additional feature for systemic inflammatory disorders such as rheumatoid arthritis, seronegative spondyloarthropathies, polymyalgia rheumatica, Reiter’s syndrome, and psoriatic arthritis. In such cases, the neck pain does not warrant pursuit of diagnosis, for the diagnosis is evident from the primary features of these conditions, such as widespread distribution of arthritis, arthralgia, or muscle pain.

Longus colli tendonitis is a rare condition that involves inflammation and edema of the upper portion of the longus colli muscle. The presenting features are neck pain, limitation of neck movement, and difficulties swallowing.\textsuperscript{31} Medical imaging reveals edema in the prevertebral space and prevertebral muscles of the neck, and calcification can occur in the
longus colli. Although alarming, the condition is self-limiting within about 2 weeks.31

**Widespread Pain**
The neck can be one of several regions affected in widespread pain conditions such as fibromyalgia, but in such cases, the diagnosis is that of the widespread pain. A pursuit of the cause of the neck pain in particular is neither warranted nor required.

**Rare Conditions**
Because the cervical spine contains many synovial joints, in principle, these could be affected by crystal arthropathies, which need to be considered in the differential diagnosis of neck pain. However, gout has a predilection for joints of the appendicular skeleton, and although it can affect the spine, it does so rarely.32 Other crystal arthropathies have not been reported affecting the cervical spine.

Injuries to peripheral nerves of the shoulder girdle, such as the long thoracic nerve and the spinal accessory nerve, may not be readily apparent because they do not cause sensory problems, and patients may not be immediately aware of their motor deficits. Pain occurs not because of a cervical lesion but as a result of a neuroma developing on the proximal stump of the severed nerve and affecting deep sensory afferents.33 Because these afferents relay to cervical segments, the pain of the neuroma will be perceived as cervical pain.

**Spurious Conditions**
Diffuse idiopathic skeletal hyperostosis, ossification of the posterior ligament, and Paget disease are conditions that can affect the neck, but there is no evidence that they cause neck pain. Paget disease has been expressly reported as not causing pain when it has affected the cervical spine.34

Although commonly invoked as a diagnosis, cervical spondylosis is no more than a radiographic change with age; it is no more frequent in patients with neck pain than in patients with no pain.35–37 Likewise, osteoarthritis of the cervical spine has no relationship to neck pain. If
anything, the data show that patients with osteoarthritis of the cervical synovial joints are slightly less likely to have pain, although not significantly so statistically.  

A rubric commonly used for the diagnosis of neck pain is “soft tissue injury,” but this term means no more than neck pain in the absence of a fracture, without the nature of the “injury” and its location being specified.  

“Myofascial pain” is purportedly a diagnosis of neck pain when it affects the muscles of the neck. However, no signs for the diagnosis of this condition have been shown to be reliable, and none has been shown to be valid.

Unknown
Because detectable causes of acute neck pain are rare, for most cases, the cause is unknown. For this reason, the IASP offered the rubric cervical spinal pain of unknown origin. However, although this term serves the strict requirements of taxonomy, it is unwieldy. No less wieldy is the term neck pain of unknown origin. For this reason, a term commonly used is idiopathic neck pain.

CHRONIC NECK PAIN
The literature provides little evidence concerning the diagnosis of chronic neck pain. In contrast, there is an abundance of evidence concerning neck pain after whiplash, but it is not clear the extent to which the latter can be translated legitimately to chronic neck pain of spontaneous origin.

Chronic neck pain amounts to neck pain that has persisted beyond 3 months. Commonly in practice, chronic neck pain is attributed to cervical spondylosis or cervical osteoarthritis, but as discussed earlier, these radiographic features have no statistically significant relationship to pain. By some practitioners, chronic neck pain is attributed to myofascial pain, but for this concept, there are no reliable or validated diagnostic criteria.

To some extent, the guidelines for the pursuit of diagnosis of acute neck pain apply to chronic neck pain, but by the time neck pain has become chronic, many of the serious causes of neck pain will have declared themselves. However, some exceptions apply.

Some tumors may be slow growing. Some spinal infections may remain
cryptic for a long time. For the diagnosis of cervical spondylodiscitis, delays of 12 to 15 weeks have been reported.\textsuperscript{39} It is, therefore, appropriate to use cervical magnetic resonance imaging (MRI) to clear patients with chronic neck pain of cryptic lesions before pursuing other diagnostic tests. Other cryptic lesions include osteitis fibrosa cystica\textsuperscript{40} and other bone lesions.

The reason for the lack of evidence on the diagnosis of chronic neck pain is that, apart from cryptic lesions, no feature on history, physical examination, or medical imaging has been shown to be diagnostic of any cause of chronic neck pain. It is for that reason that some physicians resort to minimally invasive tests for the diagnosis of chronic neck pain.

**Cervical Disk Stimulation**

Cervical disk stimulation is a test for neck pain stemming from a cervical intervertebral disk. The test involves introducing spinal needles, along an anterolateral approach, into the disk suspected of being the source of pain and into adjacent disks that serve as controls\textsuperscript{41} (Fig. 71.5). Once the tip of the needle is placed at the center of the disk, a small volume of contrast medium, or normal saline, is injected into the disk in order to stress it (see Fig. 71.5). A positive response is one in which stimulation of the suspected disk reproduces the patient’s pain but stimulation of adjacent disks evokes no pain.\textsuperscript{41} However, caveats apply to the validity of cervical disk stimulation.

In the first instance, cervical disk stimulation can be false positive in patients whose neck pain stems from the cervical zygapophysial joints at the tested segment. In such patients, anesthetizing the zygapophysial joints relieves their pain completely. Because the innervation of the zygapophysial joints is topographically separate from that of the disk, local anesthetic blocks of the joints cannot anesthetize the disk. Therefore, the positive response to disk stimulation must be false either because disk stimulation also stresses the zygapophysial joints or because the tested segment is rendered hyperalgesic by the zygapophysial joint pain. Consequently, in order to be valid, cervical disk stimulation should only be performed in patients in whom cervical zygapophysial joint pain has been excluded.

It has been conventional to perform cervical disk stimulation typically at segmental levels C4–C5, C5–C6, and C6–C7, on the grounds that the C5–C6 and C6–C7 disks are the most likely sources of cervical discogenic
pain. However, this practice introduces another source of false-positive responses. A study showed that if all disks are tested, rather than just the usual three, there are often disks at other than accustomed levels that happen to be positive. Consequently, restricting the application of disk stimulation to just the lower three cervical disks generates both false-positive and false-negative responses. If one of the three disks is positive to stimulation, the response will be false positive if there happens also to be a positive disk at a segment not tested. Conversely, testing just the lower three disks will be false negative if no disk at these levels is positive but a positive disk at higher levels remains untested. To avoid these problems, the standard of care has to be that all cervical disks must be tested.

**Medial Branch Blocks**

Cervical medial branch blocks are a test for pain stemming from a cervical zygapophysial joint. The test involves anesthetizing the medial branches that innervate the joint suspected of being the source of pain (Fig. 71.6). In order to be valid, the blocks must be controlled. Placebo-controlled blocks are the consummate standard, but an acceptable compromise is comparative local anesthetic blocks. On the occasion of the first block, the patient is randomized to receive either a short-acting (lidocaine) or a long-acting (bupivacaine) local anesthetic. If the response is positive, the block is repeated using the same or other agent. A positive result is defined as complete relief of the index pain on both occasions that the joint is anesthetized.
Prevalence

No studies have provided data on the prevalence of either cervical discogenic pain or cervical zygapophysial joint pain in patients with chronic neck pain of spontaneous origin (i.e., idiopathic neck pain). The only data come from three studies conducted in pain clinics, on mixed samples of patients with neck pain with or without a history of minor trauma to the neck.\(^{47-49}\)

Two of these studies reported only on the prevalence of cervical zygapophysial joint pain, which they found to be 36\(^{47}\) and 60\(^{48}\). In the third study, the prevalence of zygapophysial joint pain was 45\%, and the prevalence of discogenic pain was 13\%.\(^{49}\) These data show that the cervical zygapophysial joints are the most common, detectable source of chronic neck pain, and that discogenic pain is substantially less common.

WHIPLASH

Neck pain after whiplash can be distinguished from other categories of neck pain by the precipitating event: a read-end motor vehicle collision. This distinction is made because the motor vehicle accident constitutes circumstantial evidence that the patient possibly has an injury that could be the cause of their pain. For patients with idiopathic neck pain, no such
etiology is available.

**Etiology**

Studies of car crash dummies\textsuperscript{50} and of human volunteers\textsuperscript{51} have shown that, during a whiplash event, the cervical spine is initially compressed from below by a rising thorax. This causes a sigmoid deformation of the spine, during which the entire spine does not move outside the normal physiologic range of motion, but individual segments, typically C5–C6, undergo an abnormal posterior sagittal rotation. Later, the head catapults forward, and the cervical spine is passively flexed. During this phase, stresses are applied to the capsules of the zygapophysial joints, particularly those at C2–C3. The stresses are not large enough to tear the capsules but are nevertheless large in magnitude.\textsuperscript{52}

**Clinical Features**

The cardinal feature of a whiplash injury is neck pain. However, the prognosis is quite favorable. Some 60\% of patients fully recover within 3 months, and 75\% within a year (\textbf{Fig. 71.7}). Only about 25\% of patients suffer disabling chronic pain, of whom a fifth are severely disabled.\textsuperscript{53}

![FIGURE 71.7](image)

**FIGURE 71.7** The recovery curve for whiplash. Most patients recover within 3 months or so, leaving a tail of about 25\% with chronic neck pain. (Based on the data of Radanov BP, Sturzenegger M, Di Stefano G. Long-term outcome after whiplash injury: a 2-year follow-up considering features of injury mechanism and somatic, radiologic, and psychosocial findings. Medicine 1995;74:281–297.)

Mathematically, the recovery curve for whiplash (see \textbf{Fig. 71.7}) suggests that it is a composite of two populations, as shown in \textbf{Figure 71.8}.

3835
Group A are patients who recover rapidly regardless of treatment and respond well to reassurance, activation, and exercises. Group B are patients who do not recover and do not benefit even from tailored conservative care. These patients have greater pain, disability, and psychological distress at onset and exhibit cold hyperalgesia and mechanical hyperalgesia remote from the cervical spine. These differences suggest that the two groups suffer different injuries or injuries of different severity.

**FIGURE 71.8** A graph showing how the recovery curve in *Figure 71.7* can be resolved into two populations of patients: those who recover quickly (A) and those destined ab initio to have persistent disability (B).

For lack of reliability, validity, or both, no features on history or physical examination have been able to identify any source or cause of neck pain after whiplash. For patients with temporary pain, which recovers spontaneously, “muscle sprain” is the most plausible conjecture, but it has never been identified in patients in a valid manner.

In case reports or small, descriptive series, lesion such as small fractures, aneurysms of the vertebral artery or internal carotid artery have been reported in individual patients but not in any substantial proportion of patients with either acute or chronic neck pain after whiplash.

In clinical studies, the source of chronic neck pain after whiplash has been traced to the cervical zygapophysial joints in 54% and 60% of patients. Studies in laboratory animals have shown that the lesion responsible for chronic zygapophysial joint pain is a submaximal strain of the joint capsule. After such strains, the affected joint becomes a source
of persistent nociceptive output which generates, in the dorsal root ganglion and central pain pathways, metabolic changes that are the hallmark of chronic pain.\textsuperscript{63–74}

**Diagnosis**

For acute neck pain after whiplash, pursuit of diagnosis is not warranted. The condition is self-evident from the presenting complaint and history of injury. Imaging is not indicated according to the Canadian C-Spine Rules\textsuperscript{15} (see Fig. 71.4). Multiple studies using MRI have not identified any lesions that might the cause of pain.\textsuperscript{75–80}

For chronic neck pain after whiplash, the only investigation that has been shown to have utility are cervical medial branch blocks. With a prevalence of 54\% to 60\%, cervical zygapophysial joint pain is the single most common basis for chronic neck pain after whiplash.\textsuperscript{52,60,61} The joints most commonly responsible are those at C2–C3 and C5–C6\textsuperscript{8} (Fig. 71.9).

![FIGURE 71.9](https://example.com/figure71.9.png)

**FIGURE 71.9** The segmental location of painful zygapophysial joints in patients with chronic neck pain after whiplash, as determined by controlled, diagnostic, medial branch blocks. \textsuperscript{8}Asterisks indicate the segments most commonly responsible.

Most often, the neck pain arises from the joints at one or other of these segments. Patients with C2–C3 zygapophysial joint pain have upper cervical pain and headache. Those with C5–C6 pain have lower neck pain and referred pain into the shoulder region. In patients with unilateral pain,
the ipsilateral joint is the cause. In patients with bilateral pain, both joints at the responsible segment are typically the source.

Less frequently, the C6–C7 zygapophysial joint is the source of pain, either alone or in combination with the C5–C6 joint. Other combinations can occur, although far less frequently such as C2–C3 together with adjacent or remote joints and C5–C6 together with joints above.

CERVICOGENIC HEADACHE

Differential Diagnosis

By definition, cervicogenic headache is explicitly pain referred to the head from the cervical spine. That implies a source of pain in the cervical spine. The differential diagnosis encompasses other causes of headache that do not lie in the cervical spine but are nonetheless innervated by cervical spinal nerves. These include aneurysms of the vertebral artery or internal carotid artery and lesions in the posterior cranial fossa that irritate or stretch the dura mater, such as tumors, hemorrhage, and infection. These conditions would be distinguished from cervicogenic headache by the onset of neurologic features or features of infection.

Diagnosis

A variety of causes of cervicogenic headache have been postulated and promoted, but few have satisfied the diagnostic criteria required by the International Headache Society. Those criteria allow for clinical diagnosis provided that the diagnostic tests used have proven reliability and validity (Table 71.2), but no clinical features have been shown to have these properties. Otherwise, the diagnostic criteria require relief of pain by controlled, diagnostic blocks.

<table>
<thead>
<tr>
<th>Diagnostic Criteria</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>A. Pain referred from a source in the neck and perceived in one or more regions of the head and/or face, fulfilling criteria C and D</td>
<td></td>
</tr>
<tr>
<td>B. Clinical, laboratory, and/or imaging evidence of a disorder or lesion within the cervical spine or soft tissues of the neck known to be, or generally accepted as, a valid cause of headache</td>
<td>a</td>
</tr>
<tr>
<td>C. Evidence that the pain can be attributed to the neck disorder or lesion based on at least one of</td>
<td></td>
</tr>
</tbody>
</table>
the following:

1. Demonstration of clinical signs that implicate a source of pain in the neck
2. Abolition of headache following diagnostic blockade of a cervical structure or its nerve supply using placebo or other adequate controls

D. Pain resolves within 3 mo after successful treatment of the causative disorder or lesion

a. Tumors, fractures, infections, and rheumatoid arthritis of the upper cervical spine have not been validated formally as causes of headache but are nevertheless accepted as valid causes when demonstrated to be so in individual cases. Cervical spondylosis and osteochondritis are not accepted as valid causes fulfilling criterion B. When myofascial tender spots are, the headache should be coded under 2. Tension-type headache.

b. Clinical signs acceptable for criterion C1 must have demonstrated reliability and validity. The future task is the identification of such reliable and valid operational tests. Clinical features such as neck pain, focal neck tenderness, history of neck trauma, mechanical exacerbation of pain, unilaterality, coexisting shoulder pain, reduced range of motion in the neck, nuchal onset, nausea, vomiting, photophobia, etc., are not unique to cervicogenic headache. These may be features of cervicogenic headache, but they do not define relationship between the disorder and the source of the headache.

c. Abolition of headache means complete relief of headache, indicated by a score of zero on a Visual Analogue Scale (VAS). Nevertheless, acceptable as fulfilling criterion C2 is >90% reduction in pain to a level of <5 on a 100-point VAS.

Certain clinical features have been shown to be reliable for establishing a diagnosis of probable cervicogenic headache. These are unilateral headache and pain starting in the neck, and three additional features such as pain radiating to the shoulder and arm, varying duration or fluctuating continuous pain, moderate, nonthrobbing pain, and history of neck trauma. The definitive diagnosis, however, requires establishing a source of pain in the cervical spine by minimally invasive tests.

Sources
Notionally, any of the structures innervated by the upper three cervical spinal nerves could be a source of cervicogenic headache. However, no diagnostic tests have been developed and validated for headache stemming from the upper cervical muscles, the transverse or alar ligaments, or the dura mater. Tests are available only for the C2–C3 intervertebral disk and the upper cervical synovial joints.

Minimally Invasive Tests
For pain stemming from an intervertebral disk, disk stimulation is the only available diagnostic test. The test is positive if provocation of a disk
reproduces the patient’s headache, provided that stimulation of other disks does not reproduce pain.41

Pain stemming from the atlantooccipital or lateral atlantoaxial joints can be tested with intra-articular injections of local anesthetic83 (Figs. 71.10 and 71.11). The test is positive if blocking the joint fully relieves the headache. However, to guard against false-positive responses, some form of control block is required, such as placebo block or a block of a nearby structure that is not the target joint. No equivalent test has been developed for pain stemming from the median atlantoaxial joint.

FIGURE 71.10  Fluoroscopy images of an atlantooccipital joint block. A: An oblique posterior view of a needle having pierced the capsule of the joint. O, odontoid process; laaj, lateral atlantoaxial joint. B: An oblique posterior view after injection of contrast medium into the joint. (Images kindly provided by Dr. Paul Dreyfuss, Seattle, Washington.)

FIGURE 71.11  Fluoroscopy images of a lateral atlantoaxial joint block. A: Posterior view of a needle inserted into the right lateral atlantoaxial joint. B: Lateral view of needle in the joint. C: Posterior view after injection of contrast medium into the joint. D: Lateral view after injection of
contrast medium.

Pain from the C2–C3 zygapophysial joint can be diagnosed using comparative local anaesthetic blocks of the third occipital nerve, which is the nerve that innervates this joint. The nerve can be anesthetized where it crosses the lateral aspect of the joint\textsuperscript{84} (Fig. 71.12).

![FIGURE 71.12 Lateral fluoroscopy view of a needle in one of three positions for a third occipital nerve block. (Reproduced with permission from Bogduk N, ed. Practice Guidelines for Spinal Diagnostic and Treatment Procedures. 2nd ed. San Francisco, CA: International Spine Intervention Society; 2013.)](image)

**Prevalence**

No studies have provided data on the prevalence of headache stemming from the C2–C3 disk. The evidence is limited to observations that disk stimulation reproduces headache in some patients\textsuperscript{7,43} and that discectomy and fusion can relieve the headache.\textsuperscript{85}

Diagnostic blocks of the atlantooccipital joints have not been applied in systematic population studies to determine the prevalence of headache stemming from these joints. The literature is limited to reports of positive responses to blocks in small samples of patients, which do not provide prevalence data, but nonetheless constitute proof of principle, namely, that in some patients, the headache can be traced to an atlantooccipital joint.\textsuperscript{86}

Responses to lateral atlantoaxial joint blocks have been reported in a few case series.\textsuperscript{49,87,88}

In these studies, the source of pain could be traced to the lateral atlantoaxial joints in 16\%,\textsuperscript{87} 13\%,\textsuperscript{88} and 9\%\textsuperscript{49} of patients presenting with headache.

The most common, documented source of cervicogenic headache is the C2–C3 zygapophysial joint. It is the source of pain in some 56\% of patients with headache after whiplash.\textsuperscript{89}
Treatment

NECK PAIN

Conservative Therapy

Traditionally, conservative therapy for neck pain has consisted of medications and therapies, delivered alone or in combination. Despite the large number of studies that have been conducted, convincing evidence of efficacy is lacking. Various literature provides no evidence of effectiveness or efficacy, evidence that certain therapies are no more effective than sham therapy or other therapies, or no evidence of any lasting benefit. In particular, no conservative therapy has been shown to eliminate neck pain, or to reduce it sufficiently to allow restoration of activities of daily living, with no further need for other health care.

There is no evidence that nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, or antidepressants provide short- or long-term benefits.\(^90\) Usual care using analgesics or NSAIDs is no more effective than placebo physical therapy,\(^91\) and adding NSAIDs to manipulative therapy provides no greater relief of pain.\(^91\) Muscle relaxants are no more effective than placebo or have not been studied beyond 8 days.\(^90\)

Soft collars do not provide any greater reduction in pain than rest, exercises, usual care, or no care, and rigid collars are no more effective than usual care.\(^90\) Traction is no more effective than sham traction.\(^92\)

Electrotherapies, such as ultrasound, or diathermy, provide no better outcome than exercises or manual therapy, usual care, or sham therapy.\(^90\) For lack of adequate studies, the evidence on transcutaneous electrical nerve stimulation is inconclusive.\(^93\)

Patient education is equal to or less effective than other conservative care. Any benefits are small and short lived.\(^94\)

There is no evidence to support relaxation therapy, cognitive-behavioral therapy, or biofeedback.\(^95\) In the short term, cognitive-behavioral therapy is more effective than no treatment but is no more effective than other treatments.\(^96\) Adding behavioral therapy to exercises does not improve the outcomes.\(^96,97\)

There is no literature on the effectiveness of multidisciplinary pain management for acute neck pain. For chronic neck pain, the few studies
that have been conducted show no benefit,\textsuperscript{98,99} or minimal benefit for pain and disability,\textsuperscript{100} but no better than that of continuing primary care.\textsuperscript{101}

Acupuncture is either no better than sham acupuncture\textsuperscript{102} or slightly more effective than sham treatment or no treatment but only in the short term.\textsuperscript{103} There is no evidence of long-term benefit.

There is evidence of moderate to high quality that cervical manipulation provides outcomes similar to those of cervical mobilization, but the literature comparing these two therapies with inactive treatments is of low quality. It shows benefits immediately after treatment but not in the short or long term.\textsuperscript{104} Spinal manipulative therapy is somewhat more effective than medications alone but not more effective than a home exercise program\textsuperscript{105} or exercise in general.\textsuperscript{90,102}

Dry needling of trigger points is no more effective than sham needling.\textsuperscript{106}

Multimodal therapy involves combinations of exercises, manual therapy, and education. It may be of benefit,\textsuperscript{107} but the evidence is inconsistent that multimodal therapy is any more effective than usual care, collars, or advice to stay active.\textsuperscript{90}

Exercise is the most studied of the conservative therapies for neck pain, but nonetheless, conclusions are limited. There is no high-quality evidence for exercise therapy, and its effectiveness remains uncertain.\textsuperscript{108} Any benefits are inconsistent, small in magnitude, and only short lived.\textsuperscript{108,109} The evidence is stronger for strengthening exercises.\textsuperscript{110}

For chronic neck pain after whiplash, the evidence on exercises is conflicting. Some have found neck-specific exercises to be more often effective than instructions to pursue physical activity,\textsuperscript{97} whereas others found exercises to be no more effective that advice to stay active.\textsuperscript{111,112}

\textbf{Injections}

A systematic review found that injections of botulinum toxin were no more effective than placebo for chronic neck pain.\textsuperscript{91} Of studies published since, one found botulinum toxin to be more effective than placebo in a small proportion of patients with chronic neck pain,\textsuperscript{113} but another found no superiority over placebo.\textsuperscript{114}

Trigger point injections appear to be as effective as ultrasound
treatment but ultrasound is no more effective than placebo treatment.

**Interventional Pain Medicine**

For the use of cervical epidural injection of steroids to treat chronic neck pain, in patients with no radicular features, the formal literature is limited. A brief descriptive study reported that 56% of 41 patients with idiopathic neck pain had 90% relief maintained for 6 months after treatment. No other outcomes corroborating pain relief were provided. Another outcome study reported 6 of 58 patients achieving complete relief of pain, and a further 8 each achieving 51% to 75% or 75% to 95% relief at 3 weeks after treatment with up to three injections. A systematic review found no other admissible evidence. A controlled study found no difference in outcome if epidural injections contained steroids or only local anesthetic. These data provide little support for the use of epidural steroids in the treatment of neck pain.

Intra-articular injection of steroids into the cervical zygapophysial joints was introduced as a treatment for neck pain during the 1980s. Some have advocated this treatment since then. A controlled trial, however, showed limited value for this treatment. In patients proven to have neck pain stemming from a zygapophysial joint, intra-articular injection of steroids was no more effective than intra-articular injection of local anesthetic, and few patients benefited from either therapy beyond 15 days.

The only treatment that has been shown to relieve neck pain completely is percutaneous radiofrequency medial branch neurotomy. The treatment involves carefully coagulating the medial branches of the dorsal rami that are responsible for mediating the patient’s pain (Fig. 71.13). The singular indication is complete relief of pain following controlled diagnostic blocks of these nerves.
A placebo-controlled trial showed that this is a valid procedure.\textsuperscript{125} The results of the original investigators\textsuperscript{125–127} have been corroborated by others.\textsuperscript{128,129} Complete relief of pain is achieved in some 70% of patients treated.\textsuperscript{125–127} Errors in diagnosis account for the failures. Some patients have false-positive responses to diagnostic blocks, even when these are controlled. In other patients, neurotomy unmask latent or previously undiagnosed sources of pain (e.g., at adjacent segmental levels).

The pooled data indicate that about 60% of patients maintain complete relief of pain at 6 months and between 30% and 50% do so at 12 months.\textsuperscript{130} Success rates are not demonstrably different between patients with legal claims and those without.\textsuperscript{126,127,129,131} Recurrence of pain is to be expected because the treated nerves regenerate. Repeat neurotomy reinstates relief. Repetition has been reported to reinitiate relief up to seven times, with the average duration of relief ranging between 8 and 18 months per repetition.\textsuperscript{126–129,132}

Complete relief of pain is accompanied by restoration of activities of
daily living and no need for other health care.\textsuperscript{125,126,130} These outcomes occur only if the technique recommended by the International Spine Intervention Society\textsuperscript{123} is used and only if the selection criteria are complete relief of pain following controlled diagnostic blocks of the medial branches to be targeted.\textsuperscript{130} If lesser diagnostic criteria are used, success rates and the degree of relief are substantially lower.\textsuperscript{133,134}

Conspicuously, radiofrequency medial branch neurotomy is the only treatment that has been shown to provide complete relief of chronic neck pain, with restoration of activities of daily living, and no other need for health care.\textsuperscript{125,126,130} Moreover, it also resolves psychological distress immediately upon relieving pain\textsuperscript{135,136} and reduces central sensitization and hyperalgesia.\textsuperscript{137} No other treatment for chronic neck pain has been shown to have these properties. A Cochrane review found that the evidence for cervical radiofrequency neurotomy was limited but only in the sense that there have not been more controlled trials; there was no dispute concerning the quality of the published studies.\textsuperscript{138} An independent review reported that radiofrequency neurotomy sets a benchmark for the treatment of chronic neck pain.\textsuperscript{139}

**CERVICOGENIC HEADACHE**

For the treatment of cervicogenic headache diagnosed clinically, no drugs have been shown to be effective, injections of botulinum toxin are not effective, and most conservative therapies are either ineffective or, at best are partially effective, in some patients, for a short time.\textsuperscript{9–11} The only consistent evidence is that exercises offer some benefit.\textsuperscript{108,140}

The best available evidence indicates that manual therapy or exercises are equally effective but to limited extents.\textsuperscript{141} In the short term, some 76% of patients achieve at least 50% reduction in pain, with 35% achieving complete relief. In the long term, 72% have a reduction of greater than 50% in the frequency of headache, but data on relief of pain are lacking.

Although intra-articular injections of steroids have been advocated for the treatment of headache stemming from the atlantooccipital or lateral atlantoaxial joints,\textsuperscript{86–88} this treatment has not been evaluated in patients in whom the target joint had been proven to be the source of pain using controlled diagnostic blocks. No controlled studies have validated the use
of steroids.

For patients whose headache can be relieved by lateral atlantoaxial joint blocks, an option for treatment is arthrodesis of the joint. The surgical literature attests to complete relief of pain being achieved, albeit in small numbers of patients, for over 2 years.¹⁴²⁻¹⁴⁴

In those patients in whom the source of headache can be traced to the C2–C3 intervertebral disk, disk excision and anterior cervical fusion reportedly can be effective.⁸⁵ For pain from the C2–C3 zygapophysial joint, intra-articular injection of steroids has been advocated,¹⁴⁵ but a controlled trial that included patients with C2–C3 zygapophysial joint pain found intra-articular steroids to be no more effective than intra-articular local anesthetic.¹²²

The most abundant evidence for headache stemming from the C2–C3 zygapophysial joints applies to thermal radiofrequency neurotomy of the third occipital nerve.¹²³ When the third occipital nerve has been shown, using controlled diagnostic blocks,⁸⁴ to be responsible for mediating the headache (Fig. 71.14), lasting relief can be achieved by coagulating that nerve. The available evidence shows that the effectiveness of radiofrequency neurotomy is contingent on the rigor of diagnosis and the rigor of treatment.
Three controlled trials have provided salutary evidence on practices that are not effective.\textsuperscript{146–148} Radiofrequency neurotomy is not effective: when patients are selected for treatment simply on the basis of clinical criteria; when nerves are indiscriminately targeted, without having been subjected previously to controlled diagnostic blocks; or when techniques for radiofrequency neurotomy are used that have not been validated.\textsuperscript{9–11}

Radiofrequency neurotomy becomes effective when patients are selected whose headache has been completely relieved by controlled diagnostic blocks of the third occipital nerve\textsuperscript{84} and when third occipital neurotomy is performed according to prescribed standards.\textsuperscript{123} If these
diagnostic criteria are satisfied and correct technique is used, complete relief of pain can be achieved in 88% of patients, for a median duration of some 297 days,\textsuperscript{149} that relief being associated with restoration of activities of daily living, and no need for other health care. Such results have been corroborated by other studies.\textsuperscript{127–129} For patients in whom headaches recur, relief can be reinstated by repeating the neurotomy. By repeating neurotomy as required, some patients have been able to maintain relief of their headache for longer than 2 years,\textsuperscript{149} for up to 5 years,\textsuperscript{129} and beyond.\textsuperscript{127}

A surgical alternative for cervicogenic headache has been explored.\textsuperscript{150} Based on complete, or near-complete, relief of headache following nerve root blocks and likewise following zygapophysial joint blocks, 34 patients underwent posterior fusion of C1–C3 using Brook’s triple wire fusion. Another 10 patients underwent fusion variously at C1–C2, C2–C3, or C1–C3 based on positive responses to nerve root blocks but no response to zygapophysial joint blocks. At 1 year after surgery, 3 patients had no pain, 22 had only mild pain, and 16 had moderate pain rated as less than 5/10. At 4 years, 7 patients had no pain, 22 had mild pain, and 10 had moderate pain. In only 2 patients did pain scores deteriorate to preoperative levels.

**Summary**

The literature provides few options for the evidence-based management of neck or cervicogenic headache. A minimalist clinical pathway captures the practices and advice for which the evidence is most consistent or for which outcomes are strongest (Fig. 71.15).
For acute neck pain, the best advice is to avoid passive therapies and to provide advice to remain active, coupled with home exercises to maintain neck movements. If physicians are tempted to prescribe analgesics, they should do so aware that the effect may be no more than that of a placebo.

Resolution may occur as a result of the treatment or because of natural recovery. Nevertheless, if resolution commences, the treatment should be reinforced in order to encourage recovery until resolution is complete.

If pain continues, the best option remains advice coupled with formal exercise therapy. However, the evidence is conflicting as to whether advice alone or exercises alone are sufficient, and the effect may be small.

Beyond conservative therapy, medial branch blocks should be entertained, on the grounds that the cervical zygapophysial joints are the

**FIGURE 71.15**  A clinical pathway for the management of acute and chronic neck pain.
most likely, identifiable source of pain. If controlled blocks are positive, then thermal radiofrequency neurotomy becomes an option for treatment.

If blocks are negative, or if medial branch neurotomy fails to provide relief, there are no proven options. With that understanding, physicians and their patients might explore unproven options.

For neck pain, those options include other conservative therapies or surgery. For cervicogenic headache, the options include investigation of the atlantooccipital and atlantoaxial joints or the C2–C3 disk, with treatment by intra-articular steroids or arthrodesis.9–11

Introduction

There are three imperatives for the practitioner when they encounter a new patient with what seems to be acute low back pain. The first imperative is to determine whether or not the presenting complaint is, indeed, low back pain as conventionally defined and whether or not it is acute. The second imperative is to determine whether any associated referred pain is somatic referred pain or radicular pain. The third imperative is to identify if the pain is caused by serious pathologies. Once those imperatives are addressed, the management of acute low back pain becomes very straightforward.

DEFINITION

The International Association for the Study of Pain (IASP) construed low back pain as pain arising from one or other of the components of the lumbar spine and referred to it by the rubric: lumbar spinal pain.\(^1\) It defined lumbar spinal pain as pain perceived anywhere in the region bounded by the lateral margins of the erector spinae muscles, an imaginary transverse line through the tip of the last thoracic spinous process, and an imaginary transverse line through the tip of the first sacral spinous process (Fig. 72.1).\(^1\) This definition serves to distinguish lumbar spinal pain from thoracic spinal pain, gluteal pain, and loin pain, for pain in these latter regions invites a different approach to diagnosis and management because its causes are likely to lie outside the lumbar spine. Gluteal pain invites a consideration of disorders of the hip or pelvis. Loin pain invites consideration of disorders of the urinary tract and other viscera.
The adjective acute serves to indicate pain of recent origin. In practice, this means pain that has started within recent hours or days. For taxonomic purposes, the IASP set an upper limit and defined acute pain as pain that has been present for no longer than 12 weeks. A further refinement identifies subacute pain as pain that has been present for longer than 5 or 7 weeks but less than 12 weeks. These distinctions are pertinent because the evidence on effective management differs for acute, subacute, and chronic low back pain.

**REFERRED PAIN**

The definition of lumbar spinal pain does not restrict the location of pain to the region of the lumbar spine. The emphasis is where the pain is
primarily perceived or where it appears to start. However, lumbar spinal pain can spread to distant regions, in which case it is known as somatic referred pain.

Somatic referred pain is caused by convergence. Second-order neurons in the spinal cord that receive afferent nerves from the lumbar spine also subtend afferent nerves from distant sites. In the absence of other, localizing information, the central nervous system cannot distinguish the exact source of input, whereupon spinal pain can be perceived as also arising from distant sites. The precise definition of somatic referred pain, therefore, becomes pain perceived in regions innervated by nerves other than those that innervate the actual source of pain (but which share the same central connections).

Experiments in human volunteers and studies in patients undergoing invasive tests or treatments have shown that somatic referred pain can be perceived in the gluteal region, groin, thigh, leg, and even as far as the foot. The referred pain typically spreads as a continuous area extending from the back into the lower limb, but it can sometimes “skip” regions to become a remote island of pain (Fig. 72.2). The distinction between somatic referred pain and local pain in the lower limb is that referred pain is always concurrent with back pain. If the back pain ceases so does the referred pain. Conversely, when the back pain is more severe, the referred pain tends to spread further into the lower limb.

Somatic referred pain is distinctly different from radicular pain,
otherwise known in the lower limb as sciatica. Somatic referred pain is perceived as a dull, aching sensation; it radiates slowly over relatively wide areas; it tends to be sessile, meaning that once it occupies a particular region; it tends to stay there, although perhaps waxing or waning in intensity. Patients can have difficulties identifying the boundaries of an area of somatic referred pain, but they can clearly identify its centroid or principal location. In contrast, radicular pain is lancinating in quality, like an electric shock, and travels into the lower limb along a narrow band (Fig. 72.3).

![The pattern of radicular pain. Radicular pain is felt along a narrow band traveling into the lower limb.](image)

**CAUSES**

The serious causes of back pain are those conditions that threaten the welfare of the patient if not recognized and treated. Various, they are conditions that threaten the integrity of the spinal cord or cauda equina, can spread to become systemic, or can compromise circulatory homeostasis.

Extrinsic disorders are ones, which by way of hemorrhage or inflammation, can irritate the anterior surface of the lumbar spine, with or without actually penetrating the anterior muscles or vertebrae. Notable among them are aneurysms of the abdominal aorta or aneurysms of retroperitoneal arteries such as the gastroduodenal artery. Back pain may be a feature of visceral disorders, such as pancreatitis, that cause retroperitoneal inflammation, but in these disorders, back pain is typically additional to abdominal pain. Aneurysms, however, can present with back
pain as the sole symptom. Indeed, back pain has been the sole symptom of substantial proportions of patients who have died suddenly from ruptured aortic aneurysm.16

Serious intrinsic causes of back pain encompass fractures of the lumbar spine; primary tumors and metastases; and infections of the vertebrae, intervertebral disks, or paraspinal muscles. However, these causes of low back pain are rare. In primary care settings, fractures occur in between 1% and 4% of presentations, malignancy occurs in less than 0.2%, and infection in 0.01%.17,18 Other serious causes are so rare that they have been described only in case reports, and their prevalence has not been estimated.

Although not serious in the sense of being life-threatening, nonetheless notable causes of back pain are the several seronegative spondylarthropathies, such as ankylosing spondylitis and Reiter’s syndrome. These conditions need to be recognized because they require specialist rheumatology management.

For the remaining 96% to 99% of cases, the causes of acute low back pain are unknown. The principal reason for this is that conventional investigations, such as medical imaging, are not able to identify causes of back pain other than fractures, malignancy, or infection. So, when applied in mass surveys, they have not detected elusive sources of pain. However, such surveys have served to refute certain conditions as causes of back pain.

Spondylosis or degenerative changes, spondylolisthesis, and spondylolysis occur commonly in subjects without back pain, and their appearance on medical imaging is not related to low back pain to either a statistically significant or clinically significant extent. Therefore, none of these conditions is diagnostic of the cause of pain.19

Certain causes of back pain can be identified using invasive, diagnostic tests, but these are not indicated for acute low back pain and have not been systematically applied to samples of patients with acute low back pain in order to determine the cause of their pain. Their utility is limited to the investigation of chronic back pain (see Chapter 73). However, it should be understood that among patients with acute low back pain are ones whose pain will eventually become chronic. Therefore, the diagnosable causes of
chronic back pain will be present among patients with acute low back pain. However, there is no imperative to diagnose these conditions while patients are in the acute phase. Investigations can be reserved until the patient approaches having chronic pain (see Chapter 73).

Management Algorithm

Because it will not be possible to make a diagnosis in the vast majority of patients with acute low back pain, their management cannot be based on finding and treating a particular cause of pain. Ultimately, their back pain, and any associated disabilities, will need to be treated as undiagnosed symptoms, using what is known to work. However, for that approach to be safe, the practitioner must be confident both that the patient does, indeed, have lumbar spinal pain and that he or she has not missed any serious causes of pain.

Figure 72.4 describes a suitable algorithm based on these principles. The algorithm starts with TRIAGE, which calls for consideration of extraneous and serious causes of back pain. The algorithm proceeds to MANAGEMENT but is promptly followed by CONCERN. Concern not only involves checking if the patient is responding or not to management but also introduces VIGILANCE. Vigilance means checking for the emergence of features of serious conditions that may not have been present or evident at the time of presentation. If a serious condition is not evident, management is resumed either to REINFORCE previous interventions or to SUPPLEMENT these with additional measures if required. The algorithm continues in an anticlockwise spiral, until the patient exits the algorithm because he or she has recovered, because a serious condition has been detected, or because his or her pain has become chronic or threatens to do so, whereupon a new algorithm is followed.
An important feature of this algorithm is that it neither supposes nor expects that a practitioner will necessarily detect serious causes of acute back pain on the occasion of the first consultation. Indeed, for some conditions, it may not be biologically possible to do so. Some tumors and infections may not be detectable, clinically or on medical imaging, for several weeks after the onset of pain. For this reason, the algorithm emphasizes vigilance for the emergence of serious conditions. Conversely, the algorithm reminds practitioners to consider, and keep being alert to, serious conditions for the opposite of vigilance is negligence.
**TRIAGE**

Triage serves to check that the patient does indeed have back pain, that the pain is not a symptom of a vascular or visceral disorder, that the pain is likely to be of spinal origin, but that a serious cause is not responsible. Questions about these issues will not necessarily be answered in a single step. Rather, if a systematic approach to history and examination is taken, cues will emerge at various stages in the inquiry that will alert the practitioner to possibilities. These cues should be collected so that if sets of cues implicate a serious condition, the diagnosis of that condition can be pursued further. On the other hand, if cues are sought but do not arise, the practitioner can be confident that because of the absence of cues, a serious condition is unlikely. The discipline required, however, is that cues are looked for, and their absence is established by having looked for them and not by assuming that they will not be present because they are unlikely to be present.

A disciplined approach involves taking a comprehensive history thoroughly and can be assisted by reference to a “red flag” checklist (Fig. 72.5). A “red flag” is a clinical feature that alerts the practitioner to the possibility of a serious cause of pain and invites further consideration of that cause. Alone, a “red flag” is not meant to be diagnostic; it is only an alerting feature. Therefore, it is not surprising that individual “red flags” have poor positive predictive value. The diagnosis of a serious cause of back pain requires other measures. A “red flag” serves only to invite consideration of applying those other measures.
FIGURE 72.5 A checklist for “red flag” clinical indicators, suitable for inclusion in medical records used in general practice, based on Bogduk and McGuirk and McGuirk et al. The “red flag” checklist (see Fig. 72.5) is not based on the positive predictive value of “red flags.” Rather, it was derived on the basis of case reports of conditions that were overlooked but could have been detected earlier if only the right questions were asked. The “red flag” checklist therefore serves to remind practitioners not to overlook various, rare possibilities. In a large study, the checklist proved effective in detecting all serious conditions while missing none.

The cardinal risk factors for fractures of the lumbar spine are trauma and the prolonged use of corticosteroids, particularly in the elderly. Therefore, inquiry should be made about these factors, particularly in the elderly.

Asymptomatic stress fractures of the pars interarticularis are common in
the general population, but among sportspeople, they are a likely cause of acute back pain. Therefore, participation in sport should be on the agenda in any inquiry of the patient’s history.

Infections of the lumbar spine are often cryptic at onset; pain may be the only feature. Among the risk factors for infection is any reason for the patient to have an infection. This includes any history of a breach in the body’s defense mechanisms, such a penetrating injury, a surgical or dental procedure, tattooing, venipuncture, catheterization, skin lesions, immunosuppression, and diabetes mellitus. Otherwise, malaise and fever are strong alerting features to infection as a possible cause of back pain.

Unusual domains of inquiry pertain to hobbies, occupational exposure, and travel. These domains relate to the acquisition of unusual infections by fungi, parasites such as hydatid, and other exotic organisms. When these conditions have been missed in practice, it has not been for lack of clinical acumen but because elementary questions about exposure have not been asked. A particularly exotic example is exposure to spear grass (a plant found in Northern Australia), whose seed can burrow into tissues using an osmotically driven corkscrew action. In an unpublished case, a patient suffered unremitting pain, due to a seed buried in the patient’s spine, whose diagnosis was delayed because no one asked about exotic exposures.

A past history of cancer and weight loss are the cardinal features of malignancy affecting the lumbar spine that is not yet producing other features.\(^{17}\) Otherwise, the checklist (see Fig. 72.5) reminds practitioners to undertake a systems review for associated features. These are elaborated in the following text under the “Medical History” section.

**Medical History**

Eliciting the medical history systematically is the cardinal tool for triage. Taking a history serves not only to check for serious conditions but also to help the practitioner understand subjective aspects of the patient’s condition and helps develop the rapport to forge the doctor–patient relationship that is essential for effective medical care.\(^{23}\)

A comprehensive history can be elicited systematically by pursuing an inquiry strategy in several domains that, generically, are pertinent to any
pain problem (Table 72.1). For acute low back pain, some of these domains are rarely relevant, but several are pivotal.

**TABLE 72.1** Domains of Inquiry for the Systemic History of Any Pain Problem

| Site | Distribution | Duration of illness | Quality | Intensity | Frequency | Periodicity | Time of onset | Mode of onset | Precipitating factors | Aggravating factors | Relieving factors | Associated features |

The extent to which each domain of history is explored will depend on the practitioner’s role in the patient’s management. Physicians will need to elicit a more detailed history because they are expected to identify any “red flag” conditions, they will be responsible for ordering any special investigations that might be required, and they will have responsibility for the longer term management of those patients whose pain persists. In such cases, the history elicited initially will be useful for monitoring the progress of the condition and the development of any of its features.

A paramedical practitioner will not need to elicit such a detailed history if he or she is working in cooperation with, and on referral from, a physician who has assumed primary responsibility for the patient and who has already taken a comprehensive history. However, he or she should still address the basic features of history and any cues alerting to a “red flag” condition and any other aspect of the history that pertains to his or her role in the management of the acute condition. A paramedical practitioner acting as the sole health care provider inherits the responsibility for taking a comprehensive history and the responsibility for alerting the appropriate medical practitioner if a “red flag” condition is suspected.
Site
Establishing the site of pain is fundamental to assessment. Although the patient might report pain in the back, the actual location of pain may not accord with the definition of lumbar spinal pain. Pain in the loin, or pain in the buttock, are not back pain and invite a different algorithm for assessment.

Likewise, radicular pain is not back pain. Although its cause may lie in the lumbar spine, radicular pain is perceived in the lower limb, not in the back. Its assessment requires a different algorithm (see Chapter 70).

If a patient with back pain also has pain in the abdomen or pelvis, the latter takes priority. The patient should be assessed for visceral or vascular disease before back pain is the focus of attention.

Distribution
A patient with back pain may also have somatic referred pain. The distribution of referred pain does not help in the diagnosis of the source of pain for the patterns of referral are related to the segmental innervation of the source, not to the specific source itself. However, the distribution of referred pain is one factor that helps distinguish somatic referred pain from radicular pain. Of all the things that have been revealed by research over the last 70 years, this distinction still seems to have failed to permeate education on back pain.\(^3\)

Somatic referred pain tends to spread over broad areas. The patient usually finds it difficult to identify the boundaries of where it is felt, but he or she can indicate its centroid. Once established, somatic referred pain is sessile in nature; although the area in which it is felt may fluctuate in size with the intensity of the pain, the center of its location tends to be fixed. In contrast, radicular pain is typically perceived along a narrow band that travels longitudinally into the lower limb (see Fig. 72.3). Other distinguishing features relate to the quality of pain.

Duration of Illness
It is pertinent to confirm that the patient has acute low back pain, and not recurrent or chronic pain, for the evidence pertaining to management and treatment is quite different for each of these conditions. The present algorithm pertains to acute low back pain. So, the practitioner should
confirm that the pain has been present for less than 12 weeks. If the pain is subacute, its initial management will not be different from that of acute pain, but different options for treatment may later apply.

Quality
Determining the quality of pain is perhaps the most difficult domain of inquiry for patients with back pain. Patients often find it difficult to describe the quality of their pains and may default to describing their impacts using words like severe or horrible. In such a case, the practitioner should explain that intensity is a different feature that will be assessed separately (see the following text) and should steer the patient back to considering the quality. The practitioner should not prompt the patient with suggestions as that may lead to unreliable recording of the quality.

Somatic low back pain and somatic referred pain tend to be dull and aching in quality; in some instances, the pain feels like an expanding pressure. If patients can find such words to describe the quality of their pain, it serves to corroborate a somatic source of the pain.

Radicular pain is lancinating, shooting, or electric in quality. Although not diagnostic of the source or cause of pain, these features distinguish radicular pain from somatic referred pain. Making this distinction is pivotal to the efficient and effective management of patients with somatic referred pain. It protects them from mistakenly undergoing investigations in the pursuit of disk herniations or other causes of neuropathy. It protects them from undergoing presumptive treatment for radicular pain, such as epidural steroids, which do not work for back pain or somatic referred pain.

Intensity
Intensity of pain means its magnitude as measured on a valid scale. A seminal article stated that if pain is not measured initially, it cannot later be said to have been relieved.

A patient can provide a measure of the intensity of his or her pain by using a validated instrument such as a Visual Analog Scale or a Numerical Pain Rating Scale. High scores, however, are difficult to interpret in a valid manner. Although they might indicate severe pain because of serious pathology, high scores may be no more than an
indication that the patients feel that they are suffering because of the pain’s impact, even though the cause of their pain may not be serious. Other features help to indicate if the patient has a serious cause for severe pain (see “Associated Features” section in the following text).

The particular relevance of establishing the intensity of pain is that it is a relative risk factor for poor outcome.\(^{28}\) Patients with pain of high intensity may require more concerted management regardless of whether the reason for high intensity is physiologic or psychological.

**Periodicity**
Periodicity is a domain of inquiry that is not relevant to back pain. It pertains more to visceral disorders and headache, in which pain can occur in bouts with regular frequency during a day or during a month. It is nevertheless mentioned here in the interests of complying with a generic, systematic approach to taking a history for any pain.

**Time of Onset**
Time of onset pertains to when pain that is not constant actually starts. That may be at a particular time each day or a particular day in a given week or given month. This domain of inquiry is more pertinent for certain types of headache or for visceral pain, which may be cyclical, but it is not irrelevant for back pain. Characteristic, and almost pathognomonic, of ankylosing spondylitis is early morning stiffness. In this context, regardless of whether or not patients distinguish back stiffness from back pain or conflate the two, the key feature is that the symptom is perceived in the morning.

**Mode of Onset**
The mode of onset means the manner in which pain commences: for example, suddenly or gradually. Pain of sudden onset invites exploration of any event (such as an accident) associated with the onset. The magnitude and directions of forces involved may provide clues to the structure(s) likely to have been injured. A sudden onset of severe pain, for no obvious reason, is not diagnostic of any cause but constitutes an alerting feature to possible serious causes. When the onset of back pain has been gradual, or otherwise unremarkable, there is little relevance to this
variable.

Precipitating Factors
Precipitating factors are events, activities, or movements that brought on the original onset of pain or that trigger episodes of intermittent pain. A history of significant trauma is an alerting feature to fracture being the cause of pain, but otherwise particular precipitating factors have no bearing on the cause of pain. However, inquiry into precipitating factors becomes relevant to understanding how the patient may be disabled for undertaking work, domestic, or other physical activities.

Aggravating Factors
Aggravating factors are activities, movements, or postures that worsen the intensity of pain. These factors are of little value for diagnostic purposes because regardless of its cause, back pain is typically aggravated by movement of the spine or by sustained postures. More informative—and alerting—is low back pain that is not aggravated by particular postures or movements. That suggests a source which is not subject to compression loading in the lumbar spine or tension in its joints and ligaments. Visceral and vascular disorders have this property, as can malignancy until it starts to affect spinal joints.

Relieving Factors
Relieving factors are those that things that lessen the intensity of pain and/or that decrease the frequency of episodic pain. They are the complement to aggravating factors. Pain that is not relieved by rest should invite a concerted consideration of possible, sinister causes.

Associated Features
The domain of associated features is the most critical and revealing domain of inquiry about low back pain. Serious causes of pain will usually be evident through the features that they produce, other than pain. Conversely, case reports that describe missed diagnoses often show that the diagnosis could have been made earlier if only a thorough inquiry about associated features had been conducted earlier. Inquiry into associated features is prompted by the second and third columns of the
“red flag” checklist (see Table 72.1).

Risk factors for cardiovascular disease constitute alerting features to aortic aneurysm in the differential diagnosis of back pain. These include a family history of cardiovascular disease, high cholesterol, hypertension, older age, and smoking. The risk is amplified by a history of cerebrovascular disease, ischemic heart disease, or peripheral vascular disease.\textsuperscript{13}

The lung is one of several sites of primary tumors that metastasize to the spine, but there are few clinical features of early lung cancer. Asking about respiratory problems, and cough in particular, as well as smoking as a risk factor, serves to remind practitioners about the possibility of lung metastases.

Inquiry about urinary function is indicated for a variety of reasons. The urinary tract may be a source of infection. Prostatic cancer may cause problems with urinary stream or voiding. Spinal tumors can affect the sacral nerves and thereby cause problems with bladder continence. Urethritis, especially if concurrent with uveitis, is pathognomonic of Reiter’s syndrome.

Similar considerations apply to the reproductive system, which includes the breast in females, because the breast, ovary, and testis can be sources of metastases to the spine. However, primary tumors in the reproductive system will not be detected by history unless they happen to produce associated features.

Even more cryptic are disorders of the hematopoietic system. These may be impossible to detect clinically, but the oncology literature is replete with case reports of patients, with a history of neoplastic blood diseases, presenting with back pain.\textsuperscript{29–33}

The endocrine system harbors several possible causes or risk factors for back pain. These include thyroid cancer as a source of spinal metastases, diabetes mellitus as a risk factor for spinal infection, and osteoporosis either primary or caused by corticosteroids as a cause of pathologic fracture. Osteitis fibrosa cystica, caused by hyperparathyroidism, can be a cause of spinal pain with no other features.

The musculoskeletal system should be assessed in order to determine if back pain is but one manifestation of a systemic disease such as
rheumatoid arthritis or polymyalgia rheumatica. These conditions are
declared by pain in the appendicular skeleton, and the condition is no
longer one of isolated back pain.

The presence of neurologic features is a game changer. The diagnostic
pursuit of numbness, weakness, or disturbed control of the bladder or
bowel immediately takes precedence over the assessment of back pain. If
the cause of back pain is not revealed on finding the cause of the
neurologic features, the assessment of back pain can be resumed once the
neurologic disorder has been diagnosed and stabilized.

Inquiry about skin lesion is relevant on two counts. Superficial
infections could be the source of spinal infections. Otherwise, skin lesions
are among the features of seronegative spondylarthropathies. Likewise,
disturbed gastrointestinal function can be a feature of bowel cancer, which
can metastasize to the spine, or be a feature of seronegative
spondylarthropathies.

**Psychological and Social History**
To complete a comprehensive medical history, the practitioner should
explore relevant aspects of the patient’s affect and his or her social
situation. Sensitive appraisal of these aspects can enhance rapport which is
so important to the doctor–patient relationship and help the practitioner
develop empathy.

One psychological feature of particular relevance in acute low back pain
is fear. Patients with back pain may be scared of its possible association
with serious pathology; they may be scared of making the pain worse by
what they do; they may be scared of what they think may be its prognosis.
Other psychological features of relevance in acute low back pain are
anxiety and depression caused by what the patient thinks the implications
of the pain might be. These features need to be identified because they are
as much a part of the presenting complain as the back pain itself. If the
back pain cannot be promptly stopped, fears will need to be managed,
along with the back pain, because persistent fears or misapprehensions can
impede the patient’s rehabilitation.

Social features of relevance include the patient’s home situation and the
degree of support he or she has from family members, friends, and his or
her employer. Delving gently into the effects of the pain on the patient’s home relationships, on his or her work, and on his or her leisure interests helps the practitioner understand the interplay of disability and handicap in each area of the patient’s life.

**Physical Examination**
Examination of the lumbar spine has traditionally involved inspection, palpation, and movement testing, or as described in an aphorism by Apley “look, feel, move.”\(^{34}\) There is very little evidence of the validity of physical signs detected by examination of the lumbar spine.\(^{34,35}\) So, arguably, there is not much point in going through the process. Nevertheless, there are two reasons for conducting a physical examination. In the first instance, patients expect to be examined, and performing an examination is an indication that the physician is interested in the patient and concerned about them. The fact that nothing found on examination is diagnostic is immaterial in this context. The second reason is ironic. Of greater significance than finding positive features on examination is finding no physical features in the lumbar spine. Absence of somatic signs prompts a serious consideration of visceral and vascular causes of low back pain. A pertinent aphorism is if patients have no signs in their back, turn them over and examine their abdomen and pelvis.

**Inspection**
Physical signs detectable by visual inspection of the patient include general and specific features. General observations are static posture both standing and sitting (for signs of scoliosis, kyphosis and loss of lordosis), dynamic posture when walking (for antalgic gait), and bodily deformity. Specific observations include scars, puncture marks, swelling, and other local changes of shape.

**Palpation**
Physical signs detectable by palpation include altered sensitivity (hypoesthesia or hyperesthesia), relationships of bony landmarks, and tenderness. If tenderness is present, it may be diffuse or focal, and if focal, the practitioner may note its relationship to bony landmarks such as spinous processes.
Movement Testing
Movement testing may include assessing active, passive, and accessory ranges of movement. Active and passive ranges of thoracolumbar movement can be tested in the three basic planes of the body: flexion and extension in the sagittal plane, left and right side bending in the frontal plane, and left and right rotation in the transverse plane. If appropriate, movements can be tested in combinations of those ranges such as “quadrant extension” (extension with rotation, as in looking backward over the shoulder).

Some craft groups contend that the accessory ranges of passive intervertebral motion can and should be tested. The evidence from the available literature indicates that conventional, physical examination procedures lack reliability, validity, or both. Nothing found by various maneuvers or tests of the accessory ranges of spinal movement reliably implicates any source of cause of pain with any validity.

The exception to this may be spinal assessment by the McKenzie method. Two studies have shown that careful, specialized examination can identify patients with sacroiliac joint pain and patients with internal disk disruption. These studies, however, were based on patients with chronic low back pain, in whom these two conditions are common. Their prevalence in patients with acute low back pain is not known, and therefore, the validity of McKenzie assessment in these patients has not been established.

Other Examination
Although classical teaching prescribes a neurologic examination for patients with low back pain, it is neither warranted nor justified. If a patient reports a history of neurologic symptoms, such as weakness or numbness, a neurologic examination becomes mandatory, but in that context, the indications for neurologic examination are the neurologic symptoms—not the back pain. Neurologic diseases do not present with back pain as the only feature. In patients with back pain as the sole feature, physicians might elect to perform a neurologic examination in order to appear thorough, but they should be under no illusion that it serves to establish a diagnosis. This guideline should not be confused with
neurologic examination in a patient with radicular pain. Neurologic examination is, indeed, indicated if the patient has radiculopathy, but in that context, it is pain in the leg—not pain in the back—that is the indication for neurologic examination.

Given the possibility of vascular and visceral disorders, examination of the abdomen is pertinent in the initial assessment of a patient with acute low back pain. This includes auscultation for bruits and checking for hypotension, both of which are signs of aortic aneurysm.¹³

A component of physical examination that has not been formally studied pertains to the demeanor of the patient. This can be helpful in identifying patients with serious causes of pain. Patients with infections and cancer are typically serious, subdued, or quietly guarded in their presentation. They avoid movement and are apprehensive about being examined. Their general demeanor is grim—as if, intuitively, they know that something serious is wrong. That appearance is distinctly not histrionic. Although they may rate their pain as severe, they do not incessantly draw attention to it. Beware the quiet patient with severe pain.

**Ancillary Investigations**

Much evidence from research has overturned past habits of routine investigations for acute low back pain. Imaging investigations, such as plain radiography, computed tomography (CT) scanning, or magnetic resonance imaging (MRI), are not justified either “just in case” or to reveal something that is not evident on history. The same may be said for blood tests such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), alkaline phosphatase, serum calcium, and (especially) human leukocyte antigen (HLA) B27. In the absence of specific clinical indicators, the yield of these investigations is zero or close to it.

Further investigations should be pursued only if triggered by an alerting “red flag” feature, and in that event, the investigations should be tailored to the particular entity of concern. For that purpose, Table 72.2 lists various options for first- and second-line investigations for particular suspected pathologies. In some instances, laboratory investigations precede imaging.

CRP, C-reactive protein; CT, computed tomography; ESR, erythrocyte sedimentation rate; FBC, full blood count; IEPG, immunoelectrophoretogram; MRI, magnetic resonance imaging; PSA, prostate specific antigen.

Plain radiography lacks sensitivity and specificity for any cause of back pain other than fractures. It is indicated only to those patients who have risk factors for fracture (see Table 72.2).

Neither CT nor MRI has ever been shown to demonstrate a cause of back pain in patients with no clinical indicators of fracture, infection, or cancer or in the absence of neurologic signs. In that regard, the use of CT or MRI in patients with back pain should not be confused with its use in patients with radicular pain or with neurologic signs. In those conditions, it is the neurologic features that are the indication for investigation—not the
back pain.

Apart from not being diagnostic, medical imaging has the liability of needlessly alarming patients. To the uninformed patient, the vocabulary of radiology reports sounds serious and significant. Terms such as spondylosis, spondylolisthesis, and degenerative changes sound like the patient has a disease that both explains his or her pain and requires treatment. Yet, the evidence shows that these conditions are not related to pain.\textsuperscript{19} Moreover, applying these false and alarming labels is associated with worse prognosis.\textsuperscript{38}

Nor is it an argument that patients expect imaging. They do so only when they remain uninformed. A controlled study has shown that 5 minutes of explanation deters most patients from wanting unnecessary radiographs.\textsuperscript{39} The arguments against imaging include their lack of sensitivity and specificity, the very low likelihood of finding anything, the possibility of false-positive findings and the distress that they can cause, the possible false sense of security from a negative result, and the health hazards of radiation exposure.

Studies have shown that imaging did not detect an occult cancer if patients were under 50 years, had no history of cancer, with no weight loss, and no signs of systemic illness.\textsuperscript{40,41} In patients over the age of 50 years, or with unexplained weight loss, or with signs of systemic illness, imaging did not detect cancer if their ESR was less than 20 mm per hour. Therefore, for suspected cancer, the indications for imaging are either a past history of cancer or a raised ESR. The appropriate imaging is either bone scan or MRI. Both are equally sensitive, but MRI has greater specificity.

In sportspeople in whom a stress fracture is suspected, the imperative is to detect a stress reaction before actual fracture. Doing so allows the pars interarticularis to be protected from further stress and allowed to heal. Once fractures occur, there is no guarantee that they will unite. Bone scan has been the traditional investigation, but it lacks specificity; it cannot distinguish between a stress reaction and an actual fracture. MRI can detect and distinguish both and should be the preferred investigation.

\textbf{Formulation}
After taking a comprehensive history, performing an examination, and reviewing any previous investigations, a practitioner will have noted any alerting “red flags,” and appropriate further investigations will have confirmed a serious cause for back pain or excluded it for the time being. Conversely, if none of the “red flags” on the “red flag” checklist are present, the practitioner can be confident that there is no serious cause of pain currently detectable. However, the practitioner must nonetheless remain vigilant for any change in symptoms or new symptoms that might herald the manifestation of a serious condition. That includes instructing the patient to report immediately any such change in symptoms.

Having excluded serious causes, for the time being, the practitioner can formulate an assessment based on the information gathered from history and examination. For purposes of forthcoming management that formulation would encompass the location and extent of pain, its intensity, any fears or beliefs that the patient may have about the pain, and the disabilities that either the pain or fears are producing. Each of these becomes a target of management. The formulation will not be an attempt at diagnosis of the specific source and cause of the pain; that is inappropriate in the acute phase.

**INITIAL MANAGEMENT**

All contemporary practice guidelines recommend that the first line of care for all patients with acute low back pain should be explanation, reassurance, encouragement to continue physical activity, and supporting the patient to take responsibility for his or her own rehabilitation.\(^{42-46}\)

Practice guidelines hold in reserve certain second-line interventions, but their effectiveness is either questionable or small. Therefore, it is imperative that first-line interventions be as effective as possible. Fortunately, medical management based on these first-line recommendations has been found to be effective in field trials.\(^{21,47,48}\)

The precepts of good medical management of a patient with acute low back pain can be encapsulated by the patient’s cardinal complaints: “I hurt; I can’t move; I can’t work; and I’m scared.”\(^{49,50}\) For effective management, all these issues need to be addressed.
Pain

Modalities used in the management of acute low back pain include patient education, medication, physical therapies, and activation. Of these, the only ones well supported by evidence are patient education and activation, and they are the mainstays of caring for patients with acute low back pain.

Patient Education

Effective patient education has two elements: explanation and information. The practitioner should provide explanation of the pain and information about the good prognosis based on the favorable natural history. These elements should be delivered with a good dose of reassurance.

Explanation is the foremost tool for the management of acute low back pain. It has two aspects: what the patient does not have and what the patient does have.

The practitioner should explain to patients that the chances of a serious cause are extremely low and are even lower because of their negative responses to the “red flag” checklist. If pressed, the practitioner can explain why there is no need for any special investigations. If patients ask about x-rays, the practitioner should take the time to explain why they are not indicated and what the health risks of x-rays are.

Lumbar spine radiographs may be false-negative in up to 41% of patients with known vertebral cancer.\textsuperscript{51} Osteomyelitis does not appear before 2 to 8 weeks of evolution of the disease; a normal radiologic picture does not exclude the diagnosis of spinal infection.\textsuperscript{52} A lumbar spine series delivers 40 times the radiation dose received from a chest x-ray\textsuperscript{51,53} and delivers to the gonads a radiation dose equivalent to that from having a daily chest radiographs for 6 years.\textsuperscript{51,54–56} Explaining this to patients constitutes evidence-based practice.

Once the “red flag” issues have been covered, the practitioner should provide a calm and clear explanation of why the patient has pain. It does not matter if this explanation is not biologically valid; it simply has to indicate to the patient that the practitioner does know what is going on. In this regard, it is not so much what the practitioner says that is important but the manner in which they say it. Providing a confident explanation is the opposite of appearing uncertain, or alarmed, about what the problem
might be. Providing such an explanation is the opposite of panicking and pursuing unnecessary investigations that alarm the patients and reinforce their fears that something serious is wrong.

Individual practitioners may develop their own pattern, in offering an explanation. One that has been tested is to explain to patients, in simple terms, that they have internal disk disruption: a small injury that is presently inflamed and sore but which will settle. Depending on the situation, practitioners might prefer an alternative model that does not nominate a specific diagnosis that may later prove wrong. They might care to explain to patients that they have strained their back muscles or that their muscles are sore because they have been undertaking activities in an inefficient manner.

Whatever the model used, the art of explanation can be encapsulated by the eight C’s (Table 72.3). The explanation should be calm (delivered in such a way as to allay anxiety), clear (expressed in terms the patient can readily understand), and credible (fitting the patient’s circumstances and intelligible to him or her). The practitioner’s manner in presenting the explanation should be confident (precluding uncertainty which breeds doubts in the patient’s mind), convincing (which requires monitoring the patient’s response to the explanation and addressing any uncertainties), and concerted (which means the practitioner should show he or she is trying hard to help the patient). Throughout the explanation, the practitioner should show that he or she cares about the patient and his or her complaint and have concern (which does not mean alarm about possible, serious causes of pain; it is related to caring, taking the patient seriously). All of these attributes amount to the opposite of being fast, perfunctory, and dismissive.

Explanation is reinforced by the second tool at the disposal of the practitioner: information. This involves informing the patient of the evidence on the natural history of acute low back pain. Provided that patients are managed properly, the natural history is very favorable. Some 80% can be expected to recover fully, if managed well. Explaining this fact constitutes evidence-based practice. The practitioner should explain to the patient, in terms that the patient will understand, that the odds are in his or her favor and that there is every chance of recovering (even regardless of treatment), but that it may take time. During that time, there are certain measures that both the practitioner and the patient can take to ease the situation while this recovery takes place.

The evidence for this approach is strong. A systematic review found 24 studies, of which 14 (58%) were of high quality, and showed that patient education is effective for the management of patients with acute or subacute low back pain.

Some guidelines recommend issuing the patient with an educational booklet about back pain. This might serve to standardize information provided, and practitioners might consider it an aid in their endeavors, but booklets have little effect when used alone. They are not a substitute for explanation, support, and encouragement provided personally by a practitioner following the eight C’s (see Table 72.3).

Medications
Medications have no proven place in the management of acute low back pain. Paracetamol (acetaminophen), at a dose of 4 g per day, is no better than placebo for relieving acute low back pain, in either the short term or long term. Nonsteroidal anti-inflammatory drugs (NSAIDs) are statistically more effective, on average, than placebo but barely so. Their superiority over placebo is less than the minimally important clinical change for back pain. Meanwhile, the risk of harm, from the side effects of NSAIDs, outweighs any trivial effect that they have on pain.

An earlier Cochrane review recommended that muscle relaxants be used with caution because of their side effects. More recent reviews found
that muscle relaxants were more effective than placebo but only in the short term, that is, over a matter of days,\textsuperscript{62,64} and that they had a significantly higher risk of harm from side effects.\textsuperscript{62} However, a recent series of controlled trials have shown that adding orphenadrine or methocarbamol,\textsuperscript{65} or diazepam,\textsuperscript{66} or cyclobenzaprine\textsuperscript{67} did not improve outcomes for pain or function achieved by treatment with naproxen alone. Benzodiazepines have been shown to be no more effective than placebo.\textsuperscript{62}

There is no published evidence that antidepressants\textsuperscript{45,62} or antiseizure drugs\textsuperscript{45,62} are effective for acute low back pain. Nor is there evidence that opioids are effective.\textsuperscript{45,62} The use of these agents for acute low back pain lacks any evidence base.

**Superficial Heat**

Instead of drugs, an expedient and effective alternative for the short-term relief of acute low back pain is superficial heat, in the form of low-level heat wrap therapy. Applying heat to the back has been shown to be more effective than placebo, both in general patients\textsuperscript{68–71} and in workers with back pain,\textsuperscript{72} and is more effective than either ibuprofen or paracetamol (acetaminophen).\textsuperscript{73} It has been rated as a cost-effective intervention.\textsuperscript{74}

**Physical Therapies**

Evidence is not lacking on the effectiveness of physical therapies commonly used to treat acute low back pain. The available evidence shows either that these therapies provide relief of pain to no greater degree than does sham therapy or that any superiority over sham treatments is small in magnitude and clinically insignificant.\textsuperscript{75} For the relief of pain, exercises are no more effective than no exercises.\textsuperscript{75} When exercise therapy has been compared with other therapies, the evidence is inconsistent as to which is better if at all.\textsuperscript{75} Manipulative therapy is not more effective than either inactive treatments (such as education pamphlets) or active treatments such as exercise.\textsuperscript{75–77} Two trials of acupuncture showed inconsistent effects, and two trials showed reduction of pain by an average of 9 points out of 100, compared with sham therapy,\textsuperscript{75} but the minimal clinically important change for back pain is greater than 20/100. Meanwhile, five trials show no clear effects on
function, which is the cardinal problem for patients with acute low back pain. Massage may provide short-lasting but small benefits greater than those of sham therapy or other, active therapies.

Other interventions, commonly used in the past, for the relief of acute low back pain, either lack formal evidence of efficacy or have been shown to be ineffective. They should be avoided not only because they are ineffective but also because they conflict with the precept of empowering the patient to become responsible for his or her own rehabilitation. In this category are application of cold, therapeutic ultrasound, low-level laser, bed rest, lumbar supports, traction, transcutaneous electrical nerve stimulation, and back school.

Multidisciplinary pain management has explicitly been shown to be not effective for acute low back pain, so it is not indicated early in the course of management. For subacute back pain, a systematic review found low-quality evidence that multidisciplinary rehabilitation might improve pain and function more than does usual care but not more than do other interventions, such as light mobilization, graded activity, a brief clinical intervention including education and advice on exercise, and psychological counseling.

Activation
Multiple studies and reviews have consistently shown that maintaining activity is a crucial component in the management of acute low back pain. The emphasis lies not in treating a particular pathology but in resuming or maintaining activity, in a holistic sense, in order to prevent the patient being disabled by his or her pain. The intervention should be combined with explanation, information, reassurance, and encouragement in empowering the patient to take responsibility for his or her own management.

The practitioner should explain to the patient that the evidence shows that those who resume activities have a much more favorable prognosis: They recover more quickly and more thoroughly than patients who resort to rest and avoidance of activities. A model of explanation that has successfully been used is to explain that muscle tightness is a normal reaction to pain but one that can be deleterious; allowing the back to seize
up or become stiff not only interferes with movement but can also add to the pain. The objective of treatment, therefore, is to prevent and overcome stiffness.

This can be achieved by teaching the patient a set of simple stretching exercises. These are not exercises that require supervision or attendance at a facility, such as a physiotherapy practice or gymnasium. They are exercises that can, and should, be executed virtually anywhere that the patient needs them. In order to reduce stiffness and keep the patient mobile, the patient should perform the exercises at strategic times of the day, such as upon rising, before going to work, at coffee breaks, or lunchtime. In the sense of a “warm-up,” they can be applied as a preparatory and preventive measure prior to undertaking a major activity, such as commencing chores. As a first-aid measure, they can be applied to ease exacerbations of pain, after sustained activity or after prolonged sitting. Providing a first-aid measure is one of the crucial steps in empowering the patient to be able to look after themselves. Exercises that the patient can do by themselves, and for themselves, are crucial to avoiding passive interventions and becoming dependent on them.

Work
All guidelines on occupational low back pain emphasize the benefits of returning to work or remaining at work. Patients who do so inherit a better prognosis than those who do not.

The obstructing factor in this context lies not in the patient but in the attitude of the treating practitioner. It is easier, and faster, to write a certificate for time off work than to explain to the patient why they do not need one. What is difficult is to change the attitudes of practitioners. Changing patients is far less of a problem.

The practitioner should share with the worker the evidence of the benefits of returning to work. They should inquire as to why the patient feels or believes that he or she cannot return to work.

Fears of aggravating the pain will already have been partly addressed by confidently providing a credible explanation for the pain, coupled with an explanation that activity will not do harm. That message is reinforced by helping the patient resume movements and empowering them to do so.
Those movements include work.

Some patients may have pain of high intensity that temporarily impedes their ability and capacity to resume their accustomed work. For such patients, modified work duties may be required. Unfortunately, there is no evidence, in the form of controlled trials, that vindicates the prescription of modified duties. Their reputation rests on anecdotal and observational data. The strongest evidence lies in a cohort study, which found that keeping patients at work, with modified duties as required, resulted in a greater proportion of patients fully recovered, and fewer recurrences, than did usual care.\(^\text{93}\)

Prescribing modified duties imposes a responsibility. The practitioner should not forget the patient. The objective of modified duties is to have the patients remain at work but progressively to restore their capacity for former duties. During this period, the patients and their progress need to be monitored. As soon as they are able, the patients should return to full work. A certificate and its expiry date do not magically achieve this. It is the continued involvement of the practitioner that does so.

Inquiry into the patient’s beliefs about work may reveal extraneous but pertinent issues. They may resent their work environment or their supervisor. They may harbor fears about recurrences of accidents in which they were injured. Such issues raise agendas that are separate and additional to the back pain. Those agendas need to be pursued and managed parallel to the back pain itself.

In the first instance, the practitioner needs to elicit from the worker the beliefs and concerns that they have. Mistaken beliefs can be discussed and corrected. Misplaced concerns can be allayed. Otherwise, workplace intervention may be required. If the practitioner themselves cannot exercise this, the services of a skilled practitioner in occupational medicine should be recruited.

The evidence strongly supports the efficacy of workplace intervention. Whether as an isolated intervention, or adding it to medical management, workplace intervention improves outcomes.\(^\text{94}\) It is conspicuous, however, that the contents of the workplace intervention are immaterial. The effective ingredient does not lie in the specifics of ergonomic or related changes. What counts is that the worker has an advocate who acts on his or
her behalf and in his or her interests. This is done in the context of solving problems with the participation of supervisors and management. Solutions may lie in modifying the physical work environment, the social work environment, work flow, or work demands. The solution should be cast in a manner such as to benefit all parties. The worker returns to an improved environment. The employer avoids the problem of additional injuries and claims and the burden of increased insurance premiums. Advocacy is paramount in these negotiations. Workers typically do not have access to management, whom they may regard as intransigent and uncaring. The occupational physician has the appropriate “social rank” to appear before management and to explain the circumstances to them.

Workplace intervention takes time and requires a particular, skilled aptitude. General practitioners and others may not have this time or aptitude. That, however, is not a pretext for overlooking or neglecting workplace intervention. Persisting problems with return to work, in a practice or in a region, are an indication that specialist skills need to be recruited.

Fear
Fear is the most damaging characteristic that a patient with acute low back pain can harbor. Their fears might pertain to biologically, what is wrong; medically, what is going to be done; or socially, what is going to happen. Such fears inhibit the patient’s recovery. It is important, therefore, that any such fears be discovered and addressed.

It is not necessary, nor expected, for a practitioner to address the fears that a patient might have at the first consultation. However, the possibility of fears should be noted and their exploration resumed at follow-up visits.

The practitioner can explore possible fears in the course of a normal consultation, either by being alert to what the patient might mention, or allude to, spontaneously, or they can check for fears through simple questions, such as what do you think is the cause of pain, what do you think needs to be done, and what do you think is going to happen.

Fears about the biology of back pain are covered by providing a credible, convincing explanation, reinforced by repetition if necessary. Fears about prognosis and consequences are covered by providing information to the patient about the favorable natural history of acute low
back pain. Fears about management are covered by providing the patient with a concerted plan, which empowers them and does not leave them abandoned. Fears about work, employment, and future are encompassed by the workplace intervention.

If required, formal behavioral therapy can be of benefit. A systematic review found that for patients with acute low back pain, cognitive-behavioral therapy was effective for reducing fear-avoidance beliefs, although having no effect on pain or disability. 95

**REVIEW**

An old medical myth is that if the patient does not return, he or she must be alright. This myth has been dispelled. A longitudinal study, in British primary care, followed patients after they presented to general practitioners with acute low back pain. 96 They did not return to the general practitioners, who possibly assumed that they had recovered. Research nurses found that only 25% of patients had recovered and the remainder continued to suffer, but they did not return to their general practitioner because they felt that they had not been helped.

Patients with acute low back pain should not be abandoned, and they should not feel abandoned. The risk of doing so is that patients will exaggerate and prolong their disability, if left to fend for themselves. The singular measure against this eventuality is planned concern.

The treating practitioner should schedule a follow-up of the patient. This might be a conventional consultation, or it might be no more than a telephone follow-up. If patients have recovered, and report that they do not need further care, no more need be done, but if patients have not recovered, face-to-face follow-up is indicated.

An algorithm with scheduled follow-up allows busy practitioners to divide their management into initial triage, at the first consultation, and further exploration, at subsequent consultation(s). This removes the perceived burden of having to get everything done on the first occasion.

If the patient is progressing well, further follow-up can be decreased or dispensed with. If they are not progressing, the review consultation provides the opportunity for the succeeding steps in the algorithm
**VIGILANCE**

Vigilance in this context means the practitioner keeping careful watch for any development in the patient’s condition that may require intervention. This is most easily done in review consultations. Serious disorders may not be evident at the first consultation. Repeating the checklist for “red flags” serves to detect the emergence of any new features, which may require changes to the management plan. Relying on clinical monitoring, in this way, obviates the need for precipitous, and inappropriate, use of investigations at the first consultation.

If “red flag” features emerge, management appropriate for those features can be pursued. If “red flag” features do not emerge, the previous management can continue.

**REINFORCEMENT**

During the review consultation, the practitioner should assess the progress of the patient. If previous management appears to be working, no change is required. If progress to recovery seems to be slow, the practitioner should assess why this might be the case.

The practitioner should check if the patient understood the previous plan of management and if they are complying with it. The review consultation provides the opportunity to reinforce previous explanations, if they were not understood, and to check, for example, if the patient has been able to undertake an activation program correctly.

If the patient is not complying, the reasons for that need to be elicited. Misunderstandings can be corrected. If unjustified resistance is the reason, that raises an agenda in the management plan that is not back pain.

If progress is not occurring despite adequate compliance, consideration needs to be given to implementing interventions not previously used. If activation exercises were not prescribed at the first consultation, they can be introduced now. If the patient is having difficulties restoring movement, a supervised exercise program, conducted in a cognitive-behavioral milieu, can be effective.⁹⁷

**Yellow Flags**

Slow progress to recovery may be due to undetected, or unrevealed,
psychosocial factors, referred to as “yellow flag” indicators. These pertain to the patient’s beliefs and behaviors concerning physical activity and domestic, social, and vocational responsibilities.

When patients believe that physical activity might harm their back, and that they should not undertake activities that make their pain worse, they avoid activities. For most patients with acute low back pain, these beliefs are not justified. Explanation, reassurance, and encouragement to resume activities are the cardinal tools for overcoming these mistaken beliefs. If required, a graded plan of resuming activities can be developed and followed. Some patients may take longer to regain activities. The guiding principle is that increments should be pursued, even if they are small.

Patients may seek to avoid domestic activities and responsibilities, such as cooking, cleaning, maintenance, shopping, and housework, for fear of pain. Avoiding such activities amplifies their disability. Encouragement to resume these activities may be not enough to convince some patients. The accustomed manner in which they do things may not be efficient. They may need help to analyze how else they might acquit the required activity in a manner that does not aggravate their pain. The guiding principle is not to abandon the activity but to find alternative means to achieve its purpose. In this regard, the practitioner provides his or her own intellect to help solve the patient’s problem.

Patients may avoid social activities, claiming that their back pain prevents them from doing so. But back pain does not directly preclude social activity. The mediating factor is fear that social activity will aggravate their pain. If the patients can regain movement at home, they can apply the same principles away from home. They should be helped to understand that becoming a recluse will not improve their prognosis; if anything, it will hinder their recovery. Encouragement should be coupled with suggestions of what to do if their pain threatens to be aggravated when they are “out.” Instead of being an embarrassment, doing the stretching exercises can be turned into an asset.

If psychosocial problems prove insurmountable, they—rather than the back pain itself—become the paramount problem, and referral to a psychologist may be warranted. Trained psychologists are more likely to achieve better outcomes if they can see patients early in the development
of problems.

Perhaps, the most destructive of the “yellow flags” is aversion to work. Patients may believe that work caused their pain, that work aggravates their pain, that work is too heavy for them, and that they should not work. Such beliefs require sensitive analysis and discussion. In the majority of cases, the patient’s beliefs about work will not be valid. The practitioner cannot afford to be dismissive and assertive. They need to understand the patient’s work and, in a compassionate manner, be able to indicate how work can be resumed in a safe manner. It may be helpful to engage the services of an occupational physician who is familiar with the patient’s industry and can develop a return to work plan in the context of a workplace intervention.

Discussion

Acute low back pain is unlike other conditions encountered in primary care. A specific diagnosis is rarely possible. No treatment constitutes a quick fix. It is not a complaint that can be cured by writing a prescription, a referral, or a request for imaging.

Acute low back pain requires an unconventional approach. Because there is no specific treatment, its management relies on supporting the patient while natural history takes its course. If managed well, some 70% of patients can expect to recover, with recurrence rates as low as 16%. Good outcomes can be obtained even in patients eligible for workers compensation claims.

The imperative is to avoid nocebo effects. These arise if the practitioner is dismissive or trivializes the complaint, if they say “nothing is wrong” or “it’s all in your head,” or if they behave as if they do not know what is wrong or appear disinterested.

The opposite is achieved by being calm, clear, credible, confident, convincing, concerted, caring, and concerned. Patients recognize this and appreciate it as helpful. They rate their care as excellent, significantly more often those under usual care.

Although this approach is consonant with contemporary practice guidelines, unfortunately, it has not been widely adopted. The reasons for
this have not been explored. It may be that acute low back pain requires a unique aptitude and attitude. It may be that the effort required, particularly for patients with psychosocial dimensions to their complaint, requires unfamiliar or new skills. It may be that the recommended algorithm is incompatible with busy practice and the reimbursement that primary physicians attract. These, however, are ideologic, political, and socioeconomic matters. They are not scientific evidence that refutes what can be made to work in primary care.

The recommended algorithm does not provide a cure for all patients. Among patients with acute low back pain are ones destined (statistically) to develop chronic pain. If reiteration and reinforcement of simple interventions does not result in progress and resolution, patients at risk of becoming chronic should be identified before they do so. Appointments to pain clinics or spine specialists may take time to obtain, and they are easier to cancel than to obtain. Therefore, for patients with persistent pain, steps for early referral to appropriate resources become part of the closing phases of the algorithm for acute low back pain. The management of these patients follows a different algorithm, with a different evidence base (see Chapter 73).

Conclusion

The chances of a successful outcome for a patient with acute low back pain are governed largely by the natural history of the condition. Most patients with acute low back pain will recover spontaneously if simply left alone. There is no need for diagnostic interventions other than to pursue any suggestion of “red flag” conditions such as infection and neoplasm, but mercifully, they are rare. There is no need for therapeutic interventions other than those that provide symptomatic relief and even they are only required if the pain is very intense. What patients with acute low back pain need is a caring approach by practitioners who understand the relevant scientific evidence; reassurance that the pain will very likely, on the basis of the natural history, settle by spontaneous healing; and follow-up with vigilance by a practitioner keeping careful watch for any development in the patient’s condition that may require intervention if the pain does not
resolve.

The patient may have associated problems in other domains, the psychological and social phenomena that may coexist with low back pain, but those are secondary problems that generally will resolve when the pain settles. Caring practitioners will address, or have addressed, the psychological and social concomitants of pain if they impact on the patient sufficiently to warrant specific treatment but will never allow those issues to obscure the main aim of helping the patient cope with the pain until it goes away.

CHAPTER 73
Chronic Low Back Pain
WADE KING and NIKOLAI BOGDUK

Introduction

Chronic low back pain is a huge problem in terms of its prevalence and the effects it has on people who suffer it. The size of the problem is magnified by the effects it has on the family and friends of those who suffer it, on health care practitioners who seek to address it, and on funding authorities and governments that organize or provide health care for it.

Health care practitioners who encounter a new patient with what seems to be chronic low back pain face three or four imperatives.

• The first imperative is to determine the type of pain, meaning whether or not it is, in fact, low back pain as conventionally defined, and if it is chronic.

• The second imperative is to consider any associated referred pain, to determine whether it is somatic referred pain or radicular pain.

• The third imperative is to identify any “red flag” condition that may be present, meaning serious pathologies like infection and neoplasia, which are rare but important causes of low back pain.

When those issues are addressed, the practitioner can decide whether or not to pursue definitive diagnosis of the source and cause of the pain. That decision governs the options that will then become available for management of the patient’s problem. Treatments for chronic low back pain fall into two categories, general and specific. General measures are those that can be applied to all patients irrespective of the source and cause of their pain. Specific measures are those that can be applied to particular sites of pain generation and so require precise identification of the source of the pain, and if possible also its cause. For those practitioners who would employ specific treatments, a fourth imperative applies.
• The fourth imperative is to diagnose at least the source of the pain, if not also its cause, for a specific diagnosis is crucial to the application of specific, targeted treatments for chronic low back pain.

Once the practitioner has decided either to pursue definitive diagnosis or not and has addressed the imperatives pertinent to that decision, management of the patient becomes a matter of considering the various therapeutic options and offering treatment(s) with the best evidence of effectiveness for the condition as the practitioner conceives it. The decision to apply any treatment must be based on a mutual agreement with the patient after he or she has been given enough information about the treatment to enable him or her to give informed consent (or informed dissent, if the patient does not want to undergo a particular treatment).

**DEFINITION**

The International Association for the Study of Pain (IASP) construed back pain as synonymous with lumbar spinal pain, which it defined as pain perceived anywhere in the region bounded by the lateral margins of the erector spinae muscles, an imaginary transverse line through the tip of the last thoracic spinous process, and an imaginary transverse line through the tip of the first sacral spinous process (see Fig. 72.1).¹

This definition serves to distinguish lumbar spinal pain from thoracic spinal pain, gluteal pain, and loin pain, for pain in these latter regions invites a different approach to diagnosis and management because its causes are likely to lie outside the lumbar spine. Gluteal pain invites a consideration of disorders of the hip or pelvis. Loin pain invites consideration of disorders of the urinary tract and other viscera.

Chronic low back pain is defined, by convention, as back pain that has persisted for longer than 3 months.¹² Some authorities consider this rubric can be applied earlier if the pain shows no signs of improving.³ Establishing the duration of pain is relevant because the evidence base for the causes and management of chronic low back is distinctly different from that which applies to acute or subacute low back pain.

**REFERRED PAIN**

The definition of low back pain does not restrict the location of pain to the
region of the lumbar spine. The emphasis is where the pain is primarily perceived, or where it appears to start. Thereafter, lumbar spinal pain can spread to distant regions, in which case it is known as somatic referred pain.

When assessing a patient with chronic low back pain, a prime consideration is making the distinction between somatic referred pain and radicular pain. Identifying which of the two types the patient has is pivotal to management because the causes of somatic referred pain and radicular pain are quite different, and their mechanisms are different. So they invite different investigations and different treatments. Investigations and treatments that may be appropriate for radicular pain are totally inappropriate for a patient who only has somatic referred pain. The cardinal distinctions between somatic referred and radicular pain lie in the quality of pain and its manner of spread.

Somatic referred pain is typically dull and aching in quality; patients sometimes compare it to a feeling of deep pressure. Its distribution tends to occupy a broad area with diffuse boundaries that are hard to define, and the patient may demonstrate it with an open hand rather than with a pointing finger. Although the distribution may extend further into the lower limb when severe, the center of the pain is relatively fixed in location and the patient can usually indicate it readily, whereas its boundaries may be harder to delineate.

Somatic referred pain arises because of convergence, in the central nervous system, between nociceptive afferents from the lower back and from the lower limb onto common second-order neurons. In the absence of accurate, somatotopic information, the patient cannot identify the actual source of pain and perceives it as arising throughout the area subtended by the common neuron and, therefore, in the lower limb.

Typically, somatic referred pain spreads from the lumbar spinal region in a contiguous fashion, as if expanding from the lumbar region (see Fig. 72.2). As a rule, the more severe the back pain, the more distant is the spread of the referred pain. However, in some patients, the referred pain can “skip” regions such as the thigh and be perceived only in the calf.

Radicular pain, in contrast, is typically sharp and shooting (“lancinating”) in quality; it is often described by patients as “stabbing”
pain and sometimes as “like electric shocks.” Its distribution is much more precisely defined. Typically, it travels down the length of the lower limb in a narrow strip (see Fig. 72.3)\(^4,7,8\) that the patient can demonstrate with one finger. Also, it more often extends all the way down the lower limb to the foot. The mechanism of radicular pain is irritation of the dorsal root ganglion of a spinal nerve.\(^4\)

Some authors maintain that somatic referred pain does not extend below the knee and that, therefore, pain below the knee must be radicular in origin. This is not correct, for it has been shown that pain from the lumbar zygapophysial joints and intervertebral disks can be referred beyond the knee, even into the foot.\(^5,6,9,10\)

**SOURCES**
Experiments in normal volunteers have shown that noxious stimulation of the muscles of the back,\(^11,12\) the interspinous ligaments,\(^12–14\) the zygapophysial joints,\(^5,9,10\) the sacroiliac joints,\(^15\) and the intervertebral disks\(^6,16–18\) can all evoke pain in the back. Back pain can also be evoked by mechanical\(^18\) or chemical irritation of the dura mater.\(^19\) All these structures, therefore, become the possible sources of pain in patients who present with low back pain. Notably, of all the structures in the lumbar spine, the intervertebral disks appear to be the most sensitive to experimental, noxious stimulation.\(^18\)

**CAUSES**
Although the possible sources of back pain have been demonstrated, its causes have been more elusive. Pain arising from muscles or ligaments in the back is presumed to be caused by strains of these structures, but direct evidence of the resultant pathology has not been produced. However, the structures for which the cause of pain has been well established are the lumbar intervertebral disks and the lumbar zygapophysial joints.

**Lumbar Intervertebral Disks**
When intervertebral disks are affected by overt pathology such as infection, there is no dispute about the source or cause of pain. The inflammation caused by infection constitutes a source of chemical
irritation of the nociceptive fibers that innervate the affected disk. Less obvious are the mechanisms of pain in mechanical disorders of the disk.

Lumbar disks can be affected by internal disk disruption. As described in greater detail in Chapter 101, this condition has a distinctly different epidemiology and different structural features from those of disk degeneration. It is caused by fracture or fatigue failure of the vertebral endplate and is characterized by degradation of the nuclear matrix and the development of internal radial and circumferential fissures. It has been produced in laboratory animals and can be diagnosed in patients, if special tests are used (see “Prevalence” section in the following text). The prevailing model is that pain arises from chemical irritation of nociceptors around the internal fissures and from mechanical stimulation of nociceptors in the posterior anulus fibrosus because it is subjected to greater than normal compression loading as a result of degradation of the nuclear matrix (see Chapter 101).

**Lumbar Zygapophysial Joints**

Laboratory studies have shown that the lumbar zygapophysial joints are susceptible to small fractures, or avulsions of the capsule, when subjected to compression or excessive torsion. Postmortem pathoanatomic studies have shown such injuries in people who have been injured in motor vehicle accidents. However, no studies have validated antemortem methods of diagnosing such injuries, for example, by high-resolution computerized tomography (CT) scan.

**PREVALENCE**

Conventional methods of assessment and investigation typically fail to identify the cause of chronic low back pain in the majority of patients. This has fostered belief in the claim that a cause cannot be found in over 80% of patients with chronic low back pain.

This figure has been used to justify not pursuing a diagnosis of chronic low back pain but moreover to regard chronic back pain as being not due to injury or disease but as a psychosocial complaint. This figure has been endorsed and enshrined by various authorities in the past in support of disdaining pursuit of diagnosis.
The source of this figure is rarely, if at all, quoted by its advocates, but it can be found by a simple search of the literature.\textsuperscript{29,30} The source is a study of acute low back pain, published in 1966, in which British general practitioners claimed that a diagnosis was not possible in 80\% of cases.\textsuperscript{31} For diagnosis, the study relied on history, conventional examination, and plain radiography, for these were the only methods available in 1966. Given the limitations of history, physical examination, and plain radiography, it is not surprising that a diagnosis could not be established. In the intervening 50 years, methods have been developed and applied in order to pinpoint, if not the actual cause, then at least the source of pain in large proportions of patients with chronic low back pain. These methods are not indicated for acute low back pain even today, as explained in Chapter 72, so, in that sense, what was written in 1966 would still be considered correct about acute low back pain, but it is totally inappropriate for chronic low back pain in the modern era.

Although it may not be possible to identify the actual cause of back pain, in many instances, the source of pain can be established by using diagnostic nerve blocks (see Chapter 98). The paradigm is that if a structure is the source of pain, it can be identified as such if anesthetizing the structure (or its nerve supply) abolishes the pain. However, in patients with chronic pain, diagnostic blocks are susceptible to false-positive responses. Therefore, in order to be valid, diagnostic blocks need to be controlled.\textsuperscript{32,33} Furthermore, other variables need to be rigorously defined and measured, such as magnitude of relief and duration of relief of pain.\textsuperscript{32,33}

Diagnostic blocks can be applied to pursue sources of pain in the ligaments or muscles of the lumbar spine or its synovial joints. Although diagnostic blocks have, from time to time, been performed as tests for pain from muscles or ligaments, no studies have performed the blocks rigorously. So, no dependable data are available as to the prevalence of low back pain stemming from muscles or ligaments. The opposite applies to synovial joints.

Using physiologic controls, multiple studies have purported to trace the source of chronic low back pain to the lumbar zygapophysial joints. Prevalence rates of 15\%,\textsuperscript{34} 40\%,\textsuperscript{35} and 45\%\textsuperscript{36–38} have been reported. What
is contentious about these figures, however, is that complete relief of pain was not a diagnostic criterion. Rather, the investigators accepted 50% relief or 80% relief. They assumed that any pain not relieved stemmed from another, concurrent source, but that source was not identified. Meanwhile, other studies have shown that rarely do patients with chronic low back pain have concurrent sources of pain: from the zygapophyssial joints, the sacroiliac joint, or the intervertebral disks.\textsuperscript{39,40} Therefore, insofar as concurrent sources of pain have not been identified, partial relief of pain must be viewed as a spurious diagnostic criterion. Placebo responses have not been excluded.

When studies have looked for complete relief of pain following blocks of the lumbar zygapophysial joints, substantially lesser prevalence estimates have been encountered. In general populations, the prevalence of complete relief of pain is about 5% or less.\textsuperscript{41–44} Therefore, lumbar zygapophysial joint pain may not be as common as has been held to date.

One study, using placebo controls, however, did find that 34% of an elderly population obtained at least 90% relief of pain.\textsuperscript{35} A later study found that zygapophysial joint pain was age dependent. Among patients in whom a source of pain can be established, the likelihood of a zygapophysial joint being the source of back pain is only 2% in patients aged 20 to 35 years; it rises to between 5% and 10% in patients aged 35 to 50 years and 20% in patients aged 50 to 65 years.\textsuperscript{45,46} In patients over the age of 65 years, the likelihood rises to between 30% and 40%, and in this age group, zygapophysial joints are the most likely source of back pain.\textsuperscript{45,46}

In elderly patients, it is tempting to attribute their pain to osteoarthrosis, but there is no correlation between the joint being painful and the radiologic features of osteoarthrosis on plain radiographs\textsuperscript{4,47–49} or on CT scan.\textsuperscript{50} It has been proposed that painful lumbar zygapophysial joints express inflammatory changes evident on magnetic resonance imaging (MRI) using a fat-saturation setting,\textsuperscript{51} but this has yet to be corroborated by studies using controlled diagnostic blocks.

Earlier studies using controlled, intra-articular blocks traced the source of chronic low back pain to the sacroiliac joints in about 20% of patients.\textsuperscript{40,52} A later study corroborated this prevalence as an average
figure but showed that the prevalence of sacroiliac joint pain differed with age. The likelihood of the sacroiliac joint being the source of pain was low (2% to 10%) in patients under 65 years of age, but in older patients, it varied between 5% and 21% depending on body mass index.

Pain stemming from the posterior sacroiliac ligaments (or “posterior sacroiliac complex”) can be diagnosed using controlled blocks of the lateral branches of the sacral dorsal rami. However, although techniques for such blocks have been described and validated, they have not been applied in population studies. So, the prevalence of sacroiliac ligament pain is not yet known.

The diagnosis of internal disk disruption requires disk stimulation and postdiscography CT. The disk is stimulated with an injection of contrast medium in order to determine if stimulating it mechanically reproduces the patient’s pain. CT scanning is performed after disk stimulation to determine if the painful disk exhibits the radial or circumferential fissures that are characteristic of internal disk disruption.

In patients with chronic low back pain, the prevalence of internal disk disruption is about 40%. Of the diagnosable causes of chronic low back pain, the likelihood of internal disk disruption being the cause of pain is effectively 90% in patients under the age of 50 years, falling to 60% after the age of 50 years, and 20% after the age of 65 years.

**REFUTED CAUSES**

Research has shown that many conditions, traditionally considered to be possible causes of chronic low back pain, are actually not causes. Multiple studies have shown that spondylolysis or spondylolisthesis cannot be held as causes of back pain in adults. These conditions occur with equal prevalence in subjects with no symptoms and in patients with back pain. Similarly, so-called “degenerative changes” (better called “spondylosis”) occur only slightly more frequently in patients with back pain than they do in asymptomatic individuals. The difference in prevalence is so small as to render “degenerative changes” not diagnostic. They represent no more than normal age changes.

**ACCEPTED CAUSES**
There is no dispute that tumors and infections can cause low back pain, but these conditions are rare. Although specialist practitioners may be accustomed to greater prevalences because they are in referral practice, the prevalence of serious causes of back pain in primary care can be estimated to be no more than 5%. Given that the prevalence of tumors and infections is less than 1% in patients with acute low back pain, if all patients with acute low back pain progressed to chronic back pain, the prevalence of tumors and infections would remain less than 1%. If only 20% of patients progressed to chronic back pain, included all those with tumors or infections, the prevalence of those conditions would be concentrated by a factor of 5, to 5%.

**UNTESTED CAUSES**

In its Classification of Chronic Pain, the IASP recognizes, in principle, certain causes of chronic low back pain that are promoted by some practitioners. These include muscle sprain, ligament sprain, segmental dysfunction, and trigger points. However, the IASP requires that for the diagnosis of these conditions, techniques be used that are of known reliability and validity, but no technique has been shown to be both reliable and valid for the diagnosis of these entities. Therefore, they remain as only theoretical or imaginary constructs.

**Assessment**

The assessment of a patient with chronic low back pain serves three objectives. Foremost, the practitioner has a duty of care not to miss any serious causes of pain. Second, information should be gathered to formulate the type of diagnosis on which the practitioner intends to base treatment. Third, information should be gathered to determine the physical and emotional state of the patients, along with their social circumstances so that any management plan takes these into consideration.

Chronic pain is often accompanied by associated psychological and social problems. The relationships between them are encapsulated in the biopsychosocial model of pain, expounded in 1977. According to this model, chronic pain has three domains, the biologic, the psychological,
and the social. The biologic domain includes the causative bodily impairment and the neurophysiologic mechanisms that generate the experience of pain in the patient’s cerebral cortex; these biologic features of pain are essential to it: Without them, there would be no pain. The psychological domain includes affective features of distress and suffering, such as anxiety and depression; these psychological features are secondary to the experience of pain. They result from the patient’s response to the pain experience, and without that experience, they would not exist. The social domain includes issues such as impacts on family relationships and social activities. They are largely secondary to affective changes, so their existence depends on both the biologic and psychological domains. The biologic domain of pain is the crux of the condition, the sine qua non of the patient’s problems. In assessing a patient with chronic low back pain, the practitioner should focus on the biologic domain as the core issue but is advised to be aware of psychological and social issues that may relate to it.

As described in greater detail in Chapter 72, the initial assessment relies heavily on eliciting a medical history, undertaking physical examination, and then employing, judiciously, ancillary investigations indicated by the clinical features. The processes of history taking and physical examination, if undertaken empathetically, help in developing the rapport which underlies an effective doctor–patient relationship; more than that, they yield cues that guide the rational utilization of ancillary investigations, both to pursue any suspicions of serious causes of pain and to explore the possibilities of source(s) and cause(s) of pain consistent with the clinical features.

The extent to which each domain of patient assessment is explored will depend on the practitioner’s role in the patient’s management. Physicians will seek information that is more or less diagnostic information depending on whether they pursue definitive diagnosis that would enable specific, targeted treatment, or intend to apply only general treatments that do not require precise identification of the pain source. All physicians will need to elicit a more detailed history than paramedical practitioners because physicians are expected to identify any “red flag” conditions, they will be responsible for ordering any special investigations that might be required,
and they will have responsibility for the longer term management of those
patients whose pain persists. In such cases, the history elicited initially will
be useful for monitoring the progress of the condition and the development
of any of its features.

Paramedical practitioners will not need to undertake a detailed
assessment if they are working in cooperation with, and upon referral
from, a physician who has assumed primary responsibility for the patient
and who has already taken a comprehensive assessment. However, they
should still address the basic features of history and any cues alerting to a
“red flag” condition and any other aspect of assessment that pertains to
their role in the management of the patient’s condition. A paramedical
practitioner acting as the sole health care provider assumes the
responsibility for taking a comprehensive assessment and the
responsibility for alerting the appropriate medical practitioner if a “red
flag” condition is suspected.

In order for the medical history to be comprehensive, that is, not
neglecting anything, it can be guided by a systematic approach that is
applicable to any form of pain (see Table 72.1). Being systematic ensures
that no domain of inquiry is overlooked or forgotten, but which could have
yielded valuable cues toward diagnosis.

That systematic approach can be supplemented by reference to a “red
flag” checklist (see Fig. 72.5). As explained in Chapter 72, a “red flag” is a
feature, identified in the history, that alerts the practitioner to the
possibility of a serious cause of pain. A “red flag” of itself is not
diagnostic, nor is it intended to be. Serious causes of pain will be
diagnosed (or excluded) by subsequent investigations. A “red flag” serves
only to alert the practitioner to consider the serious cause that is prompted
by the “red flag” and to decide if investigations should be pursued or not.\textsuperscript{62}
The “red flag” checklist was not developed on the basis of the predictive
power of particular features. Rather, it was developed on the basis of case
reports of unusual, unexpected, or cryptic causes of back pain that were
overlooked during the patient’s original management but which would
have been identified if relevant questions had been asked at the time or if
remotely possible causes of pain had been entertained.\textsuperscript{62,63}

Triage is much more important when patients present with chronic low
back pain than it is for those with acute low back pain. With acute low back pain, there is little point in trying to establish the exact source and cause of the pain because such information will not affect the approach to management (as explained in Chapter 72).64 With chronic low back pain, diagnosis is pivotal to management: If the precise source of the pain can be identified, specific, targeted treatment can be applied.

**MEDICAL HISTORY**
Before commencing inquiry into the history of the patient’s complaint of pain, it is convenient to establish the patient’s age. This is pertinent because certain malignancies are distinctly more common in the elderly, and because certain diagnosable conditions are more likely in the elderly, or conversely in younger patients. In this regard, age alone is not an absolute determining factor, but it raises the threshold of suspicion. Other features in the history may subsequently raise or reduce that threshold.

Confirming the site of pain is important to establish whether the patient has lumbar spinal pain, as defined,¹ rather than loin pain or gluteal pain. Loin pain suggests a visceral source (perhaps a ureter, a kidney, or its vessels), whereas primary gluteal pain suggests a hip disorder rather than spinal pain.

Pain located in the lumbar or sacral spinal region can arise from many sources, but there is a partial rule concerning sacroiliac pain. Pain from the sacroiliac joint, or from the posterior sacroiliac complex of ligaments and muscles, tends to be located over that sacroiliac region, and radiates distally¹⁵,⁴⁰; rarely, if ever, has it been found to extend above the L5 level. So, pain located exclusively below L5 increases the likelihood of the sacroiliac joint or the posterior sacroiliac ligaments being the source.

Another consideration of site is to distinguish between the pain which is the focus of the assessment (the “index pain”) and any other pain the patient may have. For example, a patient may have a painful knee, but subsequently, he or she may develop pain in the lower back and leg on that side. For the purpose of the assessment, the antecedent knee pain should be excluded from the description of the “index pain” (namely, that in the low back and leg), although the knee pain should also be noted as a concurrent problem.
If the patient with back pain also has abdominal pain, the presentation converts from one of back pain to one of abdominal pain. Assessment of the abdominal pain takes precedence and requires a different algorithm (see Chapter 47).

The **duration of illness** means how long the patient has been experiencing the pain, and it establishes whether the pain is chronic; if so, it is somewhat reassuring with respect to pathology. Patients are unlikely to have a serious cause if their condition has not deteriorated over several months or if new signs or associated features have not developed. However, the practitioner should not be complacent about “red flags,” for there are exceptions. Tumors may grow slowly. Chronic spinal infections can remain indolent and not produce additional features for a long time; in one study, delays of 1 to 8 years were encountered in 47% of infected patients. 65

The **distribution** of pain needs to be interpreted carefully as it is a discriminating variable between somatic referred and radicular pain. The first point to note is that pain in the buttock and/or lower limb can stem from any source of pain in the lumbar spine. The cardinal distinctions between somatic referred pain and radicular pain lie in the quality of pain and its manner of spread, as described earlier (see “Referred Pain” section in the preceding text). Making this distinction prevents mistaking somatic referred pain for radicular pain, and thereupon pursuing the diagnosis and treatment of disk herniation, which is a cause of radicular pain but not a cause of back pain.

The **quality** of pain is the other cardinal discriminating variable between somatic referred and radicular pain. Somatic referred pain is typically dull and aching in quality, whereas radicular pain is typically sharp and shooting in quality; it is often described by patients as “stabbing” pain and sometimes as “like electric shocks.”

The **intensity** of pain is a very significant feature and should be assessed with care. Ideally, it should be measured by the patient themselves, using (under supervision) a valid instrument. Suitable instruments include a visual analogue scale (VAS) or a numerical pain rating scale (see Chapter 23). If the intensity tends to fluctuate, scores should be recorded for the average intensity when the patient is active and the most intense pain
experience recently. The resultant score(s) should be recorded for monitoring with the progress of the condition.

The importance of pain intensity is twofold. First, it signifies the significance of the pain to the patient and is the single most important factor in the patient’s decision to seek medical treatment. Few people would bother to seek medical advice about pain of very slight intensity. Consequently, regardless of the actual score recorded by the patient, that degree of pain is patently concerning enough to the patient for them to seek medical treatment. In that regard, it is worth noting that when a patient describes severe pain, he or she is usually conveying the degree of suffering that the pain induces and suffering is a function of many factors additional to noxious stimulation by the pain generator (see “Psychosocial History” section in the following text).

Second, the pain intensity recorded at the initial assessment provides an invaluable guide to the progress of the condition and the effectiveness or otherwise of treatment(s) applied; a relevant aphorism is that pain cannot be said to have been relieved unless it has been measured.66

Although important for the reasons outlined, measuring pain intensity is not usually helpful as a discriminating variable in the assessment of chronic low back pain. Serious causes of pain may cause intense pain but so can conditions such as internal disk disruption. Meanwhile, some patients may rate their pain as intense because of the suffering that it causes, in which case the intensity is not necessarily proportional to magnitude of nociception arising from the source of pain.

The periodicity means whether the pain is constant or intermittent, it is not usually helpful as a discriminating variable in the assessment of chronic low back pain because most patients will complain of constant pain. If the pain is reported as intermittent, the practitioner should distinguish between pain that is present constantly but waxes and wanes in intensity and pain that is truly intermittent and occurs in episodes. If the pain is truly intermittent, practitioner should record the frequency and duration of the episodes.

The variables periodicity, time of onset, and mode of onset pertain to pain that occurs in distinct episodes. They describe the frequency of episodes; when the pain starts during a particular day, week, or month; and
if it comes on suddenly or gradually. These variables are relevant in the
diagnosis of various forms of headache and visceral pain, which have
metabolic triggers, but they are not pertinent to chronic low back, which is
typically constant. If the pain is reported as intermittent, the practitioner
should be careful to distinguish between pain that is present constantly but
waxes and wanes in intensity and pain that is truly intermittent and occurs
in episodes. If the latter, practitioner should record the frequency and
duration of the episodes.

Time of onset becomes relevant in the assessment of chronic low back
pain if the patient describes early morning stiffness, which later is relieved
on commencing movements. This feature is highly alerting to the
possibility of ankylosing spondylitis being the cause. If it has not been
noted previously when the patient was in the acute phase, noting it now,
when the patient has chronic pain, still serves to engage a rheumatologist
in the management of the patient.

Precipitating factors are events or movements that trigger an episode
of pain. Aggravating factors are postures or activities that make the pain
worse. Relieving factors are actions that reduce the pain. None of these
factors is diagnostic of any particular cause of pain, but they construct a
picture of the patient’s disabilities.

Features such as aggravation of pain by flexion, extension, or rotation
are not valid determinants of pain stemming from intervertebral disks,
zygapophysial joints, or sacroiliac joints. Anecdotally, however,
sacroiliac joint pain is strongly suggested when a patient’s pain is triggered
or aggravated by sitting on the ipsilateral buttock and relieved by sitting on
the contralateral buttock.

Associated features, as explained in detail in Chapter 72, often provide
cues to serious causes of pain. The “red flag” checklist (see Fig. 72.5)
itemizes features that amount to past history and features that amount to a
systems review.

Fever or night sweats raise the possibility of infection. Otherwise, the
risk factors for infection encompass any manner of penetration or breach
of the body’s first line of defense: epithelium. These include surgical or
dental procedures, catheterization or venipuncture, tattooing, illicit drug
use, and skin lesions.
A history of weight loss—especially unexplained weight loss—or a past history of cancer constitutes grounds for suspecting malignancy.

Inquiring about occupation, leisure interests, and travel is relevant for what might be called exotic disorders, such as fungal infections and parasitic infections. Urban dwellers would not normally be exposed to such organisms, but individuals with unusual occupations or hobbies may be exposed, and individuals who live in or travel to rural or tropical environments may get exposed. Not inquiring about these domains can result in exotic conditions, such as hydatid cysts, being overlooked.

A systems review should address cardiovascular risk factors, for these are major alerting features for aortic and other aneurysms as a cause of back pain. Inquiring about respiratory, urinary, and reproductive functions may identify sources of malignancy in these systems. Symptoms of urinary dysfunction may alert the practitioner to urinary tract infection, and the combination of back pain, urethritis, and uveitis is pathognomonic of Reiter syndrome.

Hematopoietic neoplasms are notoriously cryptic causes of persistent back pain. They escape early diagnosis because they typically produce no other manifestations and are not regularly considered in the differential diagnosis. However, the oncology literature is replete with case reports of patients, with a history of blood diseases, who present with back pain (see Chapter 72).

The endocrine system should be assessed for possible sites of primary tumors, but more particularly, chronic use of corticosteroids is a risk factor for osteoporosis fractures of the lumbar spine, and diabetes mellitus is a risk factor for cryptic infection. Osteitis fibrosa cystica, as a manifestation of hyperparathyroidism, may present with spinal pain as the sole feature.

Assessing the musculoskeletal systems serves to identify conditions in which back pain is but one feature, the others being arthropathies in the appendicular skeleton. These include rheumatoid arthritis and the seronegative spondyloarthopathies. Likewise, inquiry should be made about the skin and gastrointestinal tract because the spondyloarthopathies are associated with rashes or vesicles and with diarrhea.

Neurologic symptoms are a game changer. If a patient reports or acknowledges numbness, weakness, or impaired continence of the bladder
or bowel, the presentation converts from one of back pain to one of a neurologic disorder. Assessment of the neurologic disease takes precedence and requires a different algorithm. Once the neurologic disease has been diagnosed, if back pain continues to be unexplained, its assessment can be resumed.

The circumstances of onset pertain to what was happening when the complaint of pain originally started and its manner of onset at that time. Having the patient describe the first episode of pain can help determine the etiology of the pain: whether there was an apparent external cause or not or if the pain is truly idiopathic. In this regard, no particular features are diagnostic, but certain features of history constitute circumstantial evidence when matched with what is known from biomechanical studies.

Serious falls are an obvious risk factor for fractures of the lumbar spine. For the average individual, a serious fall would be one from a height. Older patients, however, who have osteoporosis, can suffer fractures after minimal trauma.

The biomechanics evidence implicates compression injuries in the etiology of internal disk disruption (see Chapter 101). These injuries can occur acutely, as in falls onto the buttocks or as a result of repetitive compressions incurred during heavy lifting or pulling over a period of time. However, internal disk disruption is a progressive disorder. Pain may not occur at the time of injury or may be not more than sense of discomfort. Overt or significant pain may be delayed until fissures develop in the anulus fibrosus, and the anulus becomes chemically irritated or mechanically stressed. The pattern of internal disk disruption, therefore, is one in which a reason for compression injury can be implicated, followed by a subsequent, progressive onset of disabling pain.

Otherwise, a knowledge of biomechanics can provide useful information from an accurate description of the circumstances in which injury may have occurred. Assessing the magnitudes of forces (i.e., “stresses”) applied, the directions in which those stresses were likely to be acting, and the patient’s posture at the time can, when combined with knowledge of the anatomy and the loading capacities of the various structures of the lumbar spine, enable the practitioner to make a reasonable guess as to the structure(s) likely to have been injured. Sudden, severe
rotation invites consideration of torsional injuries to the zygapophysial joints or the anulus fibrosus. Falls onto a buttock, or a longitudinal impact to an extended lower limb during a motor vehicle accident, are postulated risk factors for injuries to the sacroiliac joint. Sportspeople, whose activities involve forceful or repeated extension and rotation, are at risk of sustaining painful stress reactions in the pars interarticularis, or overt fractures of the pars.\textsuperscript{70,71}

**PSYCHOSOCIAL HISTORY**

The psychological and social history bring to light psychological and social factors that are of greater significance when low back pain is chronic rather than acute. Persistence of pain over a long period tends to generate associated issues which if left unchecked may give rise to significant psychological comorbidities and social disruptions.

In the psychological domain, these may range from minor affective disquiets like uncertainty, mild fear, and diminished quality of life to major affective disorders such as anxiety, depression, and catastrophizing. As part of the initial assessment, the practitioner should probe gently for clues to disturbances of affect and, if any are apparent, record them to be addressed as part of the management plan.

In the social domain, issues of concern may include inability to work, loss of income, diminished contact with people outside the family, inability to perform usual tasks around the home and disturbances of family relationships. Again, the practitioner should probe sensitively for clues to such issues and plan to address any that become evident.

**PHYSICAL EXAMINATION**

After completing the medical history, the practitioner should proceed to perform a physical examination of the patient. There are several reasons for this. First, the examination may yield clues that clarify any suspicions raised by “red flag” features. Second, examination findings may reinforce clues from the history to the presence of injuries or impairments that are known sources and causes of chronic low back pain. Third, physical examination undertaken sensitively helps in developing the rapport which underlies an effective doctor–patient relationship. Finally, but not least
importantly, many patients expect to be examined and they may feel that a practitioner who does not examine them is not very interested in their case.

Conventional physical examination will not provide a definitive diagnosis of chronic low back pain because there are no physical signs that are pathognomonic of its known sources and causes. The diagnostic purpose of physical examination is to reveal features that may be added to cues gained from the other domains of patient assessment to guide the rational application of valid ancillary investigations which can determine the source of low back pain. Some practitioners use physical features to guide treatment and/or to monitor progress, for example, in focusing on improving range of motion, or to classify patients, but these applications are not diagnostic in a pathoanatomic sense.

A systematic physical examination encompasses inspection, palpation, and movement testing. The notes in the following text should be read in conjunction with the corresponding sections of Chapter 72.

**Inspection** may reveal general and specific features. General observations may include bodily deformity (malformations, amputations, prostheses), static posture both standing and sitting (for signs of scoliosis and kyphosis and loss of lordosis), dynamic posture when walking (for antalgic gait, other gait abnormalities), and performing gross movements (for transfers of weight such as pushing on the thighs while bending forward and straightening afterward). Specific observations include scars, puncture marks, swelling, and other local changes of shape.

**Palpation** reveals features such as altered sensitivity (hypoesthesia or hyperesthesia), relationships of bony landmarks, and tenderness. If tenderness is present, it may be diffuse or focal, and if focal, the clinician may note its relationship to bony landmarks such as spinous processes.

**Movement testing** addresses ranges of active thoracolumbar extension, flexion, sidebending, and rotation, which may be restricted mechanically or by pain. Although not diagnostic, these abnormalities provide an indication of the disabilities that the patient has because of the pain. If one or more active ranges are restricted, the examiner should test the patient in the corresponding passive ranges to determine whether the restriction is due to anatomic limitation or to pain. No valid diagnostic information can be gained by testing accessory ranges of movement.
In one arena, developments have occurred. A specialized protocol of examination, based on detecting centralization of pain and other features, has been tested. The resultant data show the method has reliability for the detection of sacroiliac joint pain\(^76\) and of internal disk disruption\(^77\); the data for its validity for definitive diagnosis of those entities is less convincing. It does not detect zygapophysial joint pain.\(^76,77\) Whatever its value, this protocol requires special training.\(^78\)

As for acute low back pain (see Chapter 72), physical examination is perhaps most informative when the patient exhibits no signs in the lumbar region. In that event, consideration needs to be given to a visceral or vascular cause of pain. Palpation for a pulsating mass and auscultation for bruits are cardinal actions for the assessment of aortic aneurysms.

**Neurologic examination** is neither necessary nor productive in the assessment of patients with chronic low back pain. Neurologic examination is indicated if the patient has neurologic symptoms, but in that event, the presenting feature is the neurologic disturbance and not back pain. In the absence of neurologic symptoms, neurologic examination serves only to satisfy the examiner that features which should not be present are, indeed, not present.

**REVIEW OF PREVIOUS INVESTIGATIONS**

Many patients with chronic low back pain will present with the films or digital images of multiple imaging studies they have undergone before. Before considering these, the practitioner should take pause and reflect on two caveats.

The first caveat is that a great deal of evidence\(^4\) shows that imaging appearances do not correlate with pain, so the practitioner should be careful not to be misled by appearances that are irrelevant to the patient’s index pain. The second caveat is that radiologic reports have been shown to have much less than perfect reliability,\(^79\) so the practitioner should inspect the images themselves rather than rely on printed reports. With those two cautions in mind, it is suggested that before looking at any imaging, practitioners should formulate an idea, based on the clues gained from the history and examination, of what they might expect to see on the imaging. Then, they should peruse the images (not the reports) and note
whether what they expected, or anything like it, is apparent; if so, that reinforces the impression gained from other clues; if not, such as when there are abnormal radiologic appearances at distant spinal levels or on the other side from the index pain, they can probably regard those appearances as irrelevant. Practitioners unfamiliar with spine imaging should consult a colleague who can help them read and interpret the images.

Patients may have undergone an invasive diagnostic or treatment procedure, but this may have not been performed in an optimal manner. The patient’s response may or may not have been recorded accurately. Practitioners with appropriate knowledge can review any films to check for accuracy of the procedure, and they can check with the patient or any postprocedural pain charts to see what the response to the test was. Practitioners without pertinent knowledge should check with a colleague who does have the appropriate knowledge to confirm the validity of any procedures.

With these precautions in mind, previous investigations can serve either or both of two purposes: They can complement and enhance the assessment developed from history and examination, and they can be used to avoid requesting the same or additional investigations.

Provisional Diagnosis

To complete the patient assessment, the practitioner who wishes to pursue definitive diagnosis and specific, targeted treatment should formulate a provisional diagnosis. This is achieved by combining the symptoms and other subjective features apparent from the medical history with the physical signs elicited by clinical examination, and the relevant appearances seen on previous imaging (and the results of any other previous investigations such as blood tests, if any), to form a concept of the patient’s presentation. This concept should then be developed into a hypothesis of the most likely explanation(s) for the patient’s pain. Otherwise, the practitioner might raise a diagnostic hypothesis on the basis of the pretest probabilities (i.e., what is likely according to epidemiologic data). The practitioner’s hypothesis should be expressed as one or a short list of the known sources of chronic low back pain as described in the
Classification of Chronic Pain\textsuperscript{1} published by the IASP; the putative diagnoses include discogenic pain (most commonly, internal disk disruption), zygapophysial joint pain, and sacroiliac pain (from either the sacroiliac joint or the posterior sacroiliac complex).

The evidence base shows that a definitive diagnosis can rarely, if ever, be determined after the initial assessment of a patient with chronic low back pain. So the provisional diagnosis should be appreciated as nothing more than a “best guess” of the known sources and causes of chronic low back pain. Its purpose is as a guide to further investigation, designed to test the provisional diagnosis and either confirm the pain source by the results of valid diagnostic tests or refute that “guess” and guide the practitioner to arrange other valid tests that allow definitive diagnosis of the actual pain source.

Definitive diagnosis will enable specific, targeted treatment. In the rare case in which the pain proves to be due to a “red flag” condition, it can be treated as appropriate to its nature. In the much more common situation in which the pain is proven due to one of the known spinal injuries and impairments that cause chronic low back pain, it can then be treated with a specific, targeted treatment with predictable effectiveness (see “Treatment” section in the following text).

If, after performing a comprehensive patient assessment, a practitioner who intends to apply targeted treatment is not able to formulate a provisional diagnosis of the likely source(s) of the patient’s pain, he or she should make no attempt at specific treatment. The evidence base shows that specific treatment not based on valid diagnosis is unlikely to abolish the pain but is likely to aggravate the patient’s situation by subjecting them to (further) interventions that only add to the frustration of undergoing misguided treatments which prove ineffective. The moral and ethical imperatives for a practitioner who wishes to apply specific treatment but cannot formulate a provisional diagnosis of likely source(s) and cause(s) of chronic low back pain is to refer the patient to someone else who can.

If, after performing patient assessment, a practitioner intends to apply only general forms of treatment, there is no need for them to formulate a provisional diagnosis of the likely specific sources and causes of the patient’s pain. If no particular cause is evident, or if the practitioner
chooses not to venture a putative diagnosis, the IASP Classification of Chronic Pain\(^1\) includes the diagnostic term lumbar spinal pain of unknown or uncertain origin. Although technically and literally correct, this label is unwieldy and may be somewhat unpalatable. In the past when the knowledge base was very limited, “nonspecific chronic low back pain” was an alternative preferred by some, but this is neither a default nor legitimate diagnosis. It means no more than the cause of back pain has not been pursued. Yet, it is misused to imply, in a definitive sense, that there is no cause or that no cause can be found. This rubric is particularly egregious, when it is used to convince patients that they should not pursue diagnosis. There is no term in common use that means “I chose not to look.”

If a “red flag” has been identified during the initial assessment, the suspected serious cause of pain becomes the provisional diagnosis. Further investigations should be undertaken either to confirm or to rule out the suspected condition. Table 72.2 provides a guideline for the selection of appropriate investigations. If investigations prove positive, further management becomes that for the condition diagnosed. The problem is no longer one of back pain.

If no “red flags” are detected, the practitioner can be reasonably confident that a serious condition is not the cause of pain. In that event, the practitioner can formulate a provisional diagnosis of spinal causes of chronic low back pain.\(^1\)

For confirmation, whether the provisional diagnosis is a “red flag” or a hypothesis of known spinal causes of pain, the provisional diagnosis must be tested by applying ancillary investigations.

**Ancillary Investigations**

Special investigations can be undertaken for either or both of two purposes. One is to “clear” the patient of serious or cryptic causes of pain that may not be evident from history and physical examination. The second is to test a putative diagnosis.

**CLEARANCE**
The best investigation for “clearing” the patient is MRI. MRI has sufficient sensitivity and specificity to detect unusual causes of pain, such as occult tumors, and neoplastic infiltrations that would otherwise escape detection.

There is no justification for progressing through plain radiography, bone scan, and CT before considering MRI. Each of those other investigations has little or limited ability to detect cryptic disorders. For screening purposes, MRI can detect fractures, which would be seen on plain radiographs, but MRI will also detect soft tissue lesions, which plain radiography cannot do. The increased vascular uptake that bone scan demonstrates will be evident on MRI with greater specificity. Although CT provides better resolution of bone, bony lesions will not escape detection by MRI.

**NOT INDICATED**

Electrophysiologic testing is one investigation not indicated for chronic low back pain. There is no lesion that causes low back pain and produces conduction block in the nerves of the lower limb, so nerve conduction studies cannot show anything useful about back pain. Some practitioners are accustomed to using conduction studies because they confuse somatic referred pain with radicular pain and explain that they are testing for radiculopathy, but even that practice is without foundation. It has been shown that even in patients with radicular pain, conduction studies are not diagnostic. Conduction studies are indicated only if peripheral neuropathy is in the differential diagnosis of radiculopathy. Back pain is not radiculopathy, and peripheral neuropathy is not a differential diagnosis for chronic low back pain.

Likewise, CT is not an appropriate investigation for chronic low back pain. Its use is based on confusion between radicular pain and somatic referred pain. CT is useful for the detection of disk herniations in patients with radicular pain, but somatic referred pain is not caused by disk herniation. The only role for CT in back pain would be as a substitute when MRI is not available as a screening test. In that regard, CT is not an alternative to MRI, for there are conditions that MRI can detect that CT cannot detect. CT is an alternative to MRI for bureaucratic or economic reasons, not for medical ones.
Plain radiography is not indicated in patients with chronic low back pain. The lesions that it can detect are some fractures and gross lesions of bone. These are rare causes of chronic low back pain and are better detected by MRI or CT if it must be an alternative.

Establishing a definitive diagnosis has merit and purpose on either of two fronts. A definitive diagnosis might be made of a condition for which there is no proven treatment. This might appear to lack utility because establishing a diagnosis does not lead to better treatment. However, that argument assesses only the positive utility of establishing a diagnosis; investigations can also have negative utility. Establishing a diagnosis serves to protect patients from futile pursuit of other diagnoses and to protect them from trials of therapy that have no prospect of fixing the condition that has been diagnosed. It also protects patients from false accusations that their pain is only psychological, that they are imagining it, or that there is nothing wrong. Otherwise, there is positive utility to establishing a diagnosis of conditions for which there is a proven treatment.

**MAGNETIC RESONANCE IMAGING**

Certain features evident on MRI are fairly indicative of internal disk disruption. These are described in greater detail in Chapter 101. In summary, here, the two features are Modic lesions and high-intensity zones (HIZs).

Modic lesions occur in the spongiosa of the vertebral body above or below a disk with internal disruption (Fig. 73.1). Type 1 lesions appear dark on T1-weighted images but bright on T2-weighted images and represent bone marrow edema. Type 2 lesions appear bright both on T1-weighted images and T2-weighted images and represent fat deposition (implicitly postinflammatory). They occur in about 33% of patients with chronic back pain and correlate significantly with the affected disk being painful, the pooled data indicating a positive likelihood ratio of about 3 (see Chapter 101).
HIZs in the posterior anulus (Fig. 73.2) represent the cross-sectional appearance of a circumferential fissure. They occur in 20% to 30% of patients with chronic low back pain and correlate with the affected disk being painful. Although figures differ between studies, the pooled data show that an HIZ has a positive likelihood ratio greater than 3 for the affected disk being the source of pain (see Chapter 101).
Modic lesions and HIZs each have similar positive likelihood ratios. Either sign inherits the same diagnostic power. Given that the pretest probability of internal disk disruption is 40%, a likelihood ratio of 3 increases diagnostic confidence to 67% that the affected disk is the source of pain. For most purposes, this degree of confidence may be enough. It is enough on which to base conservative therapy, if that therapy is appropriate for internal disk disruption. It is enough for medicolegal purposes because 67% exceeds the threshold for “on balance of probabilities,” that is, 50%. This level of confidence, however, may not be enough if invasive therapies are contemplated.

**DISK STIMULATION**

The definitive, diagnostic test for internal disk disruption is disk stimulation supplemented by postdiscography CT scanning (see Chapter 101). The test involves placing needles into the center of the disk to be tested and into two adjacent disks which serve as controls (Fig. 73.3). Contrast medium is injected into each of the disks with manometry to measure the intradiscal pressure, and the patient’s response to stimulation is recorded. Further details about the conduct of the test have been published elsewhere. Upon completion of the disk stimulation, a CT scan of each of the disks is obtained.
The criteria for a positive test are that stimulation of the target disk, to an injection pressure less than 20 psi (0.14 kPa), reproduces the patient’s pain to an intensity greater than 7/10, provided that stimulation of adjacent disks is not painful. Subsequently, the CT scan should show a grade III or IV fissure in the disk.

The validity of disk stimulation has been challenged on the alleged grounds that it has too high a false-positive rate. That challenge has been refuted by studies that collectively show that the false-positive rate is not greater than 10% and may be substantially less.\(^{20}\)

The indication for disk stimulation is the need to establish a diagnosis of discogenic pain in general or internal disk disruption in particular.
Depending on the circumstances, the test could be used for its negative diagnostic utility. For example, establishing a diagnosis of discogenic pain could protect patients from undergoing futile therapy for a presumed diagnosis of sacroiliac joint pain. A negative response to disk stimulation could protect patients from undergoing surgery based on a presumption of discogenic pain. The positive diagnostic utility lies in selecting patients, and disks, for treatments that target painful disks.

**SINUVERTEBRAL NERVE BLOCKS**

The sinuvertebral nerves (also known as recurrent meningeal nerves or recurrent nerves of Luschka) innervate the meninges, ligaments, and periosteum of the spinal canal and the anulus fibrosus of the intervertebral disk and carry sensory information, including pain, from those structures.  

Sinuvertebral nerve block (SVNB) is a diagnostic intervention aimed at identifying a painful disk by interrupting transduction of pain in the sinuvertebral nerve(s) that supply the target disk. The procedure is also sometimes called selective nerve root sleeve block. It involves introducing a spinal needle, under fluoroscopy, through the relevant intervertebral foramen and injecting a local anesthetic agent in such a way as to ensure the injectate flows inward and upward to reach the vicinity of the back of the disk. Somatic discogenic pain is relieved by anesthetic agent that reaches the disk, whereas associated radicular pain is relieved by agent that reaches the vicinity of the dorsal root ganglion.

SVNBs have been reported as useful in numerous publications. Although such papers suggest that SVNBs have roles in the diagnosis of discogenic pain, they do not provide data that evaluate their diagnostic validity.

An exploratory study assessed the potential utility of SVNB as an alternative to the more invasive disk stimulation test. The results showed the sensitivity of SVNB was 73.3% (95% confidence interval [CI], 50.9% to 95.7%), but technical issues resulted in a target specificity of only 40% (95% CI, 15.2% to 64.8%). These results indicate that SVNB cannot yet replace disk stimulation but encourage future studies to improve its target specificity.
LUMBAR MEDIAL BRANCH BLOCKS
Lumbar medial branch blocks (LMBBs) are the diagnostic test for pain stemming from one or more of the lumbar zygapophysial joints. Intra-articular blocks are used by some practitioners, but intra-articular blocks have not been formally validated. LMBBs have been validated for face validity (target specificity) and for construct validity (the extent to which they achieve their purpose). In other words, LMBBs do not anesthetize other structures that might be an alternative source of pain, and they protect normal volunteers from experimentally induced pain from the joint anesthetized.

LMBBs involve placing the tips of needles onto each of the two nerves that innervate the target zygapophysial joint and injecting 0.3 to 0.5 mL of local anesthetic onto each nerve (Fig. 73.4). Details for the conduct of the procedure are available elsewhere.

FIGURE 73.4 Fluoroscopy views of stages in the conduct of a left L4 medial branch block. A: Oblique view of a needle placed at the target point of the L4 medial branch on the neck of the L5 superior articular process. B: Posterior view of the needle resting on the target point. C: Declined oblique view showing the needle on the neck of the superior articular process. D: Oblique view after injection of a test does of contrast medium. E: Posterior view showing contrast medium concentrated around the target point. F: Declined oblique view showing contrast medium against the neck of the superior articular process. (Reproduced with permission from Bogduk N, ed. Practice Guidelines for Spinal Diagnostic and Treatment Procedures. 2nd ed. San Francisco, CA: 3929)
Single, diagnostic blocks carry a high false-positive rate.\textsuperscript{36,38,92} Therefore, for valid diagnosis, LMBBs have to be controlled. Comparative local anesthetic blocks have been used in the past, but doubts have been raised about their validity (see Chapter 98). Because of the low prevalence of lumbar zygapophysial joint pain and false-positive responses, even comparative blocks still have substantial false-positive rates. Consequently, operators who use comparative blocks need to appreciate that some of their positive responses will be doubtful. The only way to reduce this doubt is to perform placebo-controlled blocks.

With these reservations in mind, it is possible to use LMBBs to determine if a patient has back pain stemming from one or more lumbar zygapophysial joints. An algorithm for the efficient use of blocks has been described.\textsuperscript{93} It recommends multilevel screening blocks in the first instance in order to identify patients who do not have zygapophysial joint pain, which is the most common response. Patients who report relief of the pain from screening blocks can then be subjected to repeat testing, with controlled blocks, in order to identify the joint or joints that are the source(s) of pain (see Chapter 98).

In terms of positive diagnostic utility, positive responses to medial branch blocks are the singular indication for treatment by lumbar medial branch thermal radiofrequency neurotomy (RFN) (see Chapter 102). This is the only treatment specific for lumbar zygapophysial joint pain for which there is rigorous evidence of effectiveness.

**SACROILIAC JOINT BLOCKS**

The definitive test for sacroiliac joint pain is controlled blocks of the joint using intra-articular injections of local anesthetic. These blocks require accurate access to the cavity of the joint, which at times, may be difficult to achieve (\textit{Fig. 73.5}). Details concerning the procedure are available elsewhere.\textsuperscript{94} Once access to the joint has been achieved, and confirmed by injection of a small volume of contrast medium to create an arthrogram, 1 to 2 mL of local anesthetic agent can be injected in order to anesthetize the joint.
FIGURE 73.5  Fluoroscopy views of stages in the conduct of an intra-articular injection into a right sacroiliac joint. A: A near anteroposterior view, slightly contralateral oblique, showing a needle having entered the joint. B: A lateral view showing the needle having entered the joint. C: A near anteroposterior view after injection of a small volume of contrast medium. Linear streaks run between the various silhouettes of the joint margins (arrows), and the cavity of the joint blushes. D: A lateral view after injection of contrast medium. The image of the contrast medium is faint. It can be seen to outline the inferior perimeter of the joint cavity (arrows). E: An ipsilateral oblique view after injection of more contrast medium, showing contrast medium forming linear streaks between the joint margins. F: A contralateral oblique view through the right ilium showing how the contrast medium outlines the perimeter of the joint (arrows) and forms an auricular-shaped blush across the surface of the joint. (Images reproduced with permission from Bogduk N, ed. Practice Guidelines for Spinal Diagnostic and Treatment Procedures. 2nd ed. San Francisco, CA: International Spine Intervention Society; 2013.)

The criteria for a positive response should be complete relief of pain, on
each occasion, after controlled blocks are performed.\textsuperscript{94} For reasons not fully articulated and defended, some practitioners settle for the criterion being greater than 75\% relief of pain.\textsuperscript{95} Intuitively, the greater the degree of relief, the more convincing the response would be that the joint is, indeed, the source of pain.\textsuperscript{94}

The positive diagnostic utility of sacroiliac joint blocks (SIJBs) is that patients with a positive response can be directed to treatments specific for sacroiliac joint pain. The negative diagnostic utility is that establishing a diagnosis of sacroiliac joint pain protects patients from the futile pursuit of other diagnoses or from undertaking treatments that lack any rationale for treating sacroiliac joint pain.

\textbf{SACRAL LATERAL BRANCH BLOCKS}

In principle, it seems plausible that the ligaments behind the sacroiliac joint could be a source of pain. These ligaments are innervated by the lateral branches of the S1–S3 dorsal rami and are not anaesthetized by intra-articular blocks of the sacroiliac joint. A plausible diagnostic test for pain stemming from these ligaments would be blocks of the sacral lateral branches. However, no studies have yet systematically established the prevalence of this source of pain and whether it occurs in isolation or in company with sacroiliac joint pain. Furthermore, technical concerns have arisen.

Sacral lateral branches are elusive targets. They run at various depths within multiple layers of dense ligaments. Consequently, the original technique which involved injecting local anesthetic at a single site, lateral to each dorsal sacral foramen, fails to capture the target nerves reliably.\textsuperscript{95} Needles need to be placed at multiple sites, at multiple depths, in order to capture the nerves, but even that technique is imperfect.\textsuperscript{54}

Missing a nerve invalidates a block, but only in a negative sense: Patients who might have had a positive response are missed. If a technique manages to capture all the target nerves, and if the response to blocks is positive, for that response to be valid, it needs to be corroborated by controlled blocks.

No studies in the literature have reported using controlled blocks of the sacral lateral branches. One study used an approximation.\textsuperscript{96} Blocks using
bupivacaine were performed twice to corroborate responses, but different agents or placebo controls were not used. This study did not explicitly report the prevalence of positive responses, but implicitly, the yield was at least about 17% in 304 patients with pain predominantly caudal to L5, with the criterion for a positive response being at least 75% relief of pain following each of the two blocks.

The cardinal application of sacral lateral branch blocks is to select patients for sacral lateral branch neurotomy. The rationale is that if blocks of these nerves temporarily relieve the patient’s pain, then coagulating the nerves should provide long-lasting relief.

Treatment

The patient whose main complaint is chronic low back pain primarily wants that pain to be treated effectively so he or she becomes pain free. In the light of the literature on the treatment of chronic low back pain, such a wish by the patient may seem naive, as most publications on the effectiveness of treatments for chronic low back pain report partial relief only and then only for relatively short periods. Some publications on treatments report no relief of pain at all but instead report relief of para-phenomena such as pain-related disability or pain-related depression. Although such treatments may be of some benefit in their own ways, they cannot and should not be considered legitimate treatments for chronic low back pain. Pain relief is what patients want and it should be the primary goal of treatment. Ideally the relief should be total and enduring, so patients can return to activities and a quality of life they have not enjoyed since the pain came on.

Complete and enduring relief of chronic low back pain is not an unrealistic expectation, even when the pain has been present for a long time before treatment. Complete and enduring relief is the normal expectation when other types of pain are treated effectively and it is the usual outcome achieved when pains such as chronic angina pectoris, chronic hip pain, or chronic toothache are treated by methods that address their mechanisms of pain generation effectively. The key to achieving complete and enduring relief is to identify the mechanism of the index pain
and to address that mechanism with some intervention which deactivates it. The various treatments offered for chronic low back pain should be considered with the objective of complete and enduring pain relief clearly in mind.

Metaphorically, the literature on the treatment of chronic low back pain is a political and ideologic minefield. Various craft groups appear intent in proving that their therapy is effective and should be used. Some groups promote their ideology as the preferred approach and condemn the approaches of others. Those who choose not to make a pathoanatomic diagnosis rely on nonspecific therapies, whereas those who do pursue a diagnosis are intent on having an intervention that works for the condition that they diagnose.

Common to all participants is the evolution of the literature and the standards applied to evaluating the evidence. Enthusiasm for particular therapies in the past has been tempered either by additional research or by reappraisal of previous evidence. New therapies confront higher standards of analysis and reporting than did their predecessors.

**GENERAL TREATMENTS**

Contemporary evidence is not flattering for conservative, general therapies for chronic low back pain. The evidence shows that various therapies either have no attributable effect or have small effects. This applies as much to physical therapies as to drug therapies.

Conspicuously, no general therapy has been shown to abolish chronic low back pain or to reduce it substantially so that the patient can resume normal activities of daily living and requires not other health care for the back pain. Yet, this is what patients want. When surveyed, patients with chronic low back pain indicate that although they consider 30% reductions in pain or disability worthwhile, they desire at least 80% reduction, if not complete relief. General therapies do not meet these expectations.

**DRUG THERAPY**

**Paracetamol (Acetaminophen)**

For chronic low back pain, there is very low-quality evidence (based on a single trial that has been retracted) for no effect of paracetamol
No other studies have tested paracetamol for the treatment of chronic low back pain. For acute low back pain, paracetamol has been shown to be no more effective than a placebo.

**Nonsteroidal Anti-inflammatory Drugs**

For the relief of pain, nonsteroidal anti-inflammatory drugs (NSAIDs) have a small effect greater than that of placebo. According to one review, the effect amounts to a mean difference in pain scores of 12/100, at 12 weeks after commencing treatment. Another review calculated the difference to be on 3/100. Compared with placebo, NSAIDs increase the chances of obtaining 30% relief of pain from about 30% to 50%. Studies have detected no differences in effectiveness between different NSAIDs.

**Muscle Relaxants**

There is little evidence on which to base valid conclusions about the effectiveness of muscle relaxants for chronic low back pain. A Cochrane review found muscle relaxants are effective for short-term symptomatic relief in patients with acute and chronic low back pain, but the incidence of drowsiness, dizziness, and other side effects is high, so muscle relaxants must be used with caution.

**Benzodiazepines**

There are no long-term data on the effectiveness or otherwise of benzodiazepines.

**Antidepressants**

In the treatment of chronic low back pain, tricyclic antidepressants and selective serotonin reuptake inhibitors are not more effective than placebo, for the relief of pain, or improving depression, or improving function. Recent studies have provided favorable results for duloxetine, a selective serotonin norepinephrine reuptake inhibitor (SSNRI) drug. It is significantly more effective than placebo for the relief of pain and for improving function, but the effect sizes are small.
**Pregabalin**
Pregabalin has no effects greater than those of placebo for low back pain or associated disability.\(^9^9\)

**Opioids**
In the short term, strong opioids achieve greater relief of pain than that from placebo. The effect is statistically significant, but its clinical significance is small, amounting to a mean difference of 1/10 for pain and for disability.\(^9^9,1^0^0\) The same small superiority applies for tramadol and for buprenorphine patches.\(^9^9\) No long-term data are available. Meanwhile, opioids have a higher risk than placebo for side effects such as nausea, dizziness, constipation, vomiting, and somnolence.\(^9^9\)

**PHYSICAL MODALITIES**

**Physiotherapy**
Physiotherapy involves a range of physical modalities of treatment including massage; mobilization; traction; taping and provision of lumbar supports; and often heat, cold, laser, ultrasound, and various electrical therapies used singly or in combination at the individual physiotherapist’s discretion. Some physiotherapists offer special forms of physiotherapy, such as McKenzie therapy, and some provide formal manual therapy, including spinal manipulation. The effectiveness of these modalities can best be considered singly.

**Massage**
A systematic review found very little evidence that massage is an effective treatment for chronic low back pain; patients with chronic low back pain had improvements in pain outcomes after massage but only briefly, and the relief was not sustained.\(^1^0^3\) Massage provides small effects on disability, more than those achieved in usual care, at 12 weeks, but the magnitude of the difference reduces by 52 weeks.\(^1^0^4\) Massage is significantly more effective than manual therapy, exercise, relaxation therapy, acupuncture, physiotherapy, or transcutaneous electrical nerve stimulation (TENS) in the short term.\(^1^0^4\)
Traction
The latest systematic review found that “traction, either alone or in combination with other treatments, has little or no impact on pain intensity, functional status, global improvement or return to work among people with low back pain; there was no difference regarding the type of traction (manual or mechanical); side-effects reported included increased pain, aggravation of neurological signs and subsequent surgery.”

Manual Therapy
Manual therapy, the laying on of hands by a therapist to perform soft tissue stretching, joint mobilization, and spinal manipulation, has been one of the most frequently used modalities of treatment for many decades since it developed in the late 19th century. It is the main practice of several craft groups including osteopaths, chiropractors, and manipulative therapists (specially trained physiotherapists); it is also performed by many medical practitioners practicing musculoskeletal medicine, manual medicine, and physiatry. Over the years, manual therapy has developed an aura of mystique, and many patients with chronic low back pain view it as something they rely on for almost magical relief of their condition. By its advocates, manual therapy is promoted variously as a therapeutic skill based on special understanding of bodily functions or as an orthodox remedy for musculoskeletal dysfunction.

In fact, manual therapy achieves small but statistically nonsignificant effects on pain when compared with sham therapy. It provides better short-term relief than other active therapies, but the differences between therapies are small. There is no evidence of lasting, long-term effects. A systematic review found “high quality evidence that there is no clinically relevant difference between spinal manipulative therapy and other interventions for reducing pain and improving function in patients with chronic low-back pain; spinal manipulative therapy appears to be as effective as other common therapies prescribed for chronic low-back pain, such as exercise therapy, standard medical care or physiotherapy.”

McKenzie Therapy
Systematic reviews have found limited evidence concerning the efficacy of
McKenzie therapy for chronic low back pain. Advocates of the treatment cite a study that showed no superiority over stabilization exercises and a study that showed slightly better outcomes than those of strengthening exercise at 2 months after treatment but not at 8 months.

**Transcutaneous Electrical Nerve Stimulation**
TENS is often used as an adjunct in the management of low back pain. However, despite the widespread use of TENS machines, the analgesic effectiveness of TENS still remains uncertain. A systematic review found “conflicting evidence regarding the benefits of TENS for chronic low back pain, which does not support the use of TENS in the routine management of chronic low back pain.”

**Other Physical and Electrical Modalities**
There is little published evidence for interferential, shortwave diathermy, ultrasound, laser, or taping. Ultrasound is no more effective than sham therapy, and low-level laser therapy is only slightly better than sham laser therapy. A systematic review of low-level laser found “there are insufficient data to either support or refute the effectiveness of low-level laser therapy for the treatment of non-specific low back pain.”

**Lumbar Supports**
The available evidence shows that lumbar supports provide no benefit in terms of pain relief; the authors of a systematic review reported that there was little or no difference in short-term pain reduction or overall improvement between patients with chronic low-back pain who used back supports and those who received no treatment.

**Exercise Therapy**
The evidence on exercise therapy is mixed, depending on which studies are reviewed. Some reviews have found that exercise therapy reduces pain by 10/100 more than having no exercises but offers no benefit for function. Other reviews have found that exercise therapy reduces pain by 9/100 more than does usual care and improves function by 12/100. Differences decrease to about 4/100 for pain and 3/100 for function in the
long term. When compared with minimal interventions, exercise therapy provides the same differences in benefit.\textsuperscript{104}

Proponents of high-intensity strengthening exercises have sought evidence of efficacy within the general literature on exercise for chronic low back pain but found no clear evidence of benefit over other exercises or other interventions such as physiotherapy and massage.\textsuperscript{114} Others, likewise, found trunk-strengthening exercises to be more effective than no exercises but not more effective than aerobics or McKenzie treatment.\textsuperscript{115}

Proponents of core stabilization exercises found moderate evidence that this form of exercise is effective in improving pain and function but strong evidence that it was not more effective than physiotherapy, manual therapy, general exercises, and minimal care.\textsuperscript{116} Another review found that stabilization exercises were superior to usual medical care and education, but not to manipulative therapy, and no additional effect was found when stabilization exercises were added to a conventional physiotherapy program.\textsuperscript{117}

Tai chi provides greater relief of pain than does being put on a waiting list but only by 10/100 points.\textsuperscript{104} Low-quality evidence shows that yoga offers small effects on pain and function that are better than those achieved in usual care.\textsuperscript{100,104}

**SIMPLE NEEDLE TREATMENTS**

Many practitioners offer a range of special needle treatments, including acupuncture, trigger point injection, and prolotherapy. Some perform these as monotherapies, and others provide them in combination with other treatments within the framework of musculoskeletal medicine and physiatry.

**Acupuncture**

The only positive evidence of the effectiveness of acupuncture for chronic low back pain comes from trials that showed acupuncture was more effective than no acupuncture, but these benefits were evident only immediately after treatment and not beyond.\textsuperscript{104} When compared with sham treatment, acupuncture is minimally more effective for reducing pain, but only immediately after treatment, and provides no better effect.
for improving function. There is no evidence of any lasting beneficial effects beyond the immediate effects of treatment.\textsuperscript{104}

**Trigger Point Injection**

Trigger point injection is an intervention that has been popular with general practitioners and physiatrists because it requires no special equipment and is easy to perform in consulting rooms. Despite its popularity for the treatment of various musculoskeletal conditions, there are few studies of its efficacy, and even fewer of its efficacy specifically in patients with chronic low back pain.\textsuperscript{118} Studies limited to immediate and short-term outcomes (7 days) report conflicting results. No studies have provided long-term data.

**Prolotherapy**

Prolotherapy involves the injection of sclerosing agents, such as hypertonic dextrose or phenol, into tender areas of the back muscles, ostensibly at muscle attachment sites.

Multiple reviews have found no evidence of efficacy for prolotherapy.\textsuperscript{119–121} Studies of prolotherapy and cointerventions have found some positive results for the combination of treatments, but studies in which prolotherapy alone was tested have found only negative results.\textsuperscript{121}

One study provided intriguing results\textsuperscript{122}; it showed that prolotherapy was not significantly more effective than injections of normal saline; the success rates from either treatment were the same. However, at 12 months, 46% of patients had at least 50% relief from their chronic back pain, and 20% had complete relief. These outcomes—obtained in a randomized controlled trial—dwarf those of any other conservative therapy for chronic back pain. They prompted one review of drug therapy for back pain to conclude that the most powerful drug for the treatment of back pain appears to be normal saline delivered by charismatic injection.\textsuperscript{123}

**BACK SCHOOL**

The evidence on back schools is low in quality and shows that back school is not more effective than no treatment.\textsuperscript{124} It offers no benefits greater than
those of usual care or physical therapy or exercises.

**PSYCHOLOGICAL INTERVENTIONS**
The evidence base shows that a patient with chronic low back pain has little if anything to gain from psychological therapies in terms of pain relief or even relief of psychological para-phenomena. A systematic review found that “overall there is an absence of evidence for behavior therapy, except a small improvement in mood immediately following treatment; cognitive behavioral therapy (CBT) has small positive effects on disability and catastrophizing, but not on pain or mood, when compared with active controls; CBT has small to moderate effects on pain, disability, mood and catastrophizing, immediately post-treatment when compared with waiting list, but all except a small effect on mood had disappeared at follow-up.”

Other reviews have not changed this summary. Psychology therapies, such as progressive relaxation, operant therapy, and CBT, are each slightly more effective than being put on a waiting list, by about 20/100 for pain, in the short term, but there are no long-term outcome data. Adding psychology therapies to physiotherapy does not improve the outcomes achieved by physiotherapy alone. Behavioral therapy is slightly more effective than usual care for the relief of pain in the short term but provides no benefit in the long term for either pain or function. For pain or depression, the outcomes of behavioral therapy are not different from those of exercise, and adding behavioral therapy to an inpatient rehabilitation program provides no additional benefit.

Mindfulness-based stress reduction offers improvements in pain that are greater, by 1/10, than those achieved under usual care, and similar improvements in function. However, it is not shown to be better than CBT, which is only very slightly and temporarily more effective than being put on a waiting list.

**MULTIDISCIPLINARY PAIN MANAGEMENT**
In its original form, multidisciplinary pain management involves the collaboration of practitioners of all relevant disciplines working closely as a team to manage patients with chronic pain. A pain physician elicits the
patient’s history and performs physical examination, radiologists assist by interpreting diagnostic imaging, nurses contribute their observations, physiotherapists and exercise physiologists assess any musculoskeletal disabilities, and a psychologist or psychiatrist assesses the patient’s psychological state. Others, such as occupational therapists and social workers assess the patient’s vocational, social, and financial situation. When all relevant diagnostic information is gathered, the team formulates a provisional diagnosis and applies diagnostic investigations such as nerve blocks and perhaps discography to develop a definitive diagnosis. Management is then undertaken with each team member contributing where they can help. The pain physician coordinates the management and provides pharmacologic interventions and perhaps other interventions such as specific, targeted needle treatments. Orthopedic surgeons and neurosurgeons provide surgical interventions, if indicated. Physiotherapists provide interventions in their realm and psychologists address affective issues. A rehabilitation physician supervises the patient’s recovery and rehabilitation, with the help of occupational therapists and social workers, and perhaps assisted by an occupational physician to facilitate the patient’s return to work. If required, additional specialists such as neurologists can also be involved in the management team.

Such an approach seems ideal as a concept, for it provides the patient with the best care available in each of the areas of need. Where such truly multidisciplinary pain clinics operate, outcomes are potentially as good as those achievable by all the disciplines involved. When first developed, this model of multidisciplinary pain management held promise as an appropriate way to handle complex problems such as chronic back pain, and multidisciplinary pain management soon became the iconic, preferred method of care.

Unfortunately, that ideal model has been subverted in many places by those who seek to assume the expertise of a large multidisciplinary team but in fact focus on only two or three disciplines, most commonly, psychologists and physiotherapists with a physician as nominal leader. Such people operate what they call “pain clinics” that claim to take the biopsychosocial approach to chronic pain but actually focus mainly if not exclusively on the psychological and social domains of a patient’s problem.
and largely or totally ignore the biologic domain. In such “multidisciplinary biopsychosocial rehabilitation,” there is usually no attempt at specific diagnosis, the underlying belief being that chronic pain is essentially of psychological origin and is best treated with psychological interventions, with perhaps input from a physiotherapist to make the treatment seem holistic.

The belief that chronic pain is psychological stems from early in the second half of the 20th century, when scientific knowledge of the neuroanatomy and pathology of the lumbar spine was sparse. In the 1950s and 1960s, some authors promoted the psychoanalytic concept that intractable pain is a defense against unconscious psychic conflict.\(^{127,128}\) Chronic pain was attributed to repressed hostility and aggression, guilt, resentment, loss, masked depression, and various personality disorders. Behavioral therapy was advocated as a means of managing chronic low back pain defined in that way. This model of pain was reinforced by the belief that chronic low back pain has no physical cause.

Over the 50 years since these beliefs were first espoused, research has either refuted or dispelled each of these beliefs. Multiple studies have shown that a source of pain can be established, in the majority of patients with chronic low back pain, if appropriate investigations are undertaken. Meanwhile, the concepts of chronic pain being due to psychological abnormalities, although eloquently espoused, have not found support from evidence, particularly from controlled studies.\(^{128}\) Thus, “multidisciplinary” clinics that purport to manage chronic pain without pursuing biomedical diagnosis operate on a false premise, and the outcome data show they do not provide any clinically significant relief, and certainly not total and enduring relief, of chronic low back pain.

Another belief on which “multidisciplinary biopsychosocial rehabilitation” is based is the idea that once pain becomes chronic, the process of central sensitization occurs, and the pain becomes permanent and intractable, in effect a permanent disease in its own right.\(^ {129}\) This contention has been refuted explicitly by several studies\(^ {130-133}\); it is also refuted implicitly by the many studies which show chronic low back pain can be eliminated, with restoration of function and no need for ongoing health care.
In relation to effectiveness, a systematic review of the current evidence on “multidisciplinary biopsychosocial rehabilitation” shows it is barely more effective than usual care in reducing pain and disability, with outcomes of 0.5 to 1.4 units on a 0 to 10 numerical rating scale for pain and 1.4 to 2.5 on the 0 to 24 Roland-Morris disability scale.\textsuperscript{134}

A systematic review of the current evidence on behavioral therapy for patients with chronic low back pain shows little or no difference between behavioral treatment and group exercise either for relieving pain or for alleviating depressive symptoms.\textsuperscript{126} A recent systematic review of the current evidence on psychological therapies for low back pain found “overall there is an absence of evidence for behavior therapy, except a small improvement in mood immediately following treatment; cognitive behavioral therapy (CBT) has small positive effects on disability and catastrophizing, but not on pain or mood, when compared with active controls; CBT has small to moderate effects on pain, disability, mood and catastrophizing, immediately post-treatment when compared with waiting list, but all except a small effect on mood had disappeared at follow-up.”\textsuperscript{125}

Referring doctors need to be aware of the skills, outcomes, and reputation of any clinic to which they may send their patients. Worthwhile clinics are not defined by using the title “multidisciplinary”; they are defined by the outcomes they achieve. A truly multidisciplinary approach to the management of patients with chronic low back pain has the potential to address all problems in the biologic, psychological, and social domains of chronic pain. However, patients and practitioners should not be hoodwinked into trying an intervention that is similar in name only. The summary of the evidence on “multidisciplinary biopsychosocial rehabilitation” is that it does little or nothing to help patients with chronic low back pain; so-called “pain clinics,” which use that approach are misnamed because they do not address pain, let alone relieve it.

\textbf{FUNCTIONAL RESTORATION}

Functional restoration is also “multidisciplinary” in nature, but it was more prompted by the discipline of sports medicine than by psychology. It arose from the proposition that injured workers could rehabilitate by work
hardening in the way that athletes are known to overcome musculoskeletal injuries by concerted training and perseverance. The objective was to restore function, virtually regardless of the pain.

It has become difficult to disentangle functional restoration from “multidisciplinary biopsychosocial rehabilitation,” particularly when it comes to the literature on efficacy. So-called “multidisciplinary biopsychosocial rehabilitation” has adopted some of the principles and practices of functional restoration, particularly those of intensive training, whereas functional restoration has adopted behavioral therapy from “multidisciplinary biopsychosocial rehabilitation.” It is unclear the extent to which behavioral therapy is a critical component of functional restoration, but the evidence of its ineffectiveness is as quoted earlier; the evidence on a group program of exercise and education using a cognitive-behavioral approach shows it is not significantly more effective than providing an educational booklet.

SPECIFIC, TARGETED TREATMENTS

For certain sources of pain, minimally invasive treatments can be used to relieve that pain. These treatments are the ones that involved penetrating the body with needles electrodes, or other devices, but without actually opening the body in order to achieve access. The rationale for minimally invasive treatments is that if the source or cause of back pain can be identified, then rectifying the cause, ablating the cause, or ablating the nerves that innervate the source should relieve the patient’s pain (and any disabilities caused by that pain). Minimally invasive therapies are, therefore, target specific and can be addressed according to their target.

Discogenic Pain

Discogenic low back pain is pain arising from an intervertebral disk. Ostensibly, it is caused by stimulation of nociceptors in the disk that are stimulated by internal chemical processes or mechanical loading of the anulus fibrosis. The cardinal cause is internal disk disruption (see Chapter 101).

A variety of interventions have been explored for the management of lumbar discogenic pain. Variously, they target the pathology of internal
disk disruption at a macroscopic or molecular level or target the nerves that transduce the pain. They involve coagulating fissures in the anulus fibrosis or the nociceptors around them, injecting chemicals intended to antagonize degradative processes in the disk, and injecting “biologics” designed to inhibit cytokines and proteolytic enzymes and to promote healing of connective tissues. These interventions and their effectiveness are covered in detail in Chapter 101 and are only summarized briefly here. In essence, however, none has been proven to be effective, as promised by the rationale for minimally invasive treatments.

Intradiscal Therapies
Of the treatments that use coagulation, intradiscal biacuplasty has been shown to be more effective than usual care, but it is successful in only a proportion of patients and only to a small degree. Although fair to reasonable success rates have been reported for other ablative therapies for the relief of pain, none has yet been vindicated in terms of restoring function and eliminating the need for other health care.

For various chemical therapies, the literature shows that intradiscal steroids are not effective, and etanercept has only short-term effects. Open-label studies have not been able to reproduce the outcomes reported in a controlled trial of methylene blue, and good results reported for proliferants have not been reproduced by anyone else.

Studies of biologics are in their infancy. For agents such as fibrin sealant, platelet-rich plasma, and α₂-macroglobulin, pilot studies have announced modest, positive outcomes, but rigorous controlled studies have not been conducted. An open-label study reported good results from intradiscal injection of stem cells, but a controlled trial found no convincing superiority over sham therapy.

In effect, although many investigators have promoted or evaluated intradiscal treatments specifically targeting painful disks, none has yet been proven to be a useful solution to this common source of chronic low back pain.

Epidural Injection of Corticosteroid
Epidural injections of corticosteroids, by the caudal or interlaminar route, have been used extensively to treat lumbar radicular pain, for which they
had a reputation of effectiveness (see Chapter 99). Because of this reputation, and because they are relatively easy to perform, they have also been used to treat presumed discogenic back pain. The evidence shows that such injections are no more effective than epidural injections of local anesthetic.\textsuperscript{137–139} Injection of either agent may be palliative for a limited period, but neither has been shown to provide lasting relief. Notionally, chronic low back pain might be palliated by repeated caudal or interlaminar blocks, but the efficacy, safety, and cost-effectiveness of perpetual blocks have not been established.

Meanwhile, epidural injections are not without dangers. Complications and side effects of caudal injections include dural puncture, increased intracranial pressure, nerve damage, vascular injury, hematoma formation, cerebrovascular or pulmonary embolism, intravascular injection, intracranial air injection, chemical meningitis, arachnoiditis, infection, abscess formation, increased back pain, and increased leg pain, among others.\textsuperscript{140} Unwanted effects of interlaminar epidural injections of steroid reported include epidural hematomas; spinal cord or cauda equina injuries; infectious complications such as epidural abscess, meningitis, discitis, and osteomyelitis; dural puncture; subdural air; pneumocephalus; arterial gas embolism; seizures; transient blindness; retinal necrosis; chorioretinopathy; stroke; chemical meningitis; and increased pain.\textsuperscript{141}

Transforaminal Injection of Steroid
Transforaminal injection of steroids (TFIS) offers the prospect of delivering corticosteroids across the back of a painful disk. In that location, they putatively can combat the inflammatory effects of exudates from the disk into the retrodiscal, epidural space, and if they diffuse into the disk, they could exert the same effects within the disk. Given that steroids have a local anesthetic effect,\textsuperscript{142} TFIS could also block the sinuvertebral nerves that innervate the posterior disk. A suitable indication for such injections would be relief of pain following bilateral diagnostic blocks of the four sinuvertebral nerves that principally supply the disk.

Evidence for the effectiveness of TFIS for discogenic low back pain is only in its infancy. A small pilot study, published only as a university thesis, showed that TFIS was moderately effective in patients with
discogenic chronic low back pain but no radicular pain. With success defined as complete or at least good relief on the Oxford Pain Chart scale, 81% (95% CI, 66% to 96%) of 27 patients had a successful outcome at 1 week, and 52% (95% CI, 33% to 71%) at 6 weeks, after a single TFIS treatment.

Zygapophysial Joint Pain
Intra-articular Steroids
Zygapophysial joint pain has been, and still is, treated by intra-articular injection of steroid. However, this treatment was never been evaluated in patients with back pain proven to arise from the zygapophysial joints. It is not surprising, therefore, that multiple controlled trials have found it to be no more effective than sham therapy.

Facet Joint Nerve Blocks
For patients with positive responses to controlled diagnostic blocks of the lumbar medial branches, some physicians advocate repeating the blocks as a treatment, whenever the pain returns. This intervention amounts to converting a diagnostic procedure into a therapeutic one. The outcomes are the same regardless of whether steroids are added or not to the local anesthetic agent used.

Patients can obtain at least 50% relief of pain, for several weeks after each injection, but the treatment is not curative. Blocks need to be repeated in order to maintain relief. However, although pain can be reduced, the treatment makes little to no difference in terms of return to work or use of opioids for pain.

Lumbar Medial Branch Thermal Radiofrequency Neurotomy
Lumbar medial branch thermal RFN is a procedure designed to treat pain stemming from one or more lumbar zygapophysial joints. It involves coagulating the nerves that innervate the painful joint, using electrodes that generate a heat lesion around their tip (Fig. 73.6).
The procedure advocated by the International Spine Intervention Society, and described in its Practice Guidelines,\textsuperscript{148} was developed over many years on the basis of anatomical studies, laboratory studies, and pilot clinical studies. In particular, the technique described recognizes the importance of placing electrodes parallel to the target nerve, to ablate the nerve adequately and along a maximal length; using a large-gauge (16 gauge) electrode placed at multiple sites, in order to accommodate variations in the location of the nerve; and creating multiple lesions over
the nerve at 80°C. Furthermore, the indication for the procedure is complete, or near complete, relief of pain following controlled diagnostic blocks of the target nerve.\textsuperscript{148}

This procedure was validated in an early benchmark study.\textsuperscript{149} That study showed that at 12 months after treatment, some 60% of patients had 80% relief of their pain, and 80% of patients had 60% relief. It also showed denervation in the myotomes of multifidus that were innervated by the target nerves, which meant that the procedure had adequately coagulated those nerves.

A larger benchmark study has since corroborated and extended these outcomes. The study was conducted in two neighboring practices.\textsuperscript{150} The data from each practice differed only in that one practice performed treatments over a longer period of survey and performed more repeat treatments when pain recurred. Patients were selected on the basis of complete relief of pain following comparative local anesthetic blocks. Successful outcome was defined as complete relief of pain, accompanied by restoration of activities of daily living, and no need for continuing care for back pain. In the two practices, the initial success rates were 58% (44% to 72%) and 53% (40% to 66%). In the first practice, the median duration of relief from the first treatment was 15 months, with an interquartile range of 10 to 28 months. In the second practice, the corresponding figures were 15 (10 to 29) months. Repeat treatments were performed to reinstate relief if pain recurred after the first treatment. A total of 35 treatments in 29 patients were performed in the first practice, and 66 treatments in 30 patients in the second practice, resulting in a median duration of relief, per treatment, of 13 months, over a 5-year period.

This study is the only one that has achieved complete relief of back pain, coupled with restoration of function, and eliminated of any other health care. It sets the benchmark for outcomes from lumbar RFN. Critically, however, it assiduously followed the guidelines for selecting patients and for technique used.\textsuperscript{148} Patients were treated only if they reported complete relief of pain from controlled, diagnostic blocks, and meticulous surgical technique was used. These outcomes have never been matched by any other study, but no other study has followed the same rigorous guidelines for selecting patients or for surgical technique.
Other studies, including controlled trials, have selected patients on the basis of single diagnostic blocks, with the definition of a positive response being 70% relief in one study\textsuperscript{151} and only 50% or less in others.\textsuperscript{152–156} Single blocks incur a high false-positive rate,\textsuperscript{36–38,92,157,158} and they do not identify the 30% or so of patients who fail to get any relief when blocks are simply repeated.\textsuperscript{159} Therefore, studies that used single blocks to select patients for lumbar RFN must have been confounded by patients who did not have the condition for which they were treated, which would substantially decrease their success rate. This effect could only be compounded by using 50% relief for the definition of a positive block.

Three controlled trials\textsuperscript{153,160,161} placed their electrodes at locations remote from any nerve. Therefore, by definition, they performed a sham treatment. The controlled trials that did this amount to comparing one sham with another. Other controlled trials did not disclose where they placed their electrodes.\textsuperscript{154}

Two controlled trials\textsuperscript{152,155} placed electrodes perpendicular to the target nerve. Doing so does not necessarily prevent coagulation of the nerve, but the coagulation would be limited in length, which reduces the duration of effect. The studies would underestimate the duration of effect and would be compromised for showing differences between treatments over time.

Mixed in with the literature on thermal RFN, which applies lesions to the target nerve at 80° C, are reports of “pulsed RFN” which uses electrodes placed well away from the target nerve and heated to only 41° C, with indifferent results.\textsuperscript{156}

The studies with these technical and procedural flaws do not constitute valid evidence of the effectiveness or otherwise of lumbar thermal RFN, more so when a study has multiple flaws, such as suboptimal selection of patients and suboptimal surgical technique. Yet, almost all of the literature on lumbar RFN is so affected. Most egregious in this regard is the fact that authors of reviews have ignored these technical flaws and wide variations of technique, despite having been warned about them in the literature,\textsuperscript{162,163} and despite the authors of one controlled trial having acknowledged the flaws of their own study.\textsuperscript{164} The negative conclusions of reviews are not valid if they are based on flawed studies. Those conclusions might well apply to lumbar RFN when performed poorly, but
they do not apply to lumbar thermal RFN being performed correctly in appropriately selected patients.

The latter theme has been highlighted when authors of controlled trials have responded to letters to the editor criticizing their studies. In particular, on two occasions now, studies have been criticized for inaccurate surgical technique and for poor selection of patients.\textsuperscript{162,165–167} In both instances, the authors expressly replied that they studied how lumbar RFN was practiced in The Netherlands.\textsuperscript{168,169} Consequently, their results cannot be generalized to how lumbar RFN is practiced elsewhere and especially not when it is practiced according to the International Spine Intervention Society guidelines.\textsuperscript{148}

Only two controlled trials have used correct surgical technique, but both were compromised by patient selection. The study of Tekin et al.\textsuperscript{156} selected patients on the basis of a single diagnostic block. This would have compromised the success rate of their treatment but would not have compromised the comparison with a credible sham treatment—because the study was randomized. It showed a clear superiority of success rates in favor of lumbar RFN. The study of Nath et al.\textsuperscript{170} used comparative blocks to select patients, but those patients had concurrent, other pain problems, such as radicular pain. So, complete relief of pain and restoration of function could not be achieved in this sample. Nevertheless, insofar as the patients could distinguish their back pains from their other pains, those who underwent active treatment report greater improvements in pain, greater reduction in use of analgesics, and greater global satisfaction than those treated with sham therapy.

**Sacroiliac Pain**

Sacroiliac pain includes pain stemming from the sacroiliac joint and pain stemming from its posterior ligaments. The quest for effective treatments is hampered by confusion between sacroiliac joint pain and sacroiliac ligament pain. The two conditions differ with respect to the structures that are the source of pain, and the means by which the two conditions can be diagnosed. Yet, in many published trials of possible treatments, this distinction has not been made. So, it is not evident which condition was being treated or, indeed, if the patients did, in fact, have sacroiliac pain of
either type.

Sacroiliac Joint Injection of Steroids
The mainstay for treating sacroiliac joint pain has been intra-articular injection of steroids. The attraction of this form of treatment is that it is relatively simple to perform, for anyone with an access to a fluoroscope (or CT scanner). Moreover, there is no proven alternative treatment for sacroiliac joint pain, although other methods have been tried.

The reputation of intra-articular steroids for sacroiliac joint pain rests on descriptive studies, of various degrees of quality, that report various degrees of success for short or longer periods.\textsuperscript{171,172} The best quality, outcome study investigated 150 patients with presumptive sacroiliac joint pain based on clinical examination.\textsuperscript{173} All underwent a first intra-articular injection of bupivacaine and triamcinolone, from which 88 had at least 75\% pain relief. Of these 88, 58 underwent a second injection of the same agents, from which 39 had relief again. Of these 39 patients, 13 had at least 50\% relief that lasted less than 6 weeks, but 26 (45\%) had relief that lasted longer than 6 weeks (36.8 ± 9.9 weeks).

This study hints that intra-articular steroids might be a useful treatment for sacroiliac joint pain, but several caveats apply. For a condition for which there is no other treatment, the modest success rate (45\%) is notionally tolerable. The limited duration of relief (36 weeks) is also tolerable, for the treatment could be repeated if pain recurred.\textsuperscript{171} However, the definition of success (50\% relief) is weak. No studies have produced evidence that this limited degree of relief reduces the burden of illness. No studies have shown that reducing sacroiliac joint pain by 50\% is enough to restore function to reasonable levels and to reduce, if not eliminate, the need for other health care.

More rigorous data are required before intra-articular steroids can be promoted as a mainstream treatment for sacroiliac joint pain. Without such evidence, this treatment is destined to remain contentious, for pundits and those who pay for treatment will not be able to distinguish between something that physicians do and something from which patients genuinely benefit to a worthwhile degree.

Sacral Lateral Branch Neurotomy
Sacral lateral branch thermal RFN is a procedure in which the lateral branches of the S1–S3 dorsal rami are coagulated with radiofrequency electrodes. Rationale for this treatment should be to relieve pain stemming from the posterior sacroiliac ligaments, and the indication should be complete relief of pain following controlled, diagnostic blocks of the target nerves, but this has not been expressed in the literature.

The literature is both confused and confusing. Sacral lateral branch RFN was portrayed, adopted, and is still applied as a treatment for sacroiliac joint pain. In nearly all studies of this procedure, the initial indication for treatment has been a positive response to injections of local anesthetic and steroid into the sacroiliac joint. Indeed, a recent Appropriate Use Criteria for sacroiliac procedures reinforced this attitude. It maintained that if sacroiliac joint pain was diagnosed by an intra-articular block, it would be appropriate to entertain treatment by sacral lateral branch RFN, and the next step would be to perform sacral lateral branch blocks. This recommendation portrays intra-articular blocks and lateral branch blocks as complementary, but they are not.

It has been shown in normal volunteers that anesthetizing the sacral lateral branches protects subjects from posterior ligament pain, but it does not protect them from sacroiliac joint pain. Consequently, sacral lateral branch RFN cannot be a logical treatment for sacroiliac joint pain. It is a logical treatment only for posterior sacroiliac ligament pain. Under those conditions, intra-articular blocks are immaterial and irrelevant. They have no role in the selection of patients for sacral lateral branch RFN. The sole indication for sacral lateral branch RFN becomes relief of pain following controlled blocks of the sacral lateral branches.

Because of this confusion, most studies of sacral lateral branch RFN are ill founded. Three studies selected patients on the basis of positive responses to a single SIJB. Four studies required two intra-articular SIJBs. None of these blocks constitute evidence that the patients had pain that might be relieved by sacral lateral branch RFN. Therefore, the outcomes reported amount to no more than what to expect when the procedure is performed arbitrarily in patients with sacroiliac joint pain.

Two studies selected patients on the basis of an initial intra-articular SIJB and a subsequent lateral branch block. Neither of the blocks
was controlled. Under this protocol, the intra-articular block was irrelevant, but the lateral branch block at least provided prima facie evidence that the patients had pain from the posterior ligament complex. However, because the lateral branch blocks were not controlled, uncertain is the extent to which responses were contaminated by false-positive responses.

In those studies,\textsuperscript{183,184} 56\% and 52\% of patients reported at least 50\% relief of pain at 9 months and at 6 months, respectively. This is a modest outcome both in terms of success rate and in terms of degree of relief. The pilot study\textsuperscript{183} reported only on relief of pain. The later study\textsuperscript{184} reported that disability scores also improved, but only 23\% of patients reduced their opioid use.

Only one study has selected patients solely on the basis of lateral branch blocks.\textsuperscript{96} The blocks were not controlled, but patients had to report at least 75\% relief on both occasions that a block using bupivacaine was performed. The patients were randomized to active or sham treatment. At 6 months after sacral lateral branch RFN, 27\% of patients had greater than 50\% relief of pain, and 18\% reported being totally free of pain. At 9 months, these figures were 52\% and 15\%. The proportion of patients who achieved good outcomes at 1 month was nearly six times greater than that of patients who underwent sham therapy, but the small sample size prevented demonstrating an absolute statistically significant difference. This study constitutes the only evidence for sacroiliac joint pain RFN in appropriately selected patients.

Although the development of sacral lateral branch RFN was inspired by the success of cervical and lumbar medial branch neurotomy, the outcomes of lateral branch neurotomy have not mirrored those achieved by medial branch neurotomy. Most studies have reported only the achievement of 50\% relief of pain. The one study that most closely adhered to the rationale for lateral branch neurotomy\textsuperscript{96} achieved complete relief of pain in only 18\% of patients. The reason for this low yield is not known. There may be limitations to surgical technique, or it may be that 75\% relief from diagnostic blocks, and not using controls, is not a sufficiently rigorous selection criterion. For medial branch neurotomy, the best outcomes have been achieved after complete relief of pain following controlled diagnostic
blocks (see “Lumbar Medial Branch Thermal Radiofrequency Neurotomy” section in the preceding text).

A systematic review rated the evidence on sacral lateral branch RFN as moderate.\textsuperscript{53} The treatment seems effective for providing some relief of pain mediated by sacral lateral branches, but that relief is limited in extent and duration, and the indications for the procedure are unclear.

INVASIVE TREATMENTS

Invasive treatments are ones in which the body must be opened and entered. In the context of chronic low back pain, invasive treatments are those in which subcutaneous pockets are created for the implantation of devices and those in which the lumbar spine is exposed for direct access.

Implanted Devices

For the control of severe, chronic low back pain unresponsive to any other treatment, devices can be implanted to deliver drugs intrathecally or to provide spinal cord stimulation. Intrathecal drugs and spinal cord stimulators are not routine treatments for uncomplicated chronic low back pain. Typically, they have been reserved for the treatment of patients in whom surgery has failed to provide relief and whose diagnosis has become failed back surgery syndrome. The assessment and treatment of these patients is described in Chapter 75.

Spinal Surgery

In the past, surgery had a reputation as a successful treatment for chronic low back pain. However, because surgery is a major undertaking with serious hazards, it was reserved for patients in whom conservative therapy had failed, as a “last port of call.”

The reputation of surgery was established by the early literature, which claimed high success rates for the treatment of low back pain. With the advent of evidence-based medicine, the tenor of that literature has changed (see Chapter 74). Randomized controlled trials showed firstly that surgery was not substantially more effective than concerted conservative care, and secondly that, although it might improve pain and function, surgery was not curative. The language in the literature changed from success rates in
terms of patients free of pain and not using analgesics to success rates for
achieving only a minimal clinically important change, with patients still
taking opioids.

As with other interventions, the selection of patients is a critical factor
in determining the outcomes of spinal surgery. Operations performed on
the indications of imaging findings are doomed to failure in proportion to
the extent that imaging findings do not correlate with pain. Despite this,
many surgeons continue to operate on “bulging disks” as if this is a
sufficient diagnostic criterion for the cause of pain, with predictable results
for their unfortunate patients.

The literature on the effectiveness of surgery for chronic low back pain
is explored in greater detail in Chapter 74. In essence, the contemporary
evidence shows that surgery offers the prospect of some degree of relief of
pain, greater on average than that offered by conservative therapies, but
absent from the modern literature are any data on success rates for
achieving complete relief of pain, or sufficient relief to restore function
and eliminate the need for further health care. The effectiveness of surgery
is contentious. Indeed, in the United Kingdom, the National Institute for
Health and Care Excellence has decreed that surgery for back pain should
be performed only in the context of a controlled trial.185 Disk stimulation
might be required for entry into such trials, but there is no justification for
it to be a part of routine practice.

Conclusion

Patients with chronic low back pain wants their pain to be relieved
completely.97 Against this standard, the literature reflects the parlous state
of medical science for the treatment of chronic low back pain. Treatments
and interventions for which there was enthusiasm in the past have proved
not to be real answers. However, there are some treatments that do provide
satisfactory outcomes, and those options can be considered as general and
specific.

General measures are available for practitioners who cannot apply
specific, targeted interventions (or refer patients for them) and for those
patients who for any reason will not undergo specific, targeted treatment.
General treatment options vary greatly in their effectiveness. Those used more commonly include drugs, physical modalities, exercises, singular needle treatments, and “multidisciplinary biopsychosocial rehabilitation.”

No drugs eliminate chronic low back pain. Analgesics are at best palliative and might be used for maintenance care. It is questionable whether NSAIDs should be used. They provide benefits only marginally greater than those of a placebo, but they carry risks of side effects and complications that cannot be ignored. Opioids also offer minimal benefits greater than those of placebo, and side effects are common. By trial and error, a practitioner might find patients who can tolerate side effects and for whom opioids provide a satisfactory level of relief. Unfortunately, care has to be taken to avoid the problem of tolerance, let alone the ever-growing problem of diversion. Duloxetine may prove to be a viable alternative.

Physical modalities offer temporary relief, especially of the muscular stiffness that often accompanies chronic low back pain. Massage is more effective than physiotherapy, manual therapy, exercise, acupuncture, or TENS for relief in the short term. Ultrasound treatment and TENS are no more effective than sham therapy, and low-level laser therapy is only slightly better than sham laser therapy. There is little published evidence for interferential, shortwave diathermy, or taping. Lumbar supports confer no benefit.

Contemporary guidelines advocate exercise as preferred management for chronic low back pain. The effectiveness of exercise, however, is only palliative. Massage might be employed for respite relief. Psychological therapy might help patients for the stress that they suffer and might be used for this purpose, but in that event, the indication for referral is stress not pain.

“Multidisciplinary biopsychosocial rehabilitation” has been proven both inappropriate and ineffective for relief of chronic low back pain. It is inappropriate because the main beliefs on which it was founded have been proven false. The belief that a cause cannot be found in over 80% of patients with chronic low back pain has been shown clearly to be false. The belief that chronic pain becomes permanent and intractable, and a disease in its own right, has also been shown to be false. Otherwise, no
studies have produced data that show that “multidisciplinary biopsychosocial rehabilitation” provides any clinically significant benefit. No general treatment has been proven, on a regular basis, to abolish pain or reduce it to tolerable levels, restore function, and eliminate the need for further health care. At best, various general therapies might reduce pain by a modest or small degree and improve function slightly, but this amounts to palliative care.

The patient may well have associated problems in other domains: the psychological and social phenomena that may coexist with chronic low back pain, but those are secondary problems that may resolve or be greatly diminished if the pain is eliminated. Caring practitioners will address, or have addressed, the psychological and social concomitants of chronic pain if they impact on the patient sufficiently to warrant specific treatment, but doing so is not a surrogate for treating the pain.

Special investigations can be undertaken to determine the cause or source of pain in a large proportion of patients. Establishing a definitive diagnosis can rationalize management, by preventing an aimless and futile pursuit of a cure, and it may, but does not necessarily, lead to a successful specific treatment.

For investigations to be clinically useful, they need to be conducted rationally and in a valid manner. Even in the published literature, this has not always been the case. Unknown is the extent to which investigations in conventional practice are conducted in a valid manner. Failure to do so compromises the outcomes of subsequent treatment and tarnishes the reputation of the investigation and the associated treatment.

Although clinics might offer diagnostic blocks, they do not necessarily perform them according to established guidelines. Diagnostic blocks involve more than just placing a needle and injecting a small volume of local anesthetic. Patients need to be assessed and informed of the purpose of the procedure and the protocol to be followed. That protocol needs to be rigorous and disciplined, for which reason detailed guidelines have been published.\textsuperscript{89,94}

MRI serves two purposes. It can provide “clearance” of serious causes of back pain, and with reasonable confidence, it can identify many cases of discogenic pain. Disk stimulation can be used to establish a diagnosis of
discogenic pain but is not indicated for routine practice. It can be reserved for special instances, such as when a particular disk needs to be targeted for specific therapy.

However, no treatment for discogenic pain has yet been properly validated. Intradiscal therapies are at best experimental. Ablative treatments have not proved successful. Intradiscal injection of biologic agents is still being explored. Surgery might be entertained, but surgery carries no guarantee of success.

Lumbar zygapophysial joint pain can be diagnosed using controlled medial branch blocks. These are simple procedures and pose little or no hazard when performed competently. The problem, however, is that lumbar zygapophysial joint pain is not common, especially in younger patients. Consequently, it is appropriate to start with screening blocks, in order to identify the majority of patients who are going to have negative responses. If screening blocks are negative, no further pursuit of zygapophysial joint pain is indicated. If the blocks are positive, additional blocks will need to be performed to refine the diagnosis and confirm it. Patients who prove positive to controlled blocks can be treated with lumbar thermal RFN.

If performed meticulously, in correctly selected patients, lumbar thermal RFN is the one treatment that has been shown to be capable of providing complete relief of pain, accompanied by restoration of function, and elimination of further health care. If it is to be successful, it must be thermal RFN not “pulsed radiofrequency.” A useful precaution for any referral to a clinic offering radiofrequency treatment is to ask for the guidelines that the clinic follows, the information it gives to its patients, the diagnostic strategies and the assessment instruments that it uses, and the details of the RFN procedure(s) it provides. Such documents provide a prima facie appraisal of the integrity of the clinic.

Sacroiliac joint pain can be investigated using intra-articular diagnostic blocks. Posterior sacroiliac ligament pain can be investigated using sacral lateral branch blocks. In both instances, a single block will rule out the condition if the response is negative. If the block is positive, and confirmed by controls, the patient becomes a potential candidate for treatment. Sacroiliac joint pain could be treated with intra-articular
steroids. Sacroiliac ligament pain could be treated with sacral lateral branch RFN. In both instances, whether or not it is worthwhile to pursue a 50% chance of getting 50% relief for 6 months or so is matter for discussion between the physician, the patient, and those who shall pay for the treatment. More rigorous studies could either refute these treatments or refine their disciplined application.

Many other “treatments” for chronic low back pain have not been addressed in this chapter because there is no evidence by which they can be evaluated. Yet, they are still practiced. In this regard, Dr. Archie Cochrane, the founder of evidence-based medicine, once posed the rhetorical question, “I wonder how many things are done in medicine because they can be, rather than because they should be?”

Fusion of the lumbar spine was initially developed to treat tuberculosis of the spine and to stabilize spinal deformities.\(^1\)–\(^3\) Later, it was used to treat the instability of spondylolisthesis and to prevent iatrogenic instability after disk excision for disk herniation. In due course, fusion was applied to treat chronic low back pain.

The procedures commonly used in the treatment of back pain are summarized in Figure 74.1. The procedures differ according to the direction of approach: whether the spine is fused or not, whether disks are excised or not, and if a bone graft or instruments or both are used to achieve fusion. Other, more avant-garde techniques include minimally invasive approaches through the psoas muscle.\(^4\)

**FIGURE 74.1** A classification of types of surgery used for low back pain.

Posterolateral fusions were originally performed using only a bone graft. They were later supplemented by pedicle screws and plates when it was shown that instrumentation improved fusion rates. Likewise, posterior interbody fusions are now supplemented by pedicle screws in order to enhance arthrodesis. Anterior interbody fusions are classically performed using a bone dowel, but some surgeons add screws and plates or an
interbody cage to promote bone union.

**Rationale**

It is difficult to find in the literature an explicit, stated rationale for fusion in the treatment of low back pain. Implicitly, the earliest rationale was that because back pain was aggravated by movement of the lumbar spine, instability must be causing the pain, and, therefore, stabilizing the spine should relieve the pain. According to this rationale, a specific diagnosis was not required; persistent pain was the sole indication for surgery. Some surgeons applied nominal diagnostic rubrics, such as spondylosis or degenerative disk disease, despite these conditions being no more than normal age changes, a paradox that some surgeons acknowledge.

Later, some surgeons proposed that the intervertebral disk was the source of pain and adopted discography as the diagnostic test. Painful disks could be protected from aggravation by posterolateral fusion, or the disk could be excised and replaced by a bone graft.

A contentious indication for fusion is spondylolisthesis. This condition is an attractive target for surgery because it constitutes a deformity and has been reputed to be unstable, both of which can be rectified by surgery. However, research has shown that spondylolisthesis is commonly asymptomatic, such that its presence on radiographs has no statistically significant or clinically significant association with back pain. Furthermore, studies have shown no detectable instability in spondylolisthesis. Other studies have found evidence of abnormal motion and paradoxical motion in patients with spondylolisthesis, but at the segment above, not at the affected segment.

Spondylolisthesis remains an indication for surgery in patients with radicular pain or radiculopathy, when it can be shown that the deformity is causing nerve root compression. In that event, surgery is remarkably successful at relieving radicular pain. In patients with concurrent back pain, surgery is less often effective and, to a lesser degree, for the relief of back pain.

A literature review summarized the success rates of surgery for spondylolisthesis as reported in 34 original studies. For posterior fusion
alone, the success rates ranged between 37.5% and 98%, with an average of 74.8%. For anterior fusion, the success rates ranged between 80% and 95%. These data, however, were based on irregular and sometimes ill-defined criteria for clinical success. Some studies measured success in terms of patients achieving complete relief of symptoms, whereas others reported only the proportion of patients achieving some degree of improvement. Few studies, however, reported the degree of impairment before surgery and rarely have outcomes been corroborated by quantitative measures of pain, disability, return to work, and use of other health care.

Better data are available from randomized controlled trials. Surgery for spondylolisthesis is patently more effective than conservative therapy, but surgery is neither universally nor completely effective. Only 56% of patients rate themselves as “much better,” whereas 11% consider themselves unchanged and consider their condition to be worse. Surgery is, therefore, an imperfect solution for spondylolisthesis. The implication is that fusion does not effectively target the cause of back pain in spondylolisthesis.

**Effectiveness**

Pivotal to the use of fusion for low back pain is the evidence for its effectiveness and efficacy. This evidence should be as much of interest to physicians who might refer patients for surgery as it is to surgeons who might perform the surgery. That evidence has evolved. Three epochs can be described, according to whether studies were performed before, during, or after the advent of the principles and demands of evidence-based medicine (EBM), which occurred around the turn of the 20th century.

**BEFORE EVIDENCE-BASED MEDICINE**

Before the advent of EBM, surgeons reported good outcomes from fusion in the treatment of chronic low back pain. These reports created the reputation of surgery of being a decisive option for patients for whom conservative therapy had failed to provide relief.

However, studies during that epoch used methods that nowadays would not be held in high regard. These include the following:
• Surgeons evaluating their own outcomes, as opposed to having an independent, third party assessing outcomes
• Reporting qualitative outcomes, such as “excellent” or “very good” results, without supporting quantitative data
• Not providing baseline data
• Reporting outcomes without stratifying for different presenting conditions or symptoms
• Not using validated instruments for outcome measures
• Not reporting on all variables of interest, such as pain, disability or function, and use of other health care for back pain

For example, the success rates reported during this epoch were summarized in terms such as “61% excellent and 31% good outcomes,” “88% excellent or good outcomes,” and “100% satisfactory outcomes” for posterior interbody fusion and “89% relieved,” “95% clinically favorable,” and “74% satisfactory outcomes” for anterior lumbar interbody fusion. For patients with persistent, disabling pain, or their treating physicians, such numbers are appealing.

Table 74.1 lists the outcomes reported by various studies for anterior lumbar interbody fusion in patients diagnosed by discography as having discogenic pain. Although the success rates are more modest than those of the earlier literature, many are still attractive. One in five patients, or better, could expect to achieve complete relief of their back pain.

**ADVENT OF EVIDENCE-BASED MEDICINE**

At the turn of the 20th century, the precepts, principles, and demands of EBM were increasingly applied to studies in pain medicine and were applied to studies of surgery for back pain. This encompassed conducting randomized controlled trials and prospectively using multiple, validated outcome measures. The first target was conventional fusion for chronic low back pain.

In nearly rapid succession, three randomized controlled trials were conducted in which spinal fusion was compared with conservative care. In the first trial,²⁸ surgeons were allowed to perform their procedure of choice, which encompassed anterior lumbar interbody fusion, posterior lumbar interbody fusion, and posterolateral fusion with or without pedicle screws. (A companion report showed that outcomes were not significantly different between these various options.²⁹) In the second study,³⁰ all patients were treated with posterolateral fusion with pedicle screw fixation. In the third study,³¹ surgeons were allowed to use their procedure of choice, but the type of surgery used for each patient was not reported.

In the first study, conservative therapy consisted of physical therapy supplemented with other forms of treatment such as information and education, transcutaneous electrical nerves stimulation, acupuncture, injections, cognitive and functional training, and coping strategies.²⁸ That
study found significant differences in favor of surgery (Fig. 74.2). Nonsurgical care provided no change in mean scores for back pain, whereas fusion provided a 50% decrease in pain over 6 to 12 months. By 24 months, this improvement had attenuated to a 30% reduction in pain but was still significantly greater than that achieved by nonsurgical care.

![Graphic summaries of the outcomes of three controlled trials of fusion for low back pain. The trials used different outcome instruments. In the trials of Fritzell et al. and of Brox et al., lower scores indicate improvement. In the trial of Fairbank et al., higher scores indicate improvement.](image)

These outcomes were not corroborated by the second and third trials. In the second trial, mean scores for pain and disability improved marginally, but to the same extent, in patients treated by fusion as in patients treated with behavioral therapy plus exercises (see Fig. 74.2). Similarly, in the third study, scores for pain and function improved slightly, but to the same degree, in patients treated by fusion or in a rehabilitation program (see Fig. 74.2).

These studies became the standing evidence base for spinal fusion. Whereas one study showed significant superiority over conservative therapy, two others did not. Notwithstanding this dissonance, none of the
three studies reproduced the high success rates claimed for surgery in the literature of the past.

The second target of EBM was total disc replacement, alias disc arthroplasty. Although there had been a few earlier studies, the introduction of disc arthroplasty into the United States was subjected to rigorous standards, particularly by the U.S. Food and Drug Administration. Consequently, all of the literature was of high quality methodologically.

Disc arthroplasty was heralded as offering the potential of restoring joint mechanics, and thereby reducing pain and improving function, and preserving motion would lessen adverse loading and changes in range of motion at adjacent segments. Preliminary results from descriptive studies were good in some studies and yielded outcomes comparable to those of fusion for low back pain. Recovery time seemed to be less than for fusion.

In the early controlled trials, Blumenthal et al. compared disc arthroplasty, using a particular device, with a form of anterior lumbar interbody fusion, and Zigler et al. compared arthroplasty, using different device, with circumferential fusion. These studies provide outcome data not only on disc arthroplasty but also on the conventional fusion procedures with which it was compared.

Although the Blumenthal et al. study found disc arthroplasty to be noninferior to fusion, the outcomes of both arthroplasty and anterior lumbar interbody fusion were modest. Mean pain scores improved from 70 to 30, which exceeds the minimal clinically important change (MCIC) of 20 points; and Oswestry Disability Index (ODI) improved from 50 to 25, but 64% of patients treated by surgery still took opioids, and although 64% returned to work, 53% had been working before surgery. These latter figures do not attest to any substantial decrease in the burden of illness; surgery did not seem to alter the patients’ use of other health care or restore their ability to work. The proportion of patients who were completely relieved of pain was not reported. One reviewer recommended that these data argue for caution by patients and surgeons.

The Zigler et al. study found disc arthroplasty to be slightly more effective, on average, than circumferential fusion, but it, too, reported only modest results for both surgical treatments. After arthroplasty, ODI
improved from 63.4 at inception to 34.5 at 24 months but with a standard deviation of 24.8. This latter figure indicates that a large proportion of patients were still substantially disabled. Pain scores improved from just above 70 to 37 but with a standard deviation of 30.1. This study judged outcomes as a success if the ODI improved by 15 points, which is the MCIC required by the U.S. Food and Drug Administration. On this basis, a 72% success rate was claimed. But this misrepresents MCIC. The MCIC does not amount to the least value at which success occurs. It is no more than the least value that patients equate with a detectable level of improvement. The study did not report the proportion of patients rendered substantially better or free of pain. Of patients considered to have a successful outcome, 39% still took opioids, which seems contradictory. Reviewers concluded that this study lacked sufficient detail for the interested reader to perform an independent evaluation of the data to confirm or reject the authors’ conclusions.

These results from controlled trials of arthroplasty are starkly inferior to those of a well-reported descriptive study. In the study of Bertagnoli et al., at 2 years, 32% of patients had no back pain, and a further 59% had only occasional pain; 90% took no opioids; only 41% required nonsteroidal anti-inflammatory drugs (NSAIDs) for pain. The latter figures are the sorts of outcomes that referring physicians and their patients would like to expect from surgery for back pain. Opinion leaders, however, put more stock in data from controlled trials rather than observational studies, no matter how well reported the latter might be.

**SINCE EVIDENCE-BASED MEDICINE**

The epoch since the advent of EBM is characterized by fewer pivotal studies but a continuing, steady stream of reviews, systematic or otherwise. The themes that have emerged for total disc replacement have differed from those for fusion.

On total disc replacement, reviews published in 2006 concluded that total disc replacement was not inferior to fusion, but the difference in benefit was less than 15 points for disability, and at 24 months, 64% of patients were still taking opioids after disc replacement, and 80% after fusion. In 2012, a Cochrane review remarked that the outcomes between
disc replacement and fusion differed by only 5/100 for pain, and 4/100 for disability.\textsuperscript{42} A review in 2013 reiterated this small difference in outcomes and added that the success rates were 53\% for disc replacement and 41\% for fusion, with success being defined as achieving the MCIC.\textsuperscript{43} A Cochrane review in 2013 concluded that such differences in outcome were not clinically relevant.\textsuperscript{44}

More recent reviews have included more recent studies and newer devices, but their conclusions remain unchanged. Outcomes from disc replacement are minimally better than those of fusion.\textsuperscript{45,46} For these reasons, in the United Kingdom, it has been recommended that, for the treatment of low back pain, disc replacement be offered only in the context of a randomized controlled trial.\textsuperscript{47} Despite an increasing literature, the Italian review concluded that disc arthroplasty could be a reliable option in the treatment of degenerative disk disease in years to come.\textsuperscript{47}

With respect to fusion, conventional reviews have relied essentially on the three controlled trials of surgery and nonoperative therapy (see Fig. 74.2). One published in 2006 concluded that there was insufficient evidence on the effectiveness of surgery.\textsuperscript{48} In 2015, a review concluded that there was no difference between surgery and nonoperative care for improving disability.\textsuperscript{49} A dissenting review concluded that the pooled data showed that fusion had moderate treatment effects, better than those of nonsurgical care, at 12 months, 24 months, and longer than 48 months after treatment.\textsuperscript{50} Another review acknowledged that the outcomes of fusion were comparable with those of intensive rehabilitation but commented that such rehabilitation programs might not always be available and that fusion constituted a valid alternative.\textsuperscript{51} Yet, another review concluded that because outcomes were not different, fusion and nonoperative care both remain acceptable methods of care for intractable back pain.\textsuperscript{52}

Whereas these reviews focused on the comparison of fusion with nonoperative care, another review opened a different front. It harvested data from trials not limited to those comparing fusion with nonoperative care and focused on the magnitude of outcomes from fusion. On the grounds that fusion offered an average improvement of 37/100 for pain, and 27/100 for disability, it advocated that fusion should be considered a
valid treatment for back pain.\textsuperscript{53} The implied argument seems to be that because surgery offers improvements greater than those reported for any conservative therapy, it should constitute a valid treatment. However, for a major undertaking such as surgery, these average improvements are small and do not amount to success rates. The data from controlled trials show that in terms of success rates, fusion has a success rate of 41\% for achieving just an MCIC.\textsuperscript{43} In an uncontrolled study, only 16\% of patients with workers compensation achieved MCIC, and only 36\% of patients without claims did so.\textsuperscript{54}

**Discussion**

Over the last 40 years, the literature on surgery for low back pain has evolved. More rigorous standards have been applied both to the design of studies and to how they are reported. The language has changed. Early studies proclaimed impressive success rates. These have not been corroborated by modern controlled trials. When compared with nonoperative care or with other surgical procedures, the outcomes of surgery are modest. Success rates are no longer defined in terms of the proportions of patients rendered free of pain or no longer requiring health care. That language has been replaced by a new definition of success: the proportion achieving just an MCIC.

It is not evident from the literature whether this change is due to a decrease in the effectiveness of surgery or to an exaggeration of outcomes in earlier studies. Curious in that regard is that surgeons who earlier proclaimed impressive outcomes from anterior lumbar interbody fusion\textsuperscript{19} became advocates for disc replacement\textsuperscript{34} but were unable to reproduce their own previously reported success rates. It would seem that tighter scrutiny of outcomes makes a difference to success rates.

For the physician and patient who are seeking a solution for intractable back pain, the literature and evidence on surgery is less attractive than it used to be. If there is a prospect of achieving complete relief of pain, or reducing pain to a tolerable level, only occasional studies speak of it, most do not. If surgery is to restore its former reputation, its former successes need to be reestablished under modern conditions of reporting and
reestablished by multiple studies. Success defined as achieving only an MCIC will not be marketable. Nor will surgery be marketable if some patients make small gains, whereas other patients suffer the consequences of failed surgery (see Chapter 75).

References

Failed back surgery (FBS) is a nonspecific term that implies the outcome of spine surgery did not meet the expectations established before surgery of the patient and the surgeon. It does not mean that the patient failed to get total pain relief or return to full function. Such expectations are not reliably attainable. It might be argued that when the patient is not satisfied, but the surgeon feels the outcome meets expectations, it is a failure of communication rather than the surgery.

There can be wide discrepancies between patient and surgeon with regard to expectations of outcome with patients usually having higher expectations than their surgeon. Factors associated with higher patient expectations of outcome include younger age, not widowed, prior chiropractic care, poorer function as measured by Oswestry Disability Index (ODI), and worse mental health score.

A surgeon’s expectations for outcome in a specific patient should be based on published medical evidence, the nature of the structural problem, the number and types of prior surgeries, the psychological health of the patient, and the skills and experience of the surgeon. When the surgeon communicates reasonable expectations, there is greater chance the patient will be satisfied if those expectations are met.

There are almost too many options for the treatment of patients with FBS. It seems logical that the best outcome will occur when treatment is matched to each specific patient’s structural, neuropathic, or psychological cause. This often requires a multidisciplinary approach. To be prepared to treat these challenging patients, physicians should know the reasons spine surgery might fail, the structural causes of FBS, and the best treatment options for each situation.
Causes of Failed Back Surgery

It has been said that the best surgical outcome occurs when the right surgeon does the right surgery for the right problem on the right patient at the right time. There is a significant risk for FBS when any of these rights goes wrong.

There are several studies that have looked at the structural and neuropathic causes of FBS. Clinically, it is most important to determine the structural cause for the pain whenever possible. If a structural etiology is identified, it is useful to decide whether the cause is a residual, recurrent, or new problem. Residual or recurrent structural pathology may be due to inadequate evaluation before surgery or mismatch of the surgery needed versus the surgery performed, unrecognized complications, or technical failure. New structural problems are those that developed after surgery, which might or might not be a consequence of the surgery itself.

Another model is based on the time course of the residual, recurrent, or new pain after surgery. Patients who never improve or who deteriorate in the first 4 weeks or so after surgery are likely to have residual pathology, a complication, or a technical failure. Most of these patients will still be under the care of their surgeon rather than a pain medicine specialist.

Patients who get somewhat better initially but then deteriorate may have developed instability, instrumentation failure, recurrent disk herniation, or delayed infection. Those who get better but then deteriorate after 6 months or so might have new pathology at the same or adjacent segment, which can include for example facet or sacroiliac joint (SIJ) pain or pseudarthrosis.

MISMATCH: SURGERY NEEDED VERSUS SURGERY PERFORMED (“WRONG SURGERY”)

When a surgeon chooses an operation that is not appropriate for the structural problem, the operation is likely to fail. It might prove useful, in this model, to appreciate the distinction between surgery for leg pain as opposed to surgery for back pain. True radicular (rather than referred) leg pain is usually caused by neural compression. Surgeries aimed at improving leg pain include decompression of involved neural structures in
the neural foramen, central canal, or by a disk herniation. Assuming facet and SIJ source of pain have been excluded, surgeries directed toward improving axial low back pain (LBP) include fusion for pain arising from a disk (discogenic pain) or instability, for example. It follows that if a patient had predominantly axial LBP but had a decompression or discectomy without fusion, it might not have been the “right surgery” for the clinical problem, and there is a high likelihood of poor result. In other words, there was a mismatch between the clinical problem and the surgery. The surgeon performed a “leg pain operation” for LBP.

A second type of mismatch occurs when the surgery does not address all the patient’s pathology. For example, there are patients who have pathology such as disk degeneration, disk herniations, spinal stenosis, or combinations at multiple motion segments. The surgeon might have elected to operate on only the worst segment or segments, thereby leaving the patient with residual problems at the adjacent segments. This type of patient might have required multilevel surgery or, if the number of levels is excessive, perhaps no surgery at all.

Another example is the patient with both central and foraminal stenosis. The surgeon achieves decompression of the central canal but does not achieve adequate decompression of the lateral canal. The patient may be left with leg pain due to remaining foraminal stenosis, which might incorrectly be thought to be neuropathic pain. Yet, another example is the patient with severe foraminal stenosis. A surgeon may decide to perform a limited decompression for fear of causing instability that might necessitate fusion. As a result, there is inadequate decompression and the patient does not get better. The patient needed decompression and fusion but only had decompression. This is another mismatch between the surgery needed and the surgery performed.

Another example of a mismatch between the surgery needed and the surgery performed occurs when the surgeon fails to fully consider the effect of surgery on the motion segment. For example, consider a patient with spinal stenosis and very slight spondylolisthesis and spinal stenosis who has leg pain. If the surgeon chooses decompression without fusion, many times, the spondylolisthesis progresses and the patient develops progressive LBP.
Finally, and not to be minimized, some spinal pathology is not treatable by surgery. An example would be four or five levels of painful disks.

**INCOMPLETE EVALUATION AND/OR DIAGNOSIS**

(“RESIDUAL PATHOLOGY”)

If a patient has not been fully evaluated, it is more likely that the surgery will fail. Surgery performed after an incomplete evaluation might leave significant structural pathology unattended. Incomplete evaluation is often due to over reliance on imaging studies, particularly magnetic resonance imaging (MRI), without fully appreciating the information from the history and examination. Many spine specialists use confirmatory diagnostic spinal injections to complement the other information. Plain radiographs done standing with flexion and extension views can be very valuable to disclose spondylolisthesis or deformity that was not seen on supine MRI. Pain relief after transforaminal epidural injection would suggest any foraminal stenosis seen on MRI is in fact the pain generator. Discography had been used frequently but is rarely used now due to the possibility of creating long-term degeneration of otherwise normal disks coupled with the great improvements in the quality of MRI scans.

Psychological health is one of the most important variables with respect to the outcome of surgery. Therefore, psychological evaluation is especially important for patients (“right patient”) with long-standing pain and impairment or when the surgeon has any inkling that there might be a significant psychological problem. Neither surgeons nor physiatrists perform well in identifying patients with psychological illness compared to objective psychological testing and so referral is often in the best interests of all.

Most psychological illness in the postoperative patient was present before surgery but not considered or was underestimated. Many patients with long-standing chronic LBP have some degree of psychological illness, some mild but some more severe, which might have altered surgery decision making. The most common problems described are depression, anxiety disorder, and substance use disorder. Although these disorders may not be a contraindication for surgery, treatment before surgery and psychological follow-up afterward might prove useful to
increase the chances of a good result. In addition to these familiar illnesses, there is growing evidence that a patient’s coping abilities, fear and fear-avoidance behavior, and history of sexual or physical abuse may play important roles in continuing pain, impairment, and disability and contributing to a poor outcome.16–23

**COMPLICATIONS**

Many of the complications of spinal surgery occur early in the postoperative period and should have been recognized by the surgeon. Infection usually occurs early but occasionally does not appear for weeks or months. Misplaced pedicle screws can cause new leg pain, usually in a single dermatome, and is often present immediately after surgery but can occur slightly later. Neural injury during surgery has similar symptoms and appears right after surgery. Complications that occur or are discovered later include facet or pedicle fractures; pedicle screw misplacement; and bone graft collapse, resorption, or dislocation (after interbody fusion). In addition, surgery might have been performed at the wrong level.

Pedicle screws can cause LBP by any of several mechanisms. There can be pain over the screws, sometimes attributed to chronic irritation of overlying soft tissues and bursa formation. This usually is seen months after surgery. Pedicle screw misplacement can cause leg pain if a screw breaches a pedicle and irritates or injures a nerve. This can be mistaken for neural injury due to surgical trauma. Therefore, if there is leg pain in a single dermatome, it is necessary to obtain computed tomography (CT) scan to see if there has been even slight breach of the pedicle.

Pseudarthrosis is a failure of fusion. Some patients with nonunions have pain, but others do not. Therefore, one cannot assume that the nonunion is the cause of the pain. Plain radiographs are not reliable to show if a fusion is solid. However, if standing films with sagittal flexion and extension views show motion, it would indicate nonunion. The most useful test is a CT scan that includes reformatted curved coronal sections that are taken out to the tips of the transverse processes in addition to the usual sagittal and axial images.24,25 CT also allows visualization of the anterior column to look for lucency surrounding an interbody fusion device.

Some patients undergo surgery and then develop instability, defined as
greater than 3 mm translation on standing flexion/extension x-rays. It is not uncommon to see patients with very slight spondylolisthesis before surgery for disk herniation or spinal stenosis in whom no fusion was done because the slip was so slight. Then some months after surgery, the back pain worsens, and plain x-rays reveal progression of the slip.

TECHNICAL FAILURE
Even though the surgery was appropriate for the symptoms and pathology, the surgeon may not have accomplished the technical goals. Technical failure is usually apparent on good-quality imaging studies. Inadequate decompression of a foramen is not uncommon. There may be incomplete removal of a disk herniation, especially if it was a far lateral herniation. There may be misplacement of screws or incorrect connection of internal fixation.

RESIDUAL PATHOLOGY
Spinal Pathology
Residual pathology implies that surgery did not correct all the structural problems that had been causing pain. Problems such as pain arising from facet or SIJ might not have been recognized. There might have been pathology at other levels in addition to the operated segment.

Extraspinal Pathology
Residual pathology also includes extraspinal disorders that can mimic spinal problems. When an extraspinal disorder is the cause of pain, it might have been present prior to surgery and not recognized or occurred afterward. Some of the more common problems that can mimic motion segment spine pain are shown in Table 75.1 and include primary hip disorders, SIJ pain, greater trochanteric pain syndromes (GTPS), and peripheral nerve injury or entrapment.

Table 75.1 Differential Diagnosis of Some of the More Common Extraspinal Causes of Failed Back Surgery by Symptoms, Signs, Radiology, and Injections
Painful disorders of the hip region most often are independent of spinal pathology but, at times, can coexist, especially in older patients.\textsuperscript{30} This is a challenging problem because there is considerable overlap between their respective symptoms and signs. Brown et al.\textsuperscript{31} studied a referral population with leg pain to determine if there were signs or symptoms that might differentiate between osteoarthritis of the hip and a spinal disorder. The factors that were suggestive of primary hip pathology were the presence of a limp, groin pain, or limited internal rotation of the hip. Factors more suggestive of spinal stenosis were lateral thigh pain, buttock pain, and pain below the knee, particularly in the absence of groin pain. Weight-bearing radiographs of the hip can serve as an initial screening tool.

Disorders of the structures near the hip that can mimic spine pain include GTPS, subtle sacral fractures, gluteal tendonitis, hamstring syndrome, ischial bursitis, or tendonitis. Patients with GTPS typically complain of pain in the proximal lateral thigh, often with radiation to the distal thigh and occasionally below the knee.\textsuperscript{26,29} Pain is usually increased by lying on the affected side, climbing stairs, and transition from sitting to standing. Pain may arise from the bursa itself or from the gluteal medius and minimus.\textsuperscript{32} On exam, there is tenderness over the greater trochanter, but in the variants of GTPS, there may be tenderness at the local muscle insertion sites. Diagnosis is confirmed by relief of pain with the injection

of local anesthetic into the bursa and nearby muscles.

Peripheral nerve trauma or entrapment can mimic radiculopathy.\textsuperscript{27} In the patient with FBS, the most relevant problems are lateral femoral cutaneous nerve entrapment or injury (meralgia paresthetica), which presents with pain in the lateral or anterolateral thigh, peroneal nerve entrapment, and sciatic nerve entrapment.\textsuperscript{27,28} With entrapments, pain will be in the distribution of the peripheral nerve involved, not in a true lumbar dermatome. There may be a positive Tinel sign over the area of pathology. Diagnosis can often be confirmed by nerve conduction studies, and there will be temporary relief of pain after injection with local anesthetic in the area of presumed entrapment.

RECURRENT PATHOLOGY
Recurrent pathology can recur even after perfect surgery. Disk herniations recur in up to 15\% of patients after discectomy. Foraminal stenosis can recur after if there is progressive degeneration of the same motion segment.

NEW PATHOLOGY
Pain after prior spine surgery may be totally unrelated to the index surgery. The usual structural causes of LBP can occur after an index surgery.

Structural Etiologies of Failed Back Surgery
Despite the many reasons for FBS, there are a limited number of structural etiologies for the residual or recurrent pain. The studies that looked at the most common structural causes of FBS had very similar findings (Table 75.2).\textsuperscript{4–7} The most common structural causes of pain after surgery are foraminal stenosis, recurrent or residual disk herniation, one or more painful disks, facet joints (FJs), SIJ, and neuropathic pain.

There are four studies that reported on the causes of FBS in individual series. Unfortunately, one is from 1981 and two from 2002. The most recent study was in 2010 but only looked at patients with prior fusion. It does not appear that there have been more recent descriptions despite FBS being fairly common. Because of the age of the data, some considerations are necessary. There has been much greater recognition of neuropathic pain and pain arising from the SIJ pain and FJs. Surgical techniques have improved. There is greater recognition of foraminal stenosis. It is too early to know all the causes in patients who have undergone total disk replacement. That said, the data we have is what we have to work with, coupled with experience.

Burton et al.\textsuperscript{4} in 1981 reported an analysis of several hundred patients with FBS. About 58% had foraminal stenosis, 7% to 14% had central canal stenosis, 12% to 16% had recurrent (or residual) disk herniations, 6% to 16% had arachnoiditis, and 6% to 8% had epidural fibrosis. Other less common causes in their series included neuropathic pain, chronic mechanical pain, painful disk above a fusion, pseudarthrosis, foreign body, and surgery performed at the wrong level. They were unable to establish a diagnosis in less than 5% of their patients, even though their patients were evaluated early in the CT scan era and well before MRI scans. They did use discography. In 1981, surgeons were less aware of foraminal stenosis and discogenic pain.

In a retrospective review of 181 patients with FBS seen at a tertiary care spine center, Waguespack et al. could make a diagnosis in 94% of patients. Slipman et al. also could make a diagnosis in about 89% of patients. Some patients had more than one primary diagnosis. DePalma et al. looked at the etiology of pain in patients who had lumbar fusions. The details are shown in Table 75.2

In the following section, I have used functional definitions of structural abnormalities that are a composite of those proposed by the North American Spine Society. The differential diagnoses of some of the more common causes of FBS along with some helpful symptoms, signs, radiologic findings, and response to injections are shown in Table 75.3.

**TABLE 75.3 Differential Diagnosis of Common Causes of Failed Back Surgery by Symptoms, Signs, Radiology, and Injections**

HNP, herniated nucleus pulposus; LBP, low back pain; MRI, magnetic resonance imaging; SI, sacroiliac; +/-, may be helpful.

**FORAMINAL STENOSIS**

Foraminal stenosis was found in 15% and 35% of FBS patients in the studies of Waguespack et al. and Slipman et al., half of what was seen 25
years ago. The lower prevalence may be due to increased awareness of the problem, improved imaging studies, and/or better understanding of the need for meticulous decompression. Patients with foraminal stenosis have pain that is predominantly in the leg or buttock region, often in the distribution of a single dermatome. Pain is usually worsened by standing and walking and relieved by sitting. MRI or CT scan shows narrowing of the canal at the index level or an adjacent segment.

There are no data regarding the utility of selective nerve root blocks in FBS. There are suggestions that when performed with excellent technique, they can provide some information, especially perhaps when there is no relief, which might suggest the targeted root was not the cause of pain. According to one systematic review, there is good evidence that lumbar selective nerve root blocks can aid with the identification of one or more symptomatic roots. There is moderate evidence that identifying or excluding a root as cause of pain improves surgical outcome. Other systematic reviews did not find the evidence convincing.

**PAINFUL DISK (DISCOGENIC PAIN)**

Pain that arises from within a disk is often referred to as discogenic pain. One or more painful disks was found to be the cause of FBS in 25% to 30% of patients. Painful disks can occur at the level of prior surgery, at an adjacent segment, or rarely at the index level despite prior posterolateral fusion. When there is a residual painful disk at the index surgical level, it is likely that it was not treated adequately by performing a fusion, especially an interbody fusion. When there is a painful disk at an adjacent segment, it was either present prior to surgery and not addressed or the disk degenerated after surgery. Risk factors for adjacent segment degeneration include body mass index >25 kg/m, preoperative disk degeneration, and superior FJ violation during surgery.

Although there is no totally consistent symptom complex for discogenic LBP, especially after surgery, the diagnosis is more likely when there is dominant midline LBP that might radiate to the left and right of the midline, the gluteal regions, and often to the leg in a nondermatomal fashion. Pain is usually worse sitting and during transition from sitting to standing. It may improve with standing or walking. Physical examination
is not specific. There may be decreased flexion in standing due to pain. There may be tenderness over the spinous processes but not over the FJs. When the diagnosis of discogenic pain is suggested by history and examination, MRI shows a single degenerated disk, and other potential causes of chronic LBP have been excluded, it is likely that the diagnosis is correct.

**DISK HERNIATION**

Recurrent or residual disk herniation was seen in 7% to 12% of patients with FBS. There are two common presentations of pain from a disk herniation: radicular and axial. The topography of the pain is primarily due to the location of the herniation. A posterolateral herniation is more likely to compress or irritate a nerve root and therefore present with predominant leg pain. A midline herniation, unless very large, does not compress neural elements and presents with predominant LBP. A disk that is degenerated and herniated can cause both leg pain and LBP. In the presence of epidural or perineural fibrosis, a disk herniation may cause more leg pain than expected than if there were no fibrosis.

Diagnosis of recurrent or residual disk herniation is inferred from the history and physical examination and confirmed by MRI.

**FACET JOINT PAIN**

The FJs were the cause of pain in 3% to 18% of patients with FBS. FJ injury may occur during surgery because of progressive degeneration of the motion segment at the surgical level or degeneration due to the mechanical stresses of fusion at an adjacent segment.

There has been increased interest in the role of FJs since the introduction of total disk arthroplasty (TDR). Van Ooij et al. reported that FJ arthrosis was responsible for clinical failure in 11 of 27 patients. Shim et al. reported radiologic degradation of the facets in 32% to 36% of patients after TDR. There are no reports of definitively correlated symptoms and signs of FJ pain in patients with FBS. Based on best evidence and clinical expertise, it is reasonable to perform medial branch blocks on most FBS patients as part of the routine evaluation when back pain (vs. leg pain) predominates.
unless there is another obvious cause for the problem. Features of the history that increase the likelihood of FJ pain being present are age greater than 65 years, absence of midline pain, and improvement in pain by lying supine. Other features are pain is not worse with forward flexion including sitting, not worse when rising from sitting to standing, and not worse with coughing. Features from the examination are tenderness to palpation over the FJs or transverse processes. The diagnosis of FJ pain is made when there is excellent relief of the target pain on two occasions after medial branch block.

**SACROILIAC JOINT PAIN**

There is consistent evidence that the SIJ can be a cause of pain in at least 2% to 3% in patients with FBS and may be as high as 42% in patients who have had fusion to the sacrum. The SIJ can become painful due to transfer of stress after fusion or might have been present before surgery but not recognized.

Again, there are no specific signs or symptoms specific for SIJ pain, but there are clues to the diagnosis. Virtually all patients have pain distal to the posterior iliac crest and lateral to the midline spine. Some patients will point directly over the SIJ when asked to show where the pain is centered. Pain is frequently referred to the groin, thigh, calf, and occasionally the foot—patterns that might otherwise suggest radiculopathy or even hip joint pathology. Pain may increase with single-leg weight bearing. Most often, there is tenderness directly over the SIJ. Plain radiographs, MRI, and CT are not definitive. The confirmation of SIJ pain requires relief of the target pain after fluoroscopically guided local anesthetic SIJ injection.

**SPINAL STENOSIS AND AXIAL LOW BACK PAIN**

The classic symptom of central spinal stenosis is leg pain with walking (neurogenic claudication) or standing. In addition, many if not most patients with spinal stenosis also report LBP. Anecdotally and experientially, there are patients with spinal stenosis with predominant LBP, especially in the gluteal region. Pain is worse with standing or walking, and there is complete or near-complete relief of pain sitting. This symptom complex is quite the opposite of discogenic pain but similar to FJ
pain. Patients usually experience at least temporary relief of pain after epidural steroid injection and no relief after medial branch block, again just the opposite of FJ pain. The patients with FBS and predominant LBP might have spinal stenosis at the index level or an adjacent segment that developed after surgery or was not addressed at surgery.

**NEUROPATHIC PAIN**

Neuropathic pain is pain due to injury or physiologic dysfunction of the peripheral or central nervous system (CNS). Neuropathic pain was the predominant problem in 10% to 13% of FBS patients. It is likely that there is increased attention being paid to neuropathic pain as better treatments have become available.

There are several potential mechanisms for neuropathic pain after spine surgery. A nerve root could have been damaged prior to surgery due to either sudden injury (acute disk herniation) or prolonged compression from foraminal stenosis or disk herniation. In the latter two examples, radicular type pain continues despite technically successful surgery. Alternatively, a nerve could be damaged during the surgery itself, which is sometimes referred to as a battered nerve. There can be peripheral nerve injuries such as cluneal neuroma due to nerve injury at an iliac crest donor site. Meralgia paresthetica can also be seen.

Neural injury or dysfunction can be responsible for both amplification and persistence of pain. Neuropathic pain of spinal origin usually presents with a predominance of leg pain in one or two adjacent dermatomes or along the path of a peripheral nerve. In classic presentations, the pain is described as burning, dysesthetic, or electrical, but in neuropathic disorders after spine surgery, pain is more frequently described as aching and stabbing. Pain may be constant or intermittent. It is often precipitated or aggravated by simple activities because the damaged nerves are hyperexcitable and respond abnormally to even minor mechanical changes.

In pure and uncomplicated neuropathic pain, there is no evidence of nerve root compression on imaging studies. It is important to distinguish neuropathic pain from what I call neurogenic pain. Neurogenic pain implies that a nerve is being compressed or irritated rather than its being...
permanently damaged. To further complicate matters, some patients have both neuropathic pain plus ongoing neural compression (neurogenic), which is referred to as a mixed pain syndrome.

Neuropathic pain can also be due to physiologic dysfunction in the peripheral nervous system or CNS without obvious structural nerve damage. Because of prolonged or repeated chemical or mechanical damage to afferent nerves, these nociceptors may become sensitized and hyperexcitable (peripheral sensitization). There is lowering of their activation thresholds and subsequent increased responsiveness to all stimuli. In this physiologically altered setting, innocuous stimuli may be perceived as painful (alldynia), minimally noxious stimuli may be perceived as very painful (hyperalgesia), and there can be stimulus-independent pain as well.

A similar sensitization can develop in the CNS because of “constant bombardment” by painful afferent stimuli (central sensitization). In patients with persistent axial LBP (rather than the more typical neuropathic extremity pain) despite perfect surgery and no other explanation for pain, it has been proposed that the back pain represents central sensitization and neuropathic pain.50,51

**EPIDURAL FIBROSIS**

Epidural fibrosis has been reported to occur in 16% of patients with FBS when assessed by MRI and 83% when assessed by epiduroscopy.52 Some believe epidural fibrosis is a frequent cause of pain after back surgery, but others have found no relation between amount or location of scar and pain or disability.52–54 Most spine surgeons feel that most often fibrosis is an incidental finding that does not in and of itself causes pain but perhaps has the potential to make other problems such as radiculopathy due to disk herniation or spinal stenosis worse.53 That said, it is true that some patients with FBS and fibrosis do improve after lysis of adhesions, but this is not proof that the scar itself was the cause.55 Most authors feel that further research is necessary before epidural lysis becomes standard practice.

**DECONDITIONING**

Deconditioning has been considered to be at least partially responsible for
the persistent pain and pain-related impairment and disability in many patients with chronic LBP and FBS. I view three models for this so-called deconditioning syndrome. The pure physical deconditioning model holds that loss of muscle strength and endurance is responsible for reduced activity, impairment, and disability. The cognitive-behavioral model emphasizes the fear-avoidance paradigm, which holds that some patients with chronic LBP avoid activities out of pain-related catastrophic thinking and fear. They believe that attempts to increase their function will result in increased pain and progressive structural damage, and, as a result, they markedly curtail their activity. A third model is a combination of the two in which patients have both the maladaptive fear avoidance and true physical deconditioning. As a result of the fear-avoidant decreased activity, there is disuse (perhaps better termed underuse) with progressive loss of muscle strength and endurance.

In patients with chronic LBP and deconditioning, the paraspinal musculature is most affected. There is MRI, CT scan, and ultrasound evidence that after spine surgery, many patients have decreased cross-sectional area (CSA) of their lumbar muscles. Motosuneya et al. looked at the changes in muscle CSA after five different types of spine surgery and surprisingly found some loss of muscle strength even in those patients who had anterior spine surgery. They opined that rigid fixation and resultant protection of the paraspinal muscles was at least partly responsible.

There is consistent evidence that posterior spine surgery (and possibly anterior as well) can cause loss of muscle density, histologic changes, and probably decreased strength. There is a trend in the evidence that suggests a correlation between greater muscle changes and LBP after surgery. Nearly all investigators agree there is good evidence that exercise is effective in reducing impairment and disability, but the mechanisms are not straightforward. Most likely, the deconditioning syndrome has both physical and psychological components. There can be loss of muscle volume and strength from the surgery itself and disuse. There might be a psychological component due to fear avoidance.
It has been well documented and fully accepted that many patients with chronic LBP have a psychological condition.\textsuperscript{13,14} It is no wonder then that presurgical psychological testing can predict the outcome of spine surgery quite well.\textsuperscript{13,61} It is also of note that spine surgeons and other spine specialists do not do well in the identification of psychological distress.\textsuperscript{15} In patients with chronic LBP, the most common psychological illnesses are depression, anxiety disorder, and substance abuse disorder, and so, it is logical that many of these same factors are present in patients with sufficient structural abnormalities to potentially warrant surgery.\textsuperscript{14} Most often, it appears that these psychological illnesses develop because of the injury.\textsuperscript{62} Although rarely the only cause of pain, psychological factors can make pain and function worse.

Although preoperative depression correlates with postoperative symptoms, the literature suggests that the early psychological response is a very important predictor of longer term outcome.\textsuperscript{21,22} This might be particularly relevant to management of FBS and warrants special attention to depressive illness and fear avoidance. For example, Adogwa et al.\textsuperscript{63} showed that patient outcome for revision surgery for spinal stenosis, adjacent segment degeneration, and pseudoarthrosis correlated best with preoperative Zung Depression Scale score.

In a different very useful framework, the fear-avoidance model is important for patients with FBS. Preoperative fear avoidance does not appear to be a significant risk factor of FBS, but its early appearance after surgery appears to be predictive of eventual poor outcome.\textsuperscript{22,23,64}

Fear avoidance, in the postoperative setting, is the avoidance of movements or activities due to fears of ruining the surgery, causing more pain, and/or reinjury. Fear avoidance can lead to inactivity and then disuse and deconditioning, which might worsen any disability. In turn, increased pain and depressive mood disorder might follow.

Archer and associates\textsuperscript{22} prospectively studied fear avoidance and other psychological factors before and after spine surgery. In their series, fear avoidance 6 weeks after surgery was predictive of level of pain, physical health, and disability at 6 months. In addition, preoperative depression
predicted similar poor results.

Catastrophic thinking, again in this context, is an exaggerated negative interpretation of the meaning of the pain. Patients dwell on the most negative conceivable aspects and feel helpless and hopeless. Such thinking can be present in the postoperative period and appears to correlate to some degree with fear avoidance.

Yet, another model revolves around dysfunctional childhood and with what is now termed adverse childhood events. Such patients might be at higher risk for chronic pain, impairment, disability, and FBS. Identified disruptions include childhood physical or sexual abuse; abandonment; or parents who had addictive disease, chronic pain syndromes, or severe psychological illness, among others.

It is also important to recognize that some of the psychological problems that can arise after surgery might be due to the psychological trauma of surgery itself (posttraumatic stress disorder [PTSD]) or the fear of making things worse afterward (fear avoidance and catastrophizing). Hart et al. reported a 22% prevalence of PTSD after spine surgery. This postoperative psychological distress was correlated with poorer outcome. The same authors also reported that preoperative psychiatric diagnosis was the strongest predictor of PTSD and seemed to be a stronger predictor of worse outcome than preoperative mental health.

### Establishing the Diagnosis

#### ROLE OF THE HISTORY

The history is the most important part of the evaluation of a patient with FBS. When possible, preoperative notes and imaging studies should be part of the history. The history provides the information necessary to order and interpret other diagnostic elements. The most important elements of the history include a thorough description of the current pain, a comparison of the pain before and after surgery, the time course of the reappearance of the pain, and the response of the pain to specific activities. It is also very valuable to analyze whether the type of surgery performed was appropriate for the preoperative symptoms and condition. The history
should lead to a limited differential diagnosis, suggest the emphasis for the physical examination, and provide guidelines for selecting appropriate imaging studies and diagnostic injections. It is important to remember there may be more than one diagnosis present.

**Preoperative Versus Current Pain**
Pain that is essentially the same before and after surgery in terms of severity, location, quality, and response to mechanical maneuvers suggests that the original problem was not corrected. There may have been an error in diagnosis, an error selecting the correct surgery, or an incomplete surgery. On the other hand, when symptoms have changed significantly, it is most likely that there is new pathology, either a complication of surgery, technical failure, or progression of the underlying disease.

**Location of Pain (Especially Low Back Pain Versus Leg Pain)**
It is useful to divide FBS patients into those with predominantly LBP and those with predominantly leg pain. In general, when LBP is greater than leg pain, the most common causes are discogenic pain at the level of the index surgery or at adjacent levels, FJ pain, SIJ pain, or instability. If fusion was attempted, there may be a pseudarthrosis, although pseudarthrosis itself can be an incidental finding rather than the cause of pain. When leg pain predominates, the more common causes include residual foraminal stenosis; recurrent or residual disk herniation; neuropathic pain; and also SIJ dysfunction, hip disease, or peripheral nerve injury or entrapment.

**Response to Mechanical Changes**
There are no studies that document the changes in pain in response to common activities in patients with FBS. Therefore, these correlations are extrapolated from studies in patients with chronic LBP and no prior surgery. These responses to biomechanical stresses are clues but obviously cannot be considered definitive.

Response to Sitting
LBP or leg pain that increases with sitting and with flexion in standing is more likely due to one or more painful disks or instability. Leg pain that improves with sitting is usually due to spinal stenosis.

Transition from Sitting to Standing
LBP that worsens during the transition from sit to stand suggests disk pain or SIJ and speaks against FJ pain. LBP that increases with standing suggests posterior element pathology such as FJ pain. Leg pain that increases with standing or walking suggests spinal stenosis.

Quality of Pain
The word the patient uses to describe the pain is occasionally helpful. Burning, electric shock-like pain, dysesthesia, or superficial (skin) tenderness to light touch (allodynia) suggests neuropathic pain. However, neuropathic pain after spine surgery may not fit these classical descriptors. Screening tests for neuropathic pain, although useful before surgery, are not as helpful after spine surgery.

TIME COURSE OF APPEARANCE OF PAIN
Preoperative Low Back Pain or Leg Pain Never Improves or Early Onset of Old Symptoms
When LBP never improves or recurs within days to a month or so after surgery, it is most likely that the symptomatic structural pathology was not adequately addressed by surgery, there was a complication such as wrong level surgery or the wrong procedure for this particular patient was done. Partial pain relief implies correction of only part of the structural problem. This outcome falls in the category of residual pathology, and the differential diagnosis has already been outlined.

New Leg Pain Soon after Surgery
The early appearance of new leg pain suggests direct neural injury during surgery, misplacement of a pedicle screw, or, less commonly, deep venous thrombosis.

Pain Improves but Recurs 1 to 6 Months after Surgery
Pain that improved initially but recurred in 1 to 6 months may be due to residual, recurrent, or new pathology. If pain location and description resemble preoperative symptoms, residual, or recurrent pathology is likely. Pain that has new characteristics is more likely due to new pathology. There may be recurrent disk herniation, failure (loosening of pedicle screws) of internal fixation, instability, and late infection.

**Pain Improves but Recurs and Is Different**

Pain that recurs late and has a different location or quality compared to the preoperative pain is more likely due to new pathology, which can occur at the index level or adjacent segment. Adjacent segment problems include painful degenerated disk, herniation, stenosis, or facet dysfunction. In addition, SIJ problems occur, especially if there is fusion to L5 or the sacrum.

**ROLE OF RADIOLOGIC EVALUATION OF FAILED BACK SURGERY**

The radiologic evaluation is important. The choice of the type of imaging is determined by the surgery performed and clues from the history and physical examination, which usually allow for a reasonable differential diagnosis. The best information will be obtained if the clinician consults with the radiologist regarding the suspected diagnosis, type of prior surgery, and current symptoms. The radiologist can then follow along with the testing in real time, which should yield the best information.

Radiologic examination should include plain x-rays and MRI scan. CT is important if there is suspicion that the problem involves the bony structures, nonunion of fusion or location, or fracture of internal fixation screws, or if the patient is very claustrophobic. There are only rare indications for nuclear imaging studies (infection, possible malignancy, possible rheumatologic illness), myelography (pseudomeningocele), or CT myelography.

Standard radiographs with standing flexion and extension lateral views and anteroposterior (AP) view are very important and are too frequently not performed. These standard films are used to evaluate whether the desired segment(s) were addressed as an assessment of the alignment in
multiple planes, extent of disk space narrowing if any, spondylolisthesis, and when fusion has been attempted, pseudarthrosis, or broken or misplaced internal fixation devices. There are several excellent reviews of postoperative imaging that demonstrate the normal findings based on type of surgery as well as findings that indicate a structural problem.

MRI is usually the optimal exam for most FBS patients. It is important that the radiologist knows this is a patient with FBS so the proper imaging sequences are obtained. MRI is excellent for the diagnosis of spinal stenosis, disk herniation, disk degeneration, and infection. It will show if decompression was adequate to decompress the nerve root. Arachnoiditis can easily be detected with MRI but is less valuable when there are certain types of instrumentation.

ROLE OF DIAGNOSTIC INJECTIONS

Anesthetic Injections

There are little data on the utility of diagnostic spinal injections in patients with FBS. Anesthetic injections are the standard for the diagnosis of FJ and SIJ pain. A transforaminal injection (TFI) is sometimes used to determine if a nerve that appears compressed on MRI or CT scan is in fact the pain generator. A positive TFI may be defined as relief of the target pain after anesthetizing a specific spinal nerve.

Provocation Disk Injections (Discography)

Discography had been used extensively in the evaluation of patients with chronic LBP and FBS who were suspected of having discogenic pain. However, discography has fallen into disfavor because of data that suggests injection into a disk can result in long-term degeneration. That said, it might play a very limited role in patients with FBS when definitive diagnosis is elusive, pain is refractory, and surgery is being considered.

Treatments

There is a spectrum of treatments for FBS that ranges from manual therapy, exercise, and medication through interventional pain treatments and repeat surgery. The treatment of each patient should be based on the
cause of the pain and then the best available published evidence integrated with the physician’s clinical expertise and each patient’s values and circumstances. It must be recognized that just as pain management is not necessarily a failure of spine surgery, neither is corrective spine surgery a failure of pain management.

**NONSPECIFIC TREATMENTS**

**Rehabilitation and Exercise**

Rehabilitation is usually the first line of treatment for patients with FBS. The premise is that many patients are weak and deconditioned and exercise therapy will help overcome these factors. In addition, there is evidence that exercise therapy helps patients overcome their fear avoidance, which leads to improvement in many domains, physical and psychological.

Several studies have looked at the response to exercise and rehabilitation in patients with FBS. Timm compared five types of treatment for FBS: high-tech exercise, low-tech exercise, modalities, manipulation, and control group with no treatment. Both active forms of exercise were better than control, passive modalities and manipulation. Brox et al. reported outcomes in patients treated for FBS after discectomy. The program was 25 hours per week for 3 weeks and included cognitive-behavioral therapy and lectures. At 1 year, LBP (0 to 100) improved from 65 to 51 and ODI improved from 45 to 32. Miller et al. compared the outcomes of chronic LBP and FBS patients in an interdisciplinary functional restoration program. Both groups did well with significant decreases in pain and disability. The chronic LBP patients without prior surgery had greater reductions in pain and disability, but the FBS patients were significantly more improved in strength and endurance measures, activities of daily living, and fear of exercise after the program. Karahan et al. compared isokinetic, lumbar stabilization, home exercises, and no treatment in a single-blind randomized trial of patients with FBS. They used both psychological and physical outcome measures. The isokinetic and lumbar stabilization groups had equivalent clinical and statistical improvement, both better than home exercise. All exercise groups did better than control.
Medications

The use of medications for patients with FBS is based on clinical experience, expert opinion, case series, and extrapolation from studies on patients with chronic LBP and other pain states rather than proof of efficacy in FBS. Medications might play an adjunctive role while a patient is in rehabilitation, but in some patients, medication becomes a long-term treatment.

Acetaminophen (APAP), although commonly used, has been shown to be no more effective than placebo in acute LBP. There are no studies of APAP in chronic LBP or FBS. Risk of liver disease is significant at doses above 3 g per day. There is little to recommend APAP in patients with FBS.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly prescribed for acute LBP. However, the data are mixed regarding efficacy. Newer trials report no advantage over placebo in chronic LBP. NSAIDs have side effects that can be very serious, including myocardial infarction, gastrointestinal hemorrhage, and renal and liver toxicity, among others. Although the risk of major cardiovascular event is not high, it is important. Of note is that recent studies suggest that cardiac events can occur in the first week of use with a second peak before 30 days. It is prudent to avoid NSAIDs in the elderly and patients with underlying medical problems, especially cardiac, who are at greatest risk of serious adverse events.

For most patients skeletal muscle relaxants do not provide much benefit for chronic LBP. The antiseizure medications such as gabapentin, pregabalin, and topiramate might offer some benefit, although good data are lacking.

Neither tricyclic nor selective serotonin uptake inhibitors are effective for chronic LBP. Duloxetine has been shown to be useful in some patients with chronic LBP but does not seem to have been studied in patients with FBS.

Opioid analgesics have become the most controversial medications for the treatment of pain not related to malignancy and are discussed in detail elsewhere. The most recent guideline of the American College of Physicians (ACP) states that pharmacologic therapies should be considered
in patients who have not responded to nonpharmacologic therapies. They suggest NSAIDs and tramadol as first-line therapies, and tramadol or duloxetine as second-line therapies.\textsuperscript{84} Paradoxically, this is the recommendation even though NSAIDs have little value and potentially serious adverse events. The guideline goes on to state,

Clinicians should only consider opioids as an option in patients who have failed the aforementioned treatments and only if the potential benefits outweigh the risks for individual patients and after a discussion of known risks and realistic benefits with patients (grade: weak recommendation, moderate-quality evidence).

**SOME OF THE SPECIFIC TREATMENTS FOR SPECIFIC DISORDERS**

**Discogenic Pain**

Discogenic pain can occur at the index level of prior surgery or adjacent segment. In the setting of FBS, rehabilitation and fusion surgery have been compared. For patients with mild to moderate pain after discectomy, a 3-week interdisciplinary functional rehabilitation program was equal to fusion surgery.\textsuperscript{78}

**Facet Joint Pain**

Klessinger\textsuperscript{36} studied the efficacy of radiofrequency neurotomy (RFN) in 120 patients who had undergone microsurgical lumbar disk surgery and had residual axial LBP. There were 34 who had a positive response to diagnostic medial branch blocks and then were treated with RFN. Twenty patients (58.8\%) achieved at least 50\% reduction in pain for a minimum of 6 months. Good results have been seen in patients with chronic LBP of FJ origin as well.\textsuperscript{86} Successful RFN relieves pain to a meaningful degree for about 9 to 12 months. When pain recurs, RFN can be repeated. Repeat RFN is usually successful unless there has been disease progression or technical failure.\textsuperscript{87}

**Sacroiliac Joint Pain**

There do not appear to be studies of nonsurgical therapies for the treatment of SIJ pain after lumbar surgery.\textsuperscript{41} The noninterventional options that have
been reported in SIJ pain without fusion include medications (topical and oral), physical therapy, support belts, and manual therapy. If response is poor, SIJ corticosteroid injection can be considered the next step. The duration of relief after steroid injection varies greatly. Some patients achieve long-lasting relief after one to three injections, but others require several injections each year.\textsuperscript{88} For patients who do not respond to these treatments, SIJ RFN can be effective in well-selected patients and sustained for 12 months in some.\textsuperscript{89–91} Finally, for patients with severe and refractory pain, SIJ fusion has been reported to be helpful.\textsuperscript{92}

**Spinal Stenosis**

As previously noted, spinal stenosis may involve the central canal or foramen or both. Foraminal stenosis is more common than central stenosis in patients with FBS. Central stenosis can be treated initially with rehabilitation and epidural corticosteroid injections. Patients who fail medical treatment and rehabilitation usually do well with surgery.\textsuperscript{93–96} The same paradigm seems appropriate for foraminal stenosis. If stenosis is severe and extensive decompression is needed, fusion may be required. For mixed pain syndromes, if decompression is not sufficient, medications and/or spinal cord stimulation (SCS) may be useful.

**Neuropathic Pain**

Neuropathic pain is best treated sequentially with medication trial first and perhaps SCS if medications prove ineffective. If there is limited success, SCS is often useful.\textsuperscript{97} SCS is discussed in detail elsewhere. Newer 10-kHz high-frequency SCS appears to improve efficacy and even provide improvement in the LBP component.

There are case series regarding the treatment of cluneal nerve injuries with injections of corticosteroids and sometimes with alcohol.\textsuperscript{98}

**Lysis of Adhesions**

As noted earlier, most patients develop fibrosis after back surgery, and there is debate about its significance. In one theory, the fibrosis is responsible for the pain, and therefore, lysis of the adhesions will result in improvement. There are several studies and reviews that present evidence
of effectiveness in a small number of well-selected patients.\textsuperscript{76,99,100}

**Psychological Interventions**

Psychological illness, just like structural problems, is treated according to its severity and type with a detailed discussion elsewhere in this book. Depression, anxiety disorder, substance abuse disorder, and PTSD might best be treated with some combination of individual psychotherapy, group therapy, and, when necessary, medications. In addition, time-limited cognitive-behavioral therapy can be useful for reducing catastrophic thinking with its maladaptive interpretation of pain, increasing function, insomnia, and other stress-related problems.

Indirect forms of cognitive-behavioral treatments—physical rehabilitation, for example—can be useful for fear avoidance and even catastrophic thinking. Physical rehabilitation can provide both of strength and body mechanics training and at the same time help patients overcome some of the fear avoidance, catastrophic thinking, and even depression.\textsuperscript{66,101}

Mindfulness training, also known as mindfulness-based stress reduction (MBSR), has been evaluated in a randomized controlled but short-term study in patients with FBS.\textsuperscript{102} One group received usual care plus MBSR weekly for 8 weeks, and the other usual care alone. The MBSR group had clinically and significantly greater improvement than the control group in level of pain, pain acceptance, function, and sleep quality. Results were clinically and statistically significant. In a systematic review, Reiner et al.\textsuperscript{103} found evidence that MBSR reduced pain intensity in patients with chronic pain. Schütze and associates\textsuperscript{104} showed in a small study that the combination of MBSR and physical therapy produced meaningful improvements in pain catastrophizing, physical function, and depression.

**Reoperation**

The role of reoperation is complex and depends on the structural cause of the FBS, levels of pain, and disability and psychological status. If there is an anatomical abnormality that corresponds to the patient’s pain, and the patient has failed all reasonable conservative care, surgery might be a viable option. Surgery is not likely to benefit neuropathic pain but might
be beneficial for radicular pain.

Brox et al. showed that reoperation after failure of discectomy was not better than aggressive conservative care consisting of an inpatient program for several weeks. Therefore, it appears reasonable to offer rehabilitation before contemplating surgery, although the magnitude of the conservative care used by Brox et al. is rarely available to most patients.

Indications for surgery can include recurrent disk herniation, residual spinal stenosis, pseudarthrosis, progressive deformity, and severe adjacent segment disease.

CHAPTER 76
Psychological Screening of Candidates for Spine Surgery or Placement of Implanted Devices

ROBERT EDWARDS and ROBERT N. JAMISON

Introduction

Chronic pain, generally defined as pain persisting for more than 3 months, or past the normal healing time, affects nearly 100 million adults in the United States.¹ It is estimated that 25 million adults report suffering with daily pain at any one time, and pain as a symptom accounts for 50 million primary care office visits.² Patients with persistent pain often report depression, anxiety, irritability, sexual dysfunction, and decreased energy.³ Family roles are altered and worries about financial limitations and the consequences of a restricted lifestyle are common.⁴ Chronic pain is one of the major reasons to seek health care and can impose a tremendous burden on the quality of life of those affected by this condition.⁵ According to the Global Burden of Disease Initiative of the World Health Organization, chronic pain is ranked first in associated disability and overall burden.⁶ It has been determined that chronic pain adversely affects individuals at a higher frequency than depression, substance abuse, arthritis, and Alzheimer disease.⁷,⁸

Despite multiple medical interventions and numerous treatment efforts, the incidence of chronic pain continues to rise and represents one of the costliest health care conditions in the United States.⁹ In fact, chronic pain imposes the greatest economic burden of any health condition¹⁰,¹¹ and affects more people than diabetes, heart disease, and cancer combined.⁹ Persistent back pain in particular is one of the principal drivers of these costs, both in the United States¹² and internationally,¹³ with indirect costs (e.g., lost or reduced work productivity) accounting for more than half of
Although there are many accepted and recommended treatments for chronic pain, the efficacy of these treatments is limited, and many individuals receiving treatments for their pain continue with disabling pain despite these therapies. The Agency for Healthcare Research and Quality (AHRQ) listed 20 common treatments for persons with chronic pain. They reported that the long-term effect sizes for most medical interventions for pain, including back surgery and implanted devices, tend to be small. The AHRQ article recommended that selection of therapies that have the lowest cost and lowest chance for harm be considered first because there was no clear comparative advantage for most treatments compared to another. The AHRQ also set as a priority the identification of those chronic pain patients who would most likely benefit from specific treatments for chronic pain.

Studies suggest that most patients with chronic pain present with some psychiatric symptoms. Close to 50% of patients with chronic pain have a comorbid psychiatric condition, and 35% of patients with chronic back and neck pain have a comorbid depression or anxiety disorder. Many chronic pain patients have a history of physical or sexual abuse, or a past history of a mood disorder. In surveys of chronic pain clinic populations, between 50% and 70% of patients have significant psychopathology, making psychiatric comorbidity the most prevalent comorbidity in patients with chronic noncancer pain. In addition, the presence of a long-lasting pain syndrome is a leading risk factor for suicide.

Psychological assessment is designed to identify problematic emotional reactions, maladaptive thinking and behavior, and social problems that contribute to pain and disability. When psychosocial issues are identified, treatment can be tailored to address these challenges in the patient’s life, thereby improving the likelihood and speed of recovery and prevention of ongoing or more severe problems. (4) When various first-line treatment options such as trials of medication and physical therapy fail or are ineffective, spinal surgery, spinal cord stimulation (SCS), or placement of an intrathecal drug delivery system (IDDS) are considered as treatment options, especially for those with severe intractable pain.

The purpose of this chapter is to review the major psychosocial...
variables that have been shown to be associated with poor outcome from surgery or an implanted device. We provide a brief critical review of factors that contribute to poor outcome from surgery, SCS, or an IDDS, present accepted strategies for assessing those psychological and social factors that predict outcome from surgery and implantable devices for pain and offer recommendations for future evaluation procedures in order to improve outcomes.

**SPINAL SURGERY**

Lumbar surgery with or without bone grafts and with or without implanted hardware can be controversial when employed for treating chronic pain alone. Radiologic studies have shown that 80% of asymptomatic individuals have evidence of degenerative disk disease or a bulging or herniated disk, conditions often considered an indication for surgery. Yet, no clear indicators currently exist to determine which patients with low back pain would benefit from surgery. In the United States, rates of spine surgery for back and leg pain have been steadily increasing, and there is a wide variation of the frequency of back surgery from one region of the country to the next. Outcome trials of surgery for individuals with chronic low back pain have indicated success rates that range between 41% and 57%. A number of controlled trials, however, have indicated that surgery is no better than physical therapy and multidisciplinary rehabilitation. A troublesome component of back surgery is postsurgical complications and increased pain. Rates of complications and reoperations after spine surgery have ranged from 5% to 16%

Deyo and Mirza found that 2 years after surgery, there was no significant difference between back pain patients of similar diagnosis who were treated surgically or nonsurgically. Turner et al. reviewing all published research on spinal fusion, found that approximately 65% to 75% of all patients achieved satisfactory clinical outcomes. In these studies, poorer outcome was associated with a number of factors, including greater numbers of fused levels and the use of instrumentation. Similarly, Hoffman and colleagues, in a literature review on laminectomy and discectomy, found that the mean success rate of these procedures for relief of spine pain was 67%. The popular media have highlighted these and
similar results, which appear to provide support for declarations about treatments for back pain such as that of a recent issue of Consumer Reports (June 2017) that stated “conventional approaches don’t always work and can cause other serious problems.”

Failed spine surgery can significantly impact the patient, the physician, the employer, and the third-party payer. The patient often continues to remain disabled, with perhaps even greater pain, increased medication dependence, and more emotional difficulty than prior to the surgery. The pain may be so great, or the surgery so unsuccessful, that reoperation is required, as is the case in an estimated 10% of those who undergo laminectomy and discectomy, and 23% of those who undergo spinal fusion. The patient after failed surgery places many demands on the health care system, often requiring increasing medications and multiple additional treatments. Patients often feel frustrated and discouraged. The physician may become angry with the patient for not responding to treatment and the employer can be concerned about his or her obligation to pay compensation to a permanently disabled worker.

Given that spine surgery can be effective yet the implications of failed spine surgeries can be so profound, it becomes critical to determine factors that may lead to poor results from such procedures. Improper pre- and postoperative information and treatments may also worsen surgical results. A growing body of research indicates that psychosocial factors are among the most significant influences on spine surgery results. For example, DeBerard et al. compared the outcomes of spinal fusion in patients who had been recommended for a preoperative psychological evaluation (based on surgeon recognition of the presence of psychosocial concerns) versus those who were not recommended for such evaluations. Those recommended for a psychological evaluation did less well after surgery, suggesting that even the surgeons’ perception of psychological issues was predictive of outcome. In another study, DeBerard and colleagues demonstrated that those who were identified with more negative affect (high psych) before back surgery had more repeat surgeries, had greater disability, had higher medical expenses, and had a higher incidence of disability after surgery than those with less emotional distress. Thus, presurgical evaluation and careful patient selection can be extremely
important in helping to identify those individuals who might benefit the most from lumbar surgery.

**SPINAL CORD STIMULATION AND INTRATHECAL DRUG DELIVERY SYSTEMS**

SCS with implantable or externalized systems has been available since the 1960s. The theoretical basis of the efficacy of SCS is based on Melzack and Wall’s gate control theory that proposes that stimulation of large nerve fibers overrides the transmission of small nerve fibers that transmit pain. SCS is expected to reduce, not eliminate pain by blocking the conduction of primary nerve pathways. It seems to be most successful in relieving pain in the limbs (e.g., the leg or arm), although more recently, neurostimulation devices have been developed that target axial back pain. Throughout the years, there have been improvements in SCS systems allowing for better coverage of painful areas with multiple channels, higher frequency stimulation, burst technology, electrode surfaces with increased number of contacts, and leads that are shaped to provide varying degrees of coverage. Spinal cord stimulators have reported success rates ranging from 20% to 70%. They have been found to be efficacious for neuropathic pain and radiculopathy. There has been a rapid increase in the number of implanted spinal cord stimulators, and some econometric analyses have indicated that SCS may be a cost-effective treatment option, particularly for patients with persistent neuropathic pain syndromes and complex regional pain syndrome.

Spinal infusion of analgesics, with use of an IDDS has been utilized since the 1980s. Spinally administered analgesics had initially been used for treatment of cancer pain and with the subsequent development of implantable components for continuous intrathecal infusions became an acceptable method to treat patients with intractable spasticity as well as pain. This technology consists of implanting a drug delivery device designed for long-term continuous infusion of medication. The drug delivery system consists of a collapsible drug reservoir into which the drug is injected and, powered by a battery and computer chip, allows for variable infusion rates and bolus injections through a catheter anchored in the back with the tip of the catheter positioned within the thecal sac to
deliver drug to the cerebrospinal fluid (CSF). Such infusions for cancer pain have good success rates (defined as a reduction of pain by one-third), ranging from 60% to 90%. Collectively, intrathecal infusion devices have provided pain relief in noncancer pain patients who had failed more conservative therapies and patients with an IDDS have demonstrated a reduction in side effects from oral medications, decreased need for oral analgesia, and improvement in their physical assessment. The data indicate variable success rates for noncancer pain ranging from 25% to 70%.

Although outcome studies report that SCS and/or an IDDS are efficacious in treating chronic pain, decisions for implantation have historically been based on clinical judgment of the implanting physician. Recent empirical work, though, has begun to investigate the clinical characteristics that are associated with outcomes for implantable devices. A study by Hassenbusch and colleagues compared SCS with intrathecal infusions by measuring postoperative verbal numeric scores and activity levels. The findings of this study and others suggest that IDDS were useful in reducing bilateral or axial pain (e.g., pain just in the low back), whereas SCS is better for unilateral radicular symptoms (e.g., pain down one leg stemming from nerve damage in the back). In general, patients considered for an implantable device often are not seen as poor candidates for spinal surgery, either due to previous failed surgery or lack of clear pathology accounting for the pain, and have failed to respond to conservative approaches and long-term use of oral opioids.

Implantation of these devices, however, is not without risks. Reports of infection or intrathecal granulomas causing neurologic injury are documented, and the safety of these devices for use with chronic noncancer pain patients is an important consideration. The risks associated with SCS include possible nerve injury, spinal cord puncture, bleeding, and infection. Similar risks also exist for IDDS including discomfort at the implantation site as well as possible disconnections, kinking, catheter migration, and inflammatory masses (granulomas) that build up at the tip of the catheter. Risks also include increased depression if the device becomes ineffective in reducing pain. Because of the risks associated with implantation of these devices, as well as their substantial costs, there
has been a good deal of emphasis on patient selection. As noted earlier, some studies have focused on identifying pain phenotypes that are most responsive to implantable therapies \(^48,53\); other areas of investigation include evaluation of psychosocial factors that might predict success or failure of stimulators or IDDS. Thus, a careful evaluation of each candidate for surgery or for an implantable device is judged to be important, and in clinical practice, a psychological evaluation is often a recommended or mandatory part of the evaluation process for patients being considered for implantable pain-management devices.

**AFFECTIVE DISORDERS AS PREDICTORS OF OUTCOME**

Many chronic pain patients experience some level of depression. For up to 85%, the intensity of this emotional experience is sufficient to meet the diagnostic criteria for clinical depression.\(^17\) Depressive symptoms include depressed mood, diminished interest in almost all activities, weight loss or gain, insomnia or hypersomnia, agitation or psychomotor retardation, fatigue or energy loss, feelings of worthlessness or guilt, impaired concentration, and recurrent thoughts of death unrelated to other comorbidities.\(^55\) Several studies have assessed depression using different instruments and found that it can be predictive of greater disability and poor outcomes of spinal surgery.\(^56\) Kjelby-Wendt et al.\(^57\) examining discectomy results found that patient satisfaction with surgery was strongly related to elevated scores on the Beck Depression Inventory (BDI)—in fact, elevated scores were found in 55% of dissatisfied patients but in only 18% of satisfied patients. Schade et al.\(^58\) found that depression, as assessed on a simple Likert-type scale, had strong negative correlations with return to work and overall recovery. Trief et al.\(^59\) found that high scores on the Zung depression inventory were associated with little reduction in back pain and elevated work disability after spine surgery. Finally, DeBerard et al.\(^34\) found that depression was strongly related to total medical costs in workers’ compensation patients undergoing spinal fusion.

Patients with chronic pain and a comorbid psychiatric disorder are more likely to report greater pain intensity, more pain-related disability, and a
larger affective component to their pain than those without psychiatric comorbidity.\textsuperscript{60,61} Patients with chronic pain and psychopathology, especially those with chronic low back pain, also typically have poorer pain and disability outcomes with treatment.\textsuperscript{62–64} There is a significantly poorer return-to-work rate 1 year after injury among patients with chronic pain and anxiety and/or depression compared with those without any psychopathology.\textsuperscript{65} Thus, psychiatric comorbidity, primarily major depression and anxiety disorders, is associated with greater levels of chronic pain, more disability, and a worse response to treatment.

Given the significant interpatient variability in treatment outcomes, it would be of tremendous value, from both a societal and patient perspective, to identify in advance who is most and least likely to benefit from surgery or an implanted device. In general, some risk factors have been identified that correlate with greater risk for pain or poor outcomes from treatment for pain. These include variables such as pain chronicity, psychological distress, a history of abuse or trauma, poor social support, and significant cognitive deficits.\textsuperscript{65} In particular, psychopathology and/or extreme emotionality have been seen as contraindications for certain therapies.\textsuperscript{66} Outcome studies highlight the poor response of patients with psychiatric comorbidity to many treatments.\textsuperscript{67,68} For example, spinal pain patients with both anxiety and depression have a 62% worse return-to-work rate than those with no psychopathology.\textsuperscript{69} Epidemiologic research suggests a bidirectional association between back pain and emotional distress; pain increases symptoms of depression and individuals with a preexisting depressive disorder have a disproportionately high risk for developing spinal pain.\textsuperscript{70} Similarly, cognitive processes such as maladaptive beliefs and pessimistic expectations are associated with a greater likelihood of developing chronic pain and with poorer functional outcomes among chronic low back pain patients.\textsuperscript{71} There is also evidence of a genetic predisposition toward increased depression and anxiety among persons with low back pain based on twin studies.\textsuperscript{72}

Numerous factors are likely to play a role in shaping outcomes following surgical interventions or placement of an implanted device in patients with chronic back pain. However, there does not seem to be a consensus on what factors are the strongest and most consistently
predictive of outcomes, and there is no universally accepted standard approach for screening surgical candidates or individuals considered for an implanted device. Nonetheless, a presurgical psychological evaluation is often recommended based on research demonstrating the predictive value of spine presurgical psychological evaluations.\textsuperscript{73}

A recent systematic review was carried out of the current literature, using critical appraisal and strategies to limit bias, to determine the strength of the evidence for the assumption that careful screening will help to predict pain-related and functional outcomes from lumbar surgery or SCS.\textsuperscript{74} Collectively, a statistically significant relationship was found between psychological factors and treatment outcome (e.g., high preimplant levels of distress were prospectively associated with less SCS-related pain relief) in 92\% of the studies reviewed. In particular, presurgical somatization, depression, anxiety, and poor coping were most useful in helping to predict poor response (i.e., less treatment-related benefit) to lumbar surgery and SCS. Older age and longer pain duration were also predictive of poorer outcome in some studies, whereas pretreatment physical findings, activity interference, and pain intensity were minimally predictive. Interestingly, several studies have confirmed that younger patients treated earlier in the course of their pain condition derive the most benefit from SCS,\textsuperscript{75} which might suggest that using SCS as a “last resort” could be a suboptimal management strategy.

A review of psychosocial characteristics as predictors of outcomes following SCS suggests that depression is most robustly linked to poor SCS outcomes.\textsuperscript{76} Indeed, Sparkes and colleagues\textsuperscript{76} cite multiple well-designed studies suggesting that higher levels of preimplantation depressive symptoms impact negatively on the efficacy of SCS treatment. Trief and colleagues\textsuperscript{59} found that patients with elevated state anxiety scores on the State Trait Anxiety Inventory (STAI) achieved less pain relief and lower return to work rates after surgery than did patients with lower anxiety. One particularly troublesome type of anxiety centers on the belief that increasing function and activity may increase the likelihood of reinjury. This type of fear measure has been assessed by several questionnaires including the Tampa Scale for Kinesiophobia.\textsuperscript{77} Den Boer et al.\textsuperscript{78} found that elevated scores on the Tampa scale were associated with
delayed return to work after lumbar disk surgery. One plausible explanation for this result is that patients with a heightened fear of movement might be less likely to engage in aggressive postoperative rehabilitation. Kiecolt-Glaser et al. suggest that anxiety may increase postoperative pain and such increased noxious sensations could then downregulate immune function, further compromising the surgery healing process.

**SOMATIZATION**

Estimated rates of chronic pain patients with somatization (sometimes known as hypochondriasis) vary, ranging from 1% to 12%, even though unexplained symptoms are a common problem in medical settings. The classical concept of somatization that implies that there is no pathophysiologic basis for physical complaints is quite problematic to apply to patients with chronic pain. This is because the majority of patients with chronic pain have some underlying physical condition that is at least partially responsible for their pain. The pain symptoms due to a physical or somatic cause (such as degenerative disk disease in the lumbar spine) may then be amplified by psychiatric factors, such as depression, anxiety, pain catastrophizing, fear of movement, and/or poor coping. Areas in the brain which process pain and mood together (such as the prefrontal and anterior cingulate cortices, and insula, commonly termed the medial pain system) may be the underlying brain substrates by which pain signals coming from the spinal cord are then amplified and perceived as heightened pain sensations. Hence, it is more appropriate to think of somatization as a process of amplification of bodily signals centered in the brain. There may or may not be a physical basis in the body for the abnormal physical sensations. The “somatoform pain disorders” fall within the “Somatization Disorders” classification in Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) and are meant to capture this concept of amplification of bodily perceptions, which is made worse by concomitant depression. The two diagnoses most commonly used with chronic pain patients are Pain disorders associated with psychological factors and a general medical condition, and Pain disorders associated with psychological factors. For patients with a strong
component of heightened awareness of pain, the evidence is strong that repeated invasive procedures and implanted devices almost uniformly are unsuccessful.\textsuperscript{61,74} Education about the nature of the problem and helping patients understand the risk associated with repeated treatments is also important.

Providers should resist a dualistic model that postulates that pain is either all physical or all mental in origin. This model alienates patients who may feel blamed for their pain and is not consistent with modern models of pain causation. Multiple lines of evidence suggest that pain is a product of efferent as well as afferent activity in the nervous system. We know that tissue damage and nociception are not necessary or sufficient for pain and the relationship between pain and nociception is highly complex. We are only beginning to understand the complexities of the relationship between pain and suffering, which appears to be a central phenomenon.\textsuperscript{84}

**PAIN SENSITIVITY**

Recent studies have also suggested that quantitative sensory testing (QST) may be a useful adjunct to psychological evaluation in the assessment of patients under consideration for spinal surgery or for placement of an implantable device. QST involves the administration of standardized noxious stimuli under highly controlled conditions; often, parameters such as pain threshold and tolerance in response to a variety of stimulus modalities are measured as indices of pain sensitivity. Our group recently reported that high levels of pain sensitivity may be associated with elevated risk for pain medication misuse\textsuperscript{85} and individual differences in QST responses may be useful as prognostic indicators in a variety of settings. For example, among neuropathic pain patients undergoing SCS, the degree of pretrial mechanical allodynia was inversely associated with the amount of pain relief reported by patients.\textsuperscript{86} That is, the most mechanosensitive patients reported the least SCS-related analgesic benefit. Functional neuroimaging studies have revealed that SCS functions in part by activating cortical pain-modulatory circuitry,\textsuperscript{87} and it may be that the most preoperatively pain-sensitive individuals are those whose pain-modulatory systems are the most difficult to engage. Patients with chronic
low back pain exhibit generalized patterns of hypersensitivity to pain that are consistent with central sensitization-like processes, indicating that heightened pain sensitivity in the central nervous system may represent an important pain mechanism in patients with chronic back pain.

Assessment of pain sensitivity is potentially useful in several surgical contexts. First, there is some evidence that a higher degree of preoperative pain sensitivity is associated with poorer pain and disability outcomes following spinal surgery. Such findings are consistent with data from other surgical procedures indicating that preoperative sensory phenotyping with QST can provide valuable prognostic data. Second, assessment of sensory responses to provocative tests such as discography, which involves injection of radiographic dye into the nucleus pulposus of a putatively disrupted disk, can be illuminating. The injection, performed under fluoroscopy and combined with postdiscogram CT, gives evidence of the presence and extent of disk disruption. Interestingly, the injection of a disrupted disk has been demonstrated to act as a stimulus that provokes pain, often with a pattern and intensity similar to the patient’s normally occurring pain. For example, Vanharanta et al. found that injection of moderately to severely disrupted disks provoked pain that was similar or an exact reproduction of normally occurring pain in approximately 65% of cases. On the other hand, injection into normal-appearing disks provoked exact or similar reproduction of pain in only 18% of cases. Even stronger results along the same lines were obtained by Walsh et al. Thus, discography may provide a laboratory method for administering controlled stimulation of the disk in order to assess whether certain patients with low back pain display heightened pain sensitivity.

**ANGER**

Anger is a common and prominent emotion in patients with chronic pain. Patients with low back pain, in particular, may experience and express anger about past medical care; about unfair treatment by employers, friends, and family; and about the physical and functional limitations that are endemic to low back pain. A study by Fernandez and Milburn demonstrates just how frequently patients experience this emotion. These researchers asked chronic pain patients to endorse the intensity of 10
different emotions they were experiencing and found that anger was given the highest ratings of all emotions assessed.\(^99\) High levels of anger have also been associated with postoperative complications and elevated levels of postoperative pain for spinal surgeries as well as other procedures.\(^{100}\) There are numerous reasons why anger may have a negative impact on pain-related outcomes. First, anger may lead to maladaptive lifestyle changes, such as poor health habits, lack of physical exercise, or excessive use of drugs or alcohol. Such poor health behavior profiles may impair the benefits of physical interventions and have a negative impact on the patient’s commitment to postoperative rehabilitation. Second, anger can lead to the desire for vindication or revenge, and certainly, this can influence treatment results.\(^{101,102}\) Similarly, DeGood and Kiernan\(^{103}\) have found chronic pain patients who are angry and blame their employer for their injuries report high levels of emotional distress and have poorer response to treatment. Third, anger has been shown to have an adverse effect on many health conditions, such as cardiovascular disease, headaches, asthma, and many others, which may in turn exacerbate the negative effects of pain.\(^{104}\) Final, anger appears to directly impact physiologic pain perception by increasing muscle tension near the site of the injury, activating neural circuits underlying regulation of pain, and interfering with the analgesic effects of endogenous opioids.\(^{105,106}\)

**Cognitive Factors**

A growing body of research is examining the ways in which patients’ thoughts and beliefs concerning their pain, independent of personality or emotional factors, can strongly affect treatment outcome.\(^95\) Such cognitions and coping strategies have been demonstrated to influence the level of pain experienced by the patient, level of functional ability, and adjustment to the pain and efforts to overcome it.\(^95\) For example, catastrophizing is a pain-specific psychosocial construct composed of negative cognitive and emotional processes such as helplessness, pessimism, rumination about pain-related symptoms, and magnification of pain reports.\(^{70,107}\) Overall, higher catastrophizing has been shown to be a risk factor for the development of long-term pain and for negative sequelae
of pain such as worsening physical disability, higher health care costs, and the amplification of pain sensitivity among patients with low back pain and joint pain. Retrospective survey studies in patients with musculoskeletal pain have indicated that catastrophizing often emerges as one of the most important pretreatment variables predicting surgical outcomes \cite{108, 109} and a risk factor that impairs the effectiveness of pain-relieving interventions. Fortunately, catastrophizing is a modifiable risk factor that can be ameliorated with a variety of nonpharmacologic treatments, from physical therapy to meditation. \cite{60, 70, 107} As such, it should be assessed as part of any psychosocial screening.

**COPING STRATEGIES**

Coping strategies may be defined as specific thoughts and behaviors individuals use to manage their pain or their emotional reactions to pain. \cite{110} For example, “active” pain coping generally includes engaging in positive thinking, making encouraging self-statements, distracting one’s attention from pain, undertaking as much physical activity as possible within pacing guidelines, or using physical pain-reducing techniques such as relaxation exercises and stretching. Facilitating such coping strategies seems to be an important part of many nonpharmacologic treatments for chronic pain. One recent prospective study of multidisciplinary treatment revealed that patients who entered treatment with stronger personal beliefs in their ability to control pain, and those who increased their use of positive self-statements and cognitive reinterpretation of pain showed the most substantial decreases in pain-related interference at 6 months and 18 months posttreatment. \cite{111} Coping strategies may affect the patient’s level of attentiveness to pain, the ability to persist in the face of pain, and the extent to which the patient feels entitled to be taken care of as a result of the pain. There are a number of questionnaires available to assess pain-related coping strategies, including the Vanderbilt Pain Management Inventory (PMI). \cite{112} However, the largest body of research on coping in chronic pain (and the only research directly applied to surgical screening) has used the Coping Strategies Questionnaire (CSQ). \cite{113} Gross \cite{114} administered the CSQ preoperatively to 50 lumbar laminectomy candidates. Patients who obtained good results from surgery indicated on
the CSQ that they felt better able to control the pain and also indicated they were more self-reliant. Other coping strategies assessed by the CSQ, such as hoping and praying and catastrophizing, were associated with poor surgical outcomes. These results are consistent with several other studies demonstrating that more passive coping strategies and perceived lack of pain control tend to be associated with greater pain levels, higher opioid consumption, greater levels of depression, and poorer treatment outcome. Recent research by den Boer et al. provides further support for the strong influence of coping strategies on surgical outcome. In this study, patients undergoing spine surgery for lumbar radicular syndrome were examined. “Passive pain coping” was assessed preoperatively using the Pain-Coping Inventory. Results indicated that passive pain coping, along with negative surgical outcome expectancy, predicted more severe disability and reduced work capacity at 6 months after surgery. Taken together with the just-cited study by Gross, these results demonstrate that the effectiveness of surgery may be partially mediated by the manner in which the patient thinks about the experience of pain and the strategies he or she has available to cope with the pain.

**Behavioral Factors**

All the psychosocial factors discussed up to this point are components of a patient’s internal milieu: thoughts, feelings, and personality. Factors external to the patient can also exert profound influences upon recovery from spine surgery. Especially powerful in this regard are the responses of others to the patient’s pain. Pain behavior almost always occurs in a social context, communicating to observers that the patient is in distress. Observers, in turn, may react to such behavior with attempts to relieve the patient’s pain, help him or her to avoid further problems, or be supportive of limitations in activity. Employers, and even the insurance system, may also inadvertently support pain behaviors through provision of disability benefits or time off of work. Unfortunately, such solicitous responses from others, although well intentioned, may serve to reinforce or reward pain behaviors, increasing the likelihood that patients will continue to show and experience pain. Moreover, the patients’ individual attachment style
is an important predictor of outcomes; individuals with anxious or insecure attachment styles are at elevated risk for poorer mental and physical health and for less treatment-related improvement.\textsuperscript{119} These social factors are especially important in the occupational setting. Anema and colleagues\textsuperscript{120} compared return-to-work rates in injured workers across numerous countries and found that differences in job characteristics and social disability systems were more important than medical interventions, patient, and injury-related factors in predicting occupational outcomes. In addition, these same home- and work-related social forces contribute to shaping important outcomes after spine surgery, as patients with minimal social and occupational support have more postoperative complications, pain, and disability following a variety of operative procedures.\textsuperscript{121–123}

**EARLY-LIFE TRAUMA AND ABUSE**

Strong prospective links have been observed between early traumatic experiences and the subsequent development of chronic pain.\textsuperscript{95,124} Childhood physical, sexual, and psychological abuse are reported to be risk factors for the adult development of musculoskeletal pain conditions.\textsuperscript{125} In adulthood, posttraumatic stress disorder (PTSD) has been identified as a risk factor for chronic pain, for the transition from acute to chronic pain, and for elevated severity of pain and disability in abuse victims.\textsuperscript{126–128} Overall, a disproportionately high number of chronic back pain patients have been the victims of abuse or abandonment as either adults or as children. In one study, more than half of the patients with chronic refractory low back pain evaluated at a multidisciplinary pain clinic had a history of at least one form of such childhood psychological trauma.\textsuperscript{129} These figures are substantially higher than the base rate in the US population. At present, the treatment implications for patients are unknown. Whereas some studies\textsuperscript{130} find less positive outcomes following spine surgery among patients with a significant history of childhood abuse, others have not confirmed this finding, highlighting the need for additional research.\textsuperscript{129}

**SUBSTANCE ABUSE**

Excessive use and abuse of opioid medications and alcohol appear to be
red flags for poor surgical outcome.\textsuperscript{131,132} To the extent that patients depend on such substances, their responsibility for pain relief and improvements in functional ability through participation in postoperative rehabilitation may be diminished.\textsuperscript{133} Many chronic pain patients use excessive amounts of opioids. For example, Polatin and colleagues\textsuperscript{134} found that 19\% of spine pain patients entering a work-hardening program had a history of substance use disorder, and even higher rates were reported in other studies. Unfortunately, there is little research addressing the relationship of substance use disorder and spine surgery outcome, although the results suggest that there is a higher incidence of spine surgery failures among those who continually abuse prescription medication and alcohol.\textsuperscript{135} The medical literature is clearer in demonstrating a relationship between poor surgical outcomes and smoking cigarettes.\textsuperscript{136}

**COMPONENTS OF PSYCHOLOGICAL EVALUATIONS**

Generally speaking, a goal of lumbar surgery and an implanted device for pain is to reduce pain. There are other potential positive outcomes from surgery or placement of an implanted device for pain including (1) relying less on prescription medication, (2) improving activities of daily living, and (3) returning individuals to productive lifestyles. A psychological evaluation is designed to help identify patients at risk for poor outcome and to prepare the patient so that they can achieve maximum benefit from surgery or implanted device.\textsuperscript{137} Regarding implanted devices, Medicare and many health insurance companies in the United States require implant candidates to have a psychological evaluation. As part of the evaluation, patients need to be informed of the risks as well as possible benefits from surgery or placement of an implanted device and to address realistic expectations. For SCS and IDDS, patients undergo a trial designed to determine the likely efficacy of a permanent implant. For SCS, the trial consists of temporary placement of a stimulator lead for 4 to 10 days and a successful trial, often required by Medicare and third-party payers, includes self-reported pain reduction by 50\% and overall patient satisfaction. For IDDS patients, the trial is often conducted during a brief inpatient stay. It is important to remind patients with an IDDS that they
would need to return periodically to refill their drug delivery system and for SCS patients that their time using the device directly affects battery longevity. Showing prospective implant patients a model of the device so that they can hold it and understand how it works can be important. Open discussion of any concerns about having a device implanted can also be useful. For some SCS patients, there may be some loss of normal sensation and having future magnetic resonance imaging (MRI) studies may be contradicted with some systems. For any device, future revisions or explants may be necessary in the event of infection, failed batteries, or any severe complication.

Psychological evaluations should include the assessment of sensory, affective, cognitive, and behavioral components of the pain experience, expectations of benefit of an implanted device, and identification of personality and psychosocial factors that can influence treatment outcome. Table 76.1 presents the major categories that should be addressed during a psychological interview. The sensory experience is usually best understood through description of the severity, location, and temporal characteristics of chronic pain. Distressing emotional qualities of the experience of pain as well as preexisting emotional dispositions need to be understood, as fear and depression are powerful determinants of the response and emotional reactions to pain, related disability, and overall care. Patterns of thinking may exacerbate and maintain dysfunctional pain as well as facilitate coping that enhance adjustment during painful flare-ups. There is variability in the extent to which chronic pain interferes with activities of daily living or contributes to substantial functional impairment. Clinicians have long relied on careful appraisal of nonverbal behavior in the course of physical examinations and through observation of patients outside the examining situation, for example, when engaged in spontaneous behavior elsewhere in clinics or in everyday situations. Self-report can also be useful in assessing nonverbal behavior by focusing on overt activity rather than subjective experience, for example, functional capacity or competence and disability in different situations. Finally, family socialization and important life experiences influence both effective and ineffective patterns of attempts to cope with pain. History gathering typically is the primary source of this information. Ethnic and cultural
variation and family histories of managing pain and illness may be of importance. For example, when significant others in a patient’s family have had a history of recurrent, persistent, or particularly severe pain, there is a disposition to similar patterns in the patient themselves.139

Of comparable importance are current social contexts. Patients experiencing social distress (e.g., with employers, family members or others) either directly related to painful episodes (reduced employment, isolation from the community) or unrelated to painful episodes (e.g., financial distress, difficult relationships) are likely to increase demands on the health care system. Furthermore, the presence of a supportive social environment is associated with lower levels of pain and less physical disability following surgical intervention.140

Although clinicians must be aware of the objectives of referral sources, patients similarly are typically carefully attuned to the expectations and goals of referral agencies and those engaged in the assessment. Patients frustrated with lack of success in treating pain or provision of financial and other support when unable to earn a livelihood bring different concerns to the assessment than patients who are not worried by such situations and expect the assessment will lead to effective care. Long histories of inadequate care or denial of care are more likely to lead to hostile behavior.
VALIDATED PSYCHOLOGICAL MEASURES

A psychological evaluation should include valid and reliable assessments of subjective pain intensity, mood and personality, activity interference, pain beliefs, and coping (Table 76.2). The following categories include some popular assessment tools used to measure these constructs.

Pain Intensity Measures

Because one of the obvious primary goals of surgery or placement of an
implanted device for chronic pain is to decrease the intensity of the pain, it is important to monitor pain intensity for a period before surgery or a device trial and after treatment. There are a number of ways to measure pain intensity, including numerical pain ratings, visual analogue scales, verbal rating scales, pain drawings, and a combination of standardized questionnaires. Pain intensity rating methods have evolved from designs originally developed by Budzynski and Melzack. Studies have shown that self-monitored pain intensity ratings are both reliable and valid. The daily monitoring of multiple measures of pain intensity over a 1- to 2-week period before considering a trial of SCS or IDDS has a number of benefits. First, more information is obtained than can be gained from a single index of perceived pain intensity. More specifically, averaging multiple measures of pain intensity over time increases the reliability and validity of the assessment and is preferable to a single rating of pain intensity. Second, in the case of a trial of SCS or IDDS, average pain intensity ratings can serve as a baseline to help establish whether continued treatment is needed after an appropriate trial period. Baseline measures are essential to making judgments about the overall impact of treatment for pain.

Numerical pain ratings often involve the patient’s rating of his or her pain on a scale of 0 to 10 or 0 to 100. Ideally, the external validity of the measure is improved by descriptive anchors that help the patient understand the meaning of each numerical value (e.g., 1 to 2, pain can be ignored at times; 3 to 4, pain is present but does not interfere with activity; 5 to 6, the pain is very noticeable and begins to limit function; 7 to 8, pain is quite severe and performing average daily activities is impaired; 9 to 10, pain is as worse as it can be and all activity is significantly impaired). Another popular means of measuring pain intensity is the visual analog scale (VAS), which uses a straight line with extreme limits of pain at either end. Some clinics employ electronic pain ratings available on a laptop computer, cell phone, or Internet Web site that can be used at home on a daily basis to get multiple time-stamped assessments of pain in the patient’s natural environment.
order of severity from “no pain” to “excruciating pain”—to describe the intensity of their pain. Other verbal scales can be used to describe the quality of pain, for example, piercing, stabbing, shooting, burning, throbbing. Among the self-report measures, numerical rating scales are most popular among professionals. However, there is no evidence to suggest that VAS or verbal rating scales are any less sensitive to treatment effects. All these types of measures have been shown to be acceptable in the quantification of clinical pain.

**Mood and Personality**

Patients with chronic pain often report depression, anxiety, irritability, a history of physical or sexual abuse, or a past history of a mood disorder. Patients with chronic low back pain with evidence of a personality disorder or high ratings of depression and neuroticism respond more favorably to conservative management rather than surgery or placement of an implanted device. Mental health professionals continue to debate the best way to measure psychopathology and/or emotional distress in chronic pain patients. Although most measures are helpful in ruling out severe psychiatric disturbance, unfortunately, no measure can boast perfect validity in predicting treatment outcome. The measures commonly used to evaluate personality and emotional distress include the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), the Symptom Checklist 90 (SCL-90-R), the BDI, the Hospital Anxiety and Depression Scale (HADS), and others.

The MMPI and its successor, the MMPI-2, had been the instruments traditionally used in assessing chronic pain patients and to predict outcome following spine surgery and SCS. This measure consists of 567 true/false items and yields a distinct profile for each pain patient. Studies have shown that these profiles can predict return-to-work in males as well as response to surgical treatment. Although this test was widely used to measure psychopathology, the profiles obtained for chronic pain patients could be misinterpreted because of the physical symptoms frequently reported by these patients. Patients also reported disliking the test’s emphasis on psychopathology that seemed to be unrelated to their pain problem.
The SCL-90 is a 90-item checklist with a 5-point scale that offers a global index score as well as nine subscale scores as a general assessment of emotional distress and has been used to evaluate outcomes from surgery\textsuperscript{161} and SCS.\textsuperscript{162} This self-report instrument offers easy inspection of individual items that may pertain specifically to persons with chronic pain. However, its disadvantages include the high correlation between subscales and the absence of validity scales to detect subtle inconsistencies in responses.\textsuperscript{163}

The BDI assesses depressive symptoms in chronic pain patients. This 21-item self-report questionnaire measures the severity of depression and is commonly used to evaluate the outcome of treatment. It is easy to administer and score, although one limitation is the potential for misinterpretation of an elevated depression score as a result of the frequent endorsement of somatic items by chronic pain patients, for example, fatigue, sleep disturbances, and loss of sexual interest. The BDI has been used to predict outcome of lumbar disk surgery,\textsuperscript{164} surgical management of spinal stenosis,\textsuperscript{165} and benefit of peripheral nerve stimulation.\textsuperscript{166} The Center for Epidemiologic Studies Depression (CES-D) scale is an additional tool for assessment of depressive symptoms in pain patients.\textsuperscript{167}

The HADS is a 14-item scale designed to assess the presence and severity of anxious and depressive symptoms. Seven items assess anxiety, and seven items measure depression, each coded from 0 to 3. The HADS has been used extensively in clinics and has adequate reliability (Cronbach’s $\alpha = .83$) and validity, with optimal balance between sensitivity and specificity. It has been translated into many languages and is widely used around the world in clinical and research settings.\textsuperscript{168}

**Functional Capacity and Activity Interference Measures**

Some clinicians consider pain reduction meaningless unless accompanied by a noticeable change in function. Thus, some reliable measurement of functional capacity is often desirable before the onset of therapy. Research has shown that physical impairment, defined as an objective medical condition such as an amputation, is not very predictive of disability, which is an inability to work because of a medical impairment. Rather, beliefs about an injury predict disability and physical performance after surgery.
better than pain ratings or a physical impairment.\textsuperscript{169,170} Measures that can be used to assess activity level and function include the Short-Form Health Survey (SF-36),\textsuperscript{171} the West Haven-Yale Multidimensional Pain Inventory (WHYMPI, mostly known now as the MPI),\textsuperscript{172} and the Pain Disability Index (PDI).\textsuperscript{173} It is preferable to consider functional measures that are specific to the chronic pain condition being assessed, for example, back pain patients will have different activity limitations than someone with upper extremity pain.

The SF-36, which was initially developed from the Medical Outcomes Study to survey health status, includes eight scales that measure (1) limitations in physical activities due to health problems, (2) limitations in social activities due to physical and emotional problems, (3) limitations in usual role activities due to physical health problems, (4) bodily pain, (5) general mental health, (6) limitations in usual role activities due to emotional problems, (7) vitality (energy and fatigue), and (8) general health perceptions.\textsuperscript{171} Although the SF-36 is a popular measure, pain patients tend to score very low (severe limitations) such that modest improvements can go undetected. An expanded measure known as the Treatment Outcomes of Pain System (TOPS),\textsuperscript{174} that incorporates the SF-36, has been modified specifically for patients with pain to improve sensitivity and reliability of measurement of treatment outcome.

The MPI is a 56-item measure made up of 7-point rating scales. The subscales assess activity interference, perceived support, pain severity, negative mood, and perceived control. The advantage of this self-report instrument is that it was created specifically for chronic pain patients and can be useful in classifying those patients into three types: dysfunctional, interpersonally distressed, and adaptive copers.\textsuperscript{175} Strong evidence supports the presence of these three types in the assessment of chronic pain patients.\textsuperscript{176}

Other popular functional measures include the Oswestry Disability Questionnaire,\textsuperscript{177} the Roland-Morris Functional Disability Scale,\textsuperscript{177} the Waddell Disability Instrument,\textsuperscript{178} the Functional Rating Scale,\textsuperscript{179} and the Back Pain Functional Scale.\textsuperscript{180}

**Pain Beliefs**
Pain perception, beliefs about pain, and approaches to self-managing pain are important in predicting the outcome of treatment and are particularly relevant as predictors for implantable devices. Unrealistic or negative thoughts about an ongoing pain problem may contribute to increased pain and emotional distress, decreased functioning, a greater reliance on medication, and poor outcome from surgery.\textsuperscript{181} Certain chronic pain patients are prone to maladaptive beliefs about their condition that may not be compatible with the physical nature of their pain.\textsuperscript{182} Patients with adequate psychological functioning exhibit a greater tendency to ignore their pain, use coping self-statements, remain active, and use less medication after joint replacement surgery.\textsuperscript{183}

Because efficacy expectations have been shown to influence the efforts patients will make to manage their pain, measures of self-efficacy or perceived control are useful in assessing a patient’s attitude after surgery.\textsuperscript{184} Several self-report measures assess coping and pain attitudes. The most popular tests used to measure maladaptive beliefs include the CSQ,\textsuperscript{113} the PMI,\textsuperscript{185} the Pain Self-Efficacy Questionnaire (PSEQ),\textsuperscript{186} the Survey of Pain Attitudes (SOPA),\textsuperscript{187} and the Inventory of Negative Thoughts in Response to Pain (INTRP).\textsuperscript{188} Other instruments include the Pain Beliefs and Perceptions Inventory (PBPI),\textsuperscript{189} and the Chronic Pain Self-Efficacy Scale (CPSS).\textsuperscript{190} Finally, the Pain Catastrophizing Scale (PCS)\textsuperscript{191} is a well-validated, widely used, self-report measure of catastrophic thinking associated with pain. The construct of catastrophizing incorporates magnification of pain-related symptoms, rumination about pain, feelings of helplessness, and pessimism about pain-related outcomes. Assessment of catastrophizing is important when evaluating candidacy for an implanted device because it adversely affects outcome and is a strong predictor for continued disability following surgery.\textsuperscript{192} Individuals rate the extent to which they experience the thought or feeling described by each item when they are in pain; scores on this 13-item measure can range from 0 to 52 (each item is scored 0 = not at all to 4 = all the time). The PCS has good psychometric properties in pain patients and controls.\textsuperscript{193} In recent studies of chronic pain patients, Cronbach’s $\alpha$ for the PCS has been reported as above 0.9, indicating very high levels of internal item consistency.\textsuperscript{194} Distraction has been useful in reducing
catastrophizing, as is even a brief course of cognitive behavioral therapy.

It is suspected that patients who have unrealistic beliefs and expectations about their condition are also poor candidates for pain treatment. Patients who have a high catastrophizing score, who endorse passive coping on the PMI, who demonstrate low self-efficacy regarding their ability to manage their pain on the PSEQ, who describe themselves as disabled by their pain on the SOPA, and who report frequent negative thoughts about their pain on the INTRP are at greatest risk for poor treatment outcome following placement of an implanted device.

ELECTRONIC PAIN ASSESSMENT PROGRAMS
There has been recent interest in implementing electronic pain assessment programs in clinic settings to assess and monitor persons with chronic pain prior to surgery or a trial of an implanted device. Evidence exists of the benefits of such programs in assessing risk of poor outcomes, to reduce personnel time, and to document change along the continuum of pain care. Preliminary studies suggest that a Web-based secure electronic assessment program outweighs the benefits of a paper questionnaire. In a study designed to determine the impact of an electronic pain evaluation program, chart reviews were conducted between pain patients who completed an electronic pain assessment program (N = 89) and controls who represented standard care (N = 120). Chart review findings suggested that posted reports on the patient medical record from an electronic assessment increased the presence of key pain assessment information that were not found when incorporating notes from a traditional paper-and-pencil questionnaire. In particular, information on past treatments; adverse effects; psychological symptoms of depression, anxiety, and irritability; mental health treatment; past history of smoking; litigation; and substance abuse were documented more frequently (P < .001). It is thought that a detailed evaluation would be beneficial when determining benefit from an implanted device or spinal surgery. In a second related study by Butler and colleagues, two groups of chronic pain patients (treatment as usual = 75, electronic pain assessment = 72) were interviewed after completing their initial clinic visit and completed
mailed questionnaires 3 months later. Results from this study showed that those subjects who had completed the electronic pain assessment program reported more discussion about legal issues, substance use history, and medication safety compared with those patients who were not given the electronic assessment program (P < .05). Satisfaction questionnaire responses supported both provider and patient perceived benefit of using the electronic pain assessment program. Overall, results indicate that use of a comprehensive electronic pain assessment program improves documentation of chart elements in clinic notes and can be associated with increased discussion of key, pain-relevant topics during the clinical visit and in assessing patients considered for surgery or an implanted device.

**Conclusion**

A growing body of research reviewed in this chapter indicates that psychosocial factors can strongly influence spine surgery outcome and long-term benefit from an implanted device. These results suggest that a comprehensive psychological screening should be included as a component of the diagnostic process in many spine surgery candidates and patients considered for placement of an implanted device for pain. Table 76.3 provides a set of general referral guidelines that a physician can keep in mind when considering the need for a psychological assessment. When the provider judges that a patient displays four or more of these points (listed in Table 76.3), a referral for a comprehensive psychological screening should be initiated. Such a referral is especially critical if there is a planned surgery that will be exploratory and highly invasive, for example, involving multiple levels and instrumentation, or involves a reoperation, or when placement of an implanted device is being considered for a condition that is complex and particularly protracted.

</tbody>
</table>
The major psychosocial risk factors contributing to poor surgical outcome are listed in Table 76.4.\textsuperscript{204} A comprehensive psychological evaluation helps to identify these risk factors. Research from several laboratories has found that using a scorecard approach to identifying risk factors has predictive value and that patients with a high level of overall risk respond poorly to spine surgery or invasive procedures.\textsuperscript{205–207} The results reviewed in this chapter demonstrate that spine surgery or placement of an implanted device may not be effective for patients with a high level of psychosocial risk. For such patients, a more conservative intervention may be more appropriate and effective. Fortunately, a cost-effective alternative to surgery or implantation exists—the multidisciplinary chronic pain management program (CPMP). Such programs teach patients to manage and cope with pain and its impact, through a combination of physical conditioning, education, psychological treatment, relaxation training, and vocational counseling. Several recent studies have shown that the CPMP approach can be as effective in treating patients with spinal pain as is spine surgery.\textsuperscript{25–28} The studies comparing CPMPs to spine surgery suggest that even when medical diagnostics reveal spinal pathology potentially amenable to surgery, many patients may achieve comparable results with less long-term risk by undergoing treatment in a CPMP.

TABLE 76.4 Presurgical Psychological Screening Risk Factors for Poor Surgical Outcome\textsuperscript{204}

- Personality factors (assessed by objective tests)
- Pain sensitivity
Using a comprehensive psychological screening, the surgeon or the pain physician can reduce the costs arising from procedures that have a relatively low probability of benefit and can help the high-risk patient avoid a downward slide into increasing pain and disability. Based on the results of the psychological screening, surgeons or pain physicians may decide to (1) refer the patient for treatment at a CPMP, (2) postpone elective surgery or placement of an implanted device until psychosocial factors are addressed, (3) avoid surgery and invasive procedures altogether, or (4) proceed with surgery or implantation but involve psychologists early during rehabilitation. Psychological screening offers the potential to sharpen patient selection for spine surgery and for implanted devices and tailor treatments to both the patient’s physical and psychological needs.

Pharmacology is the science that deals with the origin, nature, chemistry, effects, and uses of drugs. Commonly, pharmacology is subdivided into pharmacodynamics (how drugs work; mechanisms of action) and pharmacokinetics (how drugs are absorbed, distributed, biotransformed [metabolized], and eliminated) in the body. Pharmacology is nonclinical science done largely in animal and in vitro models in the laboratory setting. Clinical pharmacology, often termed therapeutics in the United Kingdom and some other countries, is the discipline intended to translate findings from the laboratory bench to the patient bedside. Despite attempts in the United States to develop clinical pharmacology as a subspecialty of internal medicine, and subsequently pediatrics and psychiatry, very few clinical pharmacologists are in practice and fewer still are in training programs today. By definition, the terms pharmacology and even clinical pharmacology are somewhat restrictive.

Pharmacotherapy is, simply put, the treatment of disease by medicines. This is now a recognized health science discipline and describes the practice of clinicians including many physicians, pharmacists, advanced
practice nurses, pharmacologically oriented psychologists, and others. Pharmacotherapy encompasses what those who attempted to develop clinical pharmacology envisioned without restricting practice to subspecialty-certified physicians. It is an academic discipline and numerous respected journals, and an increasing number of health science textbooks now have pharmacotherapy in their titles. This more inclusive term includes those aspects of pharmacology and findings from clinical pharmacology that apply directly to the use of pharmacologically active substances in patient care.

Clinicians must have access to contemporary information on how drugs work to use them optimally in managing pain. Pharmacology is the science of how the drugs work, not their application in treating patients. Thus, this section of Bonica’s Management of Pain has been renamed Pharmacotherapy.

Pharmacotherapy is a potent tool in pain management. However, we must use drugs wisely to provide optimal patient benefit. Several core concepts in rational pharmacotherapy are introduced in this chapter as a prelude to the four subsequent chapters on specific pharmacotherapy for pain management.

Drugs Are Both Underused and Overused in Pain Management

There is a broad consensus among pain clinicians that pain, especially chronic nonmalignant pain, is often undertreated. One of the reasons for this is concern about medication misuse. Increasing reports of adverse events and even fatalities associated with analgesic use indicate that some practitioners may use analgesic pharmacotherapy unwisely or excessively. It is important to view drugs as tools that can be used well or poorly. Adverse events are not due to the drugs per se; they are due to the way the drugs are used. Clinicians are encouraged not to label any class of drugs as “good” or “bad” but to recognize that they only become so designated because of the way they are used. However, there are some drugs within various classes that one should consider suboptimal, for example, meperidine, as discussed in more detail in the opioids chapter (Chapter
This section attempts to identify medication use that is more apt to have positive outcomes than adverse outcomes.

Pharmacotherapy Alone Is Rarely Optimal Therapy for Chronic Pain

Analgesic pharmacotherapy often is appropriate alone for acute pain. However, chronic malignant and nonmalignant pain usually responds better to multimodal treatment. Many adverse events due to medications might not occur if lower drug doses are used, and concurrent nonpharmacologic therapy often reduces drug dose requirements (Table 77.1). Using multiple drugs to address symptoms of other drugs, that is, polypharmacy, sometimes leads to complex regimens with adverse events. Although it is usually wise to simplify drug regimens, use of more than one drug in combination may reduce the risk of adverse events when the drugs are additive or synergistic and the adverse events are commonly dose-related. A common example is concurrent use of an opioid and a nonsteroidal anti-inflammatory drug (NSAID) because these two drug classes are mutually dose sparing. One might consider such use of multiple drugs for pharmacotherapy as “rational polypharmacy.”

It is often useful to consider medications for chronic nonmalignant pain as temporary interventions to facilitate the patient’s adapting to self-
management techniques such as physical activation, cognitive restructuring, or responding to medical procedures such as serial nerve blocks.

EVERY USE OF MEDICATION FOR PAIN IS AN EXPERIMENT

It is axiomatic that every drug has the potential to do harm. We should only use pharmacotherapy when the potential benefit outweighs the potential harm; that is, there is a favorable risk-to-benefit ratio. Clinicians should consider initial pain pharmacotherapy as a trial to determine outcome before committing to ongoing pharmacotherapy. All medication orders should expire at a predetermined time and only be continued after it is clear that the benefits outweigh the risks. It is helpful in most cases to tell patients that new medications are being ordered for a limited time to determine if they should be continued. This practice would eliminate many adverse outcomes from ongoing drug therapy. This practice might also lessen inappropriate patient expectations about their drug therapy for pain. It is usually unwise to continue any medication without a clear determination that it is more helpful than harmful.

In addition to risk-to-benefit considerations, clinicians should always consider cost–benefit issues. Frequently, new drugs and dosage forms offer incremental advantages over previously available agents, but the new agents do so at a markedly greater cost. The pharmaceutical industry often aggressively markets new and patent-protected drugs and dosage forms, although there is rarely a financial incentive for a pharmaceutical manufacturer or distributor to promote generic drugs because pharmacists can legally substitute generic equivalent drugs unless the prescriber specifies otherwise. At the extreme, entire older classes of drugs, which may still be agents of choice, have been largely replaced by newer, far more expensive agents. For example, tricyclic antidepressants are still drugs of choice for neuropathic pain, but no company promotes them. Aggressive marketing of various antiepileptic and serotonin norepinephrine reuptake-inhibiting drugs that are as effective or nearly as effective as the tricyclic antidepressants for this indication has resulted in the newer, more expensive drugs being considered by many clinicians as
the only drugs for neuropathic pain.

**PATIENT PREFERENCE: SYMPTOM CONTROL VERSUS SIDE EFFECTS**

Patients vary both in their desire to take medications to manage their pain and in their response to the medications. Many patients are highly averse to taking medications, especially opioids, even when those medications can greatly reduce the pain. This aversion may be due to fears or misconceptions about the medications, and clinicians should inquire about their patients’ beliefs and preferences when considering pharmacotherapy. When a patient with allergies indicates a preference for a particular antihistamine, we normally provide that medication. However, when a chronic pain patient expresses a preference for a particular opioid, many clinicians become suspect that there is an ulterior motive for specifying a drug of choice. The perceived preference may be due to prior experience, observation of other patients’ good or bad response to opioids, or misconceptions. We should ascertain the basis for our patients’ expressed preferences when feasible rather than draw our own—often inaccurate—conclusions. Obviously, we should correct wrong information on which patients express preferences.

Some chronic pain patients prefer to be more alert even though the trade-off may be more intense pain. Others prefer as much pain relief as possible with the accompanying dulling of their senses. Neither preference is right or wrong. It is very reasonable to counsel patients about the side effects of the analgesics and adjuvants we are considering and ask them their preferences regarding comfort versus alertness. One of the most problematic misconceptions among chronic pain patients is that medication will “cure” their pain. It is important to determine if the patient harbors such beliefs and to correct them when possible.

There is great interpatient variability in response to analgesics. We see this commonly with NSAIDs but cannot explain the mechanism. With opioids, it also is common, and we know several sources of genetic polymorphism that cause interpatient variability as described in more detail in Chapter 79. Clinicians should actively counsel patients about the need to adjust medications and doses to optimize response: One size does
WHENEVER POSSIBLE TREAT THE CAUSE OF THE PAIN

A commonly espoused concept in opioid pharmacotherapy is to increase the medication dose until the patient experiences either adequate pain relief or unacceptable side effects. Although there may be some wisdom in this approach, it also has two major problems. One is that opioids are not the therapy of choice for all types of pain. For example, bone pain in which there is inflammation often responds better to NSAIDs than to opioids and nearly always responds better to a combination of these two drug classes than to opioids alone. Likewise, neuropathic pain nearly always responds better to a combination of opioids and tricyclic antidepressants or anticonvulsant medications with fewer side effects than will be seen with one class alone. Again, a combination of both a neuropathic pain-specific agent with an opioid is usually synergistic. Opioids can actually blunt pain from constipation but would probably exacerbate the constipation. It is far better to identify the cause of the pain and to treat it with specific modalities than to simply use opioids and increase the dose to response. Examples of painful conditions that are indications for such alternate modalities include incision and drainage with anti-infective agents for painful infected cysts, physical therapy for myofascial pain, and massage with pressure for pain due to painful lymphatic drainage blockade.

The second limitation is that several opioid dosage forms, most notably the newer long-acting ones, are very expensive. The great interpatient variability in response to opioids supports changing drugs when a patient does not respond as expected after two or three dose increments. Such patients may well respond better to other opioids to which they are rotated. Thus, serial trials of different opioids to find the optimal drug are sometimes indicated.

SYNERGISM AND POTENTIATION

Additive effects may occur when we use two pharmacologic agents concurrently and the combined effect equals the sum of the two agents’
effects. Unless doing so provides a specific benefit, for example, dose sparing with drugs that have problematic dose-related adverse effects, additive pharmacotherapy usually is not warranted. It simply complicates the regimen, reducing patient adherence (compliance) and often increasing cost. Synergism occurs when two drugs act together to produce a supra-additive action. This often is desirable. An example is using an NSAID with an opioid for their mutually synergistic effects. Synergism occurs because of the two different mechanisms and the NSAID being anti-inflammatory with the opioid acting largely centrally while NSAID provides peripheral anti-inflammatory activity. Potentiation is an effect in which one drug enhances the action of another. An example is the concurrent use of acetaminophen and morphine, which has been demonstrated in rat model. Both drugs are simple analgesics, that is, they have no anti-inflammatory activity. The opioid is far more active than the acetaminophen, but the latter increases the effectiveness of the former by acting at the serotonergic system in the brain. Although the concurrent use of acetaminophen can be clinically useful, the net clinical advantage of combination therapy is less than occurs when an opioid is used with an NSAID producing the two-way advantage of synergism.

OUTCOMES ANALYSES OF PAIN PHARMACOTHERAPY
Clinical studies of analgesics have traditionally focused largely, if not exclusively, on efficacy. Efficacy is defined simply as the ability of an agent to have a desired effect. Studies of analgesic efficacy for chronic pain typically last only 3 to 6 weeks. Commonly, reduction in pain intensity is the measured outcome. Every pain clinician knows that long-term effectiveness is the outcome measure needed to determine the usefulness of a drug for chronic pain and that patients’ ability to function, to carry out activities of daily living, is often more important than pain intensity per se. These should be the criteria for effectiveness.

The pharmaceutical industry is beginning to conduct true effectiveness studies in support of their products. When more clinicians insist on such evidence before adopting new drugs that are supported only by the short-term efficacy studies needed for the drugs to be approved for human use,
we will see more true effectiveness studies.

Clinical outcomes studies compose only one of the three types of studies needed to assess the place of drugs in pain management. Health-related quality of life (HRQoL) research is a relatively new discipline that provides important information for a wide range of subjective complaints, including pain.\textsuperscript{8} A commonly used measurement tool for HRQoL is the Medical Outcomes Study Short-Form 36 (MOS SF-36).\textsuperscript{9} More recently, the National Institutes of Health (NIH) has been developing a state-of-the-art group of assessment tools for self-reported health, using modern technology with computerized testing and data collection (the Patient-Reported Outcome Measurement Information Systems, PROMIS). This is a measurement tool that is capable of measuring HRQoL in a wide range of clinical disease states, including pain.\textsuperscript{10} It has been widely adopted since its introduction in 2004, and researchers both in the United States and internationally are using it with increasing frequency, with substantial integration into clinical settings. Although these instruments provide useful population data, they lack the specificity, sensitivity, and brevity needed for utility as a clinical monitoring tool in chronic pain management. For that purpose, several tools are in development such as the 3-item PEG Scale (measures pain intensity and pain interference with enjoyment of life and general wellbeing)\textsuperscript{11} and PainTracker, a more extensive measurement tool that in addition measures pain location, sleep interference, activity interference, depression, anxiety, side-effects, medication utilization and satisfaction with treatment (https://www.nva.org/wp-content/uploads/2015/01/Pain-Tracker-Form.pdf). HRQoL studies provide valuable clinical information on how interventions affect patients’ ability to function, not just their subjective pain intensity report.

The third type of study that is becoming increasingly important is pharmacoconomics (PE) analyses. Pain management has become more complex, more invasive, and more expensive in recent years. Five types of PE studies that help define which interventions are apt to provide the most benefit are listed in Table 77.2.\textsuperscript{12}

| TABLE 77.2 Types of Pharmacoeconomic Analyses | 4063 |
Approved Drugs and Drugs for Nonapproved Uses

For a drug to be available for routine clinical use in the United States, the manufacturer or distributor (sponsor) must hold an approved new drug application (NDA) from the U.S. Food and Drug Administration (FDA). The FDA can legally approve an NDA only after the sponsor has completed three phases of clinical studies under a license for those studies called an investigational new drug exemption (IND). The IND specifies exactly how and in whom the investigators can use the drug and use outside of those restrictions can lead to criminal penalties. Only clinicians explicitly named on the IND or persons under their direct supervision can legally participate in the studies. Once the FDA licenses a new drug for human use, any licensed prescriber can legally use it for any human use. However, the sponsor cannot legally advertise or market the newly approved drug for indications outside of the labeling even when good scientific evidence supports such use. This includes any continuing professional education activities directly supported by the sponsor. Furthermore, the indications that are listed in the labeling (package insert) for the newly approved drug can, by law, only include those indications approved by the FDA based on clinical studies submitted by the sponsor in support of the NDA.

If the sponsor provides an unrestricted educational grant to a professional society, hospital, or other such uninterested party, that organization can sponsor continuing professional education in which presenters can discuss nonapproved (“off-label”) uses of the drug based on scientific and professional publications and findings. Thus, for example, a sponsor cannot legally promote an antiepileptic drug that is not FDA-approved for neuropathic pain management for that indication even if there is evidence of efficacy.
is good scientific evidence of the efficacy of the drugs for that indication. Neither can professionals paid directly by the sponsor make continuing education presentations in which they discuss off-label use in any program. That would be defined as marketing the drug for a nonapproved use. However, this in no way constrains licensed prescribers from prescribing the medication for off-label use as long as an NDA has been issued for another human use.

If a patient suffers an adverse event from a drug prescribed off label, the harmed parties can initiate civil (malpractice) litigation against the prescriber and the health care facility where this occurred. There normally are no grounds for criminal action against the practitioner for prescribing an approved drug even though it was for a nonapproved indication. Published scientific evidence supporting the use of the drug as prescribed is normally a good defense in such actions. The lack of such evidence greatly increases the prescribers’ exposure to civil litigation.

Pain patients often have comorbid mood disorders, and sometimes, they are already involved in litigation relating to the cause of their pain. These factors may increase the risk of litigation against pain clinicians if the patients are dissatisfied with the care they receive. Therefore, pain clinicians should remain aware of legal issues when planning and implementing pharmacotherapy for such patients. Opioids and other such potent medications are essential in pain management, however, and clinicians should not hesitate to use such pharmacotherapy when indicated. Clinicians should always carefully document what they are doing as recommended by the Federation of State Medical Boards of the United States. In its 2017 Guidelines for the Chronic Use of Opioid Analgesics (https://www.fsmb.org/Media/Default/PDF/Advocacy/Opioid%20Guidelines.pdf), the Federation explicitly states that the diagnosis and treatment of pain is integral to the practice of medicine and clinicians must understand the relevant pharmacologic and clinical issues in the use of opioid analgesics. Criteria for evaluating the use of controlled substances and information to document in the medical record when doing so are listed in Table 77.3.

Informed consent and treatment agreement
Initiating an opioid trial
Ongoing monitoring and adapting the treatment plan
Periodic and unannounced drug testing
Adapting treatment
Accurate and complete medical records to include:
- Copies of the signed informed consent and treatment agreement
- The patient’s medical history
- Results of the physical examination and all laboratory tests
- Results of the risk assessment, including results of any screening instruments used
- A description of the treatments provided, including all medications prescribed or administered (including the date, type, dose, and quantity)
- Instructions to the patient, including discussions of risks and benefits with the patient and any significant others
- Results of ongoing monitoring of patient progress (or lack of progress) in terms of pain management and functional improvement
- Notes on evaluations by and consultations with specialists
- Results of queries to the state PDMP
- Any other information used to support the initiation, continuation, revision, or termination of treatment and the steps taken in response to any aberrant medication use behaviors. These may include actual copies of, or references to, medical records of past hospitalizations or treatments by other providers.
- Authorization for release of information to other treatment providers
- Compliance with controlled substance laws and regulations

PDMP, prescription drug monitoring program.
Adopted as policy by the Federation of State Medical Boards, April 2017. Available online at: https://www.fsmb.org/Media/Default/PDF/Advocacy/Opioid%20Guidelines%20As%20Adopted%20April%202017_FINAL.pdf

RATIONAL PHARMACOTHERAPY
The criteria for rational pharmacotherapy are simple. The drug must be legal; that is, there must be an NDA for at least one human use. If the drug is used for a nonapproved use, the clinician should assure that there is good evidence supporting that use. The clinician must be confident that the potential benefit for use of the drug in that specific patient in the regimen prescribed presents potential benefits that outweigh the potential risks. To make that determination, the clinician must understand both the pharmacodynamics and pharmacokinetics of the drug. The recent increase in deaths due to methadone is attributable in part to the prescribers not understanding the long elimination half-life of the opioid. When any opioid dose is increased before the drug has reached steady-state serum levels, there is risk of toxicity from drug accumulation. Due to the relatively high cost of commercially available long-acting opioids, several
third-party payers encouraged primary care clinicians to change their patients from the more expensive analgesics to methadone. However, methadone, a pharmacologically long-acting opioid, has a much longer half-life than pharmaceutically long-acting opioids such as sustained-acting oxycodone. That difference in half-life necessitates changes in the opioid regimen when initiating methadone. After initiation, the dose should not be increased before serum levels near steady state are reached and that may require 5 to 7 days for methadone. Practitioners unawareness of the implications of this aspect of methadone’s pharmacology appears to be at least one factor in the increased number of methadone deaths observed in the last decade.\textsuperscript{13}

**Conclusion**

Pharmacotherapy is essential in the management of nearly all acute pain and the majority of chronic pain patients. Safe and rational use requires attention to the risk-to-benefit ratio in each clinical situation. It is not logical to provide analgesics for every patient in pain, nor is it reasonable to deny analgesic medication when it is needed.

Pharmacotherapy is the most common modality used to treat pain. Too often, pharmacotherapy is used as a sole intervention. Most patients with moderate to severe acute pain or any chronic pain would benefit more from multimodal therapy.

Recent statements and publications emphasizing the risks of pharmacotherapy without providing a balanced discussion of the benefits of these drugs have discouraged some clinicians from using needed medications for pain. The U.S. Drug Enforcement Administration (DEA) has taken positions that discourage opioid pharmacotherapy,\textsuperscript{14} and the American Heart Association has discouraged NSAID use due to cardiovascular risk without addressing the major improvement in quality of life that millions of patients receive from these medications.\textsuperscript{15} The DEA posits that reducing opioid use will reduce opioid abuse. Although that may be true, it would occur at the cost of countless pain patients suffering unnecessarily. The American Heart Association position looks at the cardiovascular risks associated with NSAIDs. However, it does not
consider the impact of painful inflammatory diseases such as osteoarthritis, which erode the quality of life of millions of patients.

Pain clinicians must be effective advocates for rational pharmacotherapy for their patients. To do so, we must be knowledgeable about the drugs we use. We also must assure that our patients and their families have accurate information to help them use the medications correctly. The following four chapters provide a scientific basis for that advocacy and use.

References

Nonsteroidal anti-inflammatory drugs (NSAIDs) are a diverse group of compounds with analgesic, antipyretic, and anti-inflammatory activity. Newer compounds, more specific for reducing pain and inflammation while promoting safety and tolerability, have largely replaced the prototypical NSAID, aspirin. NSAIDs remain the most widely prescribed drugs in the world with an estimated 30 million users worldwide and sales greater than $12 billion globally.\textsuperscript{1} They are valuable in the management of both acute and chronic painful and inflammatory conditions and are administered by both systemic and local (topical) routes.

The earliest agent in this class, which has been used in folk medicine for millennia, is willow bark. Hippocrates wrote about the use of powdered willow bark for pains and fever in the fifth century before the Common Era. Edward Stone formally reported salicylic acid extracted from the bark and leaves of willow, myrtle, and a number of other plants as a medication for fever in 1763. Felix Hoffmann, a chemist at Bayer Pharmaceuticals in Germany, rediscovered the acetylsalicylic acid formulation, which Bayer then named Aspirin and marketed as a remedy for pain, fever, and inflammation early in the 20th century. Only in the mid-20th century did aspirin become the generic name for that compound.

The next generation of NSAIDs were introduced in the 1960s, the first being indomethacin which was soon followed by ibuprofen. Numerous other NSAIDs followed, most of which claimed better efficacy and safety than earlier compounds. In the past two decades, several NSAIDs have been removed from commercial availability due to potentially lethal side effects after they were in general use. Phenylbutazone and oxyphenbutazone lost popularity and were withdrawn due to blood
dyscrasias. Suprofen caused nephrotoxicity. Benoxaprofen, bromfenac, and ibufenac (which was marketed in the United Kingdom, not the United States) caused serious hepatotoxicity. Two of the three cyclooxygenase (COX)-2 selective NSAIDs approved in the United States in the 1990s were subsequently withdrawn from the market, as noted in the following discussion of the COX-2 selective agents. Today, over two dozen NSAIDs are commercially available in the United States for clinical use (Table 78.1), and several others are available in other countries as well.

**Mechanism of Action**

**PROSTAGLANDIN SYNTHESIS AND PHARMACOLOGY**

NSAIDs act by inhibiting prostaglandin synthesis in vivo. Prostaglandins (PGs) are derived from arachidonic acid and other polyunsaturated fatty acids; the 20-carbon polyunsaturated essential fatty acid (arachidonic acid) is the major source in mammalian tissues. PGs derived from arachidonic acid contain two double bonds. These are PGE$_2$, thromboxane and prostacyclin. Analogous compounds synthesized from icosatrienoic (linoleic) and eicosapentaenoic acids contain one fewer or one more double bond in the side chains (PGE$_1$, PGE$_3$, respectively).

The PGs, thromboxanes, hydroxy acids, and leukotrienes, which retain the 20-carbon unsaturated fatty acid backbone, are collectively known as eicosanoids. Their release, usually as a result of trauma, is the major stimulus for eicosanoid production as PGs cannot be stored and are released as soon as they are synthesized. Cell membrane disruption causes phospholipid release which is converted to arachidonic acid by the action of phospholipase A$_2$ (PLA$_2$). Arachidonic acid then acts as a substrate for the COX enzyme.

**CENTRAL SITES OF ACTION**

PGs also are involved in the pyretic response. After injection of pyrogens, cerebrospinal fluid (CSF) PG levels rise. That effect can be prevented by pretreatment with aspirin alluding to the central sites of action. Acetaminophen (paracetamol) is analgesic and antipyretic but lacks clinically useful peripheral anti-inflammatory activity. Acetaminophen blocks PG synthetase within the blood–brain barrier; the same effect is not
seen in the periphery. Therefore, it is not an NSAID per se, although it is commonly used for many of the same indications as NSAIDs. Acetaminophen is discussed in more detail later in the chapter.

**PERIPHERAL SITES OF ACTION**

Prostanoids do not generally activate nociceptors directly; they sensitize them to mechanical stimuli and chemical mediators of nociception such as bradykinin.\(^6\) PGE\(_2\) is the predominant eicosanoid released from endothelial cells of small blood vessels\(^7\) and is a key mediator of both peripheral and central pain sensitization.\(^3\) Because it is the prostanoid most associated with inflammatory responses, the formation of PGE\(_2\) at inflammatory sites is often considered an indicator of local COX activity, and suppression of PGE\(_2\) is an indicator of a reduced inflammatory process.\(^8\) The production of PGE\(_2\) is slow in onset and of long duration in response to inflammation.\(^9\)

**COX-1 AND COX-2 SELECTIVITY**

COX is encoded by two genes.\(^10\) Although the isomerization of PGH\(_2\) into PGE\(_2\) has been well characterized biochemically and pharmacologically, the enzyme responsible, PGE synthase (PGES), was only recently purified and cloned.\(^11,12\) The existence of more than one COX isoform, and specifically one that is positively regulated by cytokines and negatively regulated by glucocorticoids, was long suspected. In the early 1990s, an inducible COX isoenzyme was cloned.\(^13\) The recognition of two COX isoforms, then designated COX-1 and COX-2, generated intense efforts to characterize the relative contribution of each isoform to prostanoid production in specific situations (Fig. 78.1).
COX-1 and COX-2 are membrane-associated enzymes with a 60% amino acid sequence homology. In spite of their structural similarity, the two COX isoforms have different gene expression profiles, distinct kinetic properties, and different interactions with PLA$_2$s and synthases. COX-1 is expressed constitutively and produces prostanoids that fine-tune physiologic processes requiring instantaneous or continuous regulation (e.g., hemostasis). COX-2 expression is usually low but can be induced by numerous factors including neurotransmitters, growth factors, pro-inflammatory cytokines, lipopolysaccharide, calcium, phorbol esters, and small peptide hormones. However, there are exceptions to the original constitutive versus inducible theory of COX expression. COX-1 expression can be induced in some stress conditions, such as nerve injury, and many tissues, including the central nervous system (CNS) and the kidney, constitutively express COX-2. In the spinal cord, there are detectable basal levels of both COX-1 and COX-2. That might enable immediate reactions to transmitter release that results in prostanoid production. A third isoform designated COX-3 that was identified in dogs is formed as a splice variant of COX-1. Because canine COX-3 can
be inhibited by therapeutic concentrations of acetaminophen, initial reports postulated that COX-3 inhibition was the mechanism of action of acetaminophen. However, this does not appear to be true; more recent evidence indicates that COX-3 is not expressed in humans.\textsuperscript{19}

**Induction of COX-2**

The original hypothesis formulated by John Vane in his Nobel prize–winning work on the mechanism of action of NSAIDs was that these compounds inhibited prostanoid production in the periphery preventing a sensitizing action of \( \text{PGE}_2 \) on the peripheral terminals of sensory fibers.\textsuperscript{20} Peripheral inflammation induces an increase in COX-2 and \( \text{PGES} \) expression in the CNS. The pro-inflammatory cytokine interleukin 1\( \beta \) (IL-1\( \beta \)) is upregulated at the site of inflammation and plays a major role in inducing COX-2 in local inflammatory cells by activating the transcription factor nuclear factor kappa B (NF-\( \kappa \)B).\textsuperscript{22} IL-1\( \beta \) is also responsible for the induction of COX-2 in the CNS in response to peripheral inflammation. However, this is not the consequence either of neural activity arising from the sensory fibers innervating the inflamed tissue or of systemic IL-1\( \beta \) in the plasma. Rather, peripheral inflammation produces some other signal molecule that enters the circulation, crosses the blood-brain barrier, and acts to elevate IL-1\( \beta \), leading to COX-2 expression in neurons and nonneuronal cells in many different areas of the spinal cord.\textsuperscript{3,23} An elevation of COX-2 also occurs at many levels in the brain and spinal cord, mainly in the endothelial cells of the brain vasculature.\textsuperscript{24} Thus, there appear to be two forms of input from peripheral inflamed tissue to the CNS. The first is mediated by electrical activity in sensitized nerve fibers innervating the inflamed area, which signals the location of the inflamed tissue as well as the onset, duration, and nature of any stimuli applied to this tissue.\textsuperscript{21} This input is sensitive to peripherally acting COX-2 inhibitors (and to neural blockade with local anesthetics, e.g., epidural anesthesia).\textsuperscript{25} The second is a humoral signal originating from the inflamed tissue, which acts to produce a widespread induction of COX-2 in the CNS. Regional anesthesia does not affect this;\textsuperscript{23,26} it only is blocked by centrally acting COX-2 inhibitors.\textsuperscript{23,25} One implication of this is that patients who receive neuraxial anesthesia for surgery may require a centrally acting COX-2
inhibitor to optimally reduce postoperative pain and the postoperative stress response. Therefore, the permeability of the blood–brain barrier to both nonselective and COX-2 selective NSAIDs is important. Inhibitors of COX-2 that better penetrate the blood–brain barrier might represent more efficient analgesics and could also act to reduce many of the more diffuse aspects of inflammatory pain, such as generalized aches and pains, depression, and loss of appetite, which are key aspects in determining the “quality of life” response to treatment. The main process by which a drug passes from the circulation into the CNS is passive diffusion. Lipophilicity and ionization are critical determinants of this transfer. The CSF represents a convenient sampling point for drugs that enter the CNS; however, there are very few NSAIDs for which the CSF pharmacokinetics has been defined. The high lipid solubility of indomethacin allows it to rapidly cross into the CSF and equilibrate with the free plasma concentration. Similar results are seen with ketoprofen.

**Pharmacokinetics**

NSAIDs are weak acids with pK\(_a\) values typically lower than 5. Because weak acids will be 99% ionized 2 pH units above their pK\(_a\), these anti-inflammatory agents are present in the body mostly in the ionized form. Although NSAIDs differ in their individual pharmacokinetic properties, some general factors affecting NSAID pharmacokinetics can enable clinicians to select among the different agents available.

**ABSORPTION**

**Oral**

Most NSAIDs are rapidly absorbed following oral administration, with peak plasma concentrations generally reached within 2 to 3 hours, although slow-release dosage forms have been developed to maintain active plasma levels for prolonged times. Factors affecting gastric emptying may profoundly affect the time course of the clinical effect of an NSAID. The extent of drug absorption from the gastrointestinal (GI) tract is more important than the rate. Rectal and topical administration minimize GI side effects that are common with these agents. In general,
the rate and extent of NSAID absorption is comparable for the rectal and oral routes.\textsuperscript{35}

**Injectables**

Intravenous (IV) and intramuscular (IM) NSAIDs forms are available in several countries. Ketorolac is the only parenteral NSAID available in the United States. Parecoxib, an injectable analog of the COX-2 selective NSAID valdecoxib, was under study, but those trials ceased when valdecoxib was withdrawn from the market. Parenteral administration may be advantageous in renal colic due to a more rapid onset than oral administration but has demonstrated no advantage over oral forms for any other indication.\textsuperscript{36} Several injectable NSAID dosage forms (e.g., diclofenac and ibuprofen) are currently available with more in development.

**Topical**

There is good evidence that topical NSAIDs can be safe and effective and that they produce less GI toxicity than systemic forms of the same drugs.\textsuperscript{37,38} These topical forms can be effective for inflammation of the knee and surface tissues; they generally are not effective for deeper structures. Topical NSAIDs must be properly formulated. Although extemporaneously compounded topical NSAIDs have been used, these often are ineffective. The vehicle and formulation can profoundly influence the efficacy of the topical dosage form.\textsuperscript{39} In the United States, a diclofenac topical patch (Flector), gel (Voltaren Gel), and liquid (PENNNSAID) are commercially available. Topical NSAID dosage forms available in several countries are listed in Table 78.2.

Intranasal

As an alternative to IM administration, intranasal (IN) ketorolac has gained popularity among those treating acute pain in situations where IV access is not readily available and/or oral administration is contraindicated. Following IN administration of ketorolac, there is a short time to peak plasma concentration of about 30 minutes. This is not only true for adolescents but also for adults and the elderly.

DISTRIBUTION

NSAIDs other than aspirin are generally lipid-soluble, weakly acidic, and highly bound to plasma proteins, primarily albumin. In most cases, <1% of the total plasma concentration exists in the unbound form. Hypoalbuminemia increases the free fraction of NSAIDs in the plasma, thus affecting the distribution and elimination of these agents. The high degree of serum protein binding increases interaction risk with other highly serum protein bound drugs. Most NSAIDs have distribution volumes between 0.1 and 0.15 L/kg.

In inflammatory joint disease, NSAID effectiveness corresponds to the affected joint synovial fluid drug levels. Those correlate closely with the drug concentration at the active site because there is simple transport of
drugs across the synovial membrane. The amount of drug in synovial fluid is dependent on the amount of albumin in the joint, which is lower than in plasma.

ELIMINATION
Hepatic biotransformation is the major elimination pathways for most NSAIDs, which are metabolized by cytochrome P450–mediated oxidation and/or glucuronide conjugation. Renal excretion of unmetabolized drug is a minor elimination pathway for most NSAIDs accounting for less than 10% of the administered dose. Some NSAID metabolites are excreted to a significant extent via the bile.

PATHOPHYSIOLOGIC CONDITIONS AFFECTING THE KINETICS OF NSAIDS
Renal Failure
Renal failure influences NSAID kinetics by reducing renal excretion of the drugs and metabolites normally eliminated in the urine and by affecting the distribution and biotransformation of drugs.

Absorption and Distribution
The absorption of NSAIDs is not impaired in renal failure patients. However, the plasma protein binding of many acidic compounds such as the NSAIDs is impaired in renal failure patients. The result is an increase in the volume of distribution of the unbound fraction of the drug in plasma.

Elimination
An increase in the unbound fraction of the drug in plasma may lead to an increase in total plasma clearance of the NSAID. The clearance of those NSAIDs for which formation of acyl glucuronides is a major elimination pathway is significantly reduced in patients with renal failure. The acyl glucuronide forming NSAIDs (diflunisal, ketoprofen, naproxen, indoprofen, benoxaprofen, tiaprofenic acid) are usually rapidly excreted in urine but accumulate in plasma of patients with renal failure. The effect of renal failure on the oral clearance of several NSAIDs (e.g., ibuprofen, fenbufen, isoxicam and piroxicam) is small. Most of these compounds
are metabolized by oxidative pathways. All NSAIDs are very highly bound to plasma proteins, and hemodialysis will not likely result in increased elimination of these agents. No dosage adjustments are therefore necessary for patients receiving NSAIDs who are undergoing hemodialysis.\textsuperscript{48}

**Hepatic Disease**

Absorption and Distribution
Because the majority of NSAIDs are low clearance drugs, mild to moderate liver disease should theoretically not interfere with their oral bioavailability. Because the liver is the major organ for the synthesis of albumin which is the major binding protein for NSAID in plasma, hepatic dysfunction would be expected to cause alterations in the unbound drug fraction in plasma.

Elimination
Because most NSAIDs have a small total intrinsic clearance (oral clearance) relative to blood flow, hepatic clearance is essentially independent of flow and reflects drug metabolizing capacity. The elimination of ibuprofen does not seem to be affected in patients with mild to moderate liver disease.\textsuperscript{50}

**Specific Drugs**

All NSAIDs are analgesic, anti-inflammatory, and antipyretic. Differences among the drugs in their approved label indications reflect the studies submitted for approval rather than the actual indications for which the drugs are effective. Characteristics and available dosage forms of commercially available NSAIDs in the United States and much of the world are listed in Table 78.2. Initial selection of an NSAID for a specific patient should be based on several factors—including the patient’s past experience, dosing frequency compatibility with the patient’s lifestyle, and cost. No population studies suggest that any one NSAID is more effective than another, but interpatient variability in response does occur. Because patients respond differently to various NSAIDs for reasons that are not well understood, it is appropriate to try an NSAID at full dose for about 3
weeks and then to rotate to another NSAID if the desired effect does not occur. There is no evidence that a patient who does not respond to an NSAID in one chemical subclass (e.g., propionic acid derivatives) will respond any better to an NSAID from another chemical subclass class than to a different propionic acid derivative NSAID.

**SALICYLATES**

**Aspirin**
The aspirin elimination half-life increases from 2.5 hours at low doses to 19 hours at high doses. It is well absorbed from the stomach and small intestine, with peak blood levels achieved 1 hour after an oral dose. There is then rapid conversion of aspirin to salicylates from a high first-pass effect, which occurs in the wall of the small intestine and the liver. The metabolic pathways follow first-order and zero-order kinetics.\(^{51}\)

Aspirin inhibits the biosynthesis of PGs through irreversible acetylation and consequent inactivation of COX. This differs from contemporary NSAIDs, which are reversible COX inhibitors.\(^{52}\) Most cells can synthesize COX; platelets cannot. Thus, the acetylation of their microsomal enzyme lasts for the life of the platelet (10 to 14 days). The ability of aspirin to acetylate proteins helps explain its anti-inflammatory superiority over most other salicylates. Aspirin is the only NSAID that has been associated with Reye syndrome, a potentially lethal disorder that produces seizures and coma. It has occurred with the use of aspirin during a viral illness in children.\(^{53}\) As a consequence, aspirin is now rarely if ever used in pediatrics.

**Diflunisal**
Diflunisal has potentially better GI tolerability than aspirin because diflunisal is not metabolized to salicylic acid in plasma according to the results of a study comparing it at 250 mg and 500 mg twice a day to aspirin at 600 mg four times a day.\(^{54}\) Diflunisal has a shorter half-life and causes less inhibition of platelet aggregation than aspirin.

**ACETIC ACID DERIVATIVES**

**Indomethacin**
Indomethacin is well absorbed following oral and rectal administration, but the extent of absorption varies widely among patients. There is also a large interpatient variability in elimination half-life caused by extensive enterohepatic recirculation of the drug. It is highly bound to serum albumin. Metabolism involves demethylation and deacetylation in the liver with subsequent excretion of inactive metabolites and unchanged drug in the bile and urine.\(^{55}\) Its clinical application is somewhat limited by a relatively high incidence of gastritis and renal dysfunction. It is used in patients with acute gouty arthritis, osteoarthritis, and headaches (such as the hemicranias). Indomethacin is often used in neonatology to facilitate closure of a patent ductus arteriosus (PDA).

**Sulindac**

Sulindac resulted from the search for a drug similar to indomethacin but with less toxicity. Sulindac is an inactive prodrug that is converted after absorption by liver microsomal enzymes to sulindac disulfide, the active metabolite.\(^{56}\) As few as 25% of the patients have GI problems, primarily constipation.\(^{57}\) Sulindac was considered in early studies to be the least nephrotoxic of the NSAIDs, but subsequent studies failed to support this contention.\(^{58}\)

**Tolmetin and Etodolac**

These two NSAIDs claim fewer side effects than others in the class. Tolmetin is excreted in the urine partly unchanged, partly conjugated and as an inactive dicarboxylic acid metabolite.\(^{59}\) Tolmetin can cause edema due to sodium retention and abnormal liver function, both of which are reversible upon discontinuation of this NSAID.

Etodolac is an acidic compound with a pK\(_a\) of 4.65 and is available as tablets and capsules with a dosage of up to 1 g daily and maximum of 1.2 g. Clinical doses of 200 to 300 mg twice a day for the relief of low back or shoulder pain have been equated to analgesia with naproxen 500 mg twice a day.\(^{60}\) Large clinical trials demonstrated a similar incidence of abdominal pain and dyspepsia is similar to several other NSAIDs, and GI ulceration occurs in less than 0.3% of patients.\(^{61}\) Dyspepsia occurs with etodolac in 10% of patients with a somewhat lower incidence of
abdominal pain.

**Ketorolac**

Oral ketorolac was approved for use in the United States approximately 3 years after the parenteral form and has an efficacy similar to that of naproxen and ibuprofen. The oral dose is 10 to 20 mg every 4 to 6 hours for no more than 5 days continuous use because of the potential for toxicity. Ketorolac tromethamine has a pKₐ of 3.5. It is formulated in a racemic mixture with the S form providing analgesia. Following oral administration, bioavailability is near 100%; however, concomitant administration with high-fat meals will result in decreased peak and time-to-peak concentrations. Time-to-peak effect is estimated at 2 to 3 hours with no difference based on dosage. However, increased dosages will provide prolonged durations of analgesia. With oral and IV administration, it is almost entirely bound to plasma proteins (>99%). This results in a small apparent volume of distribution with extensive metabolism by conjugation and renal excretion. Hypoalbuminemia will result in a higher concentration of free drug. Clearance relies on hepatic conjugation, with the metabolites primarily (92%) renal excretion. The S enantiomer is preferentially metabolized, with some studies suggesting a half-life of 2.5 hours compared to 5 hours for the R enantiomer.

Ketorolac was the first parenteral NSAID available for clinical analgesic use in the United States, having gained U.S. Food and Drug Administration (FDA) approval in 1989. The parenteral form of ketorolac can be administered at single doses of 15, 30, or 60 mg IV or as 30 mg IM every 6 hours, again up to 5 days use out of concerns for toxicity. The analgesic effect with IV ketorolac is more rapid and occurs within 30 minutes, peak effect between 1 and 2 hours, and duration of analgesia of 4 to 6 hours (FDA-approved labeling). It has demonstrated antipyretic effects 20 times that of aspirin and thus can mask febrile response when given routinely to patients postoperatively. Some have suggested that ketorolac may act at the CNS in addition to the peripheral mode of action, and dental surgery studies with ketorolac also indicate that ketorolac acts centrally. However, CSF studies contradict this claim as measurements of the drug in CSF show poor penetration.
The effectiveness of ketorolac has been well established as several studies have demonstrated efficacy comparable to or exceeding that of morphine for treatment of moderate postoperative pain treatment and with fewer side effects.\textsuperscript{67} Notwithstanding are concerns for side effects such as bleeding and renal injury. Ketorolac is known to prolong bleeding time but does not alter it beyond the upper limits of normal.\textsuperscript{68} In fact, there is evidence that indicates no clinically significant effect on surgical site bleeding when compared to placebo.\textsuperscript{69} There were early reports of death due to GI and operative site bleeding\textsuperscript{70} resulting in the drug being recalled in Germany and France. In a response to these adverse events, the drug’s manufacturer recommended reducing the dose of ketorolac from 150 to 120 mg per day.\textsuperscript{64} The European Committee for Proprietary Medicinal Products recommended a further reduction of the maximum daily dose to 60 mg for the elderly and to 90 mg for the non-elderly.\textsuperscript{71} Currently, there is consensus that the dose should be as low as 7.5 to 10 mg every 6 hours.\textsuperscript{72,73} When first used postoperatively at an initial dose of 60 mg followed by 30-mg doses every 4 hours, ketorolac was associated with acute tubular necrosis, especially in patients who had undergone procedures that required fluid restriction. Some deaths resulted. Subsequently, to minimize this risk, doses were commonly reduced by 50\% to 75\%, but concerns about nephrotoxicity continue. The appropriate analgesic dose of parenteral ketorolac is controversial. The IN route of administration may produce higher levels of the drug in the CNS and CSF\textsuperscript{74} with minimal GI side effects. Studies are underway to determine the efficacy of this drug when administered intranasally.\textsuperscript{75}

Ketorolac is the only IN NSAID commercially available. It has been praised for its rapid onset of action with its unique route of administration. It has been studied in the management of acute pain following surgeries such as abdominal, dental, or orthopedic. The early studies showed an advantage over placebo in reduction of overall pain scores and postoperative opioid use.\textsuperscript{76} The half-life of IN ketorolac is similar to that of IM ketorolac, around 5 to 6 hours. Dosing is 1 spray per nostril per dose. Each spray provides 15.75 mg ketorolac tromethamine. Side effects for IN ketorolac are similar to that of other routes of administration with the addition of potential nasopharyngeal irritation. Surgical site infiltration
with ketorolac and local anesthetic has shown favorable results\textsuperscript{77} and is widely used clinically in orthopedic surgery.

**Diclofenac**

Diclofenac is a carboxylic acid functional group with rapid and complete absorption. Substantial concentrations of drug are attained in synovial fluid, which has been hypothesized as one of the sites of action of diclofenac.\textsuperscript{78} Concentration–effect relationships have been established for total bound, unbound, and synovial fluid diclofenac concentrations.\textsuperscript{79} Diclofenac is eliminated following biotransformation to glucuronidated and sulfated metabolites that are excreted in urine with very little drug eliminated unchanged. Diclofenac may have a significantly higher incidence of hepatotoxicity than other NSAIDs. The excretion of conjugates may be related to renal function. Conjugate accumulation occurs in end-stage renal disease; however, no accumulation is apparent on comparison of young and elderly individuals.\textsuperscript{80} Dosage adjustments for the elderly, children, or patients with certain comorbidities (e.g., hepatic disease, rheumatoid arthritis) may not be required. Significant drug interactions occur with aspirin, lithium, digoxin, methotrexate, cyclosporin, cholestyramine, and colestipol.\textsuperscript{81}

Parenteral diclofenac has been used in Europe for several years and was recently approved for use in the United States. The pharmacokinetics and precautions are similar to that of oral, immediate-release formulations. IV diclofenac has proven to be useful in treating postsurgical pain after abdominopelvic surgery\textsuperscript{82} and third molar extraction.\textsuperscript{83} In comparison to ketorolac, IV diclofenac demonstrated a superior effect with regard to not only both reduction in pain scores but also lower opioid requirements following orthopedic surgery.\textsuperscript{84} In vitro assessments of hemostasis have shown that diclofenac (IV and oral [PO]) produces less platelet dysfunction than aspirin or IV ketorolac.\textsuperscript{85}

Topical diclofenac comes in many forms: liquid, gel, and patch. Liquid diclofenac comes in a 2\% formulation and uses dimethyl sulfoxide (DMSO) as a driving agent. One percent diclofenac gel has demonstrated a 17-fold reduction in systemic absorption compared to oral diclofenac with repeated administration.\textsuperscript{86} The patch form of topical diclofenac 1.3\% has
also shown little systemic absorption and slow times to peak effect (10 to 20 hours). Systemic exposure is <1% that of a single oral diclofenac 50-mg dose. They have been shown to be effective in treating acute musculoskeletal pain—such as that from sprains, strains, and overuse injuries. There has also been suggestion of its use in acute postoperative pain. However, the beneficial effects of topical NSAIDs tend to be limited to acute pain as reviews of topical diclofenac in chronic pain states have largely yielded mixed results with the exception of its use in chronic osteoarthritis. Recommended dosing among the topical formulations of diclofenac varies between products and specific applications of the products.

**PROPIONIC ACID DERIVATIVES**
This class of NSAIDs includes ibuprofen, fenoprofen, ketoprofen, flurbiprofen, and naproxen. A newer drug in this class is oxaprozin, which permits once-daily dose regime, but it has no other advantage over other NSAIDs.

**Ibuprofen**
Ibuprofen was the first NSAID to become available without prescription in the United States. It is well absorbed; peak plasma levels of 15 to 20 µg/mL are achieved about 1 to 2 hours after a single dose. The half-life is about 3.5 hours. The drug is primarily hepatic metabolized with less than 10% excreted unchanged in the urine and bile. Ibuprofen at a dose of 1,200 mg per day has a predominately analgesic effect in arthritis patients. Normally, a minimum dose of 1,600 mg a day is needed for clinically useful anti-inflammatory activity. At 2,400 mg per day, it produces GI side effects of which nausea and dyspepsia are predominant. Renal side effects of ibuprofen appear to be dose-dependent and were not reported at the recommended dosage as over-the-counter drug (200 to 800 mg per day). Even at anti-inflammatory doses of more than 1,600 mg per day, renal side effects are almost exclusively encountered in patients with low intravascular volume and low cardiac output, particularly in the elderly. Concomitant administration of ibuprofen and aspirin antagonizes the irreversible platelet inhibition induced by aspirin. Therefore, the treatment
with ibuprofen in patients with increased cardiovascular (CV) risk may limit the cardioprotective effects of aspirin.\textsuperscript{94}

In 2009, IV ibuprofen was approved for use in the United States. The pharmacokinetics of the IV form has a half-life (2 hours) similar to that of the oral formulation but show a nearly twofold increase in peak plasma concentration that occurs at a more rapid rate. Early studies have shown an ability of IV ibuprofen to reduce pain scores and opioid use following orthopedic surgery and gynecologic surgery.\textsuperscript{95} The recommended dose is 400 to 800 mg every 6 hours as needed, not to exceed 3,200 mg in a 24-hour period. The drug must be diluted prior to administration and infused over a minimum of 30 minutes.

**Ketoprofen**

Oral ketoprofen reaches peak plasma levels in 1.5 to 2 hours. The half-life is 2.4 hours with an analgesic duration of 4 to 6 hours.\textsuperscript{96} The maximum recommended dose is 300 mg. An investigational topical patch contains 100 mg of the drug. Pharmacokinetic data indicate that the plasma levels of ketoprofen 100 mg administered orally are higher than when applied by patch. Because the patch facilitates ketoprofen delivery over a full day, the drug remains continually present in the tissue adjacent to the site of application. High-tissue but low-plasma ketoprofen concentrations produce a therapeutic effect, whereas plasma concentrations remain low enough to minimize systemic adverse events.\textsuperscript{97}

**Fenoprofen**

The calcium salt of fenoprofen is more common; it is well absorbed and achieves a peak plasma level of 20 to 30 µg/mL 2 hours after a single oral dose with a plasma half-life of 2 to 3 hours.\textsuperscript{98} Steady-state plasma levels are reached within the first 24 hours of therapy. Fenoprofen is well tolerated compared to aspirin and causes minimal occult GI bleeding; nevertheless, dyspepsia remains the most common side effect. Most of the drug is excreted as glucuronide in the urine.

**Naproxen**

Naproxen sodium is also available without a prescription in the United
States. Naproxen is well absorbed from the upper GI tract. Its long half-life of 13 hours makes it suitable for twice-daily administration,\textsuperscript{99} and it takes more than 2 days to reach steady-state serum levels. Excretion is almost entirely renal, primarily as an inactive glucuronide metabolite.

Naproxen has been used for the treatment of arthritis and other inflammatory diseases with superior efficacy to aspirin.\textsuperscript{100} It causes less GI irritation than aspirin. Naproxen increases bleeding time by inhibiting platelet aggregation. When given during pregnancy, it can cross the placenta in 20 minutes and cause neonatal jaundice. Naproxen appears to have one of the safest CV profiles of all NSAIDs.

**Oxaprozin**

Oxaprozin is approved for the management of adult rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, soft tissue disorders, and postoperative dental pain. Oxaprozin has a high oral bioavailability (95%), with peak plasma concentrations at 3 to 5 hours after dosing.\textsuperscript{101} It is metabolized in the liver by oxidative and conjugative pathways and readily eliminated by the renal and fecal routes. Oxaprozin inhibits nuclear translocation of NF-κB and metalloproteases and modulates the endogenous cannabinoid system.\textsuperscript{102} In a randomized study of patients with refractory shoulder pain, oxaprozin (1,200 mg) once a day was superior to three doses per day of diclofenac (50 mg) in reducing pain and improving quality of life.\textsuperscript{103}

Oxaprozin diffuses readily into inflamed synovial tissues after oral administration.\textsuperscript{104} Although discovered more than 20 years ago, it is now under intensive investigation because of its unusual pharmacodynamic properties. Other than being a nonselective COX inhibitor, the drug is capable of inhibiting both anandamide hydrolase in neurons, with consequent potent analgesic activity and NF-κB activation in inflammatory cells.\textsuperscript{102} Moreover, oxaprozin induces apoptosis of activated monocytes in a dose-dependent manner. As monocyte–macrophages and NF-κB pathways are crucial for synthesis of pro-inflammatory and histotoxic mediators in inflamed joints, oxaprozin appears to have pharmacodynamic properties exceeding those presently assumed as markers of classical NSAIDs.\textsuperscript{105}
OXICAM DERIVATIVES

Piroxicam, the first drug in this class, provides peak serum concentration following oral dosing slowly and has a long elimination half-life of 48.5 hours. This allows once-daily dosing, but piroxicam may take up to 1 week to achieve steady-state blood concentrations.\(^\text{106}\)

**Meloxicam**

Meloxicam is approved for the treatment of osteoarthritis in the United States. It has also been evaluated for the treatment of rheumatoid arthritis, ankylosing spondylitis, and acute rheumatic pain.\(^\text{107}\) Meloxicam is a nonselective COX inhibitor that has been shown to be somewhat COX-2 preferential at low therapeutic dose. It is unclear that this is clinically meaningful at normal therapeutic doses. Therefore, meloxicam should be considered a nonselective NSAID.

In clinical trials at a low dose, meloxicam was as effective as piroxicam, diclofenac, and naproxen with less GI toxicity,\(^\text{108}\) but this may not hold true at the commonly required higher dose. Meloxicam’s half-life of approximately 20 hours makes it appropriate for once-daily dosing.\(^\text{108}\) Meloxicam has not been reported to cause deterioration in renal function in patients with moderate renal failure, and there is no evidence of drug accumulation with continued use. However, the FDA-approved labeling recommends that only the 7.5-mg dose be used in patients with renal insufficiency. Dose adjustment is not required in the elderly. Meloxicam interacts with some medications, including cholestyramine, lithium, and some inhibitors of cytochrome P450: 2C9 and 3A4. Consequently, increased clinical vigilance is indicated when using it concurrently with other medications metabolized by those enzymes. Concentration-dependent therapeutic and toxicologic effects have yet to be extensively elucidated for meloxicam.\(^\text{109}\) Its pharmacokinetic profile is characterized by a prolonged, almost complete absorption, and the drug is more than 99.5% bound to plasma proteins. Meloxicam is metabolized primarily to four biologically inactive metabolites, which are excreted in both urine and feces. Steady-state plasma concentrations are achieved within 3 to 5 days. The pharmacokinetic parameters of meloxicam are linear over the dose range 7.5 to 30 mg, and bioequivalence has been shown for a number of
different formulations. Studies are underway investigating an IV formulation of meloxicam for acute pain following major surgery. Given the efficacy of oral meloxicam and its COX-2 specificity, the results of the trial are an exciting area of interest for the further application of NSAIDs in the acute care setting.

**COX-2 SELECTIVE NSAIDs**

COX-2 selective NSAIDs were developed to reduce the incidence of serious GI adverse effects associated with the administration of traditional NSAIDs on the assumption that these side effects were COX-1–mediated. Marketing efforts to differentiate these drugs from nonselective NSAIDs led to the term COX-2 specific inhibitors. That is misleading because these drugs are selective, not specific, in their COX-2 affinity. The initial COX-2 selective NSAIDs approved by FDA were celecoxib and rofecoxib.

**Celecoxib**

Celecoxib, the first COX-2 selective NSAID, was approved by the FDA on the last day of December 1998. It now has approval for the relief of pain from osteoarthritis, rheumatoid arthritis, acute pain, dysmenorrhea, and for familial adenomatous polyposis. It has good selectivity for the COX-2 enzyme. Peak plasma levels occur 3 hours after oral administration, and the drug crosses into the CSF. Celecoxib is 97% serum protein bound with an apparent volume of distribution of 400 L. It is metabolized via cytochrome P450 2C9 and eliminated predominantly by the liver. It is not indicated for pediatric use and is a category C drug for pregnancy. The drug has a half-life of about 11 hours. Adverse events noted in the various clinical trials include headache, edema, dyspepsia, diarrhea, nausea, and sinusitis. It is contraindicated in patients who have a sulfonamide allergy or a known hypersensitivity to aspirin or other NSAIDs.

Because celecoxib does not interfere with platelet function (there is no COX-2 in human platelets), it can be administered perioperatively as a multimodal analgesic without increased risk of bleeding.

The efficacy and upper GI safety of celecoxib compared with nonselective NSAIDs was evaluated in 13,274 patients with osteoarthritis.
Patients were randomly assigned to receive either celecoxib 100 or 200 mg twice daily or nonselective NSAID therapy (diclofenac 50 mg twice daily or naproxen 500 mg twice daily) for 12 weeks. Both celecoxib doses were as effective as the nonselective NSAIDs in treating osteoarthritis and significantly more gastric ulcer–related complications occurred in the nonselective NSAID patients (0.8/100 patient-years) compared with the celecoxib group (0.1/100 patient-years) (odds ratio = 7.02; \( P = .008 \)). The number of CV thromboembolic events was low and not different between the groups. The results of the SUCCESS-I study are different from the “CLASS” trial, which did not demonstrate an advantage of celecoxib in reducing the incidence of upper GI ulcer complications, which is attributed by the SUCCESS-I study authors to the low dropout rate and design of the newer study.

**Etoricoxib**

Used in more than 80 countries worldwide, etoricoxib is yet to be approved by the FDA for use in the United States. A selective COX-2 inhibitor, etoricoxib, has a near 100% bioavailability. It is primarily metabolized by cytochrome P450 system to water-soluble metabolites. Etoricoxib is excreted in the urine (70%) and feces (20%). Half-life of etoricoxib is 22 hours, and peak plasma concentrations are obtained at 1 hour in a fasting state or 2 hours in a fed state. Etoricoxib is produced in 30-, 60-, 90-, and 120-mg tablets. The efficacy of single daily dosages of 60 or 120 mg have been shown to substantially reduce acute pain following dental surgery and total joint arthroplasty and limit opioid use without any increased incidence of adverse events compared to placebo. Despite worldwide experience with this drug, there are currently no clinical trials underway in the United States to further investigate safety and efficacy of etoricoxib.

**Valdecoxib and Parecoxib**

Valdecoxib is a derivative of isoxazole and binds noncovalently to COX-2, forming a tight and relatively stable enzyme–inhibitor complex. It is a potent inhibitor of PGE\(_2\) production in humans. Valdecoxib has good oral bioavailability (83%) and a minimal first-pass effect. It achieves
maximal plasma concentration in 3 hours with an elimination half-life of about 8 to 11 hours. Valdecoxib was approved for use in osteoarthritis (10 mg), rheumatoid arthritis (10 mg), and acute pain (up to 40 mg). Clinical studies in high-risk cardiac patients demonstrated a significantly increased incidence of major CV adverse events, and the identification of increased risk for serious skin reactions (toxic epidermal necrolysis, Stevens-Johnson syndrome, erythema multiforme) led the FDA to recommend the withdrawal of this COX-2 inhibitor from the US market in 2003. Parecoxib is a parenteral derivative of valdecoxib that has not been approved for marketing in the United States due largely to CV toxicity concerns.

**ACETAMINOPHEN**

Acetaminophen is a para-aminophenol derivative with analgesic and antipyretic properties similar to aspirin. Antipyresis is likely from direct action on the hypothalamic heat-regulating centers via inhibiting action of endogenous pyrogen. Its exact mechanism of action is unknown, but it is hypothesized to act centrally through pathways that involve serotonin, nitric oxide, eicosanoids, or opioids. Although equipotent to aspirin in inhibiting central PG synthesis, acetaminophen has no significant peripheral PG synthetase inhibition. Therefore, it lacks clinically useful peripheral anti-inflammatory activity, which makes it less desirable than NSAIDs for painful, inflammatory disorders. Doses of 600 to 650 mg are more effective than doses of 300 to 325 mg, but little additional benefit is seen at doses above 1,000 mg, indicating a possible ceiling effect.

Acetaminophen has few side effects in the usual dosage range; no significant GI toxicity or platelet functional changes occur. However, recent studies demonstrate that acetaminophen can cause blood pressure elevations. It is not clear if this presents risk of CV side effects similar to NSAIDs in light of the finding that NSAID-induced blood pressure elevation over time is associated with CV thrombotic effects.

Nephrotoxicity also can occur with acetaminophen but less frequently than it occurs with NSAIDs. Acetaminophen is almost entirely metabolized in the liver, and the minor metabolites are responsible for the hepatotoxicity seen in overdose. Inducers of the cytochrome P450
enzyme system in the liver (such as alcohol) increase the formation of metabolites and therefore increase hepatotoxicity. In certain patients (chronic ethanol users, malnutrition, and fasting patients), repeating therapeutic or slightly excessive doses may precipitate hepatotoxicity. More recently, the maximum allowable content of acetaminophen in a pill form was limited to 325 mg by the FDA with further recommendations to limit the daily dose of acetaminophen to 3 g per day.\textsuperscript{124} Toxic doses appear to be a function of baseline glutathione levels and other dose-related factors. Genetically determined glutathione is an important factor in overdose toxicity. Patients with high glutathione stores may tolerate much higher doses, but the daily limit is important for safety because many patients lack sufficient glutathione stores to safely tolerate higher daily doses. Clinicians should carefully inquire and educate patients about other over-the-counter symptom-control products that patients may be taking and which also contain acetaminophen as many over-the-counter and prescription analgesics contain acetaminophen as a component.

Acetaminophen is completely and rapidly absorbed following oral administration, with bioavailability around 85\% to 95\% after first-pass metabolism. Peak serum concentrations are achieved within 2 hours and therapeutic serum concentrations are 10 to 20 µg/mL.\textsuperscript{125} About 90\% of acetaminophen is hepatically metabolized to sulfate and glucuronide conjugates for renal excretion with a small amount secreted unchanged in the urine.\textsuperscript{126}

IV paracetamol (acetaminophen) has achieved widespread use following its introduction in Europe and eventual use in the United States. Compared to oral dosing, IV paracetamol has a 70\% higher maximum concentration. The half-life is approximately 2.5 hours and increases with lower age groups. Metabolism is identical to oral dosing. IV paracetamol offers a unique opportunity for patients who are nothing by mouth (NPO) or anesthetized. It is without surprise that many perioperative multimodal pain protocols have been developed that incorporate this drug. In fact, it has been considered the foundation for perioperative, multimodal analgesia protocols. Injectable paracetamol has been shown to reduce opioid consumption by about 35\% to 45\%\textsuperscript{127} in postoperative pain studies\textsuperscript{127,128} including after cardiac surgery.\textsuperscript{129} Other beneficial effects
have been seen with reductions in postoperative nausea and vomiting. However, it should be noted that these results have not been consistently reproduced. Propacetamol, an injectable prodrug of paracetamol, is hydrolyzed within 6 minutes of administration and 1 g of propacetamol yields 0.5 g of paracetamol.

The bioavailability of rectal acetaminophen is variable and is approximately 80% of that following oral administration. The rectal rate of absorption is slower, with maximum plasma concentration occurring 2 to 3 hours after administration. Doses of 40 to 60 mg/kg of rectal acetaminophen have been shown to have opioid-sparing effect in postoperative pain models. Widespread use of rectal acetaminophen has not gain popularity in the United States largely due to cultural preferences (Fig. 78.2).

**FIGURE 78.2** Paracetamol after heart surgery. Mean maximal plasma paracetamol concentration at times 0, 20, 40, and 80 minutes after 1 g of rectally and intravenously (IV) administered paracetamol (N = 12 + 12 patients) and 6 hours after the third dose, corresponding to before the fourth dose and at 20, 40, and 80 minutes and at 4 and 6 hours after the fourth dose in (N = 12 + 12 patients). ●, IV administered paracetamol; ■, rectally administered paracetamol; ✷, significant difference between groups. (From Holmér Pettersson P, Jakobsson J, Owall A. Plasma concentrations following repeated rectal or intravenous administration of paracetamol after heart surgery. Acta Anaesthesiol Scand 2006;50[6]:673–677. Copyright © 2006 The Acta Anaesthesiologica Scandinavica Foundation. Reprinted by permission of John Wiley & Sons, Inc.)

**NSAID Combination Medications**

Combination NSAIDs have been developed with the intent to reduce GI-related side effects. As such, combinations including a histamine receptor...
antagonist, proton pump inhibitor, and PG analogs have been developed.

Naproxen plus esomeprazole, a proton pump inhibitor, is one of such combinations and was approved by the FDA in 2010. It is available in 375/20 mg and 500/20 mg combinations. Dosing is suggested as one tablet twice daily for pain symptoms stemming from osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis. Small studies have shown an analgesic effect superior to placebo, but similar to celecoxib, in the treatment of these conditions. The addition of esomeprazole has resulted in lower upper GI-related adverse events, such as gastric or duodenal ulcers, at 1, 3, and 6 months. However, there is no significant difference in reducing gastroduodenal ulcers when compared to COX-2 selective NSAIDs, such as celecoxib and etoricoxib. The addition of a proton pump inhibitor can actually compound GI toxicity of NSAIDs; there is an increase of small intestine mucosal damage when combining the two medications. Furthermore, there appears to be no advantage in mitigating CV toxicity.

An ibuprofen/famotidine combination has also been available in the United States since 2011. This combination is available in an 800/26.6-mg tablet. It is also approved for use in osteoarthritis and rheumatoid arthritis, with three-times-daily dosing. Ibuprofen maintains its pharmacokinetics when administered with famotidine, a histamine-2 receptor antagonist. Early studies show that combining famotidine with ibuprofen reduces gastric ulcers and ulcers within the upper GI tract when compared to ibuprofen alone.

Lastly, the addition of a PG to diclofenac has been developed to accomplish more gastroprotective effects when coadministered. Diclofenac/misoprostol is formulated in 50 mg/200 µg and 75 mg/200 µg tablets. It is also approved for osteoarthritis and rheumatoid arthritis. Dosing is two to four times daily (Fig. 78.3).
SIDE EFFECTS, WARNINGS, AND CONTROVERSIES

Cardiovascular Effects

The risk of major CV events from NSAIDs has garnered much attention since valdecoxib and rofecoxib were removed from the market following evidence of increased rates of stroke and myocardial infarction (MI). On April 7, 2005, the FDA announced a series of labeling changes for all NSAIDs, including over-the-counter forms. This included an FDA boxed warning for the potential increased risk of CV events and GI bleeding associated with all prescription NSAIDs, including celecoxib.

 Manufacturers were asked to revise their labeling to include a medication guide for patients to help make them aware of the potential for CV and GI adverse events. In addition, the FDA asked manufacturers of all over-the-counter NSAIDs to revise their labels to include more specific information about potential CV and GI risks and information to assist consumers in the safe use of these drugs. CV toxicity is not completely understood, but it has been postulated that COX inhibition may disrupt the balance between antithrombotic substances like PGI₂ and prothrombotic thromboxane A₂ (TXA₂) in platelets (Fig. 78.4).
On July 7, 2015, the FDA strengthened its NSAID warning, and labeling was updated to state, “non-aspirin NSAIDs increase the chance of a heart attack or stroke.” Additional information includes the risk of MI or stroke can occur as early as the first weeks of using an NSAID and may increase with extended use. In fact, the risks of CV mortality and morbidity peak soon after MI and gradually decline to match the risk of the general population after 5 to 10 years. The risk appears to be dose-related, and no difference between individual drugs was noted at the time of the safety announcement (Fig. 78.5).
These labeling updates are challenging to providers, as NSAIDs remain such an integral part to managing both acute and chronic pain conditions. Research has failed to determine an NSAID that stands alone as being safer than others in reducing major CV events. Celecoxib, naproxen, and ibuprofen all have been shown to have similar rates of CV events. The drug dosage may indeed play a role as low doses of diclofenac (50 to 75 mg per day) have shown negligible effects on CV effects.
2015 U.S. Food and Drug Administration NSAID Warning

- Risk of heart attack/stroke can occur as early as first week after starting NSAID and may increase with prolonged use.
- Risk appears to increase with higher doses.
- There is insufficient evidence to determine the risk of individual NSAIDs.
- NSAIDs increase the risk of heart attack/stroke regardless of existing heart disease or risk factors for heart disease.
- NSAID use in patients with risk factors for heart disease increases the likelihood of heart attack or stroke.
- Patients prescribed NSAIDs following a first heart attack were more likely to die within that first year compared to patients who did not receive NSAIDs.
- NSAID use increases risk of heart failure.

The interaction between NSAIDs and antihypertensive medication has also been highlighted as cause for concern. There appears variability between individual medications as celecoxib seems to have little effect in patients already taking angiotensin-converting enzyme (ACE) inhibitors, whereas others like diclofenac appear to have an effect on both blood pressure and glomerular filtration rate (GFR). The negative effect of NSAIDs on blood pressure may be limited to those patients taking ACE inhibitor and β-blockers but not calcium channel blockers or diuretics. There is even suggestion that acetaminophen can do the same.

The risk of congestive heart failure is ill defined with use of NSAIDs; however, there are correlations between use of these drugs and clinical decompensation and preceding hospital admissions due to heart failure decompensations. The true mechanism is still elusive but is thought to revolve around sodium and fluid retention.

NSAID-induced CV toxicity should be taken seriously. Patients who have experienced an acute CV event in the past year or at risk for heart failure or hypertension should be prescribed with caution or avoided altogether. Reevaluation for efficacy, appropriate dosing, and need for continual administration should be considered on a regular basis by prescribers. With appropriate monitoring, use of the lowest effective dose, and for the shortest duration necessary, patient safety will be optimized.

**Allergy and Hypersensitivity**

All NSAIDs hypersensitivity (NHS) reactions occur in two general forms.
One syndrome is characterized by asthmatic attacks in patients with vasomotor rhinitis, nasal polyposis, and bronchial asthma. It is estimated to occur in 4.3% to 11% of asthmatics. The second includes a syndrome of urticaria and angioedema, occurring in 27% to 35% of patients with chronic urticaria. PGE$_2$ is a bronchodilator that stabilizes histamine stores in mastocytes and thus helps to inhibit the inflammatory response. In a susceptible person, the result of the inhibition of PG biosynthesis may be spontaneous degranulation of mastocytes with release of histamine in the respiratory tract and skin, leading to bronchoconstriction and asthma as well as urticaria called syndrome called Samter’s triad which is COX-1 mediated. Therefore, COX-2 selective NSAIDs may be safely administered to these patients. Other mechanisms have been postulated which include T cell activation, oxidative stress, and platelet activation as causes for the phenotypic response seen in NHS.

As mentioned previously, our general recommendation is to use any NSAID for the shortest time and at the lowest dose that is clinically appropriate. For many patients with chronic, painful, inflammatory disorders, long-term NSAID therapy continues to present a favorable risk-to-benefit ratio.

**Gastrointestinal Toxicity**

The first evidence that aspirin could damage the stomach was reported in 1938 based on endoscopic observations. In the 1950s and 1960s, case-control studies demonstrated NSAID-associated melena. NSAIDs cause hemorrhagic gastric erosions in the corpus and antrum. The mortality rate attributed to NSAID-related GI toxicity is 0.22% per year with an annual relative risk of 4.21. An estimated that 16,500 NSAID-related deaths occur due to gastric complications, which is similar to the number from acquired immunodeficiency syndrome (16,685) and exceeds the number deaths due to multiple myeloma and asthma. Risk factors identified for the development of NSAID-induced ulcers include advanced age, history of ulcer, concomitant use of corticosteroids, higher doses of NSAIDs including the use of more than one NSAID, concomitant administration of anticoagulation, serious systemic disorder, cigarette smoking, consumption of alcohol, and concomitant infection with Helicobacter pylori.
The mechanisms by which NSAIDs cause ulceration in the stomach are contact irritation of the epithelium and suppression of PG synthesis.\textsuperscript{154} NSAID-induced gastropathy correlates with the time and dose for gastric PG suppression.\textsuperscript{155} Inhibition of PG synthesis reduces the gastric mucosa ability to defend itself against luminal irritants because bicarbonate secretions, blood flow, and epithelial cell turnover are influenced by PG. Gastric bleeding from preexisting ulcers can also occur due to NSAID suppression of platelet aggregation.\textsuperscript{156} Mediators in the pathway by which decreased PG levels cause gastric irritation and damage have been extensively studied. These include leukotrienes,\textsuperscript{157} tumor necrosis factor (TNF)-\textgreek{a},\textsuperscript{158} and neutrophil adherence substances.\textsuperscript{158}

NSAID-induced enteropathy has been documented in the small intestine and colon, although the exact mechanism is not fully understood. Various strategies can reduce NSAID gastroenteropathy.\textsuperscript{159} Agents used to prevent NSAID-induced ulcers include sucralfate (efficacy controversial), histamine-2 receptor antagonists (famotidine), proton pump inhibitors (omeprazole), and PGs (misoprostol). Enteric-coated and slow-release NSAID dosage forms have not reduced ulcer risk.

NSAID-induced gastric complications prompted development of COX-2 selective agents. Preferential use of those selective agents to minimize gastropathy resulted in increased CV toxicity as mentioned previously, but the COX-2 NSAIDs have lower risk of GI complications. Nonselective NSAIDs increase the risk of GI complications by a factor of 3.7, whereas COX-2 inhibitors increase the risk by a factor of 2.6.\textsuperscript{160} This confirms prior studies that suggest use of COX-2 NSAIDs results in an improved and a better GI side effect profile compared to nonselective NSAIDs.\textsuperscript{161} The American Gastroenterological Association has strongly recommended concomitant use of histamine-2 receptor antagonists, proton pump inhibitors, or misoprostol in patients chronically receiving NSAIDs.\textsuperscript{162} Other authors have provided additional recommendations to consider probiotics in addition to a gastroprotective agent.\textsuperscript{135} According to a recent systematic review, the ideal combination to reduce upper GI complications may be a COX-2 inhibitor plus proton pump inhibitor.\textsuperscript{163}
**Hematologic Effects**

NSAIDs inhibit PG formation, and individual PGs have different, sometimes opposing, functions. TXA\(_2\) is a platelet activator and vasoconstrictor, whereas PGI\(_2\) is a platelet inhibitor and vasodilator. Furthermore, activated platelets divert some of their endoperoxides to vascular cells to further provide substrate for PGI\(_2\) formation.\(^{164}\) Platelet activity results from a balance between PGI\(_2\) effects on endothelium and TX\(_{A2}\) effects on platelets. Platelets are especially vulnerable to NSAIDs because, unlike most other cells, platelets cannot regenerate the COX enzyme. Aspirin irreversibly acetylates the COX enzyme and that inhibits platelet aggregation for the 10 to 14 day lifespan of the platelet.\(^{164}\) Other nonselective NSAIDs reversibly inhibit COX causing only a transient reduction in TX\(_{A2}\) formation. As a result, platelet activation inhibition resolves after most of the drug is eliminated.\(^{164}\) A single 300- to 900-mg dose of ibuprofen can inhibit platelet aggregation for 2 hours after administration, and the effect is largely dissipated by 24 hours.\(^{165}\) Similarly, both sulindac and diclofenac also inhibit platelet aggregation for less than 24 hours. The antiplatelet effects of long-acting NSAIDs such as piroxicam can last for several days after the drug is discontinued.\(^{166}\)

Overall, non-aspirin NSAIDs cause “transient, dose-dependent, and modest bleeding time abnormalities,” which often do not exceed normal limits.\(^{164}\)

Although in vitro studies examining the effect of NSAIDs on platelet function provide useful information, the clinical effect in patients is more important. The test primarily used to assess platelet function is bleeding time, but this test is largely operator-dependent and subject to technical artifact. In addition, its clinical utility as a preoperative tool for predicting intraoperative bleeding remains controversial. Studies show variable effects of NSAIDs on bleeding. In one total hip arthroplasty study, 140 patients taking NSAIDs had more intraoperative and postoperative blood loss than those who did not.\(^{167}\)

Unbalanced biosynthesis of PGI\(_2\) and TXA\(_2\) may also play a role in atherogenesis and thrombosis. By inhibiting PGI\(_2\), blood pressure increases which initiates early development of atherosclerosis and the architectural and functional response of blood
vessels to stress. These effects predispose individuals to an exaggerated thrombotic response upon rupture of an atherosclerotic plaque.\textsuperscript{168} Aspirin and nonselective NSAIDs suppress both COX-1 and COX-2 and therefore reduce both TXA\textsubscript{2} and PGI\textsubscript{2}. In contrast, COX-2 selective NSAIDs suppress PGI\textsubscript{2} production without affecting TXA\textsubscript{2} synthesis.\textsuperscript{169} Some authors posit that this may increase acute MI risk that has been observed with prolonged use of some of the COX-2 selective agents.

There are differences between individual NSAIDs and their ability to promote GI complications, largely due to COX-1 and COX-2 selectivity. NSAIDs with greater COX-1 activity have higher relative risks of GI complications; an exact dosage where risk increases remains ill defined. Using lower doses appears to result in fewer GI side effects; however, the efficacy of using the drugs may be lost.\textsuperscript{170} The duration of therapy is another consideration; what we know is that gastroduodenal bleeding can occur very soon after initiation of NSAID therapy in patients with a history of upper GI ulcers.\textsuperscript{171} Additionally, patients with a history of H. pylori infection may be at increased risk for developing peptic ulcers.\textsuperscript{172} At present, we lack an ideal NSAID; however, there are thoughts that NSAIDs that target microsomal PGE\textsubscript{2} synthase 1 or those that contain nitric oxide donor groups may provide analgesia while sparing GI side effects (Fig. 78.6).\textsuperscript{173}
Renal Toxicity

Aspirin and all other NSAIDs can transiently decrease renal function. This effect may occur more often in patients with chronic kidney disease (CKD). The postulated mechanism is the inhibition of the renal PG synthesis, which may be important in the autoregulation of renal blood flow. Aspirin may also block the diuretic effect of spironolactone by inhibiting its binding to the tubular-cell receptor.

The renal profile of NSAIDs appears related to sodium retention which is COX-2 inhibition–mediated, and GFR changes due to inhibition of COX-1/COX-2. All NSAIDs are associated with hypertension and edema. Most of these events are of minor clinical significance with discontinuation rates due to hypertension and edema when used for short term. The majority of cases resolve with discontinuation of therapy, generally seen between 1 and 8 weeks. The risk factors for NSAID-induced renal toxicity include the following: chronic NSAID use, multiple NSAID use, dehydration, volume depletion, congestive heart failure, vascular disease, hyperreninemia, shock, sepsis, systemic lupus erythematosus, hepatic disease, sodium depletion, nephrotic syndrome,
diuresis, concomitant drug therapy (diuretics, ACE inhibitors, β-blockers, potassium supplements), and age 60 years or older.\textsuperscript{169} It should be noted that long-term, regular use of NSAIDs in the absence of risk factors has not been associated with the development of chronic renal impairment.\textsuperscript{175}

Some authors have advocated that short-term use of NSAIDs is advisable in patients with stage 1 or 2 CKD. More caution should be exercised in patients with stage 3. In stage 4 or 5 CKD, they should avoided altogether.\textsuperscript{176} In those with end-stage renal disease, it is recommended to avoid NSAIDs as the uremic effect on platelets combined with NSAID-induced platelet dysfunction promotes hemorrhage from the GI tract.\textsuperscript{177}

**Hepatic Toxicity**

It has long been known that the cytochrome pathway of metabolism of acetaminophen in the liver can lead to development of N-acetyl-p-benzoquinoneimine (NAPQI) when glutathione stores are low. Patients with liver disease demonstrate prolonged acetaminophen half-life and reduced plasma clearance. However, cytochrome activity is not increased, and glutathione stores remain adequate negating the development of NAPQI.\textsuperscript{178} As a result, some authors have made the recommendation that acetaminophen is safe in patients with liver cirrhosis at reduced doses.\textsuperscript{179} Given that the FDA recommendations for maximum daily dose is 3 g per day, 2 g per day has been suggested.

NSAIDs are metabolized by the cytochrome system in the liver and are highly protein-bound, >95% to albumin. Cirrhotic patients are sensitive to PG inhibition, which leads to decrease in GFR and increased sodium retention. The constellation of downstream effects reduces kidney perfusion and potentially hepatorenal syndrome, which is often fatal.\textsuperscript{179} Advanced liver disease is also associated with thrombocytopenia and
coagulopathy leading to spontaneous hemorrhage. NSAIDs compound the problem by inducing platelet dysfunction as mentioned previously. Cirrhotic patients should not receive NSAIDs.

**Central Nervous System Effects**

Direct toxic reactions are of several types. Tinnitus or deafness are often early warning signs of toxicity. Toxic manifestations are directly related to free drug levels, and those vary inversely with albumin levels. The adverse event is typically reversed when the dose is reduced or discontinued. NSAIDs are the most frequently implicated drugs in hypersensitivity-induced aseptic meningitis. Ibuprofen, sulindac, tolmetin, and naproxen have been implicated in causing drug-induced aseptic meningitis. Patients typically complain of fever, headache, and stiff neck that generally commences within weeks of beginning therapy.\(^{180}\)

**Surgical Complications**

Adverse effects of NSAIDs go beyond the package inserts as complications from surgical procedures can be increased by these medications. One such complication is anastomotic leakage following colon surgery. Three observational studies have shown an increased incidence of anastomotic failure following colonic and/or rectal anastomosis.\(^{181}\) The exact mechanism is unclear; however, a reduction in leukocyte migration resulting in infection at the site of the anastomosis has been postulated.

Impaired bone healing is another potential drawback to NSAID use. Bone healing can occur in two ways. Natural fracture healing begins with a cartilage callus around the fracture site, ultimately being replaced with bone. This process is called endochondral ossification. The second method is called intramembranous ossification (or primary bone healing), such as that in total joint arthroplasties does not appear to be related to NSAID use. COX-2 appears to be involved, as animal models without COX-1 activity do not have this problem.\(^{182}\) Proposed mechanisms of this phenomenon that leads to delayed or incomplete bone union may be due to multiple downstream effects of NSAIDs. PGs stimulate osteoblast activity, lure mesenchymal cells to sites of bone injury, and stimulate angiogenesis,
which is necessary for endochondral ossification. Additionally, inhibition of COX-2 also prevents terminal differentiation of chondrocytes in fracture callus. Current opinions suggest that in the setting of primary bone healing, a short course of NSAIDs is probably safe in the absence of other risk factors for delayed union.

Delay of tendon-to-bone healing has also been suggested, but currently, clinical evidence is lacking. Lastly, soft tissue healing appears to be unaffected by NSAIDs.

Conclusion

NSAIDs are important drugs that provide excellent analgesic, antipyretic, and anti-inflammatory effects and can be especially useful as part of a multimodal regimens for acute and chronic pain. Acetaminophen does much of the same but lacks clinically useful anti-inflammatory activity. For patients without recent MI, a history of NSAID-exacerbated respiratory disease or asthma, renal insufficiency, cirrhosis of the liver, or iatrogenic or inherited coagulopathy, a short-course of NSAIDs appears to be safe. Long-term prescribing requires critical evaluation of the patient’s risk factors for developing adverse events and routine monitoring. Equally important, patients must be apprised of the risks, benefits, and alternatives of NSAID therapy.

DEDICATION

Art was a dear friend and colleague. His patience, guidance, and contributions to this field will be long remembered. It is with heavy hearts and fond memories that we dedicate this piece of work to his memory.

—Adam and Kumar

Opioid analgesics remain an important component of the multimodality management of moderate to severe acute pain and cancer pain. The use of opioids for chronic noncancer pain has become controversial due to the lack of long-term clinical trials designed to provide evidence of the long-term effectiveness and limited reliable data on the safety of long-term opioid use. Not every pain patient will benefit from opioid therapy, and more patients benefit from these strong analgesics when the drugs are used as one component of multimodal therapy that includes nonopioid analgesics and nonpharmacologic treatments. The decision to initiate opioid therapy requires a comprehensive evaluation. In this chapter, we address the principles that should guide the appropriate use of opioids. During the past 20 years, there has been a dramatic increase in our knowledge of the sites and mechanisms of action of opioids. The development of analytical methods has also been of great importance by facilitating pharmacokinetic studies of the disposition and fate of opioids in patients. These pharmacokinetic studies and recent discoveries about pain and opioid receptor–related genetic polymorphisms have begun to provide a better understanding of some of the sources of interindividual variation in the response to opioids and suggest ways to minimize some of their adverse effects. Pain management with or without opioids requires individualization of treatment and one of the next steps in improving opioid therapy depends on identifying phenotypic and genotypic patient characteristics that are associated with better or worse treatment outcomes.

The term analgesic (from the Greek an-, without + algesis, sense of pain) refers to a drug that relieves pain without a significant loss of other
sensations. Opioid (the preferred term) is any compound that binds to an opioid receptor. Opioids include the exogenous opioid receptor agonists, for example, morphine, and antagonists as well as the endogenous opioid peptides (EOPs), for example, endorphins. The term opiate originally referred to any drug derived from opium but now includes the natural opium products (e.g., morphine), the semisynthetic derivatives (e.g., hydromorphone), or completely synthetic congeners (e.g., methadone). The term narcotic was originally associated with the opioids. It is now used in a legal context to refer to any drug considered to possess abuse or addictive potential. Because it is a value-laden word, avoidance of the term narcotic when discussing opioids with patients is often advisable.

### Classification Based on Interactions with an Opioid Receptor

Opioid analgesics can be classified based on their interactions with opioid receptors, namely, mu (µ), delta (ð), and kappa (κ). A fourth member of the opioid receptor family is the nociception (NOPr) receptor. µ-Opioid receptor (MOR) agonists (agents that occupy and activate the receptor) are the major source of clinically used opioid agonist partial agonist and antagonist drugs (Table 79.1). Numerous κ-opioid receptor ligands have been developed and studied; three have been commercially available in the United States. The clinical pharmacology of κ agonists is complicated by concurrent MOR antagonist activity (see the following text and Table 79.1). ð-Opioid receptor (DOR) ligands have been identified in preclinical studies, but currently, none is available for clinical use.

NOTE: Some of these equianalgesic parenteral doses may be based on studies that used the intramuscular (IM) route, so that in contrast to intravenous (IV) dosing, the time of peak analgesia in nontolerant patients will range from one-half to 1 hour and the duration from 4 to 6 hours. Compared to the IV or IM routes of administration, the peak analgesic effect is delayed and the duration prolonged after oral administration.

These doses are recommended starting parenteral or oral doses from which the optimal dose for each patient is determined by titration and the maximal dose limited by adverse effects.

The equianalgesic oral dose is provided for comparative purposes (see Starting Oral Dose Range column).

See package insert for dosing information.

Each of the opioid receptors is a G protein-coupled receptor (GPCR) and signals via a second messenger, cyclic adenosine monophosphate (cAMP), or an ion channel. Alterations in the levels of cAMP and the transcription factor, cAMP response element binding protein (CREB) during chronic morphine treatment, are associated with numerous cellular changes, some of which can lead to the development of tolerance and physical dependence. Molecular genetic approaches have used gene-targeting (knockout) technology to disrupt the gene that codes for each of the three opioid receptors as well as all three receptors simultaneously. Mice that lack the MOR (MOR-deficient mice) do not respond to morphine with analgesia, respiratory depression, constipation, physical dependence, reward behaviors, or immunosuppression. These results confirm and extend previous pharmacologic and receptor binding studies and demonstrate that the µ receptor mediates the analgesic and adverse effects of morphine. Recent advances in techniques for studying these receptors in vivo and in vitro, including splice variant characterization, high-resolution crystallography, Designer Receptors Exclusively Activated by Designer Drugs (DREADD) receptors, and optogenetic approaches, are expanding and transforming our understanding of opioid receptor function.
Pharmacologic evaluation of the effects of the microinjection of morphine and other opioids has been combined with anatomic characterization of the distribution of opioid receptors to provide insight into the sites of action of morphine and other clinically used µ-opioids. Thus, MORs are found in the periphery (following inflammation), at pre- and postsynaptic sites in the spinal cord dorsal horn, and in the brain stem, thalamus, and cortex, in what constitutes the ascending pain transmission system (Fig. 79.1A). In addition, MORs are found in the midbrain periaqueductal grey, the nucleus raphe magnus and the rostral ventral medulla where they comprise a descending inhibitory system that modulates spinal cord pain transmission (Fig. 79.1B).

**FIGURE 79.1** A: Sites of action common to all µ opioids. The location of µ-opioid receptors (MORs). Modulation of ascending pain transmission pathways. MORs are found (A) in the periphery following inflammation, (B) at pre- and postsynaptic sites in spinal cord dorsal horn, and (C) in the thalamus and in the limbic (L) and somatosensory (SS) cortex. B: Descending modulation of pain transmission. The location of MORs. MORs are found in (D) the midbrain periaqueductal grey, the nucleus raphe magnus, and (E) the rostral ventral medulla. µ-Opioids activate a descending inhibitory system that modulates spinal cord dorsal horn pain transmission. C: Descending modulation of pain transmission. GABAergic neurons and descending inhibition. A brainstem pain inhibitory neuron (I) is tonically inhibited by a GABAergic neuron. Opioids inhibit GABAergic neurons and remove the inhibition of the pain inhibitory neurons (PIN) that project from the rostral ventral medulla to the spinal cord dorsal horn. Thus, opioids produce a disinhibition.
Opioids inhibit GABAergic neurons and remove the tonic inhibition of the pain inhibitory neurons (PIN) that project from the rostral ventral medulla to the spinal cord dorsal horn. Thus, opioids produce a disinhibition of the PIN, which results in the activation of descending inhibition and the descending modulation of pain transmission (Fig. 79.1C).

Using molecular genetic approaches, Bardoni and colleagues have identified circuity in the spinal cord dorsal horn wherein DOR activation at the central terminals of myelinated mechanoreceptors depresses synaptic input to the spinal cord dorsal horn, via the inhibition of voltage-gated (VG) calcium (CA++) channels. This circuitry may provide a basis for a more rational use of MOR agonists and the design of analgesic strategies that involve targeting the DOR for touch-evoked neuropathic pain and movement or pressure-evoked pain, two major clinical problems.

MORs are also located peripherally, and the development of peripheral μ-opioid antagonists has provided a new class of drugs to manage opioid bowel dysfunction. For example, activation of the high density of MORs in the human colon appears to be a major mechanism of opioid-induced constipation. This has led to the approval and use of methylnaltrexone and naloxegol for managing opioid-induced constipation and alvimopan for postoperative ileus. More recently, lubiprostone, a drug that activates chloride (CIC-2) channels in the intestines suggests a second mechanism of opioid-induced constipation. See also “Peripheral Effects of Opioids” section.

The opioid receptors are part of an endogenous system that includes a large number of EOP ligands. Based on cloning, three distinct families of classical opioid peptides, the enkephalins, endorphins, and dynorphins, have been identified. The physiologic roles of the EOPs are not completely understood. They appear to function as neurotransmitters, neuromodulators, and, in some cases, as neurohormones. When EOP mutant mice are compared to wild-type mice, phenotypes indicative of EOP tone have been observed in major opioid functions including locomotion, nociception, and emotional responses. For example, no change in baseline sensitivity to thermal pain was found in mice devoid of
\(\beta\)-endorphin, whereas Penk and Pdyn mutant mice showed increased pain response in the hot plate and tail flick tests, respectively.\(^{13}\) They also play a role in some forms of stress-induced analgesia and in the analgesia produced by electrical stimulation of discrete brain areas such as the periaqueductal grey.

**Classification Based on Opioid Agonist or Antagonist Activity**

The expression of agonist or antagonist activity is an important pharmacodynamic property used to classify opioids. The morphine-like agonist drugs represent one end of the pharmacodynamic spectrum. They bind predominately or exclusively to MORs and produce analgesia and the other MOR-mediated effects described below. The opioid antagonists, such as naloxone, represent the other end of the spectrum since their binding to an opioid receptor does not trigger the signaling cascade that leads to the pharmacodynamic effects seen with opioid agonists. Rather, receptor occupancy by a sufficient concentration of an opioid antagonist prevents or reverses opioid receptor-mediated agonist effects.

Between these two types of pharmacodynamic actions fall the effects of the partial agonists, the mixed agonist-antagonists and the centrally acting \(\mu\) agonist drugs. The mixed agonist-antagonist opioid drugs (see Table 79.1) can demonstrate agonist (at the \(\kappa\) receptor) or antagonist (at the \(\mu\) receptor) activity. What occurs clinically depends on whether the patient is opioid-naive or has prior exposure to a \(\mu\)-opioid agonist. Buprenorphine is a partial agonist opioid. This classification derives principally from its pharmacodynamic activity observed in preclinical test systems wherein the difference in efficacy between a full agonist and a partial agonist can be more readily measured. Clinically, the consequences of buprenorphine’s partial agonism can be observed as its ability to precipitate opioid withdrawal in some patients who have been receiving repeated doses of a \(\mu\) agonist.

The newest group are the centrally acting \(\mu\) agonist analgesics, tramadol and tapentadol (see Table 79.1). The analgesic effects of these drugs appear to result from dual actions: weak opioid receptor activity and
blockade of neurotransmitter reuptake, predominately serotonin for tramadol and norepinephrine for tapentadol. Neither mechanism alone appears to be sufficient; rather, the synergistic effects of the dual actions is necessary for analgesia.

Opioid Pharmacodynamics

CELLULAR, SYNAPTIC, AND CIRCUIT LEVEL EVENTS THAT INHIBIT PAIN TRANSMISSION

At the cellular level, activation of an opioid receptor (µ, κ, or δ) by an opioid inhibits of VG Ca++ channels and the opening of certain potassium (K+) channels. The presynaptic block of VG Ca++ channels reduces transmitter release, whereas the increase in outward K+ currents hyperpolarizes postsynaptic neurons (increasing an inhibitory postsynaptic potential). These effects on transmitter release are believed to decrease synaptic transmission of pain signals in the spinal cord dorsal horn.

At the neuronal circuit level, opioids can disinhibit an inhibitory interneuron. This is the basis of descending modulation of pain transmission as discussed earlier.

The Pharmacodynamic Effects of Opioids

The pharmacodynamic effects of opioids are discussed using the prototype morphine and the morphine-like opioids. In some cases, the term opioids refers to properties common to both morphine-like and mixed agonist-antagonist opioids. Later, individual opioids are discussed in the context of how they compare to and differ from morphine and other morphine-like opioids.

The desirable and undesirable effects of morphine can be divided into those that may occur with a single dose and those that occur with repeated administration including tolerance, physical dependence, and addiction (Table 79.2).

Central Nervous System Opioid Effects

**ANALGESIA**

The relief of pain by opioids such as morphine is relatively selective in that other sensory modalities are not affected. Although continuous dull pain has been relieved more effectively than sharp intermittent pain, morphine-like opioids can relieve severe, acute pain associated with renal or biliary colic. Some patients report that they still perceive pain but that it is no longer as distressing as it was prior to their receiving morphine. Recent reports as well as long-standing clinical observations support the concept that pain includes both sensory-discriminative aspects (e.g., perception of the location, type, intensity) and reactive or affective meaning of the pain experience (e.g., its unpleasantness). Under experimental conditions, positron emission tomography (PET) imaging studies localized and separated these two dimensions of pain. The sensory-discriminative aspects are processed in the somatosensory cortex (SSC), whereas the affective component is processed in the anterior cingulate cortex (ACC). The presence of MORs in both of these brain areas is consistent with the ability of morphine-like opioids to alter both dimensions of pain. Pain relief activates mesolimbic reward/motivation circuitry. In animal models of pain, behavioral measures that capture affective and motivational aspects of pain appear to accurately reflect the effectiveness of treatments that are useful clinically (bedside to bench translation). Navratilova and colleagues found that the relief of ongoing
pain requires opioid signaling in the ACC and subsequent downstream activation of dopamine neurotransmission in the nucleus accumbens (NAc) that mediates the reward of pain relief. These studies provide a neural explanation for the preferential effects of systemic and endogenous opioids on pain affect and demonstrate that engagement of NAc dopaminergic transmission by nonopioid pain-relieving treatments depends on upstream ACC opioid circuits. Endogenous opioid signaling in the ACC appears to be both necessary and sufficient for relief of pain averseness.\textsuperscript{22}

In contrast to nonopioid analgesics, there is no easily measurable ceiling to the dose-dependent analgesic effects of morphine-like opioids. Nevertheless, there is often a practical ceiling imposed by dose-dependent adverse effects including sedation, mental clouding, nausea, vomiting, and respiratory depression (see Table 79.2). The actual dose required for analgesia can vary greatly depending on the type or source of pain and a variety of patient factors. The most important principle that derives from these properties of the morphine-like opioids is the need to titrate the dose for each patient to an acceptable level of analgesia that balances the degree of pain relief with the limits that are imposed by concomitant adverse effects. In the United States, both state (e.g., Washington State Agency Medical Directors’ Group\textsuperscript{23}) and national guidelines\textsuperscript{5} for primary care providers who are prescribing opioids for chronic pain recommend caution in increasing opioid dosage above specified dosages.

**MOOD EFFECTS**

The morphine-like opioids can produce mood alterations including the relief of anxiety, euphoria (pleasant feelings), as well as dysphoria (unpleasant feelings). Chronic pain patients receiving opioids often report initial relief of depression (a common concomitant of chronic pain), but this usually proceeds to exacerbation of depression after a few days to weeks. Thus, the mood effects appear as both desirable and undesirable effects in Table 79.2. Reports of euphoria or dysphoria usually depend on the individual and the circumstances of the morphine experience. Most “normals” not in pain as well as many patients in pain report some dysphoria after receiving morphine. That is associated with difficulty in mental activities, dizziness, and decrease in physical activity.
The reinforcing and rewarding properties of these drugs that are associated with opioid abuse involve the mesolimbic dopamine system and appear to be distinct from those systems involved in analgesia and the production of physical dependence.24

SEDATION
Morphine-like opioids produce drowsiness and sedation, which may be useful in certain clinical situations (e.g., preanesthesia) but usually are not desirable concomitants of analgesia, particularly in ambulatory patients. The central nervous system (CNS) depressant actions of these drugs are at least additive to the sedative and respiratory depressant effects of sedative-hypnotics such as alcohol, barbiturates, and benzodiazepines. Dasgupta et al.25 using data from the North Carolina Prescription Drug Monitoring Program (PDMP) estimated that the rate of overdose deaths among those codispensed benzodiazepines and opioids were 10 times higher compared to opioids alone.

Reducing the dose and interval, that is, giving a lower dose more frequently, produces a lower peak opioid serum concentration, which may counteract excessive sedation. In addition, other CNS depressants including sedative hypnotics and antianxiety agents that add to or potentiate the sedative effects of opioids should be discontinued if possible. Concurrent administration of a central stimulant (e.g., dextroamphetamine, methylphenidate) twice daily helps counteract the sedative effects of opioids. Tolerance usually develops to the sedative effects of opioid analgesics within the first several days of repeated administration.

NAUSEA AND VOMITING
The morphine-like analgesics produce nausea and vomiting by stimulating the chemoreceptor trigger zone (CTZ) in the area postrema of the medulla. The incidence of nausea and vomiting is markedly greater in ambulatory patients suggesting that these drugs also alter vestibular sensitivity. The ability of opioid analgesics to produce nausea and vomiting appears to vary with drug and among patients; some advantage may result from opioid rotation. Alternately, a centrally acting antiemetic such as a
phenothiazine (e.g., prochlorperazine), a gastric prokinetic agent (e.g., metoclopramide), or a serotonin (5-HT3) receptor antagonist (e.g., ondansetron) may be used in combination with the opioid. For some patients, initiating treatment by the parenteral route and then switching to the oral route may reduce emetic symptoms.26 Use of a dual mechanism opioid analgesic (e.g., tapentadol) allows less μ agonist activity due to the synergistic effect of the second mechanism—in this case, norepinephrine reuptake inhibition—while maintaining the full analgesic effect. For patients highly sensitive to gastrointestinal (GI) adverse effects of opioids who cannot tolerate therapeutic doses of morphine or other μ agonists, a dual mechanism opioid can be useful.27

**RESPIRATORY DEPRESSION**

Respiratory depression is potentially the most serious adverse opioid effect. The morphine-like agonists act on brainstem respiratory centers to produce dose-related respiratory depression to the point of apnea. In humans, death due to overdose of a morphine-like agonist is nearly always due to respiratory arrest. Therapeutic doses of morphine may depress all phases of respiratory activity (rate, minute volume, and tidal exchange). However, as carbon dioxide (CO₂) accumulates, it stimulates central chemoreceptors, resulting in a compensatory increase in respiratory rate, which masks the degree of respiratory depression. At equianalgesic doses, the morphine-like agonists produce an equivalent degree of respiratory depression. Therefore, individuals with impaired respiratory function or bronchial asthma are at greater risk of experiencing clinically significant respiratory depression in response to usual doses of these drugs. Respiratory depression and CO₂ retention produces cerebral vasodilation and increased cerebrospinal fluid pressure unless the partial pressure of carbon dioxide (Pco₂) is normalized by artificial ventilation. Respiratory depression occurs most commonly in opioid-naive patients following acute opioid administration, and it is associated with other signs of CNS depression including sedation and mental clouding. It bears repeating that opioids in combination with CNS depressants such as the benzodiazepines can exacerbate opioid-induced respiratory depression and increase risk for overdose.5 Patients 65 years and older and those with anxiety disorders
and other mental health conditions are more likely to be receiving benzodiazepines and therefore at greatest risk of an interaction when opioids are initiated or the dosage is increased. With repeated drug administration, some tolerance often develops to the respiratory depressant effects. Whether this tolerance actually reduces the risk of opioid-CNS depressant combinations has not been established and appears unlikely. Opioids can both exacerbate obstructive sleep apnea and cause central sleep apnea. Obstructive sleep apnea is common in overweight chronic pain patients, and it presents risk for opioid-induced respiratory depression, especially when the patients are sleeping. Recent reports suggest that opioids, and perhaps more so methadone, may induce potentially life-threatening central sleep apnea. Respiratory depression can be reversed by timely administration of the opioid antagonist naloxone. In patients chronically receiving opioids who develop respiratory depression, naloxone should be diluted 1:10 (i.e., 400 µg in 10 mL of 0.9% sodium chloride = 40 µg/mL) with each 40-µg dose (1 mL) given in 1- to 2-minute intervals to prevent the precipitation of severe withdrawal symptoms while reversing the respiratory depression. An endotracheal tube should be placed in the comatose patient before administering naloxone to prevent aspiration associated respiratory compromise with excessive salivation and bronchial spasm. In patients receiving meperidine chronically, naloxone may precipitate seizures by blocking the depressant action of meperidine and allowing the convulsant activity of the active metabolite, normeperidine, to be manifest.

The mixed agonist-antagonists, pentazocine, nalbuphine, butorphanol, and the partial agonist buprenorphine have different dose–response characteristics for their respiratory depression curves from the morphine-like opioids. Although therapeutic doses of pentazocine produce respiratory depression equivalent to that of morphine, increasing the dose does not ordinarily produce a proportional increase in respiratory depression. Whether this apparent ceiling to respiratory depression offers any significant clinical advantage has not been determined. Also, naloxone reversal of the respiratory depression produced by buprenorphine requires relatively large doses (5 to 10 mg), is delayed in onset, and is not always effective. In addition, the respiratory depression from buprenorphine or
methadone may outlast the effects of a single dose of naloxone, continuous infusions of naloxone may be required to maintain reversal of respiratory depression.\textsuperscript{33,34}

**CONSTRICTION OF THE PUPIL**

Opioids stimulate the Edinger-Wesphal (parasympathetic) nucleus of the oculomotor nerve to produce miosis. Pinpoint pupils (along with respiratory depression and loss of consciousness) are the three pathognomonic signs of opioid overdose. These effects are antagonized by the opioid antagonist, naloxone. However, severe anoxia results in mydriasis.

**ANTITUSSIVE EFFECT**

Opioids depress the cough centers in the medulla and, in turn, depress the cough reflex. However, the receptor mechanisms involved with cough differ from those involved with other opioid effects such as analgesia. Therefore, the dextrorotatory isomers of opioids (e.g., dextromethorphan), which do not bind to opioid receptors are nevertheless effective antitussives.

**HYPOTHALAMIC EFFECTS**

Morphine affects both body temperature and circulating neuroendocrine hormone levels by actions on the hypothalamus. Morphine alters hypothalamic heat regulation resulting in a slightly lower body temperature. The release of corticotrophin-releasing hormone (CRH) and gonadotropin-releasing hormone (GnRH) are inhibited, causing a decrease in luteinizing hormone (LH), follicle-stimulating hormone (FSH), and adrenocorticotropic hormone (ACTH). Prolactin and antidiuretic hormone (ADH) release are increased. Based on observations in methadone maintenance patients, tolerance develops to the effects of morphine on these hypothalamic releasing factors.

The term opioid-induced androgen deficiency (OPIAD) describes clinically meaningful decrease in testosterone levels that occurs primarily in men receiving ongoing morphine or other potent \(\mu\) agonist opioid pharmacotherapy for chronic nonmalignant pain\textsuperscript{35} or those receiving
methadone or buprenorphine maintenance therapy. Worsening of pain, depressed mood, sexual dysfunction, and refractoriness to treatment are common in such patients. Trials of testosterone replacement therapy have been helpful at improving sexual dysfunction, pain, and quality of life; however, the effects of testosterone replacement on improving spermatogenesis or sperm motility are unclear. Inhibition of ovarian sex hormone and adrenal androgen production has been reported among women chronically consuming sustained-action opioids.

CENTRAL NERVOUS SYSTEM EXCITATION

In contrast to the obvious opioid CNS depressant effects, there are excitatory effects. Dose-dependent convulsions occur in rodents but are rare in humans. However, normeperidine, a principal metabolite of meperidine, causes anxiety, tremors, myoclonus, and generalized seizures when it accumulates with repetitive dosing. Naloxone does not reverse, and may even exacerbate, this hyperexcitability. Likewise, the metabolites morphine-3-glucuronide (M3G) and hydromorphone-3-glucuronide can cause movement disorders ranging from myoclonus to grand mal seizures when the metabolite accumulates, typically following relatively high-dose intravenous (IV) administration.

OPIOID TOLERANCE, DEPENDENCE, AND ADDICTION

The properties of the opioid analgesics that are most likely to lead to their being misused, or the patient mistreated, are effects mediated in the CNS that are seen following chronic administration. These include tolerance, physical dependence, and opioid use disorders addiction (see Table 79.2). It must be emphasized that although the development of tolerance and physical dependence are predictable pharmacologic effects seen in humans and laboratory animals in response to repeated administration of an opioid, these effects are distinct from the behavioral pattern seen in some individuals and described by the terms opioid use disorder and addiction. See Chapters 59 and 60 for more on addiction and dependence.
THE OPIOID-TOLERANT PATIENT AND OPIOID-INDUCED HYPERALGESIA

Clinically Observable Tolerance

Tolerance to opioid effects occurs, but it is widely misunderstood. It is useful to subdivide tolerance into three dimensions: (1) tolerance to analgesia, (2) tolerance to other CNS-depressing effects and nausea, and (3) tolerance to opioid-induced constipation. Effective ongoing opioid therapy for chronic pain often requires increasing the dose numerous times in the first days to weeks of therapy until a consistently effective dose is found. This may be initial tolerance or simply reflect a dose-finding period. Once an effective dose is found which keeps the patient reasonably comfortable for a few days, it is relatively uncommon to have to increase the dose further unless the painful pathology increases or a new painful disorder occurs, the patient skips doses, the dosage form is changed, a drug interaction occurs, or some other nonpharmacologic event such as diversion occurs. These types of events probably account for the majority of patient requests for increasing opioid doses. Clinically meaningful tolerance to analgesia occurs unpredictably in a minority of patients receiving opioids chronically for management of pain with a physiologic basis. Many chronic cancer and noncancer pain patients remain comfortable without increasing pain complaints for months or even years without an increase in opioid dose. A minority require escalating opioid doses for reasons that remain unclear. When a patient no longer responds to increasing doses of a particular opioid that was previously effective, consider rotation to another opioid. The management of acute postoperative pain in an opioid-tolerant patient is addressed in recent guidelines.44

Conversely, nearly everyone develops some meaningful degree of tolerance to opioid-induced sedation, respiratory depression, nausea, and inhibition of coordination after 5 to 7 days of ongoing (around the clock) opioid pharmacotherapy. At the initiation of opioid therapy, an antiemetic may be needed, but commonly, it is not needed after a few days of therapy. Many patients cannot safely drive a motor vehicle or operate machinery in the first days of opioid treatment. However, after a week of regularly scheduled opioid, most people can drive safely.45 When the dose is
increased or if patient abstains from the medication for a few days, another week may be required to reacquire tolerance to impaired eye-foot-hand coordination.

Tolerance to opioid-induced constipation does not appear to occur. Management of this common and sometimes debilitating side effect is discussed in the following text.

**Proposed Mechanisms of Tolerance**

Opioid tolerance may be classified as associative or pharmacologic. Associative or contextual tolerance refers to changes in response that result when an opioid is administered in the presence of specific environmental cues that can induce tolerance specific to that setting. Pharmacologic (nonassociative) tolerance is divided into pharmacodynamic tolerance, which is the result of neuronal adaptations that reduce the sensitivity of the system to the drug, and pharmacokinetic tolerance wherein the disposition of the drug is increased so that the effective concentration is reduced. Generally, pharmacodynamic mechanisms are thought to be most responsible for in vivo opioid tolerance. However, a contribution by associative tolerance cannot be excluded.

In the clinical setting, pharmacodynamic tolerance (hereafter, simply tolerance) develops when a given dose of an opioid produces a decreasing effect or when a larger dose is required to maintain the original effect. Some reports suggest that a degree of tolerance to analgesia appears to develop in most patients receiving opioid analgesics chronically. Although tolerance to opioid analgesia appears to develop rapidly in animal models, it does so much more slowly in humans. Other reports, however, document that many patients do not experience tolerance to analgesia, that is, the same dose of opioid continues to provide effective analgesia over days to years unless there is increase in the pathology associated with the pain.

An early sign of the development of tolerance is the patient’s complaint of a decrease in the duration of effective analgesia. The rate of tolerance development varies greatly among cancer patients; some demonstrate tolerance within days of initiating opioid therapy, whereas others will remain well controlled for many months on the same dose.
Unfortunately, pharmacodynamic tolerance cannot be adequately evaluated in the clinical situation. Factors described earlier as causing “apparent tolerance” should be considered and addressed before concluding that pharmacodynamic tolerance has occurred. Both an increase in pain and the development of tolerance often respond to an increase in the opioid dose. Because the analgesic effect is a logarithmic function of the dose of opioid, a doubling of the dose may be required to restore full analgesia. Although controversial, the experience with cancer patients suggests that there appears to be no limit to the development of tolerance, and with appropriate adjustment of dose, many, but not all, patients can continue to obtain pain relief without intolerable adverse effects. Titration to effect remains the hallmark of effective opioid therapy.

The mechanisms believed to underlie opioid tolerance may be classified into two categories: within-systems and between-systems. These mechanisms of tolerance are not necessarily mutually exclusive, as there is abundant evidence in support of anatomical and functional overlap of both processes. These adaptations can include modifications of the receptor, its coupling to G proteins and additional signal transduction events including μ-opioid agonist–induced phosphorylation of the MOR, followed by desensitization, receptor internalization, endocytosis, and downregulation.

Bohn et al. found that β-arrestin-2 knockout mice fail to develop antinociceptive tolerance to morphine and desensitization of the MOR does not occur after chronic morphine treatment. Interestingly, deletion of the β-arrestin-2 gene does not prevent the chronic morphine-induced upregulation of adenylyl cyclase activity, a cellular marker of dependence, and the mutant mice still become physically dependent to morphine. These observations have led to the design and evaluation of new opioids that activate the μ receptor signaling pathways relevant to analgesia but not β-arrestin signaling (see “Biased Ligands” section).

In vitro studies indicate that μ-opioid–mediated stimulation leads to translocation of protein kinase C to the plasma membrane and phosphorylation of the N-methyl-d-aspartate (NMDA) receptor. Between-systems processes of tolerance, on the other hand, are characterized by interactions that antagonize or compensate for the effects of an opioid, usually via some direct antiopioid mechanism. These
antiopioid factors may include nonopioid receptors, neurotransmitters, ion channels, and second messengers (see Inturrisi and Gregus\textsuperscript{51}) for additional details and references.

Preclinical studies suggest that apparent opioid tolerance may result from excitatory CNS changes that facilitate transmission of and increase sensitivity to pain.\textsuperscript{54} This condition is termed opioid-induced hyperalgesia (OIH). The basic phenomenon appears to result from the upregulation of antiopioid, pronociceptive systems. The neuroanatomical substrates and signaling pathways involved in OIH are emerging.\textsuperscript{54} However, the magnitude of the contribution of OIH to clinical opioid tolerance and its consequences for continued opioid therapy remain controversial. Case reports of OIH describe severe allodynia in patients on high-dose (IV) opioids that resolve with dose reduction. Eisenberg et al.\textsuperscript{55} has described a set of clinical criteria for diagnosing OIH. There is general agreement that during opioid withdrawal, OIH may occur and contribute to an exacerbation of pain.\textsuperscript{56} Therefore, avoid acute withdrawal. Switching from a morphine-like opioid to a mixed agonist-antagonist (pentazocine, nalbuphine, and butorphanol) or the partial agonist buprenorphine must be avoided or preceded by tapering of the µ-opioid because of the ability of these antagonist drugs to induce abrupt opioid withdrawal and cause concomitant hyperalgesia in opioid-dependent individuals.\textsuperscript{6}

A number of opioid-sparing strategies can be used to reduce the rate of the development of tolerance and to restore analgesia in high-dose opioid-tolerant patients. The combination of an opioid with a nonopioid analgesic can enhance analgesia and reduce the rate of development of tolerance because tolerance does not develop to the nonopioid component of the combination. For example, coanalgesics are a diverse group of nonopioid analgesics that can enhance the effects of opioids and have independent analgesic activity in certain painful conditions by nonopioid mechanisms. The coanalgesics include the anticonvulsants (e.g., gabapentin and pregabalin), the tricyclic antidepressants (e.g., amitriptyline, nortriptyline), the selective serotonin reuptake inhibitors (SSRIs) (e.g., paroxetine, citalopram), the selective norepinephrine reuptake inhibitors (SNRIs) (e.g., duloxetine, venlafaxine), the corticosteroids (e.g., dexamethasone, methylprednisolone), the topical local anesthetics and others (e.g.,
lidocaine patches, capsaicin cream), and the antispasmodics (baclofen) (see American Pain Society). Rotation to an alternative μ-opioid agonist usually results in a relative reduction of opioid dosage due to incomplete cross-tolerance (see the following text) among these opioids. The use of bolus or continuous epidural local anesthetics or peripheral local anesthetic blocks in patients with localized pain, for example, perineal pain, can sometimes dramatically reduce the need for systemic opioids and thus diminish opioid tolerance. However, a recent review concluded that the efficacy of therapeutic nerve blocks for many chronic pain conditions, other than headache, has not been adequately studied.

Ketamine is an NMDA receptor antagonist, and NMDA receptors are involved in the facilitation of pain transmission—a phenomenon known as central sensitization which leads to an increased sensitivity to pain following injury. Therefore, NMDA antagonists have antihyperalgesic effects in neuropathic pain states and reduce morphine tolerance in rodents. Ketamine is associated with limiting psychotomimetic effects so that dose titration must be carefully controlled. These approaches may, in some high-dose opioid-tolerant patients, allow a reduction of the opioid dose with a reduction of dose-related adverse effects without a loss of analgesia that may open the therapeutic window. However, a Cochrane systematic review concluded that current evidence is insufficient to assess the benefits and harms of ketamine as an adjuvant to opioids for the relief of cancer pain.

Animal study data on tolerance often do not translate well to humans. The rates of development and loss of tolerance are not well defined in patients. The rate and extent of tolerance can vary greatly among different opioids and among patients receiving the same doses of a single opioid.

Cross-tolerance refers to the effects of one drug that confers tolerance to another drug, usually of the same class. Although some cross-tolerance appears to occur among μ-opioid agonists, the more relevant observation is that this cross-tolerance is incomplete. Therefore, when rotating from one opioid to another, this phenomenon must be taken into account in dosage calculations by initiating dosage, depending on the opioid, with 50% to 90% dose reduction of the calculated equianalgesic dose and titrating as required for pain relief. Patients may have unique pharmacokinetic,
pharmacodynamic, or pharmacogenetic differences that make opioid dose conversions less predictable. Therefore, clinical judgment is paramount when converting one opioid to another.

THE OPIOID-DEPENDENT PATIENT

Physical dependence is the term used to describe an altered physiologic state produced by repeated administration of an opioid which requires the continued administration of an opioid to prevent the emergence of a stereotypical withdrawal or abstinence syndrome that is characteristic for the particular opioid. The signs and symptoms of opioid withdrawal are described elsewhere. The administration of an opioid antagonist to a physically dependent individual produces an immediate withdrawal syndrome. Patients who have received repeated doses of a morphine-like agonist, to the point at which they are physically dependent, may experience an opioid withdrawal reaction when given a mixed agonist-antagonist. Prior exposure to a morphine-like drug can greatly increase a patient’s sensitivity to the antagonist component of a mixed agonist-antagonist. The severity of withdrawal is a function of the dose and duration of administration of the opioid just discontinued, that is, the patient’s prior opioid exposure. The time course of the withdrawal syndrome is a function of the elimination half-life of the opioid to which the patient has become dependent (Table 79.3). Abstinence symptoms will appear within 6 to 12 hours and reach a peak at 24 to 72 hours, following cessation of a short half-life drug such as morphine, whereas onset may be delayed for 36 to 48 hours with methadone, a long half-life drug. Therefore, even for a patient in whom pain has been relieved by a procedure or treatment, it is necessary to slowly decrease the opioid dose to prevent withdrawal.

TABLE 79.3 Plasma Half-life ($T_{1/2}$) Values for Selected Opioids and Their Active Metabolites
There is not one best method to taper opioids. Several different approaches have worked well. For patients who are anxious about tapering an opioid and those who may be especially sensitive to mild withdrawal effects, a slower taper may be indicated. A decrease of 10% of the original dose per week is a reasonable starting point. Some patients who have taken opioids for a long time might find even slower tapers (e.g., 10% per month) easier.\(^\text{18}\)

Experience indicates that the usual daily dose required to prevent withdrawal is approximately one-fourth of the previous daily dose.\(^\text{61}\) This dose called, for want of a better term, the detoxification dose is typically given in four divided parts. Commonly, the initial detoxification dose is given for 2 days and then decreased by one-half (administered in four divided doses) for 2 days until a total daily dose of 10 to 15 mg per day (in morphine equivalents) is reached. After 2 days on this dose, the opioid can be discontinued. Thus, a patient who had been receiving 240 mg per day of morphine equivalent for pain would require an initial detoxification dose of 60 mg given as 15 mg every 6 hours. This dose is decreased by 50% per day over the next 3 to 5 days. Buprenorphine is also being used to taper patients from prescription opioids.\(^\text{62}\)

Cross-dependence refers to the ability of one opioid to substitute for another in preventing the withdrawal syndrome. Cross-dependence among the opioids allows rotation as described earlier and allows detoxification

with an alternate opioid. For example, methadone can be substituted for morphine earlier by switching the patient to oral methadone at one-fourth to one-eighth of the patient’s morphine dose and decreasing the dosage as described earlier.

**THE OPIOID-ADDICTED PATIENT WITH PAIN**

The term opioid use disorder or addiction describes a pattern of drug use characterized by a continued craving for an opioid that is manifested as compulsive drug-seeking behavior leading to an overwhelming involvement with the use and procurement of the drug. Within these definitions most, but not all, individuals who are addicted to opioids will have acquired some degree of physical dependence. However, the converse is not true, so that an individual can be physically dependent on an opioid analgesic without being addicted. Fear of addiction is a major concern limiting the use of appropriate doses of opioids. Recent national surveys indicate a significant increase in nonmedical use of prescription opioids. Increased reports of this problem coincided with attempts to make opioids more widely available to patients in pain. It is important to recognize the responsibility of clinicians to assess and monitor patients who are receiving long-term opioid treatment for pain to limit the abuse of these drugs. We now have the concurrence of two “perfect storms,” that is, a continuing epidemic of undertreated pain and, in some countries, such as the United States, a more recent epidemic of prescription drug abuse and overdose deaths. It is also important to recognize that although opioids are sometimes overprescribed, especially for noncancer pain, opioids are sometimes inappropriately withheld when they should be used to manage severe opioid-responsive pain, especially in patients with advanced disease.

**PERIPHERAL EFFECTS OF OPIOIDS**

In addition to the central effects, opioids have several important peripheral effects. The colon contains a dense population of MORs, and opioid-induced constipation can be a difficult clinical problem. Occupation and activation of those receptors by µ-opioid agonists inhibits peristalsis. Stimulating laxatives are the most appropriate type of laxative to manage
this, and they often, but not always, are effective. Stool softeners alone usually are not.

Peripherally acting MOR antagonists are indicated for the treatment of opioid-induced constipation in patients who have failed conventional laxative therapy.

Methylnaltrexone (Relestor) is a quaternary ammonium cation derivative of naltrexone that is charged and therefore confined to peripheral sites. It is available for subcutaneous administration (dosage 8 or 12 mg) and has a rapid onset of action. In July 2016, the U.S. Food and Drug Administration (FDA) approved an oral formulation (450 mg once daily). Methylnaltrexone is approved for opioid-induced constipation in adults with advanced illness who are receiving palliative care and adults with chronic noncancer pain.

Naloxegol (Movantik) is a PEGylated derivative of naloxone and is a substrate for the P-glycoprotein transporter. Due to the reduced GI permeability (i.e., oral absorption) and increased efflux of naloxegol out of the CNS, the CNS penetration of naloxegol appears to be negligible. It is available for oral administration (25 mg once daily). Naloxegol is biotransformed by CYP3A4 so that caution with CYP3A4 poor metabolizers or inhibitors of CYP3A4. Naloxegol is approved for opioid-induced constipation in adults with chronic noncancer pain. Entereg (Alvimopan) owes its selectivity to its slow dissociation kinetics from peripheral µ receptors. It is indicated for the inpatient management of postoperative ileus. Contraindicated in patients that have taken an opioid regularly for the past 7 days. The most common adverse reactions with these agents are abdominal pain, diarrhea, nausea, flatulence, vomiting, and headache.

A second class of drugs approved by the FDA for the management of opioid-induced constipation is believed to act on chloride 2 channels in the intestines. The one such drug available for clinical use is lubiprostone which is also approved for the management of irritable bowel syndrome with constipation (IBS-C) and idiopathic constipation.67

**EFFECTS ON SMOOTH MUSCLE AND THE CARDIOVASCULAR SYSTEM**
Other peripheral opioid effects include contraction of biliary tract smooth muscle, spasm of the sphincter of Oddi, increased ureteral and bladder sphincter tone, and a reduction in uterine tone. Except for bradycardia, most opioids have no significant effects on the heart or on cardiac rhythm. Methadone dose dependently can prolong the electrocardiographic QTc interval.\(^{68}\) The 2014 American College of Cardiology/American Heart Association clinical practice guide concludes that morphine sulfate has potent analgesic and anxiolytic effects, as well as hemodynamic actions, that are potentially beneficial in myocardial infarction and unstable angina.\(^{69}\) Patients with decreased blood volume are at risk of opioid-induced hypotension.

**PRURITUS**

Itching can result from opioid use and the probability is increased when opioids are given by epidural or intraspinal injection. Although previously thought to be due to the release of histamine from mast cells, more recently, a centrally mediated neurogenic contribution to opioid-induced pruritus has been described.\(^{70}\) Data from primate studies indicate that κ-opioid agonists and μ-opioid antagonists can block the centrally mediated opioid-induced itch.\(^{71}\) Antihistamines are used to manage this symptom, but they may also be sedating, thus limiting analgesic administration or placing the patient at greater risk of opioid-related respiratory depression. Dilute infusions of opioid antagonists reverse or decrease opioid-induced pruritus especially that due intraspinal opioids.\(^{70}\) 5-HT3 receptor antagonists reduced the incidence of pruritus after neuraxial morphine injection but not after neuraxial lipid-soluble opioids injection. Parenteral nalbuphine has also been used for opioid-induced pruritus and may be more effective than antihistamines for this indication.\(^{72}\) However, avoid mixed agonist-antagonists in μ-opioid–dependent patients. Most opioid-induced itching resolves within a few days. However, opioid rotation, dose reduction, or nondrug treatments such as cool compresses or moisturizers may be necessary for certain patients.

**OPIOID EFFECTS IN PREGNANCY AND ON THE NEONATE**
Using a private health insurance database representative of the United States beneficiaries from 2005 to 2011, Bateman et al. found that opioids were dispensed to 14% of women during the antepartum period with approximately 6% of women receiving opioids during each of the three trimesters. Although most opioid exposure represented short courses of treatment, 2.2% of women received three or more opioids during pregnancy. Pregnant opioid treated pain patients on low-dose opioid regimes can and usually are taken off the opioid. Pregnant opioid treated pain patients on high-dose opioid regimes are sometimes kept on their opioid because rapid taper can induce miscarriage. The prevalence of opioid use (prescription and nonprescription) among pregnant women has been estimated to range from 1% to 2% to as high as 21%. Pregnant women taking opioids at term may deliver an opioid-dependent infant, and those taking illicit opioids often require treatment to limit the impact of their opioid abuse on the newborn. A systematic review did not find sufficient significant differences between methadone and buprenorphine or slow-release morphine to allow a conclusion that one treatment is superior to another for all relevant outcomes. Whereas methadone seems superior in terms of retaining patients in treatment, buprenorphine seems to lead to less severe neonatal abstinence syndrome.

**ROUTES FOR OPIOID ADMINISTRATION**

The oral route is generally the preferred route for opioid administration in ambulatory care due to convenience and relatively low cost. Immediate-release oral opioid dosage forms include solutions, compressed tablets, and gelatin capsules. Although solutions are absorbed more promptly, it is not clear that this offers a clinically important advantage for most patients. The risk of patients incorrectly measuring the volume producing inconsistent and sometimes excessive doses is real.

Opioids can be administered by oral, parenteral, rectal, sublingual, transdermal, and transmucosal routes. The μ agonists can be categorized as short-acting, long-acting, and ultra-short acting. Short half-life morphine-type opioids require frequent administration to maintain analgesia. Immediate-release morphine products provide about 4 hours of pain relief and need to be dosed accordingly. Pharmacetically formulated long-
acting, extended-release, or controlled-release formulations (see Table 79.1) provide alternatives to frequent opioid administration of inherently short-acting drugs. Pharmacologically long-acting opioids (i.e., methadone and levorphanol) that have longer half-lives (see Table 79.3) can provide analgesia in some patients for 6 to 12 hours when steady-state dosing is reached. Although methadone protects against opioid withdrawal for 24 or more hours, an oral dose only provides effective analgesia for a much shorter time, typically only about 8 hours. The pharmacologically long-acting opioids, methadone and levorphanol, require an understanding of safe dosing (see the following text).

Clinicians should be cautious about using extemporaneously compounded sustained-release opioids. Although there are franchised compounding pharmacies that prepare these—and some market them aggressively—most release the active ingredient inconsistently and unreliably over time. Uneven pain control, exacerbation of pain, withdrawal, and even overdose may result. The rapid onset of action of fentanyl series μ agonists favors their use as a perioperative adjuncts and their high lipophilicity facilitates transdermal, transmucosal, and subcutaneous administration. When these highly lipophilic opioids are absorbed through or injected under the skin, they create a depot in subcutaneous fat from which the drug is slowly released. This depot effect also makes them very difficult to titrate to response. However, when these medications are administered transmucosally or sublingually, they are rapidly absorbed due to the lack of the buccal and sublingual fat. This prompt onset makes those routes useful in managing breakthrough pain. Buprenorphine also has been formulated as a long-acting transdermal patch and buccal film (Belbuca) (see Table 79.1). The IV route of administration is generally preferred in immediate postoperative and intensive care settings and for a pain crisis. Intramuscular (IM) injection is painful and may produce uneven absorption; it should generally be avoided. The subcutaneous (SC) route is preferred for injection when the IV route is impractical. The pharmacokinetics of SC administered opioids result in levels comparable to the IM route with the advantages that the SC route is far simpler to use and more comfortable for the patient. There is little or no rationale for IM opioid injections.
Table 79.1 lists relative equianalgesic doses and the starting doses recommended for commonly used opioids.

**ALTERNATIVE NONINVASIVE ROUTES**

When oral administration is not possible, consider alternative noninvasive routes before resorting to injections, infusions, or the placement of epidural or intrathecal catheters.

**SUBLINGUAL ADMINISTRATION**

Transmucosal absorption occurs following sublingual administration of a reasonably lipophilic opioid. Oral transmucosal dosing may provide less consistent absorption than oral administration due to anatomical and physiologic variability in the mucosa (e.g., thickening due to pathology, pH). This route generally should not be considered when patients can take medications orally because oral administration is simpler and oral solid dosage forms provide more exact doses than liquid doses that must be measured before administration.

Sublingual administration entails placing of a small volume of concentrated liquid or a readily dissolvable solid dosage form or film under the tongue. Other locations in the mouth that can be used are the cheek pouch (buccal administration) and the anterior lip pouch (transmucosal administration). Clinical experience supports these routes, but they have not been systematically studied. Patients should not eat or drink anything for about 15 minutes after taking an oral transmucosal dose. Doing so may increase the amount of drug that is swallowed, causing inconsistent interdose absorption.

Because opioids often cause dry mouth, it is important to counsel patients about this restriction. Some oral transmucosal dose tends to trickle down the throat or be actively swallowed, in which case that portion will undergo normal GI absorption. Factors that influence the percentage of the dose that is swallowed include the volume of liquid and the condition of the oral mucosa. In general, no more than 1 mL of liquid should be placed under the tongue or in a mucosal pouch. Larger volumes tend to increase the amount of drug that is swallowed. Additional doses can be administered in a few minutes if necessary. It is necessary to moisten the
mouth before dosing if it is dry idiopathically or due to disease or therapy. Stomatitis and excessive keratinization of the oral mucosa may make absorption inconsistent. The oral pH can influence absorption across the oral mucosa. Whereas normal mouth pH is 6.5, for many cancer patients receiving therapy, it is above 7. The percentage of sublingual opioid absorbed increases with higher pH. Because recently ingested foods and liquids can influence oral cavity pH, it is advisable to rinse the mouth with water before taking or administering an oral transmucosal dose and to not eat or drink anything for the next 15 to 20 minutes.

The rectal route of administration is an alternative for patients unable to take drugs orally. Although used commonly in the early days of modern hospice care (i.e., the 1970s to 1980s), it is less commonly used today due to alternative, nonoral dosage forms becoming available. The rectal route is simple to use and inexpensive. Some patients, however, find it esthetically unpleasant. Table 79.4 lists rectal opioid times to peak and duration of action. This route of administration is generally acceptable for short-term use and in care of terminal patients. Advantages of the rectal route include ease of use, lack of equipment that patients and families often perceive as reinforcing the sick role, and low cost. Rectal administration is contraindicated for patients with painful anal lesions.

Extemporaneously compounded rectal dosage forms can be made by compounding pharmacies for those unable to tolerate orally administered opioids. For such extemporaneously prepared forms, the rate and consistency of release of active ingredient from the dosage form and the risk of dose dumping resulting in toxicity are concerns.78

Rectally and orally administered morphine provides similar analgesic effect and serum levels. Although there is far less absorption following a rectal dose, a significant portion of an orally administered dose undergoes first-pass metabolism which is avoided with rectal administration. This effect may be unique to morphine and may not apply to other opioids. Immediate-release oral tablets, liquids, and suppositories of morphine have been used rectally with good effect.79 Do not assume dose equivalency for other oral opioid dosage forms given rectally because of differences in physicochemical and pharmacokinetic properties. Controlled-release dosage forms do not necessarily have the same effects and duration of action when administered orally and rectally. Lower peak serum levels and more interpatient variability occur with all controlled-release dosage forms when they are given rectally rather than orally. MS Contin administered rectally produces clinical effects similar to those obtained with the same dose taken orally and may produce less rectal irritation than the previously available rectal morphine suppositories.80 Some palliative care nurses administer tablets rectally in a small mass of butter or an empty gelatin capsule. This is unnecessary and may delay absorption of the opioid. Simply ensure that the rectum is empty before inserting the tablets.

Oxycodone produces similar areas under the curve (AUCs) when administered rectally and orally.81 Although rectal oxycodone suppositories are available in some countries, only oral solid and liquid forms are marketed in the United States. The commercially available oral liquid could be used rectally, but administration would be required every 3
to 4 hours for continual analgesia.

Informal, anecdotal reports of both immediate-release and controlled-release oral solid dosage forms administered via the vagina and through colostomy and ileostomy stomas also have been mentioned, but no data to support such use have been published. A comparative study of morphine administered rectally and through a colostomy led the investigators to conclude that the opioid should not be given through a colostomy due to poor and inconsistent absorption. Animal studies of methadone administered vaginally indicate possible usefulness of that route. But clinical data to support that hypothesis were not identified in a comprehensive literature search.

Nebulized opioids have been used and may provide good pain relief. However, that is not a cost-effective administration method for analgesia. Nebulized opioids are sometimes used as an alternative to sublingual administration to treat dyspnea (air hunger) in advanced disease; however, there appears to be no benefit of using nebulized versus oral morphine for dyspnea.

Very small particles are needed to deliver drug to the alveoli. Use of an administration method other than a high-quality small particle nebulizer can result in drug deposition on the palate with little or very inconsistent clinical effect. Handheld, squeeze bulb devices are not useful. Nebulized opioid administration requires sterile solutions, which increase expense as compared to oral and sublingual routes.

**EPIDURAL, INTRATHERCAL, AND INTRAVENTRICAL ADMINISTRATION**

Neuraxial or spinal administration refers to the use of epidural or intrathecal routes of administration. Both of these spinal routes are widely used, the former commonly for postoperative pain control and the latter more for chronic administration. In obstetrical analgesia, a single intrathecal opioid dose followed by continuous or intermittent epidural administration often is used. Epidural patient-controlled analgesia also is used in some settings. In addition to opioids, spinal administration for pain may include local anesthetics, ziconotide, baclofen, clonidine, or ketamine (see American Pain Society for details).
The epidural space is a fat-filled potential space that contains blood vessels (Fig. 79.2). Therefore, epidural opioid administration can cause systemic effects, albeit much more slowly and less than with IV and other systemic routes. The intrathecal route avoids some of the supraspinally mediated toxicity associated with the systemic delivery of these medications. The epidural and intrathecal routes each have advantages and disadvantages. Epidural administration allows opioid placement at any dermatomal level and does not require puncturing of the dura. However, larger doses are required and systemic effects may occur with epidural administration, increasing the risk of adverse effects. For morphine, intrathecal doses are typically one-tenth of those needed for an equianalgesic epidural dose. Intrathecal administration requires puncturing the dura, which delivers drug closer to the spinal cord receptors. Disadvantages of intrathecal use include increased potential for meningitis and risk of postdural puncture headaches. Dose-related problems associated with spinal analgesia include pruritus, urinary retention, and delayed respiratory depression.
Intraventricular administration has been used in cancer patients unresponsive to opioids administered by other routes. The Ommaya reservoir has been used for this method of drug delivery.

With any direct central administration method, the pharmacokinetics of the opioids can vary greatly from systemic administration. Physicochemical drug characteristics, especially lipophilicity, become very important with these routes.

**Characteristics of Specific Opioids**

**MORPHINE**

The oral bioavailability of morphine varies from 35% to 75%, which helps to explain some of the interpatient variability in response. Its average
plasma half-life of 3 hours is somewhat shorter than its 4- to 6-hour duration of analgesia; this limits accumulation. With repetitive administration, its pharmacokinetics remains linear, and there does not appear to be autoinduction of biotransformation even following large chronic doses. These pharmacokinetic properties contribute to the safe use of morphine over time. The two major morphine metabolites are M3G and morphine-6-glucuronide (M6G). M6G appears to contribute to the analgesic activity of morphine. M6G appears to exert its analgesic action through a different splice variant of the MOR than morphine. M6G is eliminated by the kidney and, because it has a somewhat longer half-life than the parent compound, will accumulate relative to morphine in patients with renal insufficiency. A survey of steady-state morphine and M6G levels and adverse effects in 109 cancer patients indicated that myoclonus or cognitive impairment was not associated with M6G accumulation. For a subset of the 20 patients with the highest M6G levels (>2,000 µg/mL), the M6G level and concurrent organ failure was associated with the most severe toxicity (respiratory depression and/or obtundation). It is appropriate to consider an alternate opioid for a patient receiving morphine who experiences a decrease in renal function and a concomitant increase in undesirable effects.

M3G is the predominate metabolite of morphine in humans. It lacks opioid analgesic activity but has excitatory effects in animals after direct injection into the CNS. This has led to the suggestion that M3G may be responsible for the neuroexcitatory effects sometimes seen with large chronic morphine dosing. M3G has an elimination half-life even longer than M6G, and accumulated M3G has been associated with myoclonus and hyperalgesia, although that association is not clear.

Based on single-dose studies in patients with either acute or chronic pain the relative potency of intramuscular to oral morphine is 1:6. However, with repeated administration, when patients are dosed on a regular schedule (around the clock), the parenteral to oral dose ratio is reduced to 1:2 or 1:3 (see Table 79.1). This presumably is due to accumulation of the M6G metabolite, which is active and has a longer half-life than the parent drug.

The extended-release morphine preparations provide analgesia with a
duration of 8 to 12 hours (MS Contin) or 12 to 24 hours (Kadian) and allow patients greater freedom from repetitive dosing, especially during the night. Patients may be titrated using the immediate-release morphine and, once stabilized, converted to the sustained-release preparation according to a schedule appropriate for the form used. To manage acute “breakthrough” pain “rescue” medication (immediate-release morphine) should be made available to the patient receiving delayed-release preparations.

Allergy to morphine has historically been associated more with trace plant protein in morphine derived from natural sources (opium). Today, most morphine formulations are very pure and contain so little plant protein that this problem is relatively uncommon. When it does occur, a fully synthetic opioid is indicated. True allergy to the morphine molecule is rare.

**HYDROMORPHONE**

Hydromorphone is a short half-life opioid used as an alternative to morphine by the oral and parenteral routes. It is available as both immediate-release and extended-release dosage forms. It is more soluble than morphine and is available in a concentrated parenteral dosage form at 10 mg/mL which can be advantageous for opioid-tolerant patients and cachectic patients in whom the volume of the opioid solution must be limited. Although hydromorphone is converted to a 3-glucuronide metabolite, it has not consistently been associated with neurotoxic effects in vivo, although this toxicity has occurred. The dose should be decreased by 25% to 50% in patients with renal impairment.

**METHADONE**

Methadone use in pain management has dramatically increased in recent years with mixed effects. The original interest in methadone was based on its high (1:2) oral to parenteral potency ratio, which is a reflection of its high oral bioavailability that averages 85%. It was found to be useful in opioid rotation because its incomplete cross-tolerance with opioids like morphine allow a reduction in dose to approximately 10% to 25% of the estimated equianalgesic dose when switching from morphine to methadone.
(see American Pain Society3[p49]). Methadone is relatively inexpensive, and its metabolites do not have opioid activity or apparent toxicity. As with other opioids, it may provide a larger therapeutic window in a particular patient, although this cannot be determined prior to a therapeutic trial. Preclinical studies demonstrate NMDA receptor antagonist activity of both isomers of methadone. In animals, this NMDA receptor antagonist activity included antihyperalgesic activity and the ability to prevent the development of morphine tolerance.6,93 However, it remains to be determined whether these effects occur in humans at the doses of methadone used clinically. The weak NMDA antagonist effect of methadone has been anecdotally reported to be advantageous in managing neuropathic pain; however, studies have failed to demonstrate its superiority to other opioids.

A major limitation on the use of methadone as a first-line opioid for pain management relates to its safety. Its population pharmacokinetics is variable with a plasma half-life averaging 24 hours, but that may range from 13 to 50 hours. Because initially, the duration of analgesia is often only 4 to 8 hours, repetitive analgesic dosing of methadone can lead to drug accumulation because of this discrepancy between its plasma half-life and the duration of analgesia during initial dosing. Sedation, confusion, and even death can occur when patients are not carefully monitored and dosage adjusted during the accumulation period that can last from 5 to 10 days.

Opioid-naive patients should be started on a low oral dose (e.g., 2.5 mg) every 8 hours. Opioid-tolerant patients should be switched to an oral morphine equivalent dose based on guidelines described on American Pain Society.3(p49)

A second safety issue relates to concerns about the potential for methadone to prolong the QTc interval and predispose patients to torsade de pointes (TdP), a life-threatening arrhythmia. This requires consideration of the baseline risk of QTc prolongation, monitoring of the electrocardiogram during dosing with methadone, and appropriate adjustments as described in a clinical practice guideline.68 This effect is more common at higher doses (e.g., 90 to 120 mg a day), sometimes used for pain due to advanced disease. It is very uncommon with the typical
doses used for chronic, nonmalignant pain management (e.g., 7.5 to 60 mg a day).

Finally, there persists a stigma among pain patients and the public attached to the use of methadone for the treatment of opioid addiction due to its association with managing opioid use disorder (addiction).

**LEVORPHANOL**
Levorphanol is a relatively longer half-life opioid (see Table 79.3) that sometimes can be a useful alternative to morphine, but, like methadone, it must be used cautiously to prevent accumulation. Like methadone, levorphanol appears to have NMDA receptor blocking activity.

**OXYMORPHONE**
Oxymorphone, a congener of morphine that is parenterally approximately 10 times more potent than morphine. Opana is available as immediate- and extended-release oral formulations and for parenteral administration (see Table 79.1). The extended-release dosage form (Opana ER) is indicated for every 12-hour dosing. Food enhances the oral bioavailability, so Opana ER should be taken 1 hour prior to a meal or 2 hours after a meal. Coingestion of alcohol with Opana ER may also increase plasma levels of oxymorphone. It is contraindicated in patients with severe hepatic impairment.

**OXYCODONE**
Oxycodone is available for oral dosing as immediate and extended (controlled)-release (ER) dosage forms for the treatment of severe pain. The abuse of the ER formulation by extracting the active ingredient from crushed tablets and injection of large and sometimes fatal doses by abusers led the manufacturer, Purdue Pharma, in 2010 to reformulate the ER tablets (OxyContin OP) using an abuse-resistant polymer designed to decrease abuse by crushing and extraction of the drug. Oxycodone is also available in lower doses in combination with acetaminophen for mild to moderate pain. Inhibition of CYP3A4 activity by its inhibitors, such as macrolide antibiotics (e.g., erythromycin), azole-antifungal agents (e.g., ketoconazole), and protease inhibitors (e.g., ritonavir), may increase
concentrations of oxycodone and prolong opioid effects. CYP450 inducers, such as rifampin, carbamazepine, and phenytoin, may induce the metabolism of oxycodone and, therefore, may cause increased clearance of the drug which could lead to a decrease in oxycodone plasma concentrations, lack of efficacy or, possibly, development of an abstinence syndrome in a patient who had developed physical dependence to oxycodone.

**FENTANYL**

Fentanyl is a member of the phenylpiperidine family of synthetic opioids. It is approximately 100 times more potent than morphine when given parenterally (see Table 79.1). In addition to parenteral formulations, available dosage forms include a transdermal patch (Duragesic), a sublingual tablet (Abstral), a lozenge or “lollipop” (Actiq), a buccal film (Onsolis), a buccal tablet (Fentora), sublingual spray (Subsys), and a nasal spray (Lazanda). The oral transmucosal and nasal spray dosage forms are approved to treat breakthrough cancer pain (see Table 79.1). Substantial differences exist in the pharmacokinetic profiles of transmucosal dosage forms; patients should not be converted from one fentanyl form to another on a microgram-per-microgram basis. Rather, the manufacturers dosing recommendation for each product should be followed.

Fentanyl is a lipophilic opioid that can be absorbed through the skin. The rate of absorption is controlled, and 12 to 16 hours are required to achieve a therapeutic effect and 48 hours to achieve steady-state serum levels. This lag in onset means that when switching from other routes of opioid administration to a transdermal (TD) dosage form, pain relief should be monitored to be sure analgesia is maintained. Conversely when TD fentanyl is discontinued, plasma levels will slowly decline over the subsequent 24 hours. TD fentanyl can reduce fluctuations of plasma drug levels and avoids the need for repeated injections or use of the oral route. The FDA-approved labeling (package insert) provides information on equianalgesic conversions, but these are all approximate. Like the ER opioids, the TD fentanyl should be avoided in opioid-naive patients. It is “used to manage pain severe enough to require daily around-the-clock, long-term treatment with an opioid, in people who are already regularly
using opioid pain medicine, when other pain treatments such as non-opioid pain medicines or immediate-release opioid medicines do not treat your pain well enough or you cannot tolerate them” (Duragesic package insert).

**MEPERIDINE**

The primary metabolite of meperidine (pethidine), normeperidine, has a unique neurotoxicity, which can lead to symptoms ranging from irritability to grand mal seizures. Because the half-life of normeperidine is approximately four times longer than the parent compound, normeperidine accumulates rapidly following oral administration and in patients with compromised renal function. Therefore, meperidine should not be used for longer than 24 to 48 hours. In patients receiving meperidine chronically, naloxone may precipitate seizures by blocking the depressant action of meperidine and allowing the convulsant activity of the active metabolite, normeperidine, to be manifest. Meperidine administration to patients receiving monoamine oxidase inhibitors has resulted in a fatal hyperthermia and other symptoms of serotonin syndrome. For all of these reasons, many hospitals and health centers have restricted the use of meperidine or removed it from their formularies.

Meperidine has been reported to be the drug of choice to treat both postoperative rigors (shivering and shaking chills associated with antigenic drugs or blood products). More recently, clonidine and physostigmine were also found effective shivering suppressants, suggesting that opioid, α2 adrenergic, and anticholinergic systems were possibly involved in this adverse effect.

**CODEINE**

Codeine is widely available and inexpensive. Its use is controversial, in part because codeine is prodrug that is often not effective in patients who cannot convert it to its active metabolite (morphine) by CYP2D6 and because of potential drug interactions resulting from this genetic polymorphism. Although a discussion of the complex polymorphisms of CYP2D6 is beyond the scope of this review (see Zahari and Ismail), it is important to recognize that the poor metabolizer phenotype (seen in 5% to 10% of Caucasians) inhibits conversion of codeine to morphine and
resulting in codeine not producing an analgesic response. Whereas the ultrarapid metabolizer phenotype (seen in 1% to 2% of Caucasians) may overdose as a result of the excessive conversion of codeine to morphine, these estimates of CYP2D6 phenotype distributions may differ substantially for other ethnicities. In addition, the induction of CYP2D6 by other drugs will increase the effectiveness of codeine, whereas drugs that inhibit CYP2D6 will decrease codeine’s effects inhibition. Codeine should not be taken by nursing mothers; levels that occur in breast milk can be toxic to nursing babies. For a list of drugs that interact with CYP2D6 and other relevant CYP450s, see the Flockhart Table at http://medicine.iupui.edu/clinpharm/ddis/main-table/. Consortium Guidelines for Cytochrome P450 2D6 Genotype and Codeine Therapy recommends using alternative analgesics to codeine in patients who are CYP2D6 poor or ultrarapid metabolizers. Unfortunately genotyping of pain patients is still uncommon and codeine combinations with nonopioids are commonly prescribed.

HYDROCODONE
Hydrocodone is a pure µ agonist much like morphine or oxycodone. It is commonly available as a combination dosage form (e.g., hydrocodone plus acetaminophen); in addition, there are several newly approved long-acting abuse-deterrent pure hydrocodone oral formulations. When combination hydrocodone/acetaminophen products are used, the daily dose limit is primarily due to the acetaminophen, not the opioid.

PROPOXYPHENE
Propoxyphene has been removed from many leading hospital formularies—no longer available in the European Union, New Zealand, and the United Switzerland.

TRAMADOL
Tramadol is a weak µ agonist and weak norepinephrine serotonin reuptake inhibitor. Neither mechanism alone explains its analgesic efficacy. The probable mechanism is synergism between these two weak effects. In some patients, tramadol at a dose of 100 mg four times daily may produce
analgesia similar to that of oral morphine 5 to 10 mg four times daily. Higher doses of tramadol offer no advantage and produce greater toxicity. Due to its mechanism, tramadol is more useful in neuropathic than nociceptive pain, and it appears more appropriate as a chronic than acute use analgesic because the dose must be titrated up slowly to minimize risk of lowering seizure threshold. A combination of tramadol 75% with acetaminophen 25% appears to be as effective as the single-ingredient analgesic. Tramadol has recently become a controlled substance in the United States and can be highly toxic when misused.

**TAPENTADOL**

Like tramadol, tapentadol is a centrally acting dual mechanism µ-opioid agonist and norepinephrine reuptake inhibitor. This dual mechanism likely explains its analgesia beyond its MOR activity. It has several advantages over other opioids; it is not a prodrug which requires biotransformation, has no known active metabolites, and is not metabolized by CYP450 enzyme system; which makes the possibility of CYP450 drug–drug interactions unlikely. It is available in immediate- and extended-release oral formulations. Tapentadol has comparable efficacy to morphine despite having 50-fold lower affinity to the MOR and has better GI tolerability (nausea, vomiting, and constipation) versus oxycodone. Tapentadol IR 50 mg and 75 mg were noninferior to oxycodone 10 mg for the treatment of acute pain with significantly less nausea and vomiting.

**PENTAZOCINE, NALBUPHINE, AND BUTORPHANOL**

The mixed agonist-antagonist analgesics (see Table 79.1) include pentazocine, butorphanol, and nalbuphine. They produce analgesia as a result of their κ-opioid receptor agonist activity and show µ antagonist activity in the presence of a µ-opioid agonist. This receptor dualism is manifest in the opioid-naive patient as opioid analgesia and as opioid withdrawal in patients who are dependent on a µ-opioid. Therefore, they are not appropriate choices for patients who have been receiving a µ-opioid agonist for pain management or for the maintenance treatment of opioid substance use disorder. There is a ceiling effect on the ability of the mixed agonist-antagonists to produce respiratory depression, and they
have a significantly lower abuse liability than the µ-opioid agonists. In therapeutic doses, they may produce certain self-limiting psychotomimetic effects, including confusion and hallucinations. Pentazocine is the mixed agonist-antagonist associated most commonly associated with these psychotomimetic effects. These drugs play a very limited role in the management of persistent pain because the incidence and severity of the psychotomimetic effects increase with dose escalation and because except for pentazocine, they are not currently available in oral dosage forms. Butorphanol is available for both parenteral and intranasal use. Nalbuphine is available only for parenteral use (see Table 79.1). A systematic review concluded that in patients with opioid-induced pruritus as a result of receiving neuraxial opioids for acute pain related to surgery or childbirth, nalbuphine is superior when compared with placebo, control, diphenhydramine, naloxone, or propofol.

BUPRENORPHINE
Buprenorphine is a semisynthetic opioid with relative high affinity for and slow disassociation from the MOR. It appears to fit the pharmacologic profile of a partial MOR agonist in that it has an analgesic ceiling, particularly in acute pain management, and can precipitate opioid withdrawal in patients dependent on µ-opioids. It is available for pain management as Belbuca, a buccal film; Temgesic, a sublingual tablet; and Butrans, a 7-day TD patch (see Table 79.1). Because of the concerns with opioid withdrawal in patients taking more than 80 mg morphine equivalents per day, the dosage and conversion schedules for each formulation should be carefully observed. The buprenorphine T/1/2 is very long (see Table 79.3) and will accumulate with repetitive dosing. Buprenorphine does not require dose reduction in renal failure patients. The slow disassociation kinetics of buprenorphine from the MOR is reflected in the need to use a naloxone infusion to reverse buprenorphine—induced respiratory depression. Buprenorphine is also used for the treatment of opioid dependence (see Table 79.1). Table 79.5 lists metabolites of commonly used opioids.

### Abuse-Deterrent Opioid Formulations

Nonmedical use of prescription opioid analgesics worldwide has continued to rise over the past decade. In the United States, approximately 15 million people aged 12 years or older used prescription drugs nonmedically in the past year, and 6.5 million did so in the past month.\(^\text{107}\) Prescription drugs are now misused and abused more often than any other drug, except marijuana and alcohol.\(^\text{107}\) These trends have driven interest in the development of abuse-deterrent formulations (ADFs) of opioids, in an attempt, to reduce opioid-related abuse, overdose, and death. The currently available products (Table 79.6) reduce the ability to extract the opioid

from the formulation, prevent administration through alternative routes like crushing or injecting, and/or make abuse of the manipulated product less attractive and more difficult. However, all of the currently available products can be abused without manipulation (e.g., ingesting large quantities orally) and do not prevent abuse, but rather reduce the likelihood of abuse. In addition, there is no currently available evidence that these formulations reduce the risk of opioid overdose. Table 79.7 lists various technologies currently used to deter abuse with their unique advantages and limitations.

Selecting among the Opioids for Clinical Use

Tables 79.1 and 79.4 list other morphine-like agonists that may be substituted for morphine. An alternative opioid to morphine may be selected based on the need with a particular patient to overcome an adverse effect of morphine (e.g., vomiting or sedation). Other reasons include the cost, a patient’s favorable prior experience with another opioid, or even local availability of other morphine-like opioids. There is no evidence to suggest that any other opioid has greater analgesic efficacy than morphine in the population as a whole, but interpatient variability does exist. Only clinical trial can adequately determine the opioid that is the best choice for a specific patient.

Conclusions and Insights into the Future of Opioids for Pain

Opioids are essential analgesics for the management of severe pain. The risk-to-benefit ratio can be favorable when they are used properly. Respiratory depression is a risk particularly in the opioid-naive, whereas the chronic toxicity may be related to endocrinopathy, especially androgen deficiency.

Pain management with or without opioids requires individualization of treatment. So that titration to response remains the only effective way to determine the optimal opioid and dose for a specific patient. The initial opioid should be based on past patient experience, dosing schedule compatibility with the patient’s life style and probable adherence to the regimen, and cost. Regular observation for adverse effects is essential. When adverse events occur, consider whether changing to a different opioid may be preferable to additional drugs to treat the adverse effect. If opioid efficacy wanes, consider whether nonopioid therapy might then suffice and if androgen deficiency is a contributor. Opioid rotation also should be considered. Because of the comorbidities that occur with chronic pain, opioid monotherapy is seldom indicated; rather, additional
pharmacotherapies, concurrent physical therapy, and psychotherapy are often required for appropriate pain management.

Opioid pharmacokinetics and pharmacodynamics are well characterized at all stages of life. Caution is indicated in very young, the elderly, and renally impaired patients due to the potential for opioid accumulation. Additive and synergistic effects with other CNS depressant medications are common. All opioid regimens should be reevaluated at regular intervals, and the medication should be tapered off if it is no longer needed or is no longer providing more benefits than adverse effects.

BIASED LIGANDS
We have always maintained that the ideal opioid would relieve moderate to severe pain with the efficacy of morphine without producing the undesirable effects of morphine and other µ-opioids. These adverse effects include respiratory depression, tolerance, and addiction (see Table 79.2). Today more than ever, the focus is on improving the adverse effect profile of newer opioids, and the abuse-deterrent formulations are a step in the right direction. However, the very recent recognition that opioids can be designed that act on MORs to activate signaling pathways that produce analgesia (the Gi/o signaling proteins) without simultaneous activating those pathways (the β-arrestin signaling proteins) that transduce the major limiting adverse effects of opioids.\textsuperscript{53,108,109} With the advent of these biased ligands, we appear to be on the threshold of a new era in opioid pharmacology, clinical drug development, and pain therapy.

Pain remains a major public health problem, and opioids are an important part of the analgesic armamentarium. Used wisely, opioids have great value.

DEDICATION
We dedicate this chapter to our friend and colleague, Dr. Arthur Lipman. Art was a tireless advocate for evidence-based pain management.

Skeletal Muscle Relaxants

The class of medications termed skeletal muscle relaxants is ill defined leading to much confusion for both clinicians and scientists. This confusion results from the assumption that these medications all act in a similar fashion and produce reliable skeletal muscle relaxation. Neither is true. These medications produce a range of effects that remain poorly defined (Table 80.1).\(^1\)–\(^4\) The class includes carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, and orphenadrine.\(^5\) These medications are approved by the U.S. Food and Drug Administration (FDA) for indications including spasticity, spasms, and/or musculoskeletal conditions (Table 80.2). Medications are often utilized for off-label uses and skeletal muscle relaxants are no exception. Benzodiazepines, principally diazepam, also are commonly used for adjunctive relief of skeletal muscle spasm. Chief among the challenges to clinicians using these drugs is discerning the role of the agents across the continuum of painful disorders. It should be noted that the order of medications within the subsections do not indicate management priority or expert preference.

</table>

Historically, skeletal muscle relaxants have been prescribed for acute and chronic conditions associated with muscle related pain. The majority of these agents are indicated for use during the initial presentation of acute low back pain, which often results from soft tissue mechanical injury and normally occurs in the muscles, ligaments, and/or tendons, structures around the lumbar spine. Acute pain may include local pain and tenderness, muscle spasm, and limited range of motion, but what actually constitutes painful muscle spasm remains controversial. Muscle spasm may be a variant of the myofascial pain presentation, and as such not really a spasm.
To better understand the potential pharmacologic benefit of these agents, consider the regulation of muscle activity in both the peripheral tissues and central nervous system (CNS). At the level of the peripheral muscle, tissues are composed of intrafusal fibers that signal changes in muscle length. These lie in parallel with extrafusal muscle fibers that normally serve to contract or stabilize joints. When muscle tissue is stretched, the intrafusal fibers stretch resulting in an increase in neural discharges carried by afferent nerve fibers. This signal is transmitted to the dorsal horn and synapses with α-motoneurons in the ventral horn, producing excitatory postsynaptic potentials. The result is a type of negative feedback, with muscle contraction of the intrafusal muscle fibers where the original stretch signal originated. These muscle fibers also maintain an efferent component, facilitated by small γ-motoneurons that originate in the ventral horn of the spinal cord and travel together with the α-motoneurons that innervate extrafusal muscle fibers. The γ-motoneurons adjust the sensitivity of the muscle fibers and regulate muscle tension over a wide range of muscle lengths. This complex system of afferent and efferent signaling through the motoneurons when at homeostasis leads to stabilization of muscle structures (Fig. 80.1).

**FIGURE 80.1** Neural regulation of muscle tone: possible sites of action of skeletal muscle relaxants. See text for details. +, excitatory effect; −, inhibitory effect; α, α-motoneuron; Ca$^{2+}$,
In the dorsal horn, a complex network of excitatory and inhibitory interneurons mediates motor reflexes in response to deep and cutaneous stimulation. Such reflexes mediate ipsilateral flexion and contralateral extension in response to noxious stimuli to coordinate a protective or escape response. Impulses from cutaneous afferents travel through the dorsal horn of the spinal cord and terminate on excitatory interneurons, which in turn terminate on presynaptic terminals of the intrafusal fibers further promoting excitation at the ventral horn α-motoneuron. Inhibitory centers in the bulbar reticular formation and facilitatory centers from several brain regions further regulate both corticospinal and reflex muscle activity.\textsuperscript{8,9}

Excitatory neurotransmitters in the CNS play a major role in the modulation of movement in the spinal cord and include substances like glutamate, aspartate, and substance P. These neurotransmitters are released from the terminals of primary afferent fibers to mediate reflexes that enhance motor tone at the spinal level.\textsuperscript{10} γ-Aminobutyric acid (GABA) is a major inhibitory CNS neurotransmitter that emanates from supraspinal and interneuronal inputs. GABA is believed to play a major role in presynaptic inhibition of motor neurons in the dorsal horn.\textsuperscript{10}

Any change in the homeostasis of the peripheral or CNS components related to maintaining proper muscle tone can lead to production of an acute reflex muscle spasm. When this occurs, there are two main potential issues. Either a reflex increase in muscle tone activates polysynaptic reflexes and produces hyperexcitability of α- and/or γ-motoneurons, or there is supraspinal activation of descending facilitatory systems.\textsuperscript{11} In settings of chronic muscle spasticity, the processes appear to be more involved, with pathology from supraspinal CNS descending pathways that produce excessive excitation or diminished inhibition of α-motoneurons in the dorsal horn.\textsuperscript{12}

**MECHANISM OF ACTION**

In animal studies, skeletal muscle relaxants act at various CNS sites that are important in muscle activity regulation. The exact mechanism of action for these various agents is not clear. A variety of mechanisms appear to be
associated with the activity of this diverse group of agents (Table 80.3). Animal models have historically shown that muscle relaxants exert their activity by blocking polysynaptic neurons in the spinal cord and inhibiting interneuronal activity within the descending reticular formation. Mephenesin, an early predecessor to today’s muscle relaxants, in animal models affected monosynaptic and polysynaptic reflexes. Subsequent animal data showed that mephenesin and methocarbamol prolonged the refractory period of skeletal muscle by a direct action on skeletal muscle fibers. Very little has been described about the effects of skeletal muscle relaxants such as cyclobenzaprine, methocarbamol, carisoprodol, and chlorzoxazone on neurotransmission. These medications are also known to have a significant sedative profile. This in fact was a quality that was exploited when older treatment paradigms included significant bed rest. Interestingly, other medications with sedative properties are also known to depress polysynaptic reflexes. This situation certainly sheds some degree of confusion as to the specific utility of skeletal muscle relaxants, especially in relation to the purported effects versus nonspecific sedation.

The pharmacologic capacity of other commonly used drugs is less well characterized in specific relation to muscle spasm. Diazepam, a benzodiazepine, suppressed polysynaptic reflexes in cats but required doses higher than would be used clinically. Benzodiazepines act by potentiating the postsynaptic effects of GABA within the CNS.
(parachlorophenol GABA) is a lipophilic derivative of GABA that binds to GABA\(_B\) but not to GABA\(_A\) receptors and may exert its effect, in part, by inhibiting the evoked release of excitatory amino acids (e.g., glutamate) and substance P.\(^\text{10}\) Tizanidine, a newer antispasticity agent, is an \(\alpha_2\)-adrenergic receptor agonist that may also act by decreasing spinal excitatory amino acid release.\(^\text{16}\)

**Types of Skeletal Muscle Relaxants**

**CENTRALLY ACTING SEDATIVE-HYPNOTIC MUSCLE RELAXANTS**

**Chlorzoxazone**

Chlorzoxazone may be less effective than the other skeletal muscle relaxants.\(^\text{17}\) Chlorzoxazone does not have any significant drug interactions but does have a significant adverse effect profile that includes a rare idiosyncratic hepatocellular reaction.\(^\text{18}\) The use of this agent may be questionable considering the potential lack of efficacy and significant toxicity profile.\(^\text{19}\)

**Metaxalone**

Metaxalone does not have any significant drug interactions and appears to have a fairly benign side effect profile. Hemolytic anemia and impaired liver function may occur but are uncommon. Fatalities attributed to the use of metaxalone have been reported.\(^\text{20,21}\) Metaxalone is contraindicated in patients with severe renal or hepatic impairment. Because this drug was FDA-approved over 30 years ago, there are few published placebo-controlled studies of metaxalone for musculoskeletal pain.\(^\text{22}\)

**Methocarbamol**

Methocarbamol is available in an oral form and a parenteral form for intravenous (IV) or intramuscular (IM) use. Complications with the injectable form include pain, skin sloughing, and thrombophlebitis. This drug also was FDA-approved over 30 years ago, and as a result, there are few published studies comparing it to placebo for the treatment of musculoskeletal pain.\(^\text{23}\)
Carisoprodol
Carisoprodol is a schedule IV controlled substance in the United States. It is hepatically metabolized to meprobamate. Meprobamate produces physical and psychological dependence.24–29 Substance abuse appears to be problematic with carisoprodol, probably due to meprobamate formation. In recent years, several states have begun treating carisoprodol as a controlled substance within their state formularies. Due to the dependence potential, carisoprodol should be cautiously tapered as opposed to immediately discontinued following long-term use. At the end of November 2007, the European Medicines Agency recommended the suspension of marketing authorization for carisoprodol-containing products for its 12 member states. Its Committee for Medicinal Products for Human Use concluded that the risk of their use is greater than the benefits.30 Given the unfavorable risk–benefit balance, which includes a high dependence potential, carisoprodol should generally be avoided.

ANTIHISTAMINE MUSCLE RELAXANT
Orphenadrine Citrate
Orphenadrine is a derivative diphenhydramine and accordingly exhibits antihistaminic and anticholinergic properties. There have been reports of severe adverse reactions with parenteral use (e.g., anaphylactoid reaction). Orphenadrine use with propoxyphene may cause confusion, anxiety, and tremors, perhaps because of additive effects. Orphenadrine’s anticholinergic actions have been noted to produce significant adverse effects at high dosages, for example, tachycardia, palpitations, urinary retention, blurred vision.31

TRICYCLIC ANTIDEPRESSANT-LIKE MUSCLE RELAXANT
Cyclobenzaprine
Cyclobenzaprine is more structurally and pharmacologically similar to the tricyclic antidepressants than it is to the centrally acting sedative-hypnotic skeletal muscle relaxants. As with the other skeletal muscle relaxants, cyclobenzaprine does not act directly on muscle tissue. Animal data suggest cyclobenzaprine acts primarily at the level of brain stem reducing
tonic somatic motor activity.\textsuperscript{32} Although no evidence exists in humans to support this mechanism, it is interesting to note that the newer 5-mg dose has yielded similar clinical efficacy with less sedation than the more sedating 10-mg dose.\textsuperscript{33} This may prove to be an important distinction from the centrally acting sedative-hypnotic muscle relaxants.

The value of muscle relaxant monotherapy remains the subject of some skepticism; these agents may be used as adjuncts to other therapies. This appears to apply to cyclobenzaprine as well. In an open-label study of patients with acute neck or low back pain associated with muscle spasm who were randomized to be treated for seven days with either cyclobenzaprine 5 mg orally three times daily alone or with cyclobenzaprine 5 mg orally three times daily in combination with ibuprofen at doses of 400 mg orally three times daily or 800 mg three times daily, no significant treatment differences were found among these groups.\textsuperscript{34}

Cyclobenzaprine has a similar adverse event profile as the tricyclic antidepressants. Thus, one might want to avoid using cyclobenzaprine and a tricyclic antidepressant concurrently unless the combination is truly clinically indicated. Anticholinergic side effects including dry mouth, urinary retention, and constipation occur with cyclobenzaprine. Use of cyclobenzaprine is contraindicated in the setting of arrhythmias, congestive heart failure, hyperthyroidism, or during the acute recovery phase of a myocardial infarction. Concurrent use with proserotonergic agents such as selective serotonin reuptake inhibitors (SSRIs) may predispose patients to life-threatening serotonin syndrome.\textsuperscript{35}

Cyclobenzaprine labeling suggests that concomitant use with tramadol may place patients at higher risk for developing seizures.\textsuperscript{32} Concomitant use of cyclobenzaprine with monoamine oxidase inhibitors or use within 14 days after their discontinuation is contraindicated. Cyclobenzaprine can enhance the effects of agents with CNS depressant activity. Older patients appear to have a higher risk for CNS-related adverse reactions, for example, hallucinations and confusion, when using cyclobenzaprine. Withdrawal symptoms have been noted with the discontinuation of chronic cyclobenzaprine use. Use of a medication taper may be warranted for patients with chronic use.
γ-AMINOBUTYRIC ACID AGONIST MUSCLE RELAXANTS

Diazepam
Diazepam is the most commonly prescribed and referenced benzodiazepine in the treatment of muscle spasms. It has hypnotic, anxiolytic, antiepileptic, and antispasmodic properties. Sedation and abuse potential are the main concerns with this agent and class. It is important to slowly taper this agent after long-term use, as opposed to abrupt removal to avoid any withdrawal symptoms. Recent studies have suggested that the addition of diazepam to nonsteroidal anti-inflammatory drugs (NSAIDs) for acute lower back pain have little to no benefit compared to placebo. Use in lower back pain should be cautioned.

Baclofen
Studies have shown baclofen to have superior efficacy than diazepam. Baclofen is unique in that it can be administered intrathecally in cases of severe spasticity and for patients who do not tolerate or have failed oral therapy. Baclofen should be tapered slowly after long-term use to avoid a withdrawal reaction and rebound phenomena. It should be used with caution in the elderly and for patients with renal impairment.

CENTRAL α₂ AGONIST MUSCLE RELAXANTS

Tizanidine
Tizanidine is related chemically to clonidine but has significantly less antihypertensive effect. The main adverse effect for most patients with this agent is sedation. Currently, tizanidine is FDA-approved for the management of increased muscle tone associated with spasticity resulting from CNS disorders, such as multiple sclerosis or spinal cord injury. Two studies report use of tizanidine in of back pain or muscle spasm, either alone or in combination with ibuprofen, and another study reports effectiveness in myofascial pain. A multicenter, placebo-controlled study evaluated the efficacy and safety of tizanidine in the treatment of low back pain; tizanidine was found to provide more pain relief and less restriction of movement than placebo. Drowsiness was the most common side effect, but for acute low back pain patients, this effect may actually be
desired, especially at night. A study of 105 patients with acute low back pain who received tizanidine 4 mg orally three times daily with ibuprofen 400 mg orally three times daily or ibuprofen 400 mg orally three times daily compared to placebo. The results suggested that the tizanidine/ibuprofen combination was more effective for moderate or severe acute low back pain than ibuprofen only. Use tizanidine with caution in renal impairment; clearance is decreased by 50% in patients with creatinine clearance <25 mL per minute. Coadministration with alcohol can increase the area under the curve (AUC) of tizanidine by approximately 20% and increase $C_{\text{max}}$ by approximately 15%. Use with oral contraceptives can decrease the clearance of tizanidine and place patients at higher risk for sedating adverse effects.

Recent trials of a novel delivery system for tizanidine have been promising. A trial of an intranasal delivery system has shown quicker onset of action and higher serum contractions when compared to oral administration with a similar side effect profile. This may ultimately have efficacy in the management of acute painful muscle spasm syndromes.

Acute Low Back Pain

Available data indicate that skeletal muscle relaxants are more effective than placebo to relieve acute low back pain. Unfortunately, most of the data are dated and are derived form studies for which the designs and analyses that would not be acceptable today. No data clearly show that any one agent as more efficacious than another. Some data suggest that chlorzoxazone may be less effective than other drugs and, as such, puts into question the use of this agent.

Most clinical guidelines list skeletal muscle relaxants as optional agents for use individually or in combination with an NSAID. The federal clinical practice guideline published in 1995 specifically noted that skeletal muscle relaxants alone or in combination with an NSAID were no more effective than using an NSAID alone. This conclusion has been supported in systematic reviews by van Tulder and colleagues. In the past, skeletal muscle relaxants have been shown to more effective than placebo for patients with acute low back pain with respect to outcomes such as short-
term pain relief, global efficacy, and improvement of physical outcomes.\textsuperscript{39,45–47} No quality evidence allows a direct comparison of skeletal muscle relaxants to NSAIDs. Most clinicians and researchers agreed that skeletal muscle relaxants may benefit patients with acute low back pain by reducing the duration of their discomfort and accelerating recovery. A meta-analysis of cyclobenzaprine studies for acute low back pain concluded that despite limitations in the available evidence, the combination of an NSAID with cyclobenzaprine appears to be warranted.\textsuperscript{48} More recently, NSAIDs prescribed alone or in combination with cyclobenzaprine or oxycodone/acetaminophen for lumbar back pain in the emergency department setting. The addition of cyclobenzaprine or oxycodone/acetaminophen to NSAIDs for lumbar back pain has not shown improvement of functional outcome in short-term follow-up. However, more recently, the use of extended-release cyclobenzaprine alone has suggested benefit for muscle spasm and muscle spasm associated back and neck pain. Further investigation is warranted. It is probably best to consider the use of skeletal muscle relaxants as an adjunct or alternative to NSAIDs, especially in cases where NSAID toxicity is a concern or when NSAID monotherapy proves suboptimal.

Various systematic reviews have been published reviewing the randomized controlled trials of muscle relaxants in the treatment of acute low back pain.\textsuperscript{17,43,49} These analyses concur that there is strong evidence that muscle relaxants are more effective than placebo for acute low back pain but do not indicate superiority of a specific type of muscle relaxant. Muscle relaxants also appear to be useful in acute cervical pain presentations.\textsuperscript{50–52}

Baclofen and tizanidine are well established for the treatment of spasticity secondary to upper motor neuron or spinal disorders.\textsuperscript{10,12,53} Limited clinical evidence exists for the treatment of acute muscle spasm with baclofen. As noted previously, tizanidine has some evidence but can be extremely sedating especially at doses that prove analgesic for acute back pain.

**Chronic Low Back Pain**
Despite the common use of skeletal muscle relaxants, relatively few data clarify their appropriateness in the treatment of chronic back pain.\textsuperscript{17,49} No skeletal muscle relaxant has an indication for use in chronic back pain. Despite this lack of evidence, muscle relaxants are often prescribed on a long-term basis.\textsuperscript{54} Only baclofen and tizanidine have FDA-approved indications for spasticity. As a group, these agents may provide some global palliative quality but probably do not effect the course of the underlying morbidity.

Skeletal muscle relaxants have CNS depressant effects and should be used with caution, particularly, for patients with concomitant use of alcohol, anxiolytics, opioid analgesics, or other sedating medications. There is strong evidence that skeletal muscle relaxants are associated with increased risk for total adverse effects, especially those related to the CNS.\textsuperscript{17,43,49} Many chronic pain patients appear to benefit from less pharmacotherapy, especially substances that may cloud cognitive and functional capacities.\textsuperscript{55} Pill tapers can be used where patients who are appropriate candidates for streamlining can have their muscle relaxant therapy slowly discontinued over a relatively short time, for example, 2 weeks. In some situations, patients may require more interventions, for example, behavioral medicine support. These patients are probably best managed by interdisciplinary pain programs or by a psychiatrist.

**Topical Analgesic Balms**

Applying medicines topically is an ancient practice that, although often perceived as pragmatic, can become quite problematic. Many ancient cultures utilized a variety of natural substances (e.g., herbs and plants) for a variety of medicinal uses, including analgesia. Today, a variety of topical remedies is available to patients with painful conditions, primarily as over-the-counter (OTC) analgesic balm, many of which have been available for decades. The majority of these preparations contain counterirritants such as camphor, menthol, and salicylates, either alone or in combination with each other or a variety of other medicinal ingredients. Capsaicin, a counterirritant, and non-salicylate NSAIDs are also available in prescription and OTC topical formulations. Lidocaine and a variety of
other substances used topically are discussed elsewhere in this book (see Chapter 82).

Topical drug administration would appear to maintain many potential benefits, especially in pain presentations that have a defined local and peripheral component. The most obvious benefit is avoiding negative systemic effects, for example, adverse drug effects, drug interactions, and need for an effective serum concentration. At the same time, topical administration can be prone to a variety of limitations, often inversely related to the benefits of topical application. Benefits and limitations are summarized in Table 80.4. Direct topical drug application appears to avoid numerous problems that occur with systemic administration of medications. This is especially true for NSAIDs, where toxicity with systemic administration can be problematic. As described in the following text, topical NSAIDs appear to be useful for some acute pain presentations (e.g., soft tissue injuries and postsurgical pain).

**TABLE 80.4 Benefits and Limitations of Topical Analgesics**

NSAIDs have the strongest evidence base among the topical analgesics. Moore and colleagues conducted a meta-analysis reviewing analgesic efficacy for acute pain related to soft tissue trauma, sprains, and strains. They also analyzed pain relief for chronic pain conditions, such as osteoarthritis and tendonitis. The number needed to treat (NNT) was 3.9 for the acute pain conditions and 3.1 for the chronic pain conditions. The authors noted that local skin reactions were uncommon (3.6% of patients)
in the studies. As could be expected, systemic adverse effects were extremely uncommon at less than 0.5% of patients exposed to this drug class. However, the chronic use of topical NSAIDs in osteoarthritis is not entirely clear. A meta-analysis showed benefit in the first 2 weeks but did not sustain in weeks 3 to 4 when compared to placebo. Although topical administration does not appear to afford the same therapeutic profile, this route of administration is also better tolerated and may be of benefit in patients who would not otherwise be able to use an NSAID orally.

**TOPICAL COUNTERIRRITANTS**

Topical counterirritants comprise a group of substances primarily for use by patients in a variety of OTC analgesic compounds. These include capsaicin, camphor, menthol, and salicylates, which appear to provide analgesic benefit by desensitizing peripheral nociceptive receptors. Galeotti and colleagues suggested that menthol’s analgesic properties may be mediated through selective activation of κ-opioid receptors.

Capsaicin appears to have the best evidence for use among the topical analgesics, primarily in osteoarthritis. Analgesic activity for capsaicin is attributed to depletion of substance P from peripheral nerve terminals. This requires both time and consistent dosing. A recent systematic review of topical capsaicin for musculoskeletal pain found an NNT of 8.1 for pain relief. A variety of guidelines list capsaicin as a useful adjunct for use in patients with osteoarthritis. The European League Against Rheumatism (EULAR) and the American College of Rheumatology both recommend capsaicin for the treatment of pain in osteoarthritis. The main issue related to capsaicin use is the adverse effect profile, which occurs to some extent with all patients, and is an expected consequence of the mechanism of action. In the aforementioned systematic review, side effects were problematic in approximately one-third of the patients. Typical experiences include local adverse reactions such as pain upon application, burning, stinging, and redness at the site of application. This adverse effect profile is probably the biggest disadvantage for this medication, causing either early discontinuation or reduced patient compliance leading to absence of efficacy.

The other counterirritants can be classified as rubefacients, including
salicylates. There are few good efficacy data for these medications, probably in part because these substances have been used for so long. The benefit of these agents may also be due to the actual administration process, that is, rubbing, causing increased stimulation in the area.

Although salicylates may also have activity similar to other NSAIDs, their topical mechanism remains poorly elucidated. Mason and colleagues\textsuperscript{65} reviewed the use of topical salicylates for acute musculoskeletal pain. These authors noted that topical salicylates produced a significant reduction in pain compared to placebo, with an NNT of 2.1. The benefit of this medication class for chronic use is limited by both lack of efficacy data and the potential for adverse effects with continued administration.

**Conclusion**

Skeletal muscle relaxants and topical analgesic balms comprise a cadre of substances that are commonly used for a variety of pain conditions. Skeletal muscle relaxants have value for acute back pain, mainly as adjunctive agents with other forms of analgesia and physical therapy. The use of these agents in chronic pain conditions remains controversial. This is in part due to the lack of efficacy data available for the use of these substances in chronic back pain conditions. Moreover, these agents maintain a substantial adverse effect profile that often is counterproductive for patients with chronic pain. Topical analgesic balms are commonly used for self-care in acute painful conditions.

**References**

Neuropathic pain is pain caused by a lesion or disease affecting the somatosensory nervous system.\textsuperscript{1,2} According to a recent systematic review of epidemiologic studies on neuropathic pain, the estimated prevalence of neuropathic pain is between 6.9\% and 10\% of the general population.\textsuperscript{3} Neuropathic pain may result from a large variety of insults, examples of which are listed in Table 81.1. Common examples of peripheral neuropathic pain include lumbar radiculopathy, painful diabetic neuropathy (PDN), postherpetic neuralgia (PHN), and posttraumatic/surgical neuropathy. Neuropathic pain of central origin includes central poststroke pain, pain due to multiple sclerosis, and post-spinal cord injury pain.

Neuropathic pain may be continuous or intermittent and is often described as burning or hot, electric shocks or shooting, pricking or pins, and needles. Pain evoked by nonpainful stimuli such as light touching or
cold (allodynia) and accompanying nonpainful sensations such as numbness and tingling are all suggestive of neuropathic pain. The combination of several descriptors is a strong indicator of neuropathic pain. The neurologic examination is aimed primarily at detecting reproducible negative sensory signs, such as partial or complete loss to one or several sensory modalities (e.g., light touch, cold sensation) with distinct neuroanatomical borders. Positive sensory signs, especially when accompanying negative signs, are also supportive of neuropathic pain.\(^1\)

Neuropathic pain has negative effects on multiple domains of life resulting in poor quality of life, comparable to that experienced by patients suffering from cancer or chronic heart failure. This is explained, at least in part, by misdiagnosis, undertreatment, and lack of substantial analgesic efficacy of most existing treatments.\(^4,5\)

Neuropathic pain pharmacotherapy is a key therapeutic element, which involves different drug classes including, but not limited to, antidepressants, anticonvulsants, opioids, and topical agents. However, even with the newest of these drugs, effective pain relief occurs in less than half of patients with chronic neuropathic pain.\(^1\) Meta-analyses of trials in neuropathic pain commonly report outcomes in terms of the number needed to treat (NNT) to provide 50% pain relief for one patient. Even highly recommended first-line agents result in NNTs ranging from 3.6 to 7.7, meaning that only 1 out 3.6 to 7.7 patients will experience a 50% reduction in pain.\(^6\) Most clinical trials related to neuropathic pain pharmacotherapy were conducted with a specific agent in patients who had a specific cause of the underlying disorder, with PDN or PHN being the most frequently tested disorder. At the same time, meta-analyses show that the efficacy of any given drug is generally not dependent on the cause of the underlying disorder.\(^1\) In patients with refractory neuropathic pain, combination therapy with two or more agents possessing different mechanisms has been suggested.\(^7\)

A different approach of selecting patients to clinical trials, not based on the specific causes of the underlying disorder, has recently been introduced. According to this approach, standardized quantitative sensory testing (QST) is used for subgrouping patients with peripheral neuropathic pain of different etiologies into different clusters. For example, patients
with sensory loss, patients with thermal hyperalgesia and those with mechanical hyperalgesia, regardless of the underlying cause. It is proposed that these profiles may be related to different pathophysiologic mechanisms and may be useful in future clinical trial design.\textsuperscript{8}

This chapter reviews pharmacotherapy for neuropathic pain and emphasizes the strengths and the limitations of different treatments. It also addresses unresolved issues related to pharmacologic treatment of neuropathic pain.

### Antidepressants

Four classes of antidepressant medications have been studied in neuropathic pain treatment: tricyclic antidepressants (TCAs), selective serotonin and norepinephrine reuptake inhibitors (SNRIs), selective serotonin reuptake inhibitors (SSRIs), and monoamine oxidase inhibitors (MAOIs). Certain drugs in the first two classes are commonly considered first-line recommended treatments for neuropathic pain.\textsuperscript{6,9,10} Table 81.2 lists major properties of common antidepressants.

*Dosing is per product U.S. approved dosing; dosing in pain syndromes may vary from that listed.
*These are estimates of selectivity ratio; actual selectivity ratios are concentration-dependent; numbers <1 indicate greater affinity for norepinephrine than serotonin.
*Tricyclic antidepressants may be safely administered once daily; some practitioners prefer to dose them more frequently.

TRICYCLIC ANTIDEPRESSANTS

Table 81.3 summarizes the placebo-controlled trials of various drugs for neuropathic pain and shows efficacy for amitriptyline, imipramine, nortriptyline, desipramine, clomipramine, and maprotiline at daily doses ranging from 30 to 200 mg for PHN, PDN, postmastectomy pain, central poststroke pain, and mixed type neuropathies. These results are commonly extrapolated to all types of neuropathic pain, and clinical experience suggests some broad utility for the drugs. A recent systematic review and meta-analysis found TCAs the most efficacious antidepressants for neuropathic pain with an overall NNT of 3.6 (95% confidence interval [CI], 3.0 to 4.4) and the number needed to harm (NNH) was 13.4 (95% CI, 9.3 to 24.4). The level of evidence was considered moderate. A Cochrane collaboration review of the efficacy of amitriptyline for neuropathic pain found evidence for a statistically significant benefit with an NNT of 4.6
(95% CI, 1.8 to 3.1) and NNH of 4.1 (95% CI, 3.2 to 5.7),\textsuperscript{29} and finally, another Cochrane collaboration review found the NNT of TCAs for neuropathic pain to be 3.6 (95% CI, 3.0 to 4.5).\textsuperscript{30} However, a few trials failed to demonstrate TCA efficacy for spinal cord injury pain,\textsuperscript{13} cisplatin-induced neuropathy,\textsuperscript{31} HIV neuropathy,\textsuperscript{16,17} phantom limb pain,\textsuperscript{15} lumbar radiculopathy,\textsuperscript{20} and neuropathic cancer pain.\textsuperscript{32} Inability to demonstrate effectiveness of the TCAs in these neuropathic pain types may represent a true lack of therapeutic benefit, or it may be due to study design weaknesses or other factors. More studies are needed to clarify the value of specific TCAs in different types of neuropathic pain.

*aThe study showed significant effect of venlafaxine in the manifestations of hyperalgesia and temporal summation but not on the ongoing pain intensity.

CPSP, central poststroke pain; PDN, painful diabetic neuropathy; PHN, postherpetic neuralgia; SCI, spinal cord injury; A, active drug; P, placebo; > indicates that active drug was superior to the comparator in terms of pain reduction; < indicates that active drug was not superior to the comparator in terms of pain reduction; = indicates that active drug was equal to the comparator in terms of pain reduction.

In many countries, TCAs may be overlooked as first-line neuropathic pain drugs because they are generic and are not actively marketed. Newer, more expensive drugs for neuropathic pain may be selected despite comparatively lower effectiveness (higher NNTs). The analgesic efficacy of the TCAs is likely to be independent of their antidepressant effect.14 In a large survey, over one-fifth (21%) of the patients with chronic pain have been diagnosed with depression associated with their pain.33 Concomitant chronic pain and depression favor the use of an antidepressant (TCA or another) over other medication classes.

TCAs are associated with dose-dependent adverse events, the most common being sedation, constipation, dry mouth, urinary retention, and orthostatic hypotension. TCAs can be administered once daily, usually at bedtime, exploiting their sedating properties. The dose used for neuropathic pain, typically 75 mg a day or less, is below the antidepressant dose for most patients, lowering the risk of side effects. Secondary amine TCAs (e.g., desipramine, nortriptyline) are better tolerated than tertiary amine TCAs (e.g., amitriptyline, imipramine) but are equally effective.24,28 Nonetheless, TCAs may not be tolerated by many patients. The anticholinergic effects of TCAs are a relative contraindication in patients with benign prostatic hyperplasia, cardiac conduction defects, and other morbidities sensitive to parasympatholytic action. Desipramine has only one-quarter of the anticholinergic and sedative activity of amitriptyline at comparable doses, making desipramine a TCA of choice.34 Use of a low initial dose and slow dose titration of all TCAs is important to minimize premature discontinuation due to side effects. Dry mouth is the most
common adverse event, and it is often best managed with sugarless candies or chewing gum, especially sugarless lemon candy to stimulate serous saliva flow. Sips of water provide only transient relief. The most common starting dose for TCAs is 25 mg, but frail elderly and other highly sensitive patients may tolerate an initial dose of 5 to 10 mg better. Increase the dose by the same number of milligram as the starting dose every 3 to 5 days until some diminution of pain complaints occurs or the daily dose totals 100 mg. The maximal effect often occurs within 3 weeks at that dose, generally before antidepressant effects peak.

The anticholinergic effects of TCAs can cause cardiac toxicity including ventricular ectopic activity, prolonged QT interval, myocardial infarction, and sudden death. A screening electrocardiogram (ECG) might be considered in patients over 40 years of age or who have other risk factors prior to initiating a TCA. Use TCAs with caution in patients with a history of ischemic heart disease or increased risk of sudden cardiac death; if TCA treatment is selected in these patients, consider limiting the maximum dose to 100 mg per day or less.

SELECTIVE SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

The SNRIs duloxetine and venlafaxine are newer antidepressants with effectiveness for neuropathic pain. Results with venlafaxine for neuropathic pain have been inconsistent. Venlafaxine was effective for PDN and for various forms of polyneuropathy at daily doses of 150 to 225 mg. In one placebo-controlled trial, perioperative venlafaxine at a daily dose of 75 mg prevented the development of postmastectomy pain syndrome, but in other trials on patients with postmastectomy pain and mixed type neuropathies, efficacy at a dose range of 75 to 150 mg could not be demonstrated.

Three large randomized controlled trials and one open-label 52-week extension trial showed that duloxetine was effective for PDN at daily doses of 60 to 120 mg. Duloxetine 60 mg per day has similar efficacy to duloxetine 120 mg per day, but the lower dose is far more tolerable. It can be administered once daily. At that dose, the drug significantly improved sleep and quality of life. The most common adverse
effects reported in these clinical trials were nausea, somnolence, dizziness, and constipation, all of which tended to decrease over time. Initiating treatment at a daily dose of 30 mg for 1 week followed by an increase to 60 mg per day during the second week is likely to improve tolerability. Duloxetine has not been associated with cardiac toxicity. It should not be used concomitantly with MAOIs or in patients with markedly impaired liver function.

A meta-analysis of trials for the SNRIs (i.e., duloxetine, venlafaxine, desvenlafaxine) across neuropathic pain types resulted in an NNT of 6.4 (95% CI, 5.2 to 8.4), indicating that they are less effective than the far less expensive TCAs. In the systematic review and meta-analysis cited earlier, the final quality of evidence for SNRI efficacy in the treatment of neuropathic pain was deemed high. Combined NNT was 6.4 (95% CI, 5.2 to 8.4), and NNH was 11.8 (95% CI, 9.5 to 15.2).

SELECTIVE SEROTONIN REUPTAKE INHIBITORS
Reports of the effectiveness of SSRIs in neuropathic pain management are generally not favorable. Some reports may not have separated analgesic effect from the effects of mood elevation on pain perception. One well-controlled trial documented that fluoxetine was no more effective than placebo, whereas both amitriptyline and desipramine were efficacious.

Two other trials support efficacy of citalopram and paroxetine (both at 40 mg per day) in PDN. Although SSRIs show a favorable safety profile compared to TCAs and are generally well tolerated, a meta-analysis of available trials in neuropathic pain did not detect significant overall pain reduction with the SSRIs, and therefore, they should not be regarded as first-line agents.

Antiepileptics
Interest in the antiepileptics for pain management dates back to the 1940s. Dozens of randomized controlled trials have attempted to describe the role of different antiepileptic drugs in neuropathic pain treatment. The majority of antiepileptic trials are in PHN or PDN, with less data available for other neuropathic pain types. Recent meta-analyses
strongly support the use of the calcium channel α2δ ligands pregabalin and gabapentin (including gabapentin ER and gabapentin enacarbil) as first-line therapy for PHN and PDN.\textsuperscript{6,41} Data also support the use of pregabalin for treating central neuropathic pain.\textsuperscript{41} Carbamazepine is likely effective for trigeminal neuralgia and possibly for PDN and central poststroke pain, but studies of carbamazepine were generally of short duration (i.e., less than 4 weeks) and poor methodologic quality.\textsuperscript{42} Although other antiepileptics may be beneficial in individual patients or specific types of neuropathic pain, pooled data either suggested minimal effectiveness or were inconclusive.\textsuperscript{6,41} Table 81.4 summarizes trials of the antiepileptics in neuropathic pain.

</table>
Trial compared two antiepileptics to each other, and the same trial is displayed twice in this table (once for each antiepileptic).

A significant decrease of “unpleasant feeling” and a trend toward a decrease in both the “pain intensity” and “burning sensation.”

Significant difference in “itchy pain sensations” but no difference in global pain intensity or other measures of pain.

Lamotrigine was superior to placebo in patients who received antiviral neurotoxic therapy but not in patients who did not receive this therapy.

Lamotrigine was superior to placebo in patients with incomplete spinal cord injury and evoked pain but equal to placebo in patients with complete injury and without evoked pain.

Pregabalin was not effective for preventing subacute herpetic neuralgia or postherpetic neuralgia.

No significant difference between pregabalin and placebo in pain score (primary outcome measure) but significant difference in sleep, anxiety, and clinical global impression scores.

Mean dose reported rather than maximum.

Findings from three double-blind, placebo-controlled trials.

No significant difference between topiramate and placebo in pain score (primary outcome measure) but significant difference in global pain relief score.

AHN, acute herpetic neuralgia; CPMS, central pain due to multiple sclerosis; CPSP, central poststroke pain; ER, extended release; GBS, Guillain-Barré syndrome; HIV-N, HIV neuropathy; LR, lumbar radiculopathy; NCP, neuropathic cancer pain; PDN, painful diabetic neuropathy; PHN, postherpetic neuralgia; PLP, phantom limb pain; PNI, peripheral nerve injury; RLP, residual limb pain; SCI, spinal cord injury; SHN, subacute herpetic neuralgia; TN, trigeminal neuralgia; A, active drug; P, placebo; > indicates that active drug was superior to the comparator in terms of pain reduction; < indicates that active drug was not superior to the comparator in

terms of pain reduction; = indicates that active drug was equal to the comparator in terms of pain reduction.

**PREGABALIN**

Pregabalin is the most extensively studied drug of any type for treating neuropathic pain.\(^6\) Pregabalin is believed to exert its analgesic effect by binding to the \(\alpha_2\delta\) subunit of voltage-gated calcium channels on primary afferent neurons, reducing the release of neurotransmitters from their central terminals.\(^{132}\) A recent meta-analysis of 25 placebo-controlled trials of pregabalin in various types of neuropathic pain reported an NNT of 7.7 (95% CI, 6.5 to 9.4).\(^6\) Pregabalin was effective for treating PHN and PDN in numerous multicenter, randomized, controlled trials.\(^{74,97,101–112,116,133,134}\) Pregabalin was also effective for treating spinal cord injury pain,\(^{114,115}\) posttraumatic peripheral neuropathy,\(^\) neuropathic cancer pain,\(^{61,100}\) and mixed types of neuropathic pain.\(^{116,117,119–122}\) Pregabalin did not significantly improve acute herpetic neuralgia or prevent progression to PHN in one clinical trial,\(^{96}\) but it did significantly reduce acute herpetic neuralgia and subacute herpetic neuralgia in another trial.\(^{118}\) Pregabalin did not significantly improve neuropathic pain associated with HIV\(^{98,99}\) or central poststroke pain.\(^{97}\) The effective daily dose of 300 to 600 mg reduces pain and improves sleep, functioning, and quality of life. Response rates are higher when a maintenance dose of 600 mg per day is used.\(^6\) Pregabalin has several advantages compared to other anticonvulsants: It is usually administered twice daily, can be rapidly titrated, has early onset of analgesic effect, and has linear pharmacokinetics. No common drug interactions occur with pregabalin. The most commonly reported adverse events were dose-dependent and included dizziness, somnolence, dry mouth, abnormal vision, confusion, weight gain, and edema.\(^{11}\)

**GABAPENTIN**

There is also strong evidence of gabapentin’s effectiveness for PHN and PDN at doses of 900 to 3600 mg per day.\(^{7,54–56,62–64,70–75}\) Gabapentin is available as immediate-release (IR), extended-release (ER), and gabapentin enacarbil formulations, and available data suggest similar
effectiveness for the different formulations. Gabapentin IR is normally dosed thrice daily and is commonly the least expensive dosage form. Gabapentin enacarbil is dosed twice daily, and gabapentin ER may be dosed once daily. Across 14 studies, for all gabapentin dosage forms, the overall NNT to reduce pain intensity by 50% was 7.2 (95% CI, 5.9 to 9.1). For gabapentin IR, the NNT was 6.3 (95% CI, 5.0 to 8.3). The NNT for gabapentin enacarbil and gabapentin ER was 8.3 (95% CI, 6.2 to 13.0). In addition to PHN and PDN, gabapentin has demonstrated efficacy in HIV-associated painful neuropathy, pain in Guillain-Barré syndrome, and phantom limb pain. Gabapentin was not effective for peripheral nerve injury pain in one trial. An 8-day trial of gabapentin was effective for treating neuropathic cancer pain in one trial, but in a smaller 4-week trial, gabapentin was no more effective than placebo. Results for gabapentin in spinal cord injury were mixed in three small trials. Gabapentin is believed to have similar mechanism of action to pregabalin. However, unlike pregabalin, it has nonlinear pharmacokinetics and may take days or weeks to reach an effective dose. Gabapentin is relatively safe, with few clinically relevant drug interactions. The main adverse effects are somnolence, dizziness, and peripheral edema. Some clinicians report that some patients who fail to respond to gabapentin may respond to pregabalin and vice versa.

CARBAMAZEPINE
Carbamazepine is commonly used to treat trigeminal neuralgia. Most carbamazepine studies in trigeminal neuralgia were conducted in the 1960s and 1970s using small samples sizes. In these studies, pain relief was superior with carbamazepine compared to placebo. In a more recent trial, carbamazepine was more effective than lamotrigine for treating pain associated with trigeminal neuralgia. Carbamazepine was also one of the first anticonvulsants used in PDN and was superior to placebo in two small trials. Pain reduction was similar between carbamazepine and the TCA nortriptyline in a more recent trial. Carbamazepine was more effective than placebo in patients with mixed types of neuropathic pain in one controlled trial. Effective doses of carbamazepine ranged from 800 to 2,400 mg per day in trigeminal
neuralgia, but lower doses of 200 to 600 mg per day were effective for treating other neuropathic pain types. NNT to achieve 50% pain relief with carbamazepine in a meta-analysis of trials in trigeminal neuralgia, PDN, and central poststroke pain was 1.9 (95% CI, 1.6 to 2.5). However, this figure is based primarily on old trials, most of which were conducted in small patient groups for relatively short treatment periods. All of the carbamazepine trials were classified as third tier trials, and heterogeneity associated with pooling the trials was moderately high ($I^2 = 50\%$). The analgesic mechanism of carbamazepine is related to voltage-dependent sodium channel blocking, which results in decreased ectopic nerve discharges and neural membrane stabilization. Adverse events are common and include dizziness, nausea, drowsiness, blurred vision, and ataxia. Carbamazepine can cause Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug reaction with eosinophilia and systemic symptoms (DRESS). Rare, but serious, side effects include blood dyscrasias, impairment of liver function, and reduction of sodium plasma levels and require routine blood tests to monitor them. Serum carbamazepine concentration monitoring is recommended to maximize efficacy, monitor compliance, and reduce toxicity.

**Oxcarbazepine**

Oxcarbazepine is a carbamazepine analog that is likely to have a similar analgesic mechanism. Oxcarbazepine has primarily been studied in PDN. In one PDN trial, oxcarbazepine at a maximal daily dose of 1,800 mg produced greater pain relief than placebo, with an NNT to achieve 50% pain relief of 6.0 (95% CI, 3.3 to 41.0). Two other PDN trials, including one much larger trial, found no significant difference in pain relief between oxcarbazepine and placebo. Oxcarbazepine 1,800 to 2,400 mg per day was more effective than placebo for treating mixed types of peripheral neuropathy in one trial. Adverse events are generally of mild or moderate severity, but serious adverse events and adverse events leading to treatment withdrawal were more common with oxcarbazepine than placebo in patients with PDN. The most common adverse events with oxcarbazepine are dizziness, drowsiness, headache, ataxia, altered vision, and nausea and vomiting. Hyponatremia can occur
with oxcarbazepine, making sodium concentration monitoring important. In summary, results are mixed for oxcarbazepine in PDN, and data are limited for other types of neuropathic pain.

**LAMOTRIGINE**

Lamotrigine has been studied in several types of neuropathic pain. In a few small trials, lamotrigine 200 to 400 mg per day was effective for treating central poststroke pain, PDN, HIV neuropathy, or trigeminal neuralgia. However, lamotrigine 200 to 600 mg per day was not effective for treating central or peripheral neuropathic pain in several other trials, some of which included much larger sample sizes. A meta-analysis calculated an NNT of 17.8 (95% CI, 9.3 to 210) for 50% pain reduction across several types of neuropathic pain for lamotrigine. The overall safety profile is dose-related. Common side effects include nausea, vomiting, sedation, drowsiness, dizziness, headaches, malaise, visual disturbances, and ataxia. Skin rash that may deteriorate to dangerous or life-threatening SJS or TEN is the most serious adverse event of lamotrigine. Slow titration may reduce the risk of developing these syndromes. Skin rash development requires discontinuation of lamotrigine.

**VALPROATE**

Five small trials examined the effects of valproic acid or sodium valproate in neuropathic pain. Valproic acid and sodium valproate at a daily dose of 1,000 mg were superior to placebo in reducing PHN in one study. Sodium valproate 500 mg or 1,200 mg significantly improved pain associated with PDN in two trials. In contrast, 1,500 mg of valproic acid failed to show superiority to placebo for mixed types of neuropathic pain in one randomized controlled trial, and 2,400 mg of sodium valproate was ineffective for treating central pain associated with spinal cord injury in another trial. The NNT for 50% reduction in pain intensity across all neuropathic pain types was 4.3 (95% CI, 2.7 to 9.9), but this figure was based on a limited number of trials with small sample sizes and therefore may not reflect its actual efficacy.
OTHER ANTICONVULSANTS
Topiramate was effective for PDN in one controlled trial but not in another, much larger trial. Topiramate also yielded equivocal results in one randomized controlled trial in patients with painful lumbar radiculopathy. Topiramate was titrated up to a daily dose of 400 mg in all three trials. Clinicians were hopeful that levetiracetam would be a useful agent for treating neuropathic pain, but available evidence are not supportive of this use. One very small trial described significant pain relief in patients with central pain associated with multiple sclerosis, but another trial in central pain of multiple sclerosis as well as trials in central poststroke pain, postmastectomy pain, spinal cord injury pain, and other neuropathic pain types found no significant differences between levetiracetam and placebo. Lacosamide was effective for reducing pain compared to placebo in one trial in central poststroke pain, but results were similar between lacosamide and placebo in three much larger PDN trials. Zonisamide and tiagabine have been used in open-label studies or small-scale randomized controlled trials, but currently available data are too limited to confidently assess the efficacy of these drugs.

Opioids
Sixteen randomized controlled trials tested the efficacy of oral opioids for PDN, PHN, phantom pain, nerve root pain, and neuropathic pain of diverse etiologies (Table 81.5). Six different opioids including morphine, oxycodone, methadone, levorphanol, hydromorphone, and dihydrocodeine were tested in these trials. Most trials found the tested opioid to be superior to placebo in reducing spontaneous neuropathic pain. In one trial, dihydrocodeine was found advantageous to a synthetic cannabinoid nabilone in patients with mixed neuropathies and to mexiletine in another trial on patients with phantom and residual leg pain. Dose-dependent analgesic responses to methadone and levorphanol were demonstrated in patients with mixed neuropathies in two independent trials. Two negative studies have been published: In one, morphine, up to 90 mg per day, administered for 8 days, was not more efficacious
than placebo in reducing peripheral neuropathic pain of mixed origin. In a more recent trial, morphine at the same maximal daily dose showed no superiority over placebo in patients with chronic lumbar radicular pain. Notably, a more recent contradictory study showed efficacy of hydromorphone in patient with “neuropathic back pain.” Ten trials were recently pooled together in a meta-analysis yielding a combined NNT of 4.3 (95% CI, 3.4 to 5.8). A systematic review of seven short-term (less than 24 hours) and two intermediate-term (4 weeks) randomized controlled trials concluded that opioids can reduce the intensity of dynamic mechanical allodynia and perhaps of cold allodynia in patients with peripheral neuropathic pain. These findings are clinically relevant because dynamic mechanical allodynia and cold allodynia are the most prevalent types of evoked neuropathic pain.

</table>
Although opioids clearly reduce neuropathic pain, several questions related to chronic opioid use in neuropathic pain remain unanswered. First, opioids did not demonstrate improvement in many aspects of emotional or physical functioning, as measured by various validated questionnaires. Second, studies were limited to 12 weeks or less. Therefore, no high-quality data on long-term safety and efficacy of opioids in the treatment of neuropathic pain are available. This is particularly important because of emerging reports, coming mainly from North America, on hazards associated with long-term opioid use such as addiction and death.

**Tramadol**

Tramadol is a synthetic, “weak opioid” analogue with a dual mechanism of analgesia: It has a weak affinity for μ-opioid receptors, and it weakly inhibits serotonin and norepinephrine reuptake. Randomized
controlled trials show that tramadol can reduce pain in patients with PHN, PDN, mixed forms of painful polyneuropathy, spinal cord injury pain, and postamputation pain (see Table 81.5). Its overall efficacy in PHN seems somewhat lower than that of other opioids with an NNT of 4.7 (95% CI, 3.6 to 6.7). Due to dose-dependent adverse effects, a gradual titration from 50 mg two to three times daily to a maximal daily dose of 400 mg is generally required. Common adverse events include drowsiness, nausea, constipation, dizziness, and potential for abuse. Concomitant use of serotonin reuptake inhibitors may increase the risk for serotonergic syndrome. Tramadol is metabolized in the liver by CYP3A4 and CYP2D6 and will likely interact with any drug able to inhibit or induce these enzymes.

Tapentadol

Tapentadol is a new synthetic centrally acting, “strong opioid” analgesic with both µ-opioid receptor agonist and norepinephrine reuptake inhibition mechanisms of action. Tapentadol at a maximal daily dose of 500 mg was superior to placebo in three randomized controlled trials in patients with PDN. Tapentadol is available as an extended-release formulation. Reported side effects were similar to those of other “strong opioids,” including nausea, vomiting, anxiety, diarrhea, dizziness, and abuse potential. Yet, it may have a superior gastrointestinal tolerability profile compared to that of strong opioids.

NMDA Receptor Antagonists

In spite of numerous animal studies in which N-methyl-D-aspartic acid (NMDA) receptor antagonists yielded promising results, clinical trials with oral drugs were generally negative (Table 81.6). Three small trials showed efficacy of the NMDA receptor antagonist dextromethorphan for PDN but not for PHN or neuropathies of mixed etiologies. Memantine, which also has NMDA receptor blocking properties, was not effective in PDN, PHN, or chronic phantom limb pain. A small trial (n = 19) found that a 4-week course of memantine during the immediate postamputation
period reduced phantom limb pain for up to 6 months postamputation but did not attenuate phantom limb pain in the long term (12 months).\textsuperscript{162} In contrast, intravenous administration of subanesthetic doses of ketamine produced short-term analgesia (lasting for hours) in multiple forms of neuropathic pain.\textsuperscript{165} In one trial, thrice-daily ketamine infusions for 1 week significantly reduced pain scores during treatment and for 2 weeks after the last infusion in patients with neuropathic pain attributed to spinal cord injury who were receiving oral gabapentin.\textsuperscript{166} Regardless of the difference in outcomes between short- and long-term studies, one trial showed that short-term intravenous administration of ketamine may be useful in predicting long-term response to oral dextromethorphan.\textsuperscript{167} Among other physiologic actions, magnesium sulfate is a natural NMDA receptor antagonist. In one study, a similar number of patients with PHN responded to a single dose of intravenous magnesium sulfate (7/15) compared with a single dose of intravenous ketamine (10/15).\textsuperscript{164} A recent meta-analysis determined that results for NMDA antagonists in neuropathic pain treatment were inconclusive.\textsuperscript{6} There is interest in developing less-invasive systemic ketamine dosage forms (e.g., oral, sublingual, intranasal), but long-term efficacy data are not yet available for these dosage forms.\textsuperscript{168,169}

</table>

*a* Median dose reported rather than maximum dose.

*b* Trial compared two NMDA receptor antagonists to each other, and the same trial is displayed twice in the table (once for each NMDA antagonist).

*c* Patients received a single dose of ketamine or magnesium sulfate and outcomes were tracked for 2 weeks.

*d* Memantine superior to placebo at 1 and 6 months postamputation but not at 1 year.

NMDA, N-methyl-D-aspartic acid; PDN, painful diabetic neuropathy; PHN, postherpetic neuralgia; PLP, phantom limb pain; A, active drug; P, placebo; > indicates that active drug was superior to the comparator in terms of pain reduction; < indicates that active drug was not superior to the comparator in terms of pain reduction; = indicates that active drug was equal to the comparator in terms of pain reduction.
Systemic Sodium Channel Blockers

Carbamazepine, oxcarbazepine, mexiletine, intravenous lidocaine, and topical lidocaine are all sodium channel blockers. Carbamazepine and oxcarbazepine have already been reviewed earlier in this chapter, and topical lidocaine will be discussed with other topical agents.

Mexiletine, an orally available analog of lidocaine with antiarrhythmic properties,\textsuperscript{12} was evaluated in several randomized controlled trials for the treatment of PDN. These trials are summarized in Table 81.7. With the exception of one trial in which a relatively high dose of the drug produced modest effect, no significant pain relief was demonstrated.\textsuperscript{170–172} High doses of mexiletine are commonly associated with adverse effects such as chest pain, dizziness, gastrointestinal disturbances, palpitations, tremor, and potential for worsening of existing arrhythmia.\textsuperscript{27}

</table>
A meta-analysis of randomized controlled trials demonstrated the effectiveness of intravenous lidocaine for various types of peripheral neuropathic pain syndromes. Pain was reduced by about 10 mm more (on a 100-mm scale) with lidocaine than with placebo. Major drawbacks of this therapy are the lack of data on long-term efficacy and the apparent necessity for repeated infusions for sustained pain relief. This may therefore be an impractical approach for many patients. Interestingly, a positive correlation between the response to a single lidocaine infusion and long-term response to oral mexiletine has been reported.

**Simple Analgesics**

Acetaminophen (paracetamol) is a popular analgesic due to availability and low cost. At or below the recommended dose, adverse effects are limited. However, acetaminophen has not been studied as a treatment option for neuropathic pain in any randomized controlled trials. Based on clinical experience, acetaminophen is unlikely to provide a clinically meaningful benefit in the treatment of neuropathic pain.

**Nonsteroidal Anti-inflammatory Agents**

There is a major discrepancy between the perceived lack of efficacy of nonsteroidal anti-inflammatory drugs (NSAIDs) for neuropathic pain and the widespread use of these drugs for this diagnosis. Although evidence for the role of inflammation in neuropathic pain is emerging and it is estimated that half of all clinical cases of neuropathic pain are associated with inflammation of the peripheral nerves, no controlled clinical trials
that tested the effectiveness of NSAIDs for neuropathic pain exist. Animal models of nerve injury display inflammatory responses that are attenuated by the use of NSAIDs. In humans, a pilot, randomized, open-label clinical trial which showed comparable effectiveness of lidocaine patch 5% to that of naproxen 500 mg twice daily for the treatment of neuropathic pain associated with carpal tunnel syndrome is available. An open-label study comparing ibuprofen (2,400 mg daily), sulindac (400 mg daily), and placebo in patients suffering from PDN found efficacy for the NSAIDs compared to placebo. Some conditions with a clear inflammatory basis such as acute herpes zoster have been targeted for NSAID treatment. In contrast, a recent Cochrane collaboration report found no evidence for the treatment of acute radicular pain (sciatica) with NSAIDs, although this treatment is quite prevalent.

**Topical Agents**

**CAPSAICIN**

Capsaicin is a natural vanilloid that derives from the capsicum plant. It selectively binds to the transient potential vanilloid receptor 1 (TRPV1) and causes initial nociceceptor depolarization with acute exposure, followed by substance P depletion and reduced nociceptor functionality with chronic use. Topical low-concentration capsaicin cream (0.075%) applied three to four times daily was effective in three of five published randomized controlled trials in PDN, in two PHN trials, one trial in postsurgical pain and one in patients with mixed neuropathies. Topical capsaicin was not superior to placebo in randomized controlled trials for postmastectomy pain syndrome and for HIV neuropathy. Capsaicin application is associated with burning sensation, particularly during the first weeks of treatment, an adverse event that may often limit its required long-term use.

More recently, single application of 8% capsaicin patch for 30 to 60 minutes was introduced to the market. It has been tested in seven clinical trials in patients with PHN or HIV-related distal sensory polyneuropathy (see Table 81.8). Positive results showing sustained efficacy for up to 12 weeks following a single application were reported in most of these trials.
Topical application of the 8% capsaicin patch is frequently associated local side effects including transient burning sensation and pain, pruritus, erythema, and swelling as well as transient alterations in blood pressure. Preapplication of local anesthetics and systemic analgesic administration reduce pain and burning sensations in the treated site.

**TOPICAL LIDOCAINE PATCHES**

Application of lidocaine gel/cream yielded inconsistent results in neuropathic pain (Table 81.8). The topical lidocaine 5% patch is an attractive option: It is applied for 12 hours and protects the skin from incidental touch, which might be important for patients who experience tactile allodynia. The lidocaine patch was effective for PHN in four short-term randomized controlled trials\(^{185-188}\) and also in patients with other focal peripheral neuropathies.\(^{179,188}\) The maximal recommended daily dose is three patches applied simultaneously every 12 hours. With the exception of mild skin reactions, lidocaine patches are not associated with adverse reactions, although caution is required in patients receiving oral Class I antiarrhythmic medications (e.g., mexiletine) and in patients with severe hepatic dysfunction.\(^{192}\)

PDN, painful diabetic neuropathy; PHN, postherpetic neuralgia; A, active drug; P, placebo; > indicates that active drug was superior to the comparator in terms of pain reduction; < indicates that active drug was not superior to the comparator in terms of pain reduction; = indicates that active drug was equal to the comparator in terms of pain reduction.

**TOPICAL KETAMINE**

In a small study, ketamine 1% was compared to placebo in patients with...
PHN, but no difference in pain reduction was found between treatments. Several other studies tested the effect of topically applied ketamine either alone or in combination with other agents against placebo for postchemotherapy neuropathies or mixed neuropathies under randomized controlled conditions. All studies, but one, failed to demonstrate superior efficacy of ketamine over the placebo, thus putting into question the efficacy of topical ketamine for neuropathic pain.

Cannabinoids

The past decade has seen a real surge of interest in the treatment of pain with cannabinoids. This interest has been fueled by two separate phenomena: the increased mortality rate in patients taking prescription opioid drugs and the increasing acceptance and legalization of recreational and “medical” cannabis. Although boundaries between medical and recreational cannabis use have become blurred, with increasing recreational use fueling medical acceptance of cannabis and vice versa, it has become apparent that conventional wisdom concerning cannabis use is being challenged by decreased opioid mortality in states with legalized access to medical cannabis.

Another issue of importance is the mode of drug delivery. Cannabis for therapeutic purposes (CTP) can be administered via smoking or ingesting the raw plant, vaporizing the raw plant, or in cannabis-based medicines with known quantities of active agents: delta (9) tetrahydrocannabinol (THC) with or without cannabidiol (CBD). A recent international survey of forms of administration of CTP across countries found that pulmonary delivery of cannabis is the preferred route of administration used by 86.6% (62.9% for smoking and 23.7% for vaporizing) of the participants. The oral mode of delivery of cannabis in edibles was used by 10.3% of the participants, whereas only 2.3% participants used either cannabis extracts delivered by oromucosal route (Sativex) or synthetic cannabinoids (Marinol and Nabilone) delivered orally in tablet forms. This is clearly a strange state of affairs: Pharmacologic administration of cannabis in reproducible doses is very uncommon, whereas the use of raw
plant, with no pharmacologic standardization, is the leading mode of administration. Over the last two decades, there has been a regular increase in the potency of illicit cannabis. Use of high-potency breeds is common in Europe, Canada, and Australia for both recreational and medicinal purposes. Users of CTP often seek different concentrations of active ingredients in the cannabis that is smoked, and although this might be a very positive trend, it makes comparison of cannabis across studies very complicated.

Although cannabinoids are not formally approved for the treatment of neuropathic pain by drug regulatory agencies, many patients use cannabis for pain relief. In a meta-analysis of cannabis-based treatments for neuropathic and multiple sclerosis–related pain, 7 randomized, double-blind, placebo-controlled trials were included (n = 298). The overall quality of the studies was very good. In general, the overall reductions in pain were in excess of 1.5 on an 11-point scale, and all were statistically significant. The difference in effect size in comparison to placebo was 0.8.

In a systematic review of cannabinoids for the treatment of noncancer pain, 18 trials published between the years of 2003 and 2010 involving 766 participants were included. The quality of the trials was good, and in 15 of the 18 trials, there was a significant analgesic effect for the cannabinoid being tested. Four of the trials examined the effect of smoked cannabis on neuropathic pain, all reporting positive effects with minimal or no serious adverse effects. The mean treatment duration was only 8.5 days. Seven trials examined the effects of oromucosal extracts of cannabis-based medicine. Five trials examined the effect on participants with neuropathic pain, and four of these reported positive analgesic effects. Nabilone 2 mg has been found to be as effective as dihydrocodeine 240 mg for patients with neuropathic pain. Dronabinol 10 mg has been found to be effective for central pain in multiple sclerosis (Table 81.9).

CBD, cannabidiol; MS, multiple sclerosis; N, nabilone; THC, tetrahydrocannabinol; A, active drug; P, placebo; > indicates that active drug was superior to the comparator in terms of pain reduction; < indicates that active drug was not superior to the comparator in terms of pain reduction; = indicates that active drug was equal to the comparator in terms of pain reduction.

Reported adverse events for CTP have included the following: central
nervous system–related events such as alterations in perception (blurred vision, visual hallucinations, tinnitus, disorientation, confusion, dissociation, and acute psychosis), alterations in motor function (speech disorders, ataxia, muscle twitching, numbness), and altered cognitive function (impaired memory, disturbance in attention, disconnected thought).

In summary, it appears the cannabis-based medications including smoked cannabis have a positive effect on pain reduction in patients suffering from chronic neuropathic pain. Effect sizes are small, and adverse effects are not uncommon. More study will clearly be done in the future to clarify the most efficient mode and methods of administration, minimizing the recreational effects and enhancing meaningful clinical outcomes.

**Drug Combinations**

Not uncommonly, administration of a single drug does not produce adequate analgesia. Pharmacologically, it seems reasonable to coadminister drugs with different mechanisms of action. Although combination therapy is commonly used in clinical practice, available data regarding the efficacy and safety of this practice is relatively limited (Table 81.10).

*a* Combination therapy superior to each drug alone; all are superior to placebo.

*b* Combination, each drug alone, and placebo showed similar efficacy.

*c* Combination of gabapentin + oxycodone was superior to the combination of gabapentin + placebo.

*d* Combination of ketamine + amitriptyline cream, each drug alone and their combination showed similar efficacy.

*e* Combination showed superiority over each drug in secondary outcomes only.

NP, neuropathic pain; PDN, painful diabetic neuropathy; PHN, postherpetic neuralgia; LBP, low back pain; C, combination of drugs; A, active drug; P, placebo; > indicates that active drug(s) was superior to the comparator in terms of pain reduction; < indicates that active drug(s) was not superior to the comparator in terms of pain reduction; = indicates that active drug(s) was equal to the comparator in terms of pain reduction.

Five trials compared combinations of oral opioids with an agent from another class, typically an antidepressant or an anticonvulsant against each drug alone. Three trials showed superiority of the combinations over each treatment alone, whereas the two others failed to demonstrate similar results. One of the two negative studies compared 600 mg of pregabalin plus 10 mg of oxycodone against 600-mg pregabalin plus a placebo. The 10-mg oxycodone dose might have been too small to demonstrate an analgesic effect especially because less than 30 patients were included in each treatment arm. In the other negative study, Khoromi et al. could not demonstrate superiority of morphine, nortriptyline, or their combination over placebo in patients with chronic lumbar root pain, thus questioning the efficacy of any of these.
drugs in this type of neuropathic (radicular) pain. Baron et al.\textsuperscript{216} compared the effectiveness of tapentadol prolonged release (PR) 500 mg per day or tapentadol PR 300 mg per day plus pregabalin 300 mg per day during a concurrent 8-week, double-blind comparative period in patients with low back pain with a neuropathic component. The analgesic effectiveness provided by tapentadol monotherapy was noninferior to that provided by the combination therapy. Using a different study design, Freeman et al.\textsuperscript{213} found the combination of tramadol and acetaminophen advantageous relative to placebo in patients with PDN, but monotherapy arms of the active drugs were not included in this trial.

Two other trials compared combinations of an antidepressant with an anticonvulsant against monotherapies. One\textsuperscript{70} showed superiority of gabapentin and nortriptyline over each drug alone in a mixed group of patients with PHN or PDN. In contrast, another large study showed no difference in efficacy between pregabalin combined with duloxetine at moderate dosages compared with high dosages (600-mg pregabalin, 120-mg duloxetine daily) of each drug alone in patients not responsive to monotherapy at moderate dosages.\textsuperscript{218} Notably, secondary outcome measures in this study showed superiority of the combination treatment.

Three trials assessed the efficacy of combining the NMDA receptor antagonist ketamine with other drug classes. A small trial found equal efficacy of the combination of oral amitriptyline, carbamazepine, and ketamine compared to amitriptyline, carbamazepine, and placebo in patients with mixed neuropathies.\textsuperscript{217} Eichenberg et al.\textsuperscript{220} combined ketamine and calcitonin infusions in 20 patients with phantom limb pain and found the combination to be equally effective to ketamine alone but more efficacious than calcitonin or placebo infusions alone. Adding ketamine infusion to oral gabapentin provided better pain relief than placebo infusion in a small study on patients with central neuropathic pain.\textsuperscript{166}

Five trials compared the effect of different combinations of topical agents (ketamine, capsaicin, amitriptyline, doxepin, valproate, topiramate, glycerol) to their single components and to placebo.\textsuperscript{88,190,194,195,219} Studies failed to show superiority of the combinations over monotherapies. Three of these studies also failed to show superiority of both the combinations
and/or monotherapies over placebo,\textsuperscript{190,194,195} whereas the two others and an additional study\textsuperscript{193} reported opposing results.

Another reason for considering combining drugs from different classes rather than increasing the dose of a single drug is reducing side effects. This consideration was not tested in many of the drug combination studies, as the maximal allowed dose in the monotherapy arm was equivalent to that of the combination arm.\textsuperscript{20,70,214,215} Not surprisingly, the incidence of adverse effects in the combination arms in these trials often exceeded that of the monotherapies. When high doses of monotherapy were compared to lower doses of combination treatments, the combinations did not reduce\textsuperscript{7,218} or even increased\textsuperscript{212,216} the incidence of side effects.

In summary, although some studies demonstrated superiority of drug combinations over monotherapy, others have not. Hence, the concept according to which combining different classes of drugs is clearly more efficacious or a safer alternative to monotherapy for patients with neuropathic pain has not been proven.

**Future Drugs**

Several new medications are being evaluated for treating neuropathic pain. Mirogabalin is an $\alpha_2\delta$ ligand being studied in PDN. Unlike the other $\alpha_2\delta$ ligands (i.e., gabapentin, pregabalin), mirogabalin is selective for the $\alpha_2\delta$-1 subunit, which investigators are hopeful will improve analgesic effects and limit central nervous system side effects (e.g., dizziness).\textsuperscript{221,222} Cebranopadol is a combined central opioid and nociception/orphanin FQ peptide agonist. Preclinical trials suggest potent effects for cebranopadol in neuropathic pain. In addition to increased activity in neuropathic pain, cebranopadol may produce less respiratory depression and drug tolerance than other opioids.\textsuperscript{223} The Nav1.7 sodium channel plays a potentially important role in pain sensing. Early trials of TV-45070, a potent Nav1.7 sodium channel inhibitor, demonstrated analgesic effects in PHN and erythromelalgia.\textsuperscript{224,225} Gene therapy and placental cell therapy are areas of interest that may prove valuable in PDN.\textsuperscript{226,227}
Evidence-Based Recommendations for Drug Therapy in Neuropathic Pain

Adequate response to drug therapy remains a substantial unmet need in patients with neuropathic pain. Although a considerable number of randomized controlled trials on neuropathic pain pharmacotherapy have been published, the quality of evidence is frequently not very high due to modest efficacy of many drugs, large placebo responses, heterogeneous inclusion criteria, and high level of bias in many trials. Notably, analysis of publication bias suggested a 10% overstatement of treatment effects. Studies published in peer-reviewed journals reported greater effects than did unpublished studies ($r^2 = 9.3\%$, $P = .009$).\(^6\) For these reasons, there is a clear need for evidence-based recommendations on pharmacologic treatment of neuropathic pain, which are based on systematic reviews and meta-analyses of randomized controlled trials. Indeed, such recommendations have been released over the years by various societies and organizations. Most recommendations are determined by drug treatments rather than by the cause of pain. The recommendations are generally consistent between guidelines, but some differences between them exist.

Perhaps the most recent set of recommendations is that of the International Association for the Study of Pain (IASP’s) Neuropathic Pain Special Interest Group (NeuPSIG), which was published in 2015.\(^6\) They recommend TCAs, pregabalin, gabapentin (including extended-release), and duloxetine as first-line for neuropathic pain. Lidocaine patch and high-concentration capsaicin patch are second-line treatments for peripheral neuropathic pain. Strong opioids are recommended as third line, mainly due to safety concerns. A weak recommendation against the use of cannabinoids in neuropathic pain is provided mainly because of negative results, potential misuse, diversion, and long-term mental health risks of cannabis.

The European Federation of Neurological Societies (EFNS) most recent guidelines were published in 2010.\(^9\) They confirm TCAs, gabapentin, and pregabalin as first-line for various neuropathic pain conditions (except for trigeminal neuralgia), lidocaine plasters first-line in PHN particularly in
the elderly, and SNRIs first-line in painful diabetic polyneuropathies. Second-line treatments include tramadol and capsaicin cream in PHN. Strong opioids are recommended as second line/third line despite established efficacy in neuropathic noncancer pain because of potential risk for abuse on long-term use. Capsaicin patches are promising for painful HIV neuropathies or PHN whereas cannabinoids are proposed for refractory cases. Lastly, combination therapy is recommended for patients who show partial response to drugs administered alone.

In 2014, the Canadian Pain Society revised its consensus statement on pharmacologic management of chronic neuropathic pain. They recommend gabapentinoids (gabapentin and pregabalin), TCAs, and SNRIs for first-line treatments. Tramadol and controlled-release opioid analgesics are classified as second-line treatments for moderate to severe pain. Cannabinoids are recommended as third-line treatments. Recommended fourth-line treatments include methadone, anticonvulsants with lesser evidence of efficacy (e.g., lamotrigine, lacosamide), tapentadol, and botulinum toxin. They support some analgesic combinations in selected neuropathic pain conditions. If all fail, more invasive treatments should be considered.

**Intrathecal Drugs for Neuropathic Pain**

Intrathecal (IT) therapy for patients suffering from chronic refractory pain is well established, and two major drugs, morphine and ziconotide, are U.S. Food and Drug Administration (FDA)-approved for nociceptive, neuropathic, or mixed nociceptive–neuropathic pain states. Other drugs are also used in IT therapy including clonidine, hydromorphone, fentanyl, and bupivacaine. Baclofen, indicated for spasticity, has neuropathic pain–relieving activity but is not indicated as therapy for neuropathic pain without spasticity. The place of IT therapy appears late in the algorithm of pain therapy due not only to the invasive nature of this treatment but also to other important issues such as patient selection, realistic patient expectations, patient compliance, insurance coverage for implantation, and a fully equipped staff able to deal with all aspects of implantation, follow-up, and the handling of complications.
Although there is no high-level evidence of randomized controlled trials for the long-term (over 12 months) treatment of patients with IT therapy, the evidence from observational trials indicates efficacy for chronic noncancer pain, both nociceptive and neuropathic. Lack of high-level evidence has spurred on the development of expert consensus through the Polyanalgesic Consensus Conference recommendations for both noncancer and cancer patients. For noncancer pain, first-line IT therapy includes morphine, hydromorphone, or ziconotide. Second-line IT therapy includes fentanyl, morphine/hydromorphone plus ziconotide, or morphine/hydromorphone plus baclofen/clonidine.

In summary, IT therapy is a well-accepted treatment option for patients suffering from chronic pain in whom more conservative measures have failed. Patient selection and well-trained staff are essential prerequisites for IT therapy. The paucity of the literature for randomized controlled trials with long-term results necessitates further study.

Neuropathic Pain—Not Only Pharmacotherapy

Although this chapter focuses on neuropathic pain pharmacotherapy, providers should bear in mind that neuropathic pain treatment is not limited to drug therapy and a multidisciplinary treatment approach can often yield better outcomes. Often, the burden on patients with chronic neuropathic pain is huge, and their quality of life is significantly impaired. Above all, pharmacotherapy alone frequently provides insufficient analgesic efficacy and common side effects leading to regular clinic visits for medication titration and changes. The use of additional nonpharmacologic strategies is therefore warranted, preferably with an emphasis on a multidisciplinary approach whenever possible.

CHAPTER 82
Local Anesthetics

MICHAEL M. BOTTROS, LARA WILEY CROCK, and SIMON HAROUTOUNIAN

Physicochemical Properties of Local Anesthetics

“Cocaine and its salts have a marked anesthetizing effect when brought in contact with the skin and mucous membrane in concentrated solution; this property suggests its occasional use as a local anesthetic, especially in connection with affictions of the mucous membrane.” Cocaine and its potential clinical use as a local anesthetic were described by Sigmund Freud in his 1884 paper “Uber Coca.” Almost as an afterthought, he describes cocaine’s potential use as a local anesthetic in the very last paragraph: “Indeed, the anesthetizing properties of cocaine should make it suitable for a good many further applications.” A friend of Freud, Carl Koller, utilized this property of cocaine for ophthalmologic procedures. Thus, Koller is credited with demonstrating the first local anesthetic in modern clinical practice. Although still somewhat controversial as to when cocaine was first used as a spinal anesthetic, Corning described what he believed was an extradural block using cocaine in 1885, and Bier described a spinal anesthetic effect with cocaine in 1898. Clinically useful due to its properties as both a local anesthetic and vasoconstrictor, cocaine has undesirable side effects that limit its routine use. Other local anesthetics were developed based on the chemical structure of cocaine, and the clinical application of local anesthetics became widespread in modern medicine. The use of local anesthetics has continued to increase in clinical practice, as there is increased interest in the use of regional techniques for surgery as well as in the treatment of chronic pain.

MOLECULAR STRUCTURE
The chemical structure of cocaine was determined by Richard Willstätter
in 1898, allowing for the development of the synthetic analogs of cocaine. All currently available local anesthetics have an amine group (usually a tertiary amine) and an aromatic ring. With the exception of benzocaine, these two groups are separated by an intermediate ester or amide linkage (Fig. 82.1). They are classified by their chemical bond as either amino esters (e.g., include cocaine, procaine, chloroprocaine, tetracaine) or amino amides (e.g., lidocaine, prilocaine, bupivacaine, mepivacaine). Esters and amides have distinct properties as a result of their molecular structure. The amino amide bond is more resistant to enzymatic cleavage; therefore, amide local anesthetics are more stable when compared to ester local anesthetics. Amides and esters are metabolized in distinct ways—amides by the liver microsomes and esters by plasma esterases. Chirality, acid–base balance, lipid solubility, and protein binding can all affect the activity of local anesthetics.

![Local anesthetic structure. Similarities and differences between ester and amide local anesthetics.](image)

**FIGURE 82.1** Local anesthetic structure. Similarities and differences between ester and amide local anesthetics.

**CHIRALITY**

Stereoisomers have identical sets of atoms that are configured in the same positions with different spatial arrangements. Furthermore, enantiomers are pairs of stereoisomers that appear as nonsuperimposable mirror images, commonly referred to as chiral. More than one-third of synthetic drugs are structurally defined as chiral. Commonly used local anesthetics
with the exception of lidocaine are chiral. The body responds to chiral molecules differently because stereoisomers may have different receptor binding properties.

An example of a chiral local anesthetic is bupivacaine, a potent and long-acting local anesthetic with the unfortunate potential for cardiovascular and central nervous system (CNS) toxicity. Bupivacaine is manufactured as a racemic mixture of 50% R-bupivacaine and 50% S-bupivacaine. S- and R-enantiomers have been shown to have unique pharmacodynamic properties (e.g., potency and potential for systemic toxicity). R-enantiomers, like R-bupivacaine, have greater potency for blockade of both neuronal and cardiac sodium (Na\(^+\)) channels. R-bupivacaine is 1.5 times more potent when compared to S-bupivacaine (also known as levobupivacaine) when the Na\(^+\) channel is in an inactive state.\(^6\) Because of the potential systemic toxicity and higher potency, R-enantiomers are more powerful local anesthetics with a narrower therapeutic index. S-enantiomers on the other hand, have a lower binding potential for cardiac Na\(^+\) channels and may be safer.\(^7\) Ropivacaine (a pure S-enantiomer propyl homolog of S-bupivacaine) was developed in response to the need for a long-acting amino amide local anesthetic such as bupivacaine, with a greater margin of safety.\(^8\) It has been shown in both animal and human studies to have similar clinical efficacy compared to bupivacaine but with 30% to 40% less cardiotoxicity.\(^9\)–\(^12\)

**ACID–BASE BALANCE**

The pH and acid dissociation constant (pK\(_a\)) of local anesthetics have a large effect on their onset of action. The pK\(_a\) of a specific drug is the pH at which the lipid-soluble neutral form and the charged hydrophilic form are in equilibrium. Most local anesthetics have a pK\(_a\) value close to but higher than physiologic pH, making them weak bases. At physiologic pH, local anesthetics exist in a positively charged conjugated acid and an unprotonated neutral form. When unprotonated, the local anesthetic can more easily cross into the cell through the lipid bilayer to reach its receptor binding site. At physiologic pH of 7.4, a drug with a lower pK\(_a\) will more readily cross the cell lipid membrane (higher percentage will be in the uncharged, lipophilic form). Thus, the pK\(_a\) of a local anesthetic generally
correlates with its onset. The pH inside the cell is lower, which shifts the equilibrium toward a higher ratio of positively charged local anesthetic molecules. It is the charged form that binds to the pore of the voltage-gated Na\(^{+}\) channel, causing the anesthetic effects.

Tissue that has been damaged or is infected often produces an acidic extracellular microenvironment, thus increasing the percentage of charged local anesthetic outside the cells. The positively charged local anesthetic cannot easily cross the lipid bilayer and reach the intracellular binding site. For this reason, local anesthetics are not as effective in providing adequate analgesia to infected or damaged tissue.

Just as an acidic extracellular environment can prevent adequate analgesia from reaching the intended target, an acidic intracellular environment can prolong the effect of a local anesthetic. For example, the administration of an accidental overdose of local anesthetic can result in CNS toxicity. At lower toxic doses, central inhibitory neuronal pathways are blocked. This neuronal disinhibition can result in a tonic-clonic seizure, leading to a lactic acidosis in the CNS. As the CNS becomes more acidic, the local anesthetic is essentially trapped inside the cell due to its ionization, exacerbating its CNS toxicity.

**LIPOPHILIC–HYDROPHILIC BALANCE**

The lipid solubility, or lipophilic nature of a local anesthetic, influences its ability to pass through a lipid bilayer and thus its potency and duration of action. More lipophilic local anesthetics can not only permeate neurons more readily but also result in sequestration of the local anesthetic in lipid-soluble perineural compartments such as the myelin sheath where they are sequestered. The accumulation of local anesthetics in lipid-soluble neuronal components creates a depot of local anesthetics, resulting in a slow release from these lipophilic compartments. Consequently, although the lipophilic local anesthetics may cross membranes more readily, these drugs often have a lower onset of action and prolonged duration of action.\(^{13,14}\) Increased lipophilicity often translates to greater potency due to drug ability to cross lipid membranes and a greater affinity to bind Na\(^{+}\) channels.\(^{14,15}\)
Local Anesthetic Pharmacology

PHarmacodynamics

Hodgkin and Huxley used a giant squid axon to determine that electrical
signals in the nerves are initiated by voltage-dependent activation of
inward sodium currents.\textsuperscript{16,17} In 1970, Fraizer used squid giant axons and
quaternary compounds to demonstrate that local anesthetics need to
penetrate into the cell to inhibit depolarization and action potentials.\textsuperscript{18} It
was later discovered that local anesthetics work by binding to and blocking
voltage-gated sodium channels (Fig. 82.2). Voltage-gated sodium channels
exist in three conformational states: open, closed, and inactivated. Without
a stimulus, the channel is in its closed state. In response to a change in
membrane potential, the voltage-gated sodium channel will open. After a
few milliseconds, an intracellular loop (P) (see Fig. 82.2) will fold inward
and occlude the channel pore. This renders the sodium channel inactive,
and the channel will temporarily not respond to further changes in
membrane potential. Local anesthetics can gain access and bind to the
intracellular binding site preferably when the channel is in an open state.\textsuperscript{19}

\begin{figure}
\centering
\includegraphics[width=\textwidth]{voltage-gated-sodium-channel.png}
\caption{Diagram of a voltage-gated sodium channel structure and the site of action of local
anesthetics. Local anesthetics exist in an equilibrium as a neutral base (LA) and as a charged form
(LAH\textsuperscript{+}). The uncharged form (LA) more easily passes through the lipid bilayer to the interior of the
cell. Inside the cell, it can be protonated again (LAH\textsuperscript{+}), thus allowing it to bind to, and inhibit
(close), the voltage-gated sodium channel. (Adapted from Drasner K. Local anesthetics. In: Katzung
\end{figure}

4264
Local anesthetics work by preventing action potential propagation in axons through their inhibitory action on sodium channels. These voltage-gated sodium channels contain a main α-subunit, where the local anesthetics bind and one or more β-subunits. Local anesthetics reversibly bind to the α-subunit from inside the cell and inactivate voltage-gated sodium channels, thus preventing channel activation and inhibiting sodium influx, preventing depolarization of the nerve cell membrane (Fig. 82.2). When a local anesthetic binds to the open state of a sodium channel, it stabilizes the inactive state of the channel and prevents further activation. Local anesthetics increase the threshold for electrical excitation in nerves, slow propagation of the impulse, reduce the rate of rise of the action potential, and eventually block conduction.

**PHARMACOKINETICS**

The pharmacokinetic properties of local anesthetics (i.e., absorption, distribution, metabolism/biotransformation, and excretion), patient factors (i.e., age, overall health, and the functional state of eliminating organs), and clinical circumstances must be combined in order to predict the pharmacokinetic profile of a local anesthetic in a particular patient.

**Absorption**

The plasma concentration following systemic absorption of a local anesthetic is highly dependent on the site of administration, the dose, and the physicochemical properties of the drug. The more vascular an injection site, the higher the systemic absorption of the local anesthetic. The highest systemic absorption occurs with intravenous administration. The systemic absorption of local anesthetics after regional anesthesia occurs at decreasing rate after tracheal, intercostal, caudal, paracervical, thoracic/lumbar epidural, brachial plexus, and sciatic nerve blocks and is the lowest with subcutaneous infiltration (Fig. 82.3). For example, similar plasma concentrations of lidocaine are achieved after 300 mg delivered as an intercostal nerve block, 500 mg via an epidural block, and 1,000 mg subcutaneously. All local anesthetics produce some level of vasoactivity, with most producing vasodilatation. However, the
vasoactivity of local anesthetics is dependent on the drug, the dose, as well as the organ targeted.\textsuperscript{24} Vasodilatation increases absorption of the local anesthetic into the systemic circulation. Enhanced absorption reduces the local anesthetic duration and increases the concentration of the drug in the blood. Cocaine is the only local anesthetic that consistently produces vasoconstriction (following initial vasodilatation). The addition of epinephrine to some local anesthetic nerve blocks can reduce absorption by causing vasoconstriction, thus prolonging the nerve block. The extent of this prolongation appears to vary with the site of the nerve block and the vasoconstrictor agent used. For example, 5 µg/mL of epinephrine, added to lidocaine, reduced the peak plasma concentration of subcutaneously infiltrated lidocaine by 50% but only by 20% to 30% when added to intercostal, epidural, and brachial plexus lidocaine blocks.\textsuperscript{24} See “Vasoconstrictor Effect” section for further information.
Distribution
Once local anesthetics are absorbed in the blood, they readily cross into all tissues. Organs and tissues and organs with high levels of perfusion (such as the heart and brain) will have higher levels of local anesthetics. Local anesthetics (in their unionized form) are lipophilic and therefore readily cross the blood brain barrier. Depression of the CNS by local anesthetics causes initial sedation. Local anesthetics raise the seizure threshold by decreasing the excitability of cortical neurons in epileptic patients. However, at toxic plasma (and brain) levels, local anesthetics cause seizures.25

Biotransformation and Excretion
The primary site of amino amide local anesthetic metabolism is in the liver through hepatic carboxylesterases and cytochrome P450 enzyme. An exception is prilocaine, which is metabolized in both the liver and lungs. Ester local anesthetics, with the exception of cocaine, are hydrolyzed by plasma cholinesterases and tissue esterases.25,26 The metabolites of both amino ester and amino amide local anesthetics are primarily excreted by the kidneys. Urine concentrations of ester local anesthetics are small due to their metabolism in plasma. Only 2% of procaine is found in urine, whereas 90% is found as its para-aminobenzoate metabolite, para-aminobenzoic acid (PABA).27
The rates of hydrolysis of local anesthetics inversely determine their degree of toxicity. A slowly hydrolyzed ester local anesthetic such as tetracaine is more toxic than chloroprocaine, which is hydrolyzed much faster.

Effects of Disease States on Local Anesthetic Pharmacokinetics
Because amide local anesthetics are metabolized primarily in the liver, hepatic perfusion and liver function can affect the rate of amide local anesthetic metabolism. Reduced hepatic function results in a reduced plasma clearance of and prolongation of the elimination half-life of
intravenous lidocaine. This does not significantly affect the duration of action but predisposes a patient to the toxic effects. Renal disease has little effect on the pharmacokinetic parameters such as volume of distribution at steady state and total body clearance of intravenous lidocaine. In contrast, patients with cardiac failure had reduced volume of distribution and plasma clearance of intravenous lidocaine. Metabolism byproducts of amide local anesthetics can have clinical effects if allowed to accumulate in the blood. Sedation due to high doses of lidocaine is due to the formation of the metabolites glycine xylidide and monoethylglycinexylidide. Despite ester local anesthetics, biotransformation by plasma cholinesterases, and tissue esterase, at normal doses, there appears to be little effect in patients with pseudocholinesterase deficiency.

Regional Administration of Local Anesthetics for Pain Relief

DIFFERENTIAL BLOCKADE

As sodium channels are expresses in both sensory and motor nerve fibers, the regional administration of local anesthetics can result in blocking conduction along both types of fibers. Therefore, along the desired analgesic effect on sensory fibers, other, less desired effects are often observed. Differential blockade is the gradual and sequential inactivation of differing nerve fiber types when exposed to local anesthetics. A number of factors contribute to this phenomenon:

1. Local anesthetic concentration: Higher concentrations can produce both motor and sensory block, whereas low concentrations produce only sensory block.
2. Nerve fiber size: Small diameter axons are more susceptible to block than large diameter fibers. Sensory nerve fibers are classified as A, B, and C. Type A fibers include afferent fibers responsible for proprioception (Aα), thermal sensation (Aδ), and mechanosensation (Aβ). Type B fibers are mainly visceral sensory fibers and preganglionic autonomic fibers. Type C fibers are postganglionic autonomic efferents as well as sensory afferents responsible for the
transmission of pain and heat signals. Type A fibers are thickest, and type C fibers are thinnest.

3. Degree of nerve fiber myelination: Because local anesthetics exert their effect at the node of Ranvier, myelinated fibers are more sensitive to local anesthetic effects than nonmyelinated ones.

4. Circumferential location of fibers: In nerve bundles, fibers that are located circumferentially are affected first by local anesthetics. In large nerve trunks, motor nerves are usually located circumferentially and may be affected before the sensory fibers. In the extremities, proximal sensory fibers are located more circumferentially than distal sensory fibers. Thus, loss of sensation may spread from the proximal to distal part of the limb.

Gokin et al.\textsuperscript{29} studied the preferential block of sensory and motor fibers using lidocaine in a rat sciatic nerve model. They found that the order of fiber susceptibility, ranked by concentrations that gave peak tonic fiber blockade of 50\% (IC50s), was $\text{A}_\gamma > \text{A}_\delta = \text{A}_\alpha > \text{A}_\alpha\beta > \text{C}$. Faster conducting C fibers (conduction velocity $>1 \text{ m/s}$) were more susceptible than slower ones. Therefore, this does not strictly follow the “size principle” that smaller axons are always blocked first.

**SITE OF INJECTION**

Local anesthetics are used in a wide variety of anatomical sites. These can generally be grouped into five categories: neuraxial anesthesia, peripheral nerve blockade, intravenous regional anesthesia, infiltration anesthesia, and topical anesthesia.

**Neuraxial Anesthesia**

Neuraxial anesthesia was first reported for clinical use in the late 19th century by Augustus Karl Gustav Bier, who used intrathecal cocaine on six patients undergoing lower extremity surgery.\textsuperscript{30} Since then, neuraxial anesthesia has progressed considerably and has become widely used for surgical anesthesia and pain management in a number of different clinical situations. The term neuraxial anesthesia may be further categorized into spinal, epidural, caudal, or combined spinal-epidural (CSE) anesthesia.

Spinal anesthesia involves the administration of local anesthetics into
the intrathecal (or subarachnoid) space. As the conus medullaris typically terminates near lumbar nerves L1 or L2, this technique is performed below the L2 level to avoid damage to the spinal cord. As such, this technique may be indicated when the surgical site involves the lower extremities, perineum, or lower trunk. Examples include total hip/knee arthroplasty or cesarean section surgeries.

Epidural anesthesia is categorized by the deposition of local anesthetics via catheter or needle placed into the epidural space, located between the ligamentum flavum and the dura mater (Fig. 82.4). Key differences between epidural and spinal anesthesia include location of drug deposition (epidural vs. intrathecal), onset of action (spinal is generally quicker than epidural), and local anesthetic dose (because of uptake into extraneural fat, blood, and lymphatics, epidural doses are higher than spinal). Epidural catheter analgesia (using low-dose local anesthetics, sometimes with the addition of an opioid) is typically used for truncal or lower extremity postoperative pain relief, such as postthoracotomy or abdominal resection cases.

![Epidural anesthesia diagram](From BruceBlaus/Wikimedia Commons/CC-BY-SA-4.0.)

Caudal epidural anesthesia involves the insertion of a needle through the sacral hiatus in order to gain entrance into the sacral epidural space.
Caudal anesthesia is commonly used as a regional technique in neonates and infants for abdominal and pelvic surgeries as it decreases the amount of general anesthetic and intravenous opioids required intraoperatively.\textsuperscript{31,32}

A CSE technique may be used in clinical scenarios during surgery at or below the umbilicus requiring prolonged and effective analgesia. This typically entails performing an intrathecal block for the surgical procedure itself while an epidural catheter is placed (subsequent to the intrathecal block) and used during surgery when the intrathecal block is deficient or an extended duration of relief is needed for unanticipated longer surgical procedures. Postoperatively, the epidural catheter may be used for pain control.\textsuperscript{33}

**Peripheral Nerve Blockade**

Peripheral nerve blockade is the deposition of local anesthetic near a nerve or group of nerves associated with the control of sensation and/or movement of a specific part of the body. This may be performed in lieu of or in addition to general anesthesia for surgery. This may be performed as a single-shot technique to facilitate intraoperative and immediate postoperative analgesia and analgesia. Alternatively, for a longer duration of postoperative analgesia, one can insert a catheter near the nerve/nerves and provide continuous analgesia by supplying an infusion of local anesthetic. Peripheral nerve blockade may be achieved via blind technique, but most are currently performed with concomitant use of either nerve stimulation or ultrasound to guide needle placement.

**Intravenous Regional Anesthesia**

Intravenous regional anesthesia (IVRA) was first described in 1908 by Augustus Bier, known for his prior work on spinal anesthetics, and is commonly referred to a Bier block.\textsuperscript{34} The technique involves exsanguinating the extremity to be anesthetized using passive venous drainage by raising the extremity, followed with active drainage by wrapping an Esmarch bandage around the extremity and subsequently inflating a pneumatic cuff/tourniquet. After this, local anesthetic can be injected through an intravenous catheter placed prior to the initiation of
exsanguination on the ipsilateral extremity. The volume of administration can vary based on the potency of the local anesthetic, although 30 to 50 mL of 0.5% lidocaine without epinephrine is typically used. This technique is a useful anesthetic option for short-duration (typically less than 1 hour) upper or lower extremity surgeries, such as carpal tunnel release, Dupuytren contracture release, or neuroma excision.

**Infiltration Anesthesia**

Infiltration anesthesia is the injection of local anesthetics directly into the area of terminal nerve endings. Its uses include subcutaneous infiltration prior to intravenous catheter placement or suturing, submucosal infiltration prior to laceration repairs or dental procedures, or wound infiltration to facilitate analgesia during a procedure. A “field” block refers to the common technique of infiltrative anesthesia in a circular or diamond pattern around the desired site. Pain reduction on injection can be achieved by warming the local anesthetic solution or “buffering” the solution. Buffering is performed by adding sodium bicarbonate in a local anesthetic-to-bicarbonate ratio of 9:1. This is typically performed with lidocaine as other local anesthetics such as bupivacaine have a tendency to precipitate when increasing the solution pH and is discussed in further detail in “pH Adjustment of Local Anesthetics” section. There appears to be a synergistic effect in pain reduction when warming is coupled with buffering the solution.

**Topical Anesthesia**

Topical anesthesia is direct application of local anesthetic solutions, ointments, gels, or sprays causing the superficial loss of sensation on skin, mucous membranes, or conjunctiva. These drugs reversibly block nerve conduction at the free nerve endings in the dermis or mucosa, producing anesthesia in a limited area. The main barrier for drug delivery is the stratum corneum. Topical anesthetics cross this layer via the intracellular spaces of cornified keratinocytes, openings of hair follicles and sweat glands, and/or a para- or transcellular route. Clinical applications include local analgesia on intact skin; minimizing discomfort prior to an injection; symptomatic relief of chronic pain; or numbing the outermost layers of the
cornea, conjunctiva, or oral tissues. As local anesthetics are poorly absorbed across intact skin, mixtures of local anesthetic agents (called eutectic mixture of local anesthetics, or EMLA) have been used to increase potency, as well as have lower melting points (so that local anesthetic molecules exist in their oil, rather than crystal structure at room temperature), which can promote easier absorption into tissues.40

**POTENCY, ONSET, AND DURATION**

Local anesthetics must cross the lipid membrane to bind to the intracellular portion of the sodium channel, and their anesthetic potency is related to their lipid solubility. In general, more potent local anesthetics are more lipid-soluble.

The onset of action is related to $pK_a$, dose, and concentration of the drug. As the drug $pK_a$ nears physiologic pH, there is a higher concentration of the drug as a non-ionized base, shortening the onset of action. The administration of a more concentrated local anesthetic typically shortens the onset of the effect and provides a larger degree of nerve blockade.

Degree of protein binding greatly influences duration of action. As local anesthetics target protein receptors, the greater the affinity of the drug to the protein, the longer it will remain bound to its receptor, thereby extending its duration of action (Table 82.1).

environment, and an increase in the base form of the local anesthetic. Commercial local anesthetic solutions are manufactured in acidic pH to maximize their chemical stability and water solubility, thereby increasing their shelf life. Several studies have indicated that adding sodium bicarbonate to local anesthetic solutions enhances onset, increases intensity, and prolongs local anesthetic block duration.\(^{41,42}\) This is termed buffering or alkalinization. This increases the proportion of non-ionized drug allowing a theoretical faster rate of diffusion across the cell membrane. Although these buffered solutions are typically less painful when injected,\(^{43}\) there is controversy regarding the clinical utility of this practice as clinical studies have produced inconsistent results.\(^{44}\) Care must be taken in increasing the pH of bupivacaine and etidocaine, as this may cause precipitation, leading to the injection of particulate along with the solution.\(^{45}\)

**VASOCONSTRICTOR EFFECT**

As discussed earlier, the addition of vasoconstrictors to local anesthetic solutions reduces vascular uptake, thereby indirectly increasing the concentration of the drug and increasing the duration of contact with the target nerve. This in turn increases the duration and quality (depth) of anesthetic block. It may also reduce the minimum concentration of anesthetic needed as well as reduce the peak plasma concentration of the drug.\(^{46}\) Epinephrine is the most commonly used vasoconstrictor, and its addition to neuraxial block also activates endogenous analgesic mechanisms via α-adrenergic receptors.\(^{47}\) Caution should be used with respect to injection site and local anesthetics containing epinephrine, as end organs (e.g., fingers, toes, penis, nose) may have such blood flow compromise that eventual tissue necrosis could occur. The addition of epinephrine has been shown to increase axonal degeneration following intrafascicular bupivacaine injection.\(^{48}\) However, there is debate about the role of epinephrine and direct peripheral nerve tissue injury, as this has not been proven and clinical observations suggest that this aspect of toxicity generally plays a minor role.\(^{49}\)

**MIXTURES OF LOCAL ANESTHETICS**
Local anesthetics are sometimes combined with the goal to achieve longer duration and/or quicker onset than with just one local anesthetic alone. However, there appears to be no clear advantage to mixing different anesthetic compounds as clinical trials have shown inconsistent results. Smith evaluated the combination of chloroprocaine with bupivacaine for brachial plexus block which yielded the desired faster onset and longer duration of action. However, a 1:1 mixture of 1% lidocaine with 0.25% bupivacaine for foot block showed no significant difference in mean onset times compared with either pure anesthetic alone. In the same study, the duration of action was longer with pure bupivacaine, but there was no difference between the pure lidocaine solution and the mixture. Interestingly, nerve blockade characteristics by local anesthetic mixtures appear to be affected by the pH value of the mixture. Using rat sciatic nerve preparation, Galindo and Witcher found that a 1:1 mixture of chloroprocaine 2% and bupivacaine 0.5% resulted in a nerve block with characteristics of a chloroprocaine block. However, changing the pH value of this mixture from 3.60 to 5.56 changed the characteristics to a block resembling bupivacaine.

**SPECIAL STATES: PREGNANCY**

Local anesthetics have enhanced potency in spinal and epidural anesthesia during pregnancy. In addition, the onset of blockade tends to be faster for spinal, epidural, and peripheral nerve blocks. The true mechanism is unknown but is likely due to anatomical changes from pregnancy as well as the effect of progesterone on the sensitivity of the nerve fibers themselves. As progesterone levels increase, there is an inverse correlation between the amount of local anesthetic needed and the clinical effect. For example, the dose of local anesthetic should be reduced by 30% regardless of the trimester of pregnancy. A biochemical explanation has been proposed involving pregnancy-induced hyperventilation with a resulting metabolic alkalosis causing local anesthetics to remain in ionized form for a longer time, therefore remaining longer in the area of injection and increasing the time to complete analgesia. In addition, anatomical changes may facilitate spread due to epidural venous distension secondary to increased blood volume during pregnancy, resulting in a decrease of
epidural and/or intrathecal volume. At term, increased intra-abdominal pressure, compression of the inferior vena cava and pelvic veins by a space-occupying effect, and increased epidural pressures have all been implicated in facilitated spread of local anesthetics in the epidural space.

Systemic Administration of Local Anesthetics for Pain Relief

So far, this chapter has discussed the primary mechanism of action of local anesthetics, that is, their action at neuronal voltage-gated sodium channels by local or topical application, infiltration, or regional anesthesia. Considerably less is known about the exact analgesic mechanism of action of local anesthetics such as lidocaine, when administered systemically.

Lidocaine is an U.S. Food and Drug Administration (FDA)-approved Class Ib antiarrhythmic, the intravenous administration of which has been used since the 1950s for the acute management of ventricular arrhythmias. Lidocaine exerts an antiarrhythmic effect by increasing the electrical stimulation threshold of the ventricle during diastole. However, irrespective of its antiarrhythmic effects, intravenously administered lidocaine can exert analgesic activity. This section summarizes the potential use of intravenous lidocaine in the acute and chronic pain settings and discusses the proposed analgesic mechanisms of action.

INTRAVENOUS LIDOCAINE FOR ACUTE POSTOPERATIVE PAIN

Intravenous infusion of lidocaine has been tested as a part of multimodal postoperative analgesic approach in several studies. A recent Cochrane systematic review and meta-analysis has identified 45 randomized controlled trials that have used lidocaine in the perioperative setting, mostly in abdominal surgeries. At early (1 to 4 hours after surgery), and intermediate (24 hours after surgery) time points, lidocaine treatment provided better pain relief and resulted in reduced time to first bowel movement, perhaps related to the reduction in postoperative opioid requirements. In general, the effects on early outcomes 4 hours after surgery (~50% of studies positive) were more substantial than at the 24-
hour postoperative time point (~20% of studies positive). About 48 hours after surgery, the outcomes of intravenous lidocaine and placebo were generally not different. For example, patients undergoing laparoscopic bariatric surgeries were randomized to intraoperative lidocaine (1.5 mg/kg bolus followed by a 2 mg/kg/hour infusion until the end of the surgical procedure) or corresponding placebo. The intervention resulted in less postoperative pain and nausea and reduced opioid consumption. In patients undergoing complex spine surgery, intravenous lidocaine (2 mg/kg/hour, maximum 200 mg per hour, starting at induction of anesthesia and continuing until discharge from the postanesthesia care unit) not only resulted in lower pain scores but also improved quality of life parameters. Other studies, for example, administering intravenous lidocaine in laparoscopic renal surgery, did not demonstrate any difference in lidocaine versus placebo on outcomes such as length of stay, readiness for discharge, opioid consumption, nausea, or return of bowel function. The study used a 1.5 mg/kg bolus dose at anesthesia induction, followed by 2 mg/kg/hour intraoperative infusion, and a 1.3 mg/kg/hour 24-hour infusion.

**INTRAVENOUS LIDOCAINE FOR CHRONIC NEUROPATHIC PAIN**

Several studies have been published supporting the effectiveness of intravenous lidocaine for the treatment of neuropathic pain. A systematic review and meta-analysis concluded that overall lidocaine was not only more effective than placebo in alleviating neuropathic pain but also resulted in more adverse effects. The adverse effects seen with intravenous lidocaine usually include dizziness, perioral numbness, drowsiness, blurred vision, and more rarely cardiac rhythm abnormalities and are generally dependent on lidocaine plasma concentration.

Various dosing regimens have been implemented, most of them in the range of 2 to 5 mg/kg, infused over 30 to 60 minutes. The duration of the analgesic effects is uncertain, with some studies assessing pain relief anywhere between 35 minutes and 6 hours, whereas other studies reporting pain reduction in individual patients for up to 1 to 2 weeks. However, it is unclear which patients are more likely
to have long-term effects with this approach, as daily or weekly treatments with intravenous infusions are not a particularly feasible approach for treating chronic pain.

Mexiletine, which is an orally bioavailable analog of lidocaine, has also been used for the management of chronic neuropathic pain. In a 2005 meta-analysis, the average reduction in pain intensity was demonstrated to be comparable to that of intravenous lidocaine. On the other hand, a recent meta-analysis of high-quality studies found that most (7 of 8) clinical trials with mexiletine in neuropathic pain have been negative, and considering the relatively high incidence of adverse effects, the guidelines currently recommend against the use of mexiletine for managing neuropathic pain.

The exact analgesic mechanism of action of systemic lidocaine is not completely understood. The primary discussed mechanism is the sodium channel–mediated activity affecting signal transduction and transmission in nociceptors, as discussed previously. However, it is unclear whether the main effect in neuropathic pain is peripheral (at the primary afferent fibers), or more centrally (spinal cord or brain). Data from Devor and colleagues suggest that the activity of lidocaine on silencing signal generation in the dorsal root ganglion (DRG) is the primary mechanism by which the drug alleviates pain in peripheral neuropathies. This has been demonstrated in a clinical study, where local intraforaminal application of low-concentration lidocaine (0.3%) at the DRG resulted in substantial alleviation of pain and phantom sensations in lower limb amputees.

In addition to sodium channel–mediated mechanisms, several additional mechanisms of lidocaine have been recently been proposed. Microglial hyperactivation at the spinal cord dorsal horn has been shown to contribute to sensitization of somatosensory neurons and accompany the development of thermal and mechanical hypersensitivity after peripheral nerve injury. It was shown both in vitro and in vivo that lidocaine may prevent microglial activation and injury, a mechanism that can possibly contribute to its systemic analgesic effect.

Glycine has been demonstrated as an important neurotransmitter involved in inhibition of sensitization in the spinal cord dorsal horn.
GluT1 glycine transporter, expressed on glial cells and a subset of sensory neurons, removes glycine from the synaptic cleft, resulting in disinhibition of sensory neurons.\textsuperscript{77} Lidocaine metabolites have been also shown to inhibit the GlyT1 transporter,\textsuperscript{78} thus potentially contributing to analgesia by a different mechanism.

\section*{Adverse Effects}

\subsection*{SYSTEMIC TOXICITY}

Local anesthetic systemic toxicity (LAST) is usually a result of an inadvertent intravascular injection of a local anesthetic solution during a regional anesthesia procedure.\textsuperscript{79} As stated earlier, the site of injection affects the risk of toxicity as different anatomic locations vary in systemic uptake of each drug. As discussed previously in this chapter, the route of administration of local anesthetics has a direct impact on systemic absorption. Intravenous injection is the highest, whereas subcutaneous is the lowest. However, one must be careful when injecting local anesthetic in multiple places as local anesthetic toxicity is essentially additive.\textsuperscript{80}

Local anesthetic toxicity can manifest as CNS excitation (agitation, confusion, seizure), CNS depression (drowsiness, apnea, coma), or nonspecific CNS signs (metallic taste, circumoral numbness, diplopia, tinnitus, and dizziness).\textsuperscript{81} In addition to CNS signs, cardiovascular manifestations can include hypertension (that may progress to hypotension), conduction block, bradycardia, ventricular arrhythmias, or asystole.

The key approach to managing LAST is to provide airway management, circulatory support, and diminution of systemic effects of the local anesthetic. If seizures occur, they should be rapidly controlled (preferably with benzodiazepines) to prevent injury to the patient and acidosis.

It is usually recommended to initiate lipid emulsion (20\%) therapy as soon as possible, which reduces the concentration of free local anesthetic in the systemic circulation. Studies have shown that this approach is effective in acting as a “lipid sink” to remove lipophilic local anesthetic molecules from the cardiac tissue into the lipid particles.\textsuperscript{82,83} Specific dosing guidelines are available via the American Society of Regional
Anesthesia and Pain Management (ASRA). A recent study comparing the effectiveness of removing bupivacaine from the systemic circulation by long-chain triglyceride (LCT, e.g., Intralipid) emulsion (Fig. 82.5) versus an emulsion of combined long- and medium-chain triglycerides (LCT/MCT) confirmed that LCT was more effective in clearing bupivacaine from the systemic circulation.

**FIGURE 82.5** Intralipid. A long-chain triglyceride emulsion used to clear local anesthetic from systemic circulation during local anesthetic systemic toxicity (LAST) syndrome.

**ALLERGIES**

Rare individuals are hypersensitive to local anesthetics. The hypersensitivity reactions may appear as allergic dermatitis or as an asthmatic attack. Hypersensitivity seems to occur more frequently with ester-type, rather than amide-type, local anesthetics because they are derivatives of PABA, a known allergen. There can also be cross-reactivity, primarily within the same chemical group. For example, a patient hypersensitive to procaine is more likely to develop hypersensitivity to
tetracaine than to ropivacaine. Local anesthetic preparations may contain a preservative such as methylparaben (which has a chemical structure similar to PABA), or local anesthetic–vasoconstrictor combinations may contain sulfites added for preventing vasoconstrictor oxidation. Sometimes, these additional compounds may be the cause of hypersensitivity rather than the local anesthetic itself.

**METHEMOGLOBINEMIA**

Local anesthetics such as prilocaine may cause methemoglobinemia. A popular topical local anesthetic—EMLA—contains prilocaine. The metabolism of prilocaine includes derivatives of o-toluidine, which can result in the conversion of hemoglobin (Hb) to methemoglobinemia when seen in doses greater than 10 mg/kg.

Typically, methemoglobin (metHb) concentration is lower than 1% of total Hb concentration. When 3% to 15% of Hb consist of metHb, a slight gray or pale discoloration of the skin may occur. As it increases to 15% to 20%, cyanosis occurs; concentrations >20% substantially increase the risk of headache, dyspnea, respiratory depression, unconsciousness, shock, and seizures. The treatment for methemoglobinemia includes hemodynamic support as well as methylene blue administration (1 to 2 mg/kg over 5 minutes) which reduces metHb to Hb.

**Prolonged-Duration Local Anesthetics**

Local anesthetics have been extremely effective in providing regional anesthesia and analgesia. One of the main limitations is their temporary effect, which is typically lost within a few hours. Techniques utilizing continuous infiltration of local anesthetics have been developed and are effectively used primarily for managing acute postoperative pain.\textsuperscript{86–88} One of the disadvantages of these techniques is the costs associated with catheter placement, maintenance, and the increased risks of infection associated with regional catheter use.

To address these limitations, various pharmaceutical formulations of long-acting local anesthetics have been developed. The formulations are primarily based on liposomes, which release the local anesthetic, for
example, bupivacaine, over a prolonged period of time after injection.\textsuperscript{89–91} One such formulation of bupivacaine (Exparel) is currently approved by the FDA for local infiltration in the perioperative setting.

The advantages of long-acting local anesthetics include primarily prolonged duration of action, reported to be up to 4 days following a single injection.\textsuperscript{92} Some of the disadvantages include stability issues with liposomal formulations\textsuperscript{93} and high costs associated with liposome manufacturing.\textsuperscript{94} The outcome results have been mixed, and a recent Cochrane review cites lack of evidence to support or refute the use of liposomal bupivacaine in peripheral nerve blocks for the management of postoperative pain.\textsuperscript{95} Furthermore, a Cochrane review evaluating surgical site infiltration of liposomal bupivacaine demonstrated superiority over placebo but not to bupivacaine hydrochloride in a comparison of postoperative pain scores.\textsuperscript{96} However, more work is currently being done to compare single-shot liposomal bupivacaine to continuous catheters.\textsuperscript{97}

Recently, novel approaches of simplifying the production process by developing proliposomal formulations have been introduced,\textsuperscript{98,99} and they appear to provide a similar long-acting anesthetic and analgesic effect. Future developments will hopefully enable the goal of prolonged analgesic effect with single-dose, low-cost local anesthetic solutions.

Aristotle, referencing Homer’s Iliad, suggested that “anger may be defined as an impulse, accompanied by pain, to a conspicuous revenge for a conspicuous slight,” emphasizing that “the angry man feels pain.” There was no suggestion of the separation of emotional distress from its physical consequences. Unlike many of his contemporaries, Aristotle undertook a reasoned approach to the understanding of anger but nevertheless placed it clearly in the context of emotional and physical pain. In his essay On Anger, Seneca urged his elder brother Novatus to eschew anger and agreed that he was “right to have a particular dread of this most hideous and frenzied of all emotions,” even likening the emotional experience to “a brief insanity.” It was a common thematic thread to philosophers and physicians in ancient Greece and Rome that anger tended to reveal itself as a form of madness and that attempts to control it reflected strength of character and spirit. Attempts to control anger in antiquity, however, were usually concerned with altering its often dramatic appearance, not with regulating its impact on the body. The possible harmful effects of managing the expression of anger were paid little consideration.

Scripture, too, characterizes anger as being at the heart of sin or separation from God and admonishes against the dangers of its excesses. In Hebrew, Christian, and Islamic religious writings, God is often portrayed as angry toward those who oppose his will, but the faithful are taught to suppress their angry impulses “for the anger of man does not work the righteousness of God” (James 1:20). The Qur’an teaches that “Allah loves those who restrain anger” (‘Al-‘Imran 3:134), whereas the
Psalms caution us to “be angry, but sin not” (Psalms 4:4). In other passages, we are encouraged not only to avoid expressions of anger but also to resist even the emotion itself. In the Gospel of Matthew, we find that “everyone who is angry with his brother shall be liable to judgment” (Matthew 5:22), whereas elsewhere in the Psalms, we are exhorted to “refrain from anger; and forsake wrath!” (Psalms 37:8), and in the Sunnah of Islam, the Prophet advises, again and again, “Do not become angry and furious” (Hadith-Sahih Al-Bukhari 8.137).

This deeply ingrained cultural awareness—that not only are angry actions dangerous, but the emotion of anger itself can be harmful—led to the inclusion of anger as one of the “seven deadly sins” in the religious West, a theme popularized and later woven into the fabric of Western cultures through literature, drama, and art, including in European cultures the enduring and influential classics of Dante’s Divine Comedy and Chaucer’s Canterbury Tales.

**Psychoanalytic Background**

One important difference between historical and more contemporary discussions of anger is that the former, although often concerned with the negative consequences of expressing anger, were seldom concerned with the possible harmful effects of its inhibition. Anger in psychoanalytic theory does not carry the metaphysical weight of sin, but its expression through hostility and aggressive impulses often lies at the core of conflict, competing drives, and the formation of pathologic symptoms, including pain. Although Freud was an atheist, his frequent excursions into the fields of religion, religious experience, and anthropology are testimony to his respect for the conscious and unconscious impact of culture on the individual; he was the first to emphasize the idea that the individual and culture are linked dynamically and that disturbances may occur in the developmental interaction between the two, leaving behind a disposition to future neuroses. He was also an astute observer of the phenomenon of pain from organic origins being maintained for intrapsychic reasons, long past the point of expectable physical healing and recovery.

Early in his work, Freud arrived at the idea that pain is a common
symptom of conversion and that, although there is usually an organic basis for the onset of pain, it can later be influenced and extended in duration and scope by a process through which mental conflict is displaced onto the body, resulting in the somatic expression of symptoms. Conversion, in this context, is closer to the contemporary term somatization, referring both to conversion and psychophysio logic disorders. The repression of negative affects, such as anger, resentment, and guilt, is transmuted into the expression of physical symptoms. The defensive process of somatization continues until relief from the intrapsychic burden of intolerable affect is no longer necessary or desomatization takes place through support—often psychotherapeutic—of the individual’s more mature defenses and coping strategies.

Freud’s later work was focused more on patients whose pain was less directly associated with an original organic insult and more configured with mood disturbance. In “Mourning and Melancholia,” he delineated the intrapsychic origins of depression as a process through which aggression, originally directed toward the lost object, is turned against the self8—somewhat oversimplified in the popular formula “anger turned inward.” According to this template, pain and mourning may be seen as affective responses to separation and as unconscious defenses against aggression.8–10 Freud’s successors related pain to aggression and hostility more directly, and the idea that the symptom of physical pain can be an unconscious defense against anger and aggression became a widely shared interpretation in psychoanalytic theory; however, as Merskey7 points out, the evidence has been largely anecdotal, with the relationship between anger and pain often being made more plausible by retrospective analysis.

Like Freud, Engel11 acknowledged that pain may originate with actual physical injury, but his study of the “pain-prone patient” gave the most enduring and widely influential psychoanalytic expression of chronic pain as a symbolic displacement of anger and aggression. He also suggested that patients are frequently unwilling or unable to acknowledge the hostility and aggressive impulses behind their pain, leaving them with the difficult task of attempting to adjust to symptoms that are borne of conflicts that they can neither recognize nor accept. The presence of chronic pain, then, may reflect underlying conflicts—in turn, giving rise to
intolerable affects, which, when repressed, are given dynamic expression through the body. Szasz,\textsuperscript{12} as well, held that repression of emotional distress is often the principal mechanism underlying chronic pain and suggested that, by focusing their attention on their pain, many patients are coping with their distress symbolically and through a more socially acceptable expression of their conflicts.

Burns\textsuperscript{13,14} summarizes the evidence supporting this view that repression of affect is the mechanism at the heart of chronic pain. First, he cites the phenomenon of the “conversion-V” profile on the Minnesota Multiphasic Personality Inventory (MMPI and MMPI-2), depicted by clinical elevations on scales 1 and 3, Hypochondriasis and Hysteria, with a comparatively lower score on scale 2, Depression. The resulting V configuration suggests the presence of somatic preoccupation and a hysterical constellation of defenses, deployed in the service of relieving depressed affect. Second, he further reports evidence of the link between the tendency to suppress anger and aggression and the symptomatic expression of chronic pain and disability. Finally, he points to the persistent observation that inhibition of emotion, particularly emotions arising in the context of traumatic events, has physiologic consequences.

Where the first of these three lines of evidence is concerned, the conversion-V configuration of scores on the MMPI and MMPI-2 has been studied extensively, and applied to chronic pain, for more than 40 years.\textsuperscript{15,16} The first scale of this “neurotic triad” of scores is Hypochondriasis. High scores on Hypochondriasis tend to reflect patterns of neurotic concern over physical health.\textsuperscript{17,18} The third scale, Hysteria, was developed specifically as an aid to measuring the predisposition to develop symptoms of conversion or somatization and reflects a high degree of reliance on hysterical defenses.\textsuperscript{17,18} When these two scales are clinically elevated and the second scale, Depression, which reflects both mood and neurovegetative aspects of depression, is comparatively lower, the indication of the resulting V configuration is that intolerable affect is being displaced onto somatic concerns, principally through the mechanism of repression.\textsuperscript{14–20} Much of this research occurred prior to 2008 and the publication of the revised and restructured form of the MMPI-2. In the MMPI-2-Restructured Form (MMPI-2-RF), the traditional clinical scales
are no longer available and have been replaced with restructured scales in an effort to address the shortcomings of the original instrument.\textsuperscript{21–25} However, the restructured scales function quite similarly to the original scales in their ability to identify somatization and malingering, albeit without the traditional conversion-V format.\textsuperscript{26}

Where the second line of evidence is concerned, Burns’s\textsuperscript{14} observations of trends in the scientific literature suggesting the link between chronic pain and the inhibition of anger have been replicated and amplified by numerous subsequent studies, although not always with psychoanalytic theory in the foreground.\textsuperscript{27–37} The suggestion is that patients with chronic pain are more likely to experience anger than those without pain and more likely also to inhibit their anger.\textsuperscript{31–34,36} Burns’s\textsuperscript{13} third source of evidence concerns the physiologic response, both conscious and unconscious, to efforts at inhibition. Suppression reflects the more obvious example of physiologic cost; however, repression also has a dynamic element that must be balanced in the psychosomatic economy of mind and body interrelationship.\textsuperscript{27–29,31–34,36} Within the framework of psychoanalytic theory, the physiologic exertion demanded by inhibition was often seen as related to the persistence of conversion as well as the intensity and duration of somatization.\textsuperscript{8,10,38–41}

The following case of a young woman referred for evaluation of her chronic abdominal pain will serve to illustrate the psychoanalytic perspective on inhibition and its relation to anger and pain.

Case 1: Ms. Ostrakova was a 20-year-old single library aide and part-time student at a nearby community college, who presented with a 2-year history of chronic abdominal pain. She had undergone two separate, complete gastroenterologic workups at two different medical centers, without any positive findings. She associated the beginning of her difficulties with a chicken sandwich, prepared by her elder sister, in which the meat was apparently undercooked. She explained that she had become quite ill within a short time, with fever, nausea, and vomiting. These symptoms resolved after a few days, but her abdominal pain persisted and became progressively more debilitating until, by the time she arrived in clinic, she had taken a leave of absence from both college and her job and was attempting
to manage her pain with a medication regimen that included short-acting opioids. Ms. Ostrakova was fit and slender and her demeanor, although somewhat subdued, was affable and cooperative. She had no psychiatric history or history of substance abuse, and her medical history was notable only for robust health prior to the onset of her abdominal pain. Her psychosocial history, however, was remarkable for early childhood trauma and abuse and a childhood household of domestic turmoil and violence. She described a history of fighting in school and finally being remanded at age 17 years by the juvenile court system to a residential treatment facility for “anger management” in another state. When asked about the therapeutic aspect of her 1-year treatment program, she replied, “They just taught us how to keep our anger inside, not to let it out, so we wouldn’t always get into fights. We had to avoid fighting to prove we had learned how to manage our anger.”

As the interview progressed, it became clear that the patient had learned much about recognizing anger when she experienced it, and suppressing it in the moment, but little about the potential cost to herself and her body. A psychometric assessment reflected little endorsement of depressive symptoms on the Beck Depression Inventory or the MMPI-2 but clinically elevated scores on Hypochondriasis and Hysteria, and her history reflected many of the psychosocial factors depicted by Engel as disposing toward “pain proneness.” The latter included parents who were abusive toward each other and toward their children, a father who was alcoholic and emotionally and physically domineering, and a mother who was often debilitated by pain of uncertain etiology.11,40,42

In her treatment program, the patient appeared to have gotten the message, right or wrong, that, if she showed no outward signs of anger, she would be considered successfully rehabilitated. The experience of anger, therefore, became an obstacle between her court-mandated residential treatment and her successful return home. Over time, the experience of anger was transformed by a developing awareness of intolerable affect—displaced onto her body in the more acceptable symptomatic expression of physical pain. When Ms. Ostrakova’s elder sister provided the organic insult of an undercooked chicken sandwich,
resulting in gastroenterologic distress, the patient, who might previously have responded with anger leading to physical confrontation, began instead to experience the pain associated with simple repression of her affect—unconsciously “keeping her anger inside.” This is the classic picture of somatization, depicted in psychoanalytic theory, which continues to be influential in our assessment of patients with chronic pain.

Current Research in Anger and Its Relation to Pain

The role of anger in exacerbating pain and in disposing toward the development of chronic pain is, in some respects, similar to that of other negative emotions or distressed affective states, such as anxiety and depression. According to the prevailing gate control and neuromatrix theories of pain, negative emotions can increase the intensity and duration of pain by altering or dysregulating the descending and central pain modulation systems. Precisely how this takes place remains an open question for further research, but an integrated neurobiologic model is emerging with implications for treatment of both chronic pain and disorders of anger.

PHYSIOLOGIC MECHANISMS IN ANGER AND PAIN RESEARCH

Merskey noted that pain can make individuals aggressive for purely biologic reasons, associated with the activation of the fight-or-flight mechanisms and high autonomic arousal. He added that we may not need to look much further in our attempts to explain why patients with chronic pain become angry. Whereas angry responses can be adaptive, especially when they prompt the search for constructive solutions to problems within the medical setting, chronically angry reactions of the sort observed in some patients with chronic pain are often seen as maladaptive and disruptive—indicative not of discrete situations of fight or flight but of sustained and simmering autonomic arousal. Parsing the relationship here has proven challenging because of two related questions: Does chronic pain induce sustained sympathetic arousal and therefore lead to continual expressions of anger? Does the situation of chronic pain arise
more easily among individuals who are disposed to express anger and aggression?

Robinson and Riley\textsuperscript{43} outlined four models or mechanisms through which the relationship between pain and negative emotion has been usefully described, both from a clinical perspective and as a template for empirical design:

- Negative emotion increases sensitivity.
- Pain is caused by negative emotion.
- Negative affect occurs as a result of chronic pain.
- Pain and negative emotion are concomitant.

The first of these is simply the observation that negative emotion increases somatic sensitivity. In other words, negative emotions increase awareness and recognition of pain. Evidence in support of this mechanism comes from studies in which induced changes in mood have been correlated with increased reports of pain and decreased tolerance for experimentally induced pain, as well as in the clinical observation that depressed patients tend to interpret sensations negatively, experiencing them more often as painful.\textsuperscript{43}

The second mechanism—that pain is caused by negative emotion—is most closely allied with the psychoanalytic view of pain as a symptom of underlying or repressed conflict, but inhibition of negative emotion and affect can also result in elevations of autonomic and central nervous system activity, raising serum cortisol levels and leading to neurovegetative dysfunction and increased pain. Cacioppo et al.’s\textsuperscript{53} meta-analytic study of the physiologic correlates of negative emotions concluded that the experience of anger, whether expressed or suppressed, tends to be accompanied by increased diastolic blood pressure, skin conductance, stroke volume, cardiac output, peripheral resistance, finger pulse, and heart rate, all suggesting a high sympathetic response. Considering the impact of sustained autonomic arousal, negative emotions, not surprisingly, may also be seen as causal in the expression of stress-related illness and pain in which somatic reactivity can lead to musculoskeletal disorder.\textsuperscript{34,36,43,54–57} Robinson and Riley’s third mechanism echoes Merskey’s suggestion that negative affect may be seen simply as a reaction to the situation of chronic pain, arising within a stress-
diathesis framework, whereas their fourth proposed mechanism posits that pain and negative emotion arise concomitantly from shared neurobiologic pathways. 

Taken together, these four mechanisms are broadly consistent with the gate control and neuromatrix theories of pain; however, the last—that anger, anxiety, depression, and pain share neurobiologic pathways—suggests a physiologic context in which negative emotions can alter the descending and central pain modulation processes. Serotonin, norepinephrine, and dopamine all play roles in the modulation of pain as well as in the development of negative emotions. That pain and depression both respond to certain antidepressant medications has long been cited as evidence of common neurobiologic pathways. Relative cortisol levels and dopaminergic transfer and regulation have also been implicated in the relationship between anger and pain, but the key neurotransmitter implicated in the modulation of anger is dopamine, with the focus of activity in the nucleus accumbens.

From an evolutionary perspective, the emotion of anger is clearly primitive and derived from ancient limbic regions of the brain, as opposed to the cortex and prefrontal cortex, which assume a more modulatory role in its experience and expression. The regions of primary activity for anger—along with its conceptual counterparts, appetitive impulsivity, drive, motivation, pleasure, and psychoticism—appear to be associated with the core regions of temperament: the amygdala and nucleus accumbens or ventral striatum as well as the cingulate cortex. Lara and Akiskal suggest that anger is influenced by dopaminergic transfer and regulation in these regions, with high anger being associated with either enhanced postsynaptic response to dopamine or increased synaptic dopamine concentration or both. Wood outlines evidence to suggest that the inhibition of tonic pain is mediated by activation of mesolimbic dopamine neurons, arising from the ventral tegmental area and projecting to the nucleus accumbens.

Ironically, anger may be associated both with an increase or a decrease in the experience of pain. Acute stress may activate mechanisms of pain suppression through the release of endogenous opioids and substance P within the ventral tegmental area, but prolonged exposure to
stress—as in the case of sustained anger or proneness to anger—tends to result in a reduction of dopaminergic output in the nucleus accumbens, potentiating the subsequent development of hyperalgesia. The outcome appears to be that inhibition of pain may occur initially when a painful stimulus is first perceived but that, on further exposure and evaluation, sensitization may occur. The experience of anger appears to undergo change over time, leading to associations with both traits and temperament—factors related to the thematic and serial evaluation of stimuli—an observation that has led to the study of anger-related features of both mood and personality disorders. The influence of anger on the changes involved in mood states suggests a dynamic relationship associated with the tonic and phasic balance of dopaminergic activity. In this case, the inhibition of pain may be principally related to physiologic changes occurring in the initial or situational experience of anger, such as changes in cardiovascular reactivity and autonomic arousal that have been shown to modulate the experience of pain. Pain sensitization, on the other hand, appears more associated with the ability to regulate anger and the emotional evaluation of the experience—individual differences that influence dopaminergic output. This, in turn, suggests that the experience of anger, relative to personality and temperament, as well as how we manage anger, are important variables in the modulation of pain.

Other physiologic mechanisms under study include the effects of anger on muscle reactivity, the immune system, and endogenous opioid dysfunction. Consideration of the last of these will be deferred to discussion of the related work on anger management, later in this chapter. Where the first is concerned, studies on muscle reactivity have suggested that anger may increase musculoskeletal tension in specific sites that contribute to pain. The experience of anger, whether inhibited or expressed, and the trait of hostility have been associated with increased likelihood of reporting high levels of tension near the site of pain and injury. A further mechanism through which anger may influence pain is distress-related immune dysregulation. Although brief, situational stressors involving activation of the fight-or-flight mechanisms have been shown to result in potentially beneficial changes to the immune system,
exposure to prolonged stress and negative emotion, such as sustained anger and hostility, have been associated with deleterious effects in a broad range of health concerns, immunologic suppression, and generalized inflammatory processes associated with chronic pain.\textsuperscript{85–91} Because immunologic changes must be observed longitudinally, this work has tended to emphasize the impact of sustained anger and hostility associated with enduring personality traits and temperament.\textsuperscript{87,88}

**PSYCHOLOGICAL CONSTRUCTS IN ANGER AND PAIN RESEARCH**

The etymology of “anger” is not the same for every modern language, but it appears to have come into modern English usage via Old Norse, angra, “to grieve, vex,” later angr, “distress, grief,” Old English, enge, “narrow, painful,” influenced by the Proto-Indo-European root, angh-, “painfully constricted,” and finally into Middle English, where its associations with pain endured.\textsuperscript{92} The relative importance of the term in ordinary discourse can be illustrated through the frequency of its use: Of the roughly 700,000 words in common English usage, “anger” is ranked 2,382nd in frequency of appearance in spoken and written communication.\textsuperscript{93} Focusing on the logic underpinning the ordinary language use of the word anger, Smedslund offered a contemporary definition of anger that depicts the psycholinguistic core of the construct rather than emphasizing the characteristic features of its expression: “a feeling involving a belief that a person one cares for has, intentionally or through neglect, been treated without respect, and a want to have that respect reestablished.”\textsuperscript{54,55,94} In Smedslund’s conceptual framework, the “person one cares for,” particularly in the context of pain, is ordinarily the self.

Fernandez emphasizes the dimensions of action tendency and cognitive appraisal in the study of the relationship between anger and pain.\textsuperscript{54,55,95} The former concerns the behavioral tendencies associated with anger, including aggression and impulses directed toward the restoration of control, the removal of obstacles, and the seeking of redress. This becomes an important consideration in the context of whether action is expressed or suppressed and, if expressed, how adaptively. The latter suggests a framework within which the individual seeks to explain otherwise
ambiguous interior experiences or changes in arousal. Both of these
dimensions are anticipated by and subsumed under Smedslund’s ordinary
language definition of anger, and both have proven critical to the study of
the relationship between anger and pain.

The cognitive appraisal theory of emotion—perhaps most elegantly and
economically portrayed in Lazarus’s\(^96\) cognitive-motivational-relational
theory—suggests that the experience of an emotion, like anger, is the joint
effect of (1) the event of physiologic arousal in response to incoming
stimuli and (2) the cognitive appraisal of its meaning with respect to the
particular setting in which the event occurs (Table 83.1). Cognitive
appraisal, then, is the process through which physiologic states, such as
arousal, are interpreted in light of the perceived situation. This becomes
critical in the management of anger and, by extension, to the
psychotherapeutic treatment of patients with chronic pain, because how
events are appraised tends to influence selection and deployment of coping
strategies.\(^{97–100}\) Lazarus\(^96\) further distinguished between primary and
secondary appraisals, with the former referring to the interpretation of how
a particular situation affects considerations of well-being and the latter,
referring to considerations of how to cope with the situation.\(^96\) Secondary
appraisals, he suggests, can actually shape the experience of an emotion
through the selection of a particular coping strategy.\(^96,101,102\)

gratitude (reduced pain); if anger is experienced, it is likely directed toward the impatient motorist or toward oneself for being careless.

NOTE: The same or similar events and physiologic responses may be interpreted or appraised differently, depending on the setting or circumstances, resulting in different emotional responses.

ANGRINESS MANAGEMENT STYLE

Much of the research on anger and its relationship to pain has highlighted the related constructs of hostility, aggression, and anger management style. Anger is the term denoting the emotion, characterized by physiologic arousal and accompanying conscious and unconscious impulses toward aggression. Aggression typically refers to the behavioral expression of the emotion, ordinarily through acts of vindication, punishment, and destruction, directed toward others or objects. Freud’s focus was ultimately less on anger than on aggression, as one of the two primary instinctual drives. In psychoanalytic theory, aggression in its stimulation of defensive functions and coping strategies plays an important role in the development of personality. This distinction between anger and aggression suggests that whereas anger is usually conceived as a transient state, aggression is a more durable and endogenously derived motivational force. The word anger can be used in this manner—to denote a more dispositional quality—but, frequently, the term hostility is used in reference to the tendency to make consistently negative cognitive appraisals regarding the motivations of others.

Conceptual links with aggression and hostility further raise the
distinction between state anger and trait anger, a critical consideration in researching the influence of anger on chronic pain. A good starting point for the distinction is offered by Spielberger, who characterizes state anger as a transitory emotional episode, whereas trait anger is described as a more stable pattern of personality attributes, similar to hostility. One way of representing this is that trait anger reflects a relatively stable dimension of proneness to anger in which individual differences are reflected in the frequency, intensity, and duration with which state anger is experienced over time. This, in turn, suggests that characteristic defensive patterns and reliance on particular coping strategies tend to result in what may be described as more enduring styles of anger management.

Anger management style is a term denoting the relative tendencies of individuals either (1) to suppress or internalize their anger or (2) to express or externalize their anger. The construct of anger management style is often represented in research as anger-in, anger-out, and anger-control. Anger-in characterizes the tendency to inhibit the expression of angry thoughts and feelings, whereas anger-out describes the tendency to express angry thoughts and feelings directly, whether verbally, physically, or both. High trait anger, according to Deffenbacher, is more associated with the tendency to express anger negatively, less constructively, and with less control than with the tendency to suppress anger; he further notes that there is a stronger connection between the suppressed anger and anxiety than between suppressed anger and forms of expressed anger. Anger-control refers to an individual’s perceived control over the experience and expression of anger and is usually interpreted as positive, unless too much control approaches no expression at all.

Although the International Association for the Study of Pain (IASP) appears to separate the sensory and emotional dimensions of the experience of pain, when it defines pain as an “unpleasant sensory and emotional experience associated with actual or potential tissue damage,” several studies point to the simultaneous processing of pain in the somatosensory cortex and emotion-related cerebral systems. Mollet and Harrison summarize the case for the application of emotional theories to the study of pain and propose that emotion may influence the processing of pain in several ways:
• Negative emotion increases pain intensity and decreases threshold and tolerance.
• Positive emotion decreases pain intensity and increases threshold and tolerance.
• Pain may produce negative emotion or increase the memory for negative emotion.

This template emphasizes the relationship between anger and pain and strongly implicates anger in the development and maintenance of chronic pain. It further highlights the role of anger management style as a critical influence in how pain is experienced.

Anger-In

In his study of emotion regulation, Gross\textsuperscript{114} utilized a process model to illustrate two features of trait anger-in: First that, while the mechanism of suppression tends to decrease negative emotional expression, it also decreases positive emotional expression and second that although suppression has little impact on the experience of negative emotion, it tends to decrease the experience of positive emotion. In his analysis of emotion regulation, he concluded that, as a means of regulating negative emotion, cognitive appraisal is more adaptive than suppression and tends to decrease both the experience and expression of negative emotion while increasing the experience and expression of positive emotion. He added that there may be times when cognitive appraisal cannot adequately be mobilized, and suppression may be, in the moment, the best available means of regulating negative emotion, but such instances are more likely to involve evaluation in the moment of state anger. The overarching conclusion is that suppression as a trait mechanism for modulating intolerable affect is problematic.

Engel noted that inhibition of anger, whether through repression or suppression, is a common attribute among pain-prone patients, but psychoanalytic theory offered little insight into the causal relationship or cognitive, emotional, and physiologic mechanisms through which inhibited anger can affect pain.\textsuperscript{11,31,32} More recent studies of anger-in as a form of emotional regulation confirm that suppression is a prevalent style of management among patients with chronic pain but also point to
applications of Wegner’s ironic process theory as a means of delineating the mechanisms involved.\textsuperscript{31,32,115–117} According to this template, suppression of negative emotion requires the coordination of two distinct cognitive processes: The first represents a resource-dependent operating process that serves to eliminate awareness of unwanted thoughts and feelings, whereas the second represents a monitoring process that remains vigilant to the awareness of unwanted thoughts and feelings to be suppressed (Table 83.2). Under ordinary conditions, the monitor works to identify material to be suppressed, whereas the operating process performs the suppression; however, when under stress or high demand, the operating process may not have sufficient resources to perform its task. Stress, in this context, may be reflected in both cognitive and somatic symptomatology, with cognitive dissonance thwarting both suppression and cognitive appraisal and the corresponding demands on the body being expressed through cardiovascular and musculoskeletal symptoms. Burns et al.\textsuperscript{83} reported that patients with chronic low back pain who reflect an anger-in style of management are more likely than other groups to experience high levels of muscle tension at the site of pain and injury when experiencing anger and to show relatively high systolic and diastolic blood pressure.

</tr>
</tbody>
</table>
NOTE: When the operating processes are under high stress, the monitoring processes, which ordinarily serve to identify thoughts to be suppressed, can become the source of continual unwanted reminders of events leading to overwhelming anger.

The irony implicit in Wegner’s theory of mental processing is that, under such conditions, the monitor may be serving to bring unwanted thoughts and feelings into conscious awareness without sufficient resources for suppression to take place. The result is that unsuccessful efforts to suppress anger can paradoxically lead to heightened awareness of the cognitive and emotional experience of anger, thereby increasing sensitivity to pain and influencing subsequent perceptions and interpretations of pain according to the unsuccessfully suppressed, unwanted cognitions and intolerable affect. Carson et al. conducted studies on constructs related to anger-in, including the construct of ambivalence of emotional expression (AEE) and the construct of forgiveness. Theirs and related findings suggest that those who are ambivalent about expressing their emotions and those who cannot forgive others for perceived wrongs and insults may experience higher levels of low back pain and psychological distress, mediated by higher levels of anger. Where treatment is concerned, it is possible that psychotherapeutic interventions designed to resolve patients’ ambivalence toward expressing their emotions and to encourage the development of cognitive reappraisals supportive of conciliation and forgiveness may facilitate the management of pain.

**Anger-Out**

Like anger-in, the emotional regulatory strategy of anger-out—managing anger directly with physical or verbal expression—has been shown repeatedly to be associated with increased responsiveness to pain and higher levels of chronic pain intensity and disability. It must be noted, here, that anger-out, in this context, usually refers to the trait of immediately responding to the emotional experience of anger with expression of anger—not the same as the considered, constructive expression of anger signifying the mobilization of more mature defensive processes. Hostility and tendencies toward aggression are hallmarks of trait anger-out. Bruehl et al. have done the most complete review of anger-
out studies to date and conclude that elevated trait anger-out is associated with heightened chronic pain intensity and low levels of improvement in individuals suffering from a broad range of medical conditions associated with chronic pain.\textsuperscript{33,34,36,121} They examine a number of proposed mechanisms underlying the effects of trait anger-out on acute experimental, acute clinical, and chronic pain, but the emphasis here will be on chronic pain.

The authors submit that there is little evidence for the influence of either neuroticism or the psychoanalytic construct of repression.\textsuperscript{121} The former—a willingness to overendorse a broad spectrum of symptoms—has sometimes led to spurious correlations between elevated pain and indicators of an anger-out style of management, but the available evidence tends to suggest that the relationship of anger-out to pain is independent of the broader palette of negative affect, including depression and anxiety. Where the latter is concerned, one might expect that trait anger-out would be negatively associated with the classic psychoanalytic constructs of conversion and somatization and therefore consistently lead to an amelioration of pain. As previously noted, however, the hostility and aggression embodied in trait anger-out do not promote the mature and adaptive expressions of anger reflecting successful management that might lead to reduced pain intensity and sensitivity. Other behavioral mechanisms have been considered, including the observation that individuals whose scores are elevated on measures of anger-out show decreased cardiovascular reactivity when encouraged to express their anger versus suppress it, and among a high anger-out group of women, verbal expression of anger during provocation was associated with improved blood pressure recovery, following the stressful event. Although there are some indications that these findings are related to improvement in situations involving acute pain, Bruehl et al.\textsuperscript{121} point out that implications for the effect of behavioral anger expression on chronic pain have yet to be fully delineated.

Although not specifically applied to the variable of management style, Greenwood et al.\textsuperscript{47} suggest several behavioral mechanisms that may influence the relationship between anger and pain. First, anger may foster the development of pain behaviors associated with the negative
consequences of expressing anger. The high correlation between hostility and absenteeism from work, for example, suggests that anger may contribute to the maintenance of pain-related illness. Second, the effects of anger on marital functioning may lead to spousal responses that exacerbate and maintain pain and pain behaviors. Finally, anger can impact pain by contributing to conflicts and mistrust in relationships between patients and their medical providers. Studies by Burns et al. concluded that high scorers on anger-out and hostility were correlated with patients’ reports of weaker alliances with their physicians and with interference in their abilities to improve with pain management.\textsuperscript{36,123,124}

Proposed mechanisms underlying the relationship of anger-out and pain have also included a number of physiologically based models.\textsuperscript{121} Anger-out has been associated with greater visceral adipose tissue in some studies, a potential source of impact on lower spine mechanics. Like anger-in, anger-out has also been found to be correlated with increases in stress-induced muscle tension among patients with low back pain. Neither of these models, however, can account for the effects of anger-out on acute pain responsiveness and sensitivity. Genetic mechanisms have been suggested as well, but Bruehl et al.\textsuperscript{121} assert that none has been adequately investigated, to date, despite promising connections with genetic factors related to personality traits, emotional reactivity, and endogenous opioid system functioning. A related mechanism, referred to as “trait X,” suggests that high anger-out individuals express their anger because they believe it is beneficial and it feels better to discharge it than the alternative. The idea is that behaviorally expressing anger for high anger-out individuals actually reduces arousal and restores emotional and physiologic homeostasis more efficiently. The authors comment that trait X state interactions may well reflect some degree of functional regulatory benefit, especially in the immediate aftermath of expressing anger, but the more enduring trait anger dimension has yet to be sufficiently investigated.

**Opioid Deficit Hypothesis and the Role of Endogenous Opioid Functioning**

Bruehl, in collaboration with others, has also called attention to the role of endogenous opioid dysfunction in the relationship between anger-out and
The essential premise is that mechanisms associated with anger-out may impose an excessive burden or strain on the body’s ability to produce endogenous opioids, inhibiting the natural management of chronic pain. Bruehl et al. conducted studies in which subjects with low scores in anger-out reported increased acute pain intensity following opioid blockade with naloxone versus following placebo blockade, whereas subjects high in anger-out reported smaller naloxone blockade effects. The implication is that there is less effective endogenous opioid response among those who score high in anger-out, with opioid dysfunction partially mediating the positive correlation between anger-out and chronic pain intensity.

Burns and Bruehl further established that the use of exogenous opioid analgesics remediates opioid deficits such that anger-out is related to chronic pain severity only among patients not taking opioid medications. The results suggest that regular use of opioid medications among those who are high in anger expression may compensate for overtaxed endogenous opioid mechanisms. In another, related study, Bruehl et al. investigated whether impaired central opioid inhibitory functioning, assessed via changes in plasma β-endorphin release, could explain exaggerated pain responsiveness and anger expression in high anger-out subjects. As with the opioid blockade studies and the study of the mediating effects of exogenous opioids, the results of this pain-induced endogenous opioid release study support the opioid deficit hypothesis and demonstrate that greater trait anger-out is associated with higher perceived pain intensity and less endogenous opioid release.

Taken together, these studies provide strong evidence for the idea that patients whose anger management style involves physical and verbal expression show comparative deficits in opioid analgesia because of endogenous opioid dysfunction. Bruehl et al. have taken this one step further with the opioid triggering hypothesis, suggesting that, for individuals high in anger-out, the dramatic expression of anger serves to activate endogenous opioid response that would otherwise remain quiescent when anger associated with pain and stress is either not expressed or only moderately expressed. Those who are low in anger-out appear to elicit a sufficient endogenous opioid response without
expressing their anger, but the expression of anger among high anger-out individuals may actually represent an adaptive mechanism designed to trigger the release of endogenous opioids. Patients high in anger-out may therefore have a higher threshold for the activation of endogenous opioid response, with the increased arousal of dramatic anger expression serving as a triggering mechanism.

**Measurement of Anger**

Anger, both state and trait, as well as the related constructs of aggression, hostility, and anger management style have been assessed for research purposes with a broad spectrum of tools, ranging from projective tests, like the Rorschach and thematic apperception test (TAT), to physiologic measures principally associated with autonomic arousal. Self-report questionnaires and inventories tend to predominate in anger-related research, however, both for their ease of administration and for their more readily documented validity and reliability. Several of the self-report instruments measuring anger that are more widely utilized or particularly suited to pain research are reviewed in the following discussion. Extensive commentary on each, as well as critical reviews of many instruments designed to measure some aspect of anger, are available in Tests in Print VII and the The Seventeenth Mental Measurements Yearbook, 17th ed. The instruments discussed in the following text are summarized in **Table 83.3**.

**STATE-TRAIT ANGER EXPRESSION INVENTORY-2**

The State-Trait Anger Expression Inventory-2 (STAXI-2) was developed by Spielberger and is widely regarded as the most psychometrically sound and comprehensive tool in the assessment of anger and hostility.\(^{55,105,135}\) It represents the integration and culmination of several precursors developed by Spielberger, including the State-Trait Anger Scale (STAS), the Anger Expression Scale (AES), and the first version of the STAXI-2. The instrument consists of six scales: Trait Anger, Anger Expression-Out,
Anger Expression-In, Anger Control-Out, Anger Control-In, and State Anger as well as five subscales and an Anger Expression Index. It can be administered in 5 to 10 minutes and is scored by hand, making it practical for clinical applications as well as research. The STAXI-2 purports to measure tendencies toward angry action, as well as more dispositional or trait-based hostility, along with tendencies to suppress or express the experience of anger. This makes the inventory well suited for research in anger management styles and clinically well adapted to assess the needs of patients for psychotherapeutic applications of anger management. Normative data are published for adolescents, adults, and psychiatric patients, and evidence for high reliability and validity are detailed in the testing manual.

THE TARGETS AND REASONS FOR ANGER IN PAIN SUFFERERS

Although the STAXI-2 is applied to the study of pain more frequently than other inventories of anger, it was not designed for use with chronic pain patients and does not assess specifically pain-related dimensions of anger. Fernandez\(^{55}\) developed a structured inventory, the Targets and Reasons for Anger in Pain Sufferers (TRAPS), later adapted for self-administration by Okifuji et al.,\(^{136}\) that allows chronic pain patients to rate their levels of anger on a Likert-type scale toward a variety of common objects or targets of their anger: whole world, self, God/destiny, significant other, employer, insurance company, attorney or legal system, health care providers, and person who caused the accident. Patients may also be instructed to identify and rank their reasons for being angry toward these targets. The results, especially when the TRAPS is administered in a structured interview, allow clinicians and patients to explore together the relative importance of specific targets of and reasons for anger, suggesting interventions and strategies for reducing the impact of anger on pain. Normative data and information on reliability and validity are not yet available.

MULTIDIMENSIONAL ANGER INVENTORY

Siegel developed the Multidimensional Anger Inventory (MAI) as a brief instrument designed to assess responses to anger-eliciting situations in an
attempt to increase sensitivity to the multidimensional nature of the construct.\textsuperscript{55} Factor analytic solutions arrived at the following dimensions or factors: anger arousal, hostile outlook, range of anger-eliciting situations, and anger expression, the last being divided into anger-in and anger-out. Although it was developed specifically to assess anger in cardiovascular patients, factor analytic replications in more heterogeneous populations suggest its utility on a broader scope, especially with other health-related groups. Reliability and scale validity information are available through the author’s report.\textsuperscript{137}

**NOVACO ANGER SCALE AND PROVOCATION INVENTORY**

This inventory, developed by Novaco,\textsuperscript{138} consists of two principal sections: The Novaco Anger Scale (NAS) purports to measure the general inclination toward reacting with anger, whereas the Provocation Inventory (PI) asks patients to respond to descriptions of specific situations that tend to elicit anger. The NAS contains 60 items divided equally over three subscales: (1) a cognitive subscale, measuring anger justification, rumination, hostile attitude, and suspicion; (2) an arousal subscale, measuring anger intensity, duration, somatic tension, and irritability; and (3) a behavior subscale, measuring impulsive reaction, verbal aggression, physical confrontation, and direct expression. The PI contains 25 items, each describing a situation that tends to elicit anger, with subjects being instructed to rate their degree of anger or annoyance on a 5-point Likert-type scale. The situations include scenarios such as “getting your car stuck in the mud or sand” and “being joked about or teased.” The items are grouped into five subscales summarizing the theme of the provocation: disrespectful treatment, unfairness, frustration, annoying traits of others, and irritations. The Novaco Anger Scale and Provocation Inventory (NAS-PI) attempts to characterize how an individual experiences anger and what sorts of situations provoke it. The instrument has been widely used to evaluate the role of anger in diverse environments, from community based to correctional settings, and may prove useful in evaluating the role of anger in health care settings. Normative data, reliability, and validity are well documented in the testing manual.\textsuperscript{138}
ANGER DISORDERS SCALE
The Anger Disorders Scale (ADS) is a self-report instrument consisting of 70 items distributed over five categories characterizing human emotion: provocations, cognitions, arousal, motives, and behaviors. A short form consisting of only 18 items may be used as a screening tool to obtain scores on three factors: reactivity/expressions, anger-in, and vengeance. The ADS is designed to assess and identify dimensions of anger that are associated with dysfunction and impairment in clinical populations. It yields information concerning the duration that an individual stays angry, the breadth of stimuli that may serve as triggers for an individual’s anger, and the frequency of angry episodes. Information on reliability and concurrent and discriminative validity are available in the testing manual.

MINNESOTA MULTIPHASIC PERSONALITY INVENTORY-2-RESTRUCTURED FORM
The MMPI-2-RF is a 338-item, true–false, self-report instrument designed to assess a broad range of psychopathology and personality traits and characteristics. It is arguably the best known and most widely used psychometric assessment tool available, and it and its predecessors, the MMPI and MMPI-2, have been applied to the investigation of pain in hundreds of empirical studies. Several MMPI-2-RF scales are relevant to the study of anger and its relationship to pain, with all scales relating to anger being well validated and designed to reflect some aspect of trait anger (e.g., anger proneness [ANP] and aggressiveness, revised [AGGR-r] scales).

Psychotherapeutic Management
When anger and problems with the management of anger are aspects of a patient’s presentation with chronic pain, ignoring the indication for psychotherapeutic intervention may well jeopardize any chance of successfully treating or managing his or her pain. As we have seen, trait anger and certain styles of anger management are fertile ground for the development of chronic pain, but anger may emerge as a critical factor in response to chronic pain as well. The following case of a middle-aged
Case 2: Mr. Alvarez was a 45-year-old single man, referred to the Pain Center by his new primary care physician and his new neurologist for the treatment of long-standing chronic daily headaches with tension-type and migrainous features. He arrived for his initial evaluation more than an hour late but loudly insisted upon being seen, saying that the traffic was not his fault and that he had a severe headache requiring immediate attention. He was irritable in his exchanges with support staff and paced back and forth in the waiting area, to the discomfiture and consternation of other patients. When he was finally escorted to an examination room, he informed the nurse that he hoped he did not have to wait long to see the physician. Once his pain physician joined him for the evaluation, he seemed deferential and cooperative, as he related his medical history and the history of his headaches. His physician noted, however, that he expressed considerable anger toward previous providers, toward his wife and children, and toward his employer, none of whom, according to the patient, responded with adequate sympathy to his distress or provided any respite from his pain. As his physician rose to conclude the interview, the patient looked at the prescriptions he had been given as a first line of intervention and, tossing them onto the desk, said, “I didn’t come here for more pills. I told you, I came for Botox injections, and I’m not leaving here without them.” When it was explained that authorization from his insurance carrier had to be obtained and that he might well respond favorably to a less invasive procedure, the patient’s anger became increasingly confrontational. When it became clear that he was not going to get what he wished, he vociferously decried “the incompetence of doctors” and stormed from the examining room, upsetting a chair and waste bin in the process.

In the succeeding days, as the patient’s stricken pain physician consulted with Mr. Alvarez’s referring providers and assembled his medical records, several points became clear. This was not the patient’s only reported angry exchange in health care settings and, indeed, it appeared that Mr. Alvarez frequently changed primary care physicians and
specialists, whether by his own decision or mutual agreement.

It was a surprise when Mr. Alvarez made and kept a follow-up appointment but less surprising when the outcome was much the same, with the patient discharging his anger and frustration toward staff and his pain physician. It was at the conclusion of his second appointment that he was referred to the pain psychologist to do biofeedback and learn relaxation techniques. This puzzled but did not threaten him because the physiologic benefit of treatment was emphasized, and he was affable enough during the initial visit and anamnesis, which revealed much about the relationship between his anger and his pain. He exhibited many of the behavioral mechanisms, previously mentioned, through which anger can exercise influence over pain. His anger toward his employer led to frequent arguments and resulting exacerbations of his headaches, in turn resulting in high absenteeism, which led to further conflicts at work. His anger toward his wife frequently led to retaliation in various forms on her part, which, again, resulted in exacerbations of his pain and the development of pain behaviors designed both to justify his disability and to elicit sympathy. Finally, his anger in the medical setting led to inconsistent and poorly planned care that, in turn, thwarted his attempts to gain relief, allowing his headache and associated behavioral patterns to become firmly entrenched.

It was nevertheless an unexpected development to Mr. Alvarez when the pain psychologist suggested that his anger may be exerting a dramatic impact on his headaches. The patient characterized himself as “quick to anger but quick to get over it” and cited trends within his family of origin, especially his own parents, to be dramatically expressive of anger. He added with irony, “I thought that’s what you psychologists were always saying—‘to get it off my chest and not hold it in.’” He portrayed himself honestly and clearly as a high anger-out individual, a style of anger management shown repeatedly to be associated with increased responsiveness to pain and higher levels of pain intensity and disability. In addition to doing biofeedback training and learning relaxation techniques, the goal of psychotherapy in this second case was to encourage the patient to adopt and practice more adaptive strategies for anger management. Neither Mr. Alvarez’s anger-out style
nor Ms. Ostrakova’s anger-in style, depicted in the first case, was conducive to the successful management of their chronic pain.

**CONSIDERATIONS IN THE SELECTION OF PSYCHOTHERAPY**

Where the special practice of pain psychology is concerned, supportive and psychoanalytically informed psychotherapies have been viewed as useful in the management of pain, primarily when behavioral and cognitive-behavioral treatments have failed to bring relief. The psychodynamic approach may nevertheless be a logical starting point for patients whose anger, pain, and disability are sustained by intrapsychic conflicts or unconscious motives associated with childhood trauma or primary or secondary gain. The drawbacks associated with pursuing such a course of treatment can be manifold, but there may be times when patients are unable to move forward until they are satisfied that their conflicts and motives are revealed and understood. A problem for the successful management of pain, however, is that psychotherapies focusing on the primacy of the experience of emotion are typically long term and may require many months, if not years, to result in meaningful insight and progress. Such treatments, at least near their outset, can also lead patients to an uncritical acceptance of their feelings, further validating the experience of negative emotions such as anger; therefore, the selection of appropriate psychotherapy and the skill of the psychotherapist are perhaps most critical in cases where a psychodynamic or supportive approach is indicated.

If the principal obstacles to successful adjustment to chronic pain are factors, such as anger management style and negative cognitions underlying anger and hostility, then a more direct approach to treatment would be to challenge the behaviors reflecting and maintaining anger as well as the negative cognitions driving it. Challenging established behaviors with new, more adaptive ones is the goal of behavioral therapy, whereas identifying, examining, and restructuring the negative cognitions behind negative emotions is the work of cognitive therapy. Both are well established as offering greater efficacy in the implementation of change and the modulation of the effects of anger on chronic pain, but both
depend on the patient’s willingness to collaborate with treatment and his or her readiness for and motivation to change.\textsuperscript{141,145,146}

The influence of any psychosocial risk factor, such as trait anger and hostility, may signal reluctance on the part of the patient to give up his or her pain and suffering or relinquish the refuge of disability.\textsuperscript{141} In the first case study, Ms. Ostrakova complained of pain, but her symptoms were driven by powerful and enduring unconscious conflicts associated with her history of childhood trauma and abuse. The high correlations between histories of abuse and the subsequent development of difficulties with both anger and chronic pain are well documented in the psychoanalytic and scientific literatures.\textsuperscript{11,42,147–156} For patients who have suffered abuse as children or who have been exposed as adults to situations involving catastrophic loss or harm, chronic pain may come to represent a means of psychologically symbolizing and organizing unbearable memories and intolerable affects.\textsuperscript{141} In Ms. Ostrakova’s case, coming to an understanding of the relationship between her history and the development of her symptoms may well represent an essential step toward taking an active role in her treatment, and the selection of treatment to facilitate this step is likely to involve a form of supportive and psychodynamic psychotherapy. Ironically, a year of inpatient treatment with behavioral and cognitive-behavioral interventions appears only to have altered the patient’s style of anger management from anger-out to anger-in.

Investigators have found that patients vary widely regarding how prepared they are to collaborate in their own treatment and make the changes necessary to manage their anger and their pain more effectively. Assessing a patient’s readiness to change is frequently a critical prelude to effective psychotherapeutic intervention and may shed insight into why some patients never seem to improve. Cognitive therapy often begins with the patient’s response to two questions: What do you want (to change)? What are you willing to do to get it?\textsuperscript{141,151} The first question is easy for most patients with chronic pain, but the second implies work and sacrifice and is not so easy when patients are prone to anger and preoccupied with their own suffering and deprivation. Assessing a patient’s readiness for change is one way of answering the second question.

Kerns et al. applied Prochaska’s transtheoretical model of the stages of
change to the situation of chronic pain and arrived at four successive levels in patients’ willingness to collaborate with treatment and undertake the behavioral changes necessary to manage their pain more effectively\textsuperscript{157–160}.

- **Precontemplation**: patients who have no intention of changing their current patterns of behavior—“You’re the doctor. Fix my pain!”
- **Contemplation**: patients who have begun to recognize the necessity of making changes in their behavior but have not yet committed to doing so—“I know it’s up to me. I just don’t know how to do it.”
- **Action**: patients who have committed to a plan of action and are engaged in making changes—“I’m doing something about my pain.”
- **Maintenance**: patients who are attempting to sustain the changes they have undertaken—“I’m using what I’ve learned in treatment to manage my pain better.”

Angry and hostile patients, in particular, may be stuck in the precontemplative stage of readiness for change, and their often unrealistic expectations of their physicians may lead them to feel that effective treatment is being withheld. This was the case with Mr. Alvarez, whose anger was driven by his disappointment in providers who never seemed willing to do enough to help him manage his pain. Unlike Ms. Ostrakova, however, his style of managing anger did not reflect defensive inhibition of affect, and his chronic pain was not associated with unconscious conflicts. His anger, although more volatile, also proved more tractable to the psychoeducational component of cognitive therapy, and he was ultimately able to make the transition more easily from the precontemplative to the contemplative stage of readiness for change.

**BEHAVIORAL AND COGNITIVE-BEHAVIORAL THERAPIES**

Templates for behavioral and cognitive-behavioral intervention in cases of chronic pain are offered in succeeding chapters, but it is instructive to note that their number and applications have burgeoned in recent years, largely through the proliferation of acceptance and commitment therapy (ACT), contextual cognitive-behavioral therapy (CCBT), mindfulness-based stress reduction (MBSR), and mindfulness-based cognitive therapies (MBCT) as well as mindfulness-based behavioral techniques, such as
Behavioral approaches to the treatment of anger have tended to revolve around relaxation training and applications of relaxation techniques to reducing autonomic arousal and uncomfortable musculoskeletal tension. Suinn’s template for anxiety/anger management training (AMT) represents one of the more enduring expressions of this form of treatment. He proposes a brief, structured therapy involving six to eight sessions in which guided imagery directed toward arousing anger is subsequently and serially paired with relaxation techniques designed to deactivate arousal. Patients are first instructed in the elicitation of the body’s natural relaxation response—which can be accomplished using meditation, progressive muscle relaxation, body scans or other forms of autogenic training, or diaphragmatic breathing techniques—and, once they have mastered this, the psychotherapist offers structured practice in the use of the technique to contain or defuse sympathetic nervous system reactivity cued by suggestions and visualizations of stressful images. The use of biofeedback technology in the assessment of progress can frequently hasten mastery of this strategy by presenting the patient with tangible evidence of progress.

Fernandez proposes that if the injury or perceived injustice resulting in chronic pain—whether physical or psychological in origin—cannot be altered or undone, then switching the focus to what can be changed becomes the logical object of therapy. What can be changed is the way the patient with chronic pain construes what has transpired. Recall that in Lazarus’s cognitive appraisal theory of emotion, the experience of anger is the joint effect of (1) the event of physiologic arousal and (2) the cognitive appraisal of its meaning. Whereas much of behavioral therapy directed toward the management of anger is concerned with the former, cognitive therapy is directed toward the latter. As we have seen, anger, by Smedslund’s definition, involves the appraisal by the subject that he or she—or a person for whom he or she cares—has been treated without respect. This, of course, may actually be the case in a given situation and therein lies the foundation of the biologic basis for anger, but anger, as our Greco-Roman and Judeo-Christian roots attest, does not necessarily conform to logic. The experience of anger can quickly and
easily become associated with irrational, automatic thoughts and beliefs concerning the motives of others and the sources of threat to our well-being.

The approach of cognitive therapy is to offer a corrective process to the development and maintenance of errors in our thinking and beliefs. Through the process of cognitive restructuring or reappraisal, patients are led to examine whether, in the process of trying to make sense of their anger and pain, they may be making fundamental errors in their thinking and relying on mistaken beliefs. Patients are encouraged to challenge their automatic thoughts and uncritically held beliefs regarding their experiences of anger through the template of cognitive appraisal theory—that is, that situations are ordinarily neutral until we assign meaning to them. We are often unaware of this step of assigning meaning because we do not usually stop to examine the thoughts and beliefs that influence our emotional responses to certain situations, and even when we do, we may not consider the accuracy of these thoughts and beliefs. The essence of the cognitive model of treatment suggests that much of our emotional distress and self-defeating behavior is based simply on inaccurate and irrational thinking and that once our attention is drawn to these upsetting cognitions, we can test their veracity and value to see whether they form an appropriate basis for our emotions and behavior.

As they learn to identify negative cognitions, patients begin to monitor their cognitive appraisals more rigorously and critically, cognitively restructuring their primary and secondary appraisals of situations resulting in anger. Common reappraisals of the experience of anger might include reexamining the intention of the one toward whom our anger is directed, reconsidering the harm done by the perceived slight or insult, or reinterpreting the outcome of a situation to determine whether a perceived breach of respect actually resulted in harm or injury. Fernandez’s proposed cognitive-behavioral affective therapy (CBAT) serves as a model of integrative treatment for anger in the context of chronic pain because it combines behavioral and affective interventions for self-soothing while the patient undertakes the cognitively challenging work of restructuring his or her appraisals of what has transpired. These behavioral and affective techniques target the feelings of distress inherent in the experience of
anger, providing both support and respite as the often difficult and taxing work of the cognitive therapy progresses.

In the case of Mr. Alvarez, he was taught meditation as a means of assuaging his sometimes high, reactive affect, although several negative cognitions were identified as being based on dysfunctional family-of-origin models and overrehearsed expression. His primary negative cognition—“Everyone is out to take advantage of me”—may have reflected some degree of utility in the gang-controlled streets of his childhood barrio, but it was dysfunctional and even harmful in the medical setting, where his physicians and other providers were genuinely concerned to help him. Their response to his anger was to defend themselves by disengaging and retreating, often to the detriment of his care. A corollary negative cognition—“No one will help you voluntarily; you have to demand what you need from people”—was equally destructive of the medical alliance. Through cognitive reappraisal and the opportunity to test different interpretations, the patient ultimately proved to himself that people, especially people whose job is to take care of him, really are often willing to help and that consistently making demands of others tends to result in less return than welcoming their responses to reasonable requests. Mr. Alvarez’s anger-out style, once a barrier to his receiving the best from his medical care, receded and was replaced by a more genuinely collaborative attitude toward his physicians.

Summary

The cultural background of anger lays the groundwork for understanding its role both as an emotion and as a trait, as well as its relationship to pain. Psychoanalytic theory emphasized the harmful effects of inhibiting the experience and expression of anger, placing it at the core of conflicts between competing drives and the formation of pathologic symptoms. More recent research has brought additional clarity to the relationship between anger and pain, suggesting a number of possible mechanisms through which state and trait anger can influence sensitivity to pain and the development and maintenance of chronic pain. This trend, in turn, has led to improved objective psychological measures of anger and the
observation that style of anger management may be a principal modulating factor in the relationship between anger and pain. Anger management style has become a critical consideration in the development of effective psychotherapeutic treatments for anger-related psychopathology, with behavioral and cognitive therapies for anger often resulting in improved management of chronic pain.

CHAPTER 84
Cognitive-Behavioral Therapy for Chronic Pain
LAYNE A. GOBLE, CHRISTOPHER D. SLETSEN, TAYLOR CROUCH, and KELLY BARTH

Introduction
Cognitive-behavioral therapy (CBT) is an evidence-based treatment approach that has been effectively applied to the management of chronic pain. This approach is influenced by behavioral techniques (i.e., relaxation therapies, time-based pacing, and behavioral activation) combined with cognitive therapies (i.e., cognitive restructuring) with a goal of better integrating pain management within a biopsychosocial model of care. Additional components that address common comorbidities such as sleep and relationship difficulties are often included in treatment protocols. The main outcome of CBT for chronic pain (CBT-CP) is development of healthy coping techniques to improve functioning in the face of ongoing pain complaints.

For the past three decades, the vast majority of research on psychological approaches to chronic pain has focused on traditional CBT. However, there has been a growing interest in recent years on interventions that include mindfulness and acceptance-based components, which have been called the “third wave” of behavioral and cognitive psychotherapies. As a brief (and certainly incomplete) background review, “first wave” treatments employed classic behavioral therapy, including methods such as contingency management and operant conditioning, to change behavior (e.g., Zinbarg and Griffith1). “Second wave” treatments integrated cognitive methods (i.e., identifying and modifying maladaptive cognitions) into behavioral treatment in order to change problematic
behaviors and emotions (e.g., Beck). “Third wave” treatments can also be considered cognitive-behavioral interventions, but they collectively emphasize mindfulness and acceptance-based processes while deemphasizing cognitive change or control. Each of these is reviewed within this chapter.

HISTORY AND DEVELOPMENT OF COGNITIVE-BEHAVIORAL THERAPY FOR PAIN

CBT-CP developed out of a need for an approach outside of the traditional biomedical model. Clinicians and researchers recognized that psychosocial factors had an influence on pain-related behaviors that significantly impacted treatment outcomes. Henry Beecher was a pioneer in pain management who first recognized the impact of psychosocial factors on chronic pain while serving in the Army Medical Corps during World War II. During this time, he first observed that the individuals in his care responded very differently to their traumatic injuries. Namely, he observed that soldiers with serious wounds reported less pain than did his postoperative patients at Massachusetts General Hospital. In interviews with his patients, he found that their pain experiences were mediated by the meaning that they had attributed to their injuries. He concluded, “There is no simple relationship between the wound per se and the pain experienced. The pain is in very large part determined by other factors, and of great importance here is the significance of the wound.” He found that only one in four injured soldiers requested analgesic medications despite experiencing severe wounds. Many of these soldiers were grateful to have survived their injuries and directed their thoughts to the positive aspects of their situation—namely, gratitude for having survived their injuries and thoughts of going home. He also found that similar attributions to injury also impacted individuals with injuries outside of combat settings. Beecher was one of the first researchers to acknowledge the complex interplay of the physical, psychological, and sociocultural factors that impact the chronic pain experience. This interplay of factors affected not only the experience of pain but also the behaviors and disability that accompanied chronic pain. This theory would later become the biopsychosocial model of chronic pain.
By the 1960s and 1970s, the health care community began to adopt a new view of chronic pain; first, by distinguishing acute and chronic pain as separate entities and then by developing behavioral and rehabilitation approaches to chronic pain. During this time, Wilbert Fordyce worked with John Bonica to develop groundbreaking behavioral therapies for chronic pain based on operant conditioning approaches. Essentially, he encouraged (i.e., reinforced) individuals with chronic pain to reengage in exercise and other physical activities while reducing (i.e., extinguishing) their maladaptive pain behaviors.4,5 His approach encouraged individuals to take a more active role in their recovery, thereby helping them to experience a greater sense of control over their chronic pain complaints. This approach was considered revolutionary at the time because these basic changes in behavior led to a reduction in their use of analgesic medications and improved function during their time in treatment.

The growth of cognitive therapy6 likewise expanded our understanding of psychosocial factors that impact chronic pain. This model addresses the influence that thoughts can have on our emotions, behaviors, and even physiologic processes. Albert Ellis7 and Aaron Beck6 first addressed catastrophizing as a factor that impacts the development and maintenance of depressive and anxiety disorders. Catastrophizing thoughts are irrational beliefs that one’s current or anticipated situation is exaggerated to be far worse than it actually is. Michael Sullivan8 later developed the Pain Catastrophizing Scale to assess for catastrophizing beliefs in chronic pain patients. His measure is widely used in both clinical and research settings to assess for catastrophizing beliefs in chronic pain patients. Beverly Thorn9 has also been instrumental in developing cognitive interventions for chronic pain patients.

EVIDENCE FOR COGNITIVE-BEHAVIORAL THERAPY FOR CHRONIC PAIN
There is significant evidence that CBT-CP is effective for a number of chronic pain conditions, including headache, rheumatic diseases, chronic pain syndrome, chronic low back pain, and irritable bowel syndrome.10–12

In 2016, Centers for Disease Control and Prevention (CDC) published an update to their “Guidelines for Prescribing Opioids for Chronic Pain.”13
Their first recommendation that the authors emphasized as being of primary importance was “nonpharmacologic and nonopioid pharmacologic therapy are preferred for chronic pain . . . .” This recommendation was based on a contextual review of nonpharmacologic and nonopioid therapies,\textsuperscript{14} which cites 13 guidelines and 18 systematic reviews of randomized or quasi-randomized trials of nonpharmacologic and nonopioid therapies, including studies with follow-up periods from 2 weeks to 6 months (with some CBT studies “assessing outcomes at 6 months or longer”). The overall quality of the evidence as informally rated by study authors was felt to be “moderate.”

The contextual review found that CBT had significant positive effects on disability and catastrophizing with effects lasting up to 6 months in back pain and osteoarthritis, and biopsychosocial rehabilitation was effective for both pain and disability.\textsuperscript{14} The authors concluded that these approaches should be considered first-line treatments for chronic pain.

**Components of Cognitive-Behavioral Therapy for Chronic Pain**

Several widely used CBT treatment protocols have been developed to bring together the various psychosocial interventions into a coherent approach for treating chronic pain.\textsuperscript{15,16} Treatment involves a comprehensive psychosocial assessment that is used to guide treatment planning. The assessment focuses on an individual’s pain history, along with psychosocial factors that may be impacting their pain experience. Providers use this assessment as an opportunity to tailor their treatment approach to the needs of the patient. The main components of CBT-CP typically include the following:

- Chronic pain psychoeducation to inform patients about the biopsychosocial model of chronic pain, to introduce the components of treatment, to address common barriers to treatment, and to increase self-efficacy for engaging in new pain self-management behaviors

- Relaxation techniques for stress management and to decrease muscle tension

- Behavioral activation coupled with time-based pacing to encourage
increased engagement in pleasant, physical, social, and otherwise meaningful activities while reducing the likelihood of experiencing a painful flare-up and excessive fatigue

• Sleep hygiene to improve sleep quality and to improve daytime alertness and activity
• Cognitive restructuring to identify and address maladaptive thought patterns and develop strategies to promote adaptive cognitions
• Communication skills to help improve and increase positive social interactions and reduce solicitous pain behaviors from family and friends
• Maintenance and relapse prevention to increase self-efficacy for using the pain self-management techniques developed in treatment, to address potential barriers and specific difficulties to using these techniques over time

Treatment protocols for CBT-CP are most often tailored for individual therapy, although it has also been adapted into a group therapy approach, as is employed in some pain rehabilitation programs (PRPs). Family members and close friends may also be engaged in treatment to address communication skills and reinforce behavioral activation. Adaptations have also been developed to increase access to CBT for pain, such as delivery via telehealth.

CHRONIC PAIN PSYCHOEDUCATION
The dilemma of chronic pain and its often intractable nature is that it is poorly understood, frustrating, isolating, and confusing for patients, families, and medical providers. A paramount structural element of CBT-CP is psychoeducation. Like many educational approaches, this can be efficiently and effectively accomplished in a group setting. The interaction with other group members, realizing one is “not alone” in their chronic pain, hearing similar questions and concerns, and the repetition of complex material are invaluable elements in the psychoeducational model. The isolation of chronic pain and the feeling that no one else has similar struggles is directly eliminated with this group-based approach. In addition to normalizing the patient’s symptoms and experience, the major benefit of the psychoeducational approach is that it can foster motivation and
Education about the Neurobiology of Chronic Pain

Successful psychoeducational approaches incorporate information about the neurobiology of pain. This includes description of the differences between acute pain and chronic pain and an explanation of central sensitization. Central sensitization is the process by which many chronic symptom conditions are thought to be (1) precipitated and (2) maintained in the central nervous system. The primary goal is to convey to the patients, in an understandable format, how their pain transitioned from acute to chronic, a rationale for how to manage the problem and direction for improving future functioning. Beginning with the physical origins of their problem can remove the stigma that chronic pain is purely psychological or “made up.” For example, starting with education about central sensitization followed by an explanation of how treatment can be delivered in the following simplified format: “The main precipitating factor to the development of central sensitization is a pain signal that lasts longer than it should or greater than 3 months (definition of chronic pain).” This causes an upregulated pain signal from the body and a sensitized pain receiver in the brain. As a result of these changes, four responses to chronic pain logically follow: (1) physical deconditioning, (2) emotional distress, (3) behavioral dysregulation, and (4) chemical use. Pivoting from the causative focus and instead looking at these four factors begins to shape the emphasis of the CBT model. All patients benefit from physical reconditioning to improve endurance, strength, and ability to do daily activities. Treating the emotional distress of chronic pain incorporates CBT strategies for stress, anxiety, depression, and anger management. Reducing emotional distress has obvious psychological and social benefits but is also associated with reduced symptom burden. Two major behavioral issues are also introduced during the psychoeducational sessions: overactivity followed by prolonged recovery (“pushing and crashing”) and pain behaviors. Patients are educated that addressing both of these behavior patterns yields less distress and fewer symptoms.

Resetting Expectations about the Outcomes of Chronic Pain
—the A-B-C Model

It is not uncommon that a patient with chronic pain will lament, “I wish I could go back to the way I was before having chronic pain.” In fact, the current medical approach to chronic pain (i.e., offering repeated trials of medications, interventions, and surgeries to “cure” chronic pain) actually fosters this belief that somehow, with enough trials, a cure for one’s pain is waiting to be found. For many patients with chronic pain, this will not be the case. The Mayo Clinic’s Pain Rehabilitation Center, Florida (MCPRC-F) uses the A-B-C model of the chronic pain experience (Table 84.1). This model illustrates and validates the patient experience and serves as a foundational explanation of the way people change as they experience the suffering of chronic pain. The “A” version is the person’s functional status before his or her pain symptoms became chronic. This version is generally characterized by independence, productivity, fitness, and social engagement. The “B” version is the patient’s functional status with chronic pain. This version is characterized by “pushing and crashing,” reliance on medication or interventions, decreased independence and productivity, deconditioning, and more emotional distress. The goal of CBT for pain is to help the patient move toward the “C” version of functioning. The “C” version is characterized by increasing fitness, independence, productivity, and mood, with additional emphasis on acceptance, moderation, flexibility, and stability.23

CBT-P, cognitive-behavioral therapy for pain.

This model has been an effective clinical tool to educate patients, providers, and family members about the trajectory of treatment. When teaching this model, specific emphasis is placed on the linearity and intentional movement from the “B” version to the “C” version. This

4337
concept allows for the discussion that returning to the “A” version is no longer possible, and continued emphasis and expectations in that direction are counterproductive.

**Changing Behaviors—SMART Method**

One final element from a behavior therapy perspective is the implementation of goal setting. Using the A-B-C model outlined previously, patients can be shown how their goal setting behaviors were likely altered by their chronic pain. Persons who could previously set and achieve goals easily often find themselves at a loss for how to effectively do so in their “B” version. With the unpredictability of symptoms and decreased functional capacity, goal setting can become frustrating and futile. One common method to reinstitute effective goal setting is to use the SMART method. The SMART acronym stands for Specific, Measurable, Attainable, Relevant, and Time bound. Adapted from business management, this model is easy to explain and translates well to the needs of a chronic pain patient. This model can be implemented during treatment and then modified as needed after treatment has ended. The element patients seem to struggle with the most is M—Measurable. Often, a brief explanation about behavioral coding and having the patient determine if the goal is a discrete activity or an ongoing one (i.e., posture, attitude). If it is an ongoing activity, then instructing them in the use of time sampling can be helpful.

Although comprehensive, psychoeducation is a critical foundation for CBT-CP. In our current health care model, patients with chronic pain are often fearful and skeptical about trying an intervention that does not involve medications or interventions and concerned that engaging in CBT-CP will mean that their pain is “in their head.” Spending the time to provide education to the patient about chronic pain and how CBT-CP can address the neurobiology of pain is essential for getting patients engaged in this evidence-based treatment.

**RELAXATION TECHNIQUES**

Relaxation training was one of the earliest techniques to be integrated into CBT-CP treatment protocols. Clinicians use relaxation training to help
individuals become more aware of sympathetic arousal that likely increases their pain severity and then induce a relaxation response to counter the effect of this arousal. Although these techniques may be used with biofeedback, it is important for individuals to recognize that they can be used independent of costly equipment or the assistance of a biofeedback specialist. Relaxation techniques should be presented as an active pain management strategy that individuals should practice regularly and utilize when needed. It is important for the clinician to explain relaxation training as a specific technique that actively induces a relaxation response because some people may interpret relaxation as just passively resting.

It is often very easy for individuals with chronic pain to recognize life stressors that relate to their chronic pain experience, although it may be more challenging for them to recognize the mind–body connections that impact physical sensations through sympathetic arousal (i.e., muscle contraction, dilation of the pupils, constricted blood flow to many parts of the body, and increased heart and breathing rates). Individuals will often see how prolonged stress can lead to fatigue, poor sleep, and tension in their muscles. Having individuals experience a relaxation response is often a helpful step in helping them recognize that they can take an active role in managing their chronic pain complaints. Although there are many relaxation techniques used in clinical settings, we focus on some of the most commonly used techniques in this section.

Herbert Benson is often credited with popularizing relaxation techniques with his book The Relaxation Response in 1975. He systematically looked at ways to counter the sympathetic arousal through meditation. His work has promoted relaxation techniques such as diaphragmatic breathing, progressive muscle relaxation, guided imagery, autogenic training, and other meditation techniques. There are several useful guidelines for individuals engaging in these techniques to follow. It is often recommended that individuals beginning this practice should find a quiet location that is free from distractions. Individuals new to these techniques often benefit from being guided through the induction by someone else. Although this was traditionally done by a clinician, there is a wide array of audio and video recordings that are also helpful. It is often helpful to instruct individuals to begin using these techniques at a quiet
time when they are more likely to experience the relaxation response. Later, they might try to use the relaxation techniques in more challenging situations.

Diaphragmatic breathing is a simple technique that most individuals can master with regular practice. Individuals practicing this technique learn to recognize the sensation of contracting their diaphragm by engaging in slow, deep breaths paired with stomach and chest expansion. The parasympathetic drive is thought to override the sympathetic as the individual becomes more relaxed.

In 1938, Edmund Jacobson published Progressive Relaxation to introduce his work with progressive muscle relaxation. This is a technique developed to increase neuromuscular awareness based on the idea that muscles respond to stressors with tension. Many chronic pain patients recognize muscle tension, stiffness, or chronic guarding of their muscles. This may lead to tension headaches, low back pain, temporomandibular joint disorder, and misaligned posture. Progressive muscle relaxation consists of a series of isometric muscle contractions followed by efforts to completely relax the muscles by focusing on one muscle group at a time. It is also common for individuals to combine diaphragmatic breathing techniques while doing progressive muscle relaxation. This process is thought to intercept the stress response through a direct and conscious inhibition of the excitatory neural drive to muscle fibers.

Guided imagery is another commonly used relaxation technique. Individuals are instructed to close their eyes and use their cognitive skills to imagine a peaceful and relaxing place. Individuals are instructed to use each of their senses when creating this setting to include the sensory perceptions of sight, sound, touch, smell, and even tastes if possible. Individuals often benefit from a discussion of the place they intend to use prior to using this technique for the first time.

Mindfulness meditation is another technique that has been effectively applied to chronic pain. Jon Kabat-Zinn first popularized the use of this technique for health conditions with his book Full Catastrophe Living. The purpose of this technique is to assist the individual to bring their attention to the present moment without having a specific judgment about the experience. This can be particularly challenging when an individual
perceives his or her experience in that moment to be negative, such as focusing on the pain sensation. The body scan meditation is often a useful technique for chronic pain patients as it allows the individual to practice focusing attention on different areas of the body, including painful areas, without judgment. Mindfulness meditation is also a component of acceptance and commitment therapy (ACT), reviewed at the end of this chapter.

**BEHAVIORAL ACTIVATION AND TIME-BASED PACING**

Many individuals with chronic pain come to treatment having developed a pervasive pattern of behavioral avoidance. Perhaps, the most important aim of CBT-CP is reducing this behavioral avoidance by enhancing individuals’ level of daily functioning and activity. To accomplish this goal, the behavioral activation component of treatment involves gradual exposure to previously avoided physical, recreational, and social activities. Behavioral activation has been most frequently used as a treatment approach for depression and generally involves increasing contact with valued and pleasurable environments and activities in order to provide more opportunities for reward and enjoyment. In chronic pain treatment, increasing activity engagement can help disconfirm negative expectations about pain and harm and disrupt the harmful cycle involving fear, avoidance, pain, and low mood.

In order to help patients understand why increasing their activity level is important, they are first introduced to the concept of hurt versus harm. Many chronic pain patients believe that activities will lead to increased physical damage and increased pain. Although this belief is typically true for acute pain, it is almost always inaccurate when it comes to chronic pain. Patients are taught about kinesiophobia, or the fear of movement, and the negative impacts of avoiding activity on maintenance of pain and distress. The chronic pain cycle is reviewed in detail.

Patients are encouraged to begin an exercise program (once they have been cleared by their primary care physician or other treating medical provider) in order to begin to reduce the unhelpful cycle of pain and avoidance. They are taught about the benefits of exercise in improving
flexibility and strength, decreasing pain, and enhancing mood. Walking is the most commonly chosen physical activity because it is low impact and accessible to almost everyone. Swimming, biking, yoga, and other forms of exercise are also encouraged if preferred by the patient. Patients are asked to set a specific goal for walking (or other exercise program) and monitor their progress.

For the patient suffering with chronic pain, it is important to couple behavioral activation with time-based pacing. Time-based pacing is a practical behavioral technique to help individuals to engage in physical activity while reducing the possibility of a painful flare-up or excessive fatigue. This technique is often introduced when a patient is first engaging in a rehabilitation program such as physical or occupational therapy, although it can be applied to any physical activity where a painful flare-up may occur. Individuals are encouraged to identify specific physical activities that are likely to lead to a painful flare-up and then develop time-based pacing schedules to use with these activities. The total time for the activity is interrupted by episodes of rest so that muscle groups can recover before resuming the activity again. It is also important to note that some patients who experience flare-up while sitting or lying down for extended periods of time can also apply time-based pacing.

Individuals with chronic pain often decrease physical activity due to the negative consequences of a painful flare-up. The perception that future activity will then lead to a flare-up will often result in avoidance of physical activity. Time-based pacing can be used in a useful way to expose patients to reengaging in a physical activity. Individuals can build on the SMART goals that they set earlier in treatment to choose an activity and then develop a schedule that is achievable so that the activity is likely to be repeated (i.e., positive reinforcement). Time-based pacing builds on William Fordyce’s original behavioral modification techniques for physical activity where physical activity is rewarded, whereas prolonged inactivity is disregarded.

In addition to physical activity, a later component of treatment involves increasing engagement in pleasurable activities. Due to pain and associated distress, many individuals begin avoiding social and recreational activities that they used to enjoy, which can further contribute to the cycle of
decreased mood, reduced activity level, and increased pain. Patients are asked to consider pleasurable activities they would be willing to begin engaging in more frequently. To explore options, they are given a list of pleasant activities to choose from, or they can choose their own. They then create a specific plan for implementing these activities while utilizing their pacing skill to maintain a balanced approach to activity. For most individuals, getting back to valued and enjoyable activities that were previously avoided due to pain contributes to mood improvement and increased energy and motivation to stay active.

**SLEEP HYGIENE**

Patients with chronic pain often report poor sleep due to their pain or associated anxiety. Chronic poor sleep contributes to low energy and reinforces the reduction in functioning often seen in the chronic pain cycle. The sleep hygiene component of treatment involves reviewing current sleep habits and providing basic education about sleep hygiene principles. Patients are encouraged to create a sleep-conducive environment, including minimal noise, a comfortable temperature, and appropriate light. They are guided to use the bed only for sleep (and sex), establish a calming bedtime routine, and set a regular sleep/wake schedule. Sleep-interfering behaviors are introduced and discouraged, including daytime napping, drinking caffeine after midday, consuming alcohol or a large meal prior to bedtime, and watching television or utilizing a laptop (or tablet/cell phone) in bed. Patients are taught to avoid clock watching and get out of the bed if unable to sleep. The use of relaxation techniques (introduced earlier in treatment) prior to sleep is encouraged, with a goal of reducing tension and inducing sleepiness. Additionally, the benefits of exercise are further reinforced by discussing the positive impact of daytime exercise on sleep quality. Finally, the connection between stress and sleep problems is reviewed. For many individuals, worries surface in the context of a quiet bed, which can interfere with sleep onset, so patients are encouraged to set aside time earlier in the day to engage in problem-solving and planning. After reviewing healthy sleep habits, patients select a few sleep behaviors to change and are instructed to monitor these behaviors and their impact on sleep over the next week.
COGNITIVE RESTRUCTURING

Cognitive therapy approaches are grounded in the theoretical and clinical work of Albert Ellis⁷ and Aaron Beck⁶ and were initially developed to treat anxiety and depressive disorders. These approaches are based on the premise that thoughts, emotions, and behaviors are interrelated. When individuals experience dysfunctional thoughts, they are very likely to then experience related negative emotions and maladaptive behaviors that lead to a mood disorder. Applications were later developed to address dysfunctional thoughts specific to the experience of living with chronic pain. Beverly Thorn’s⁹ work has been central in forwarding cognitive therapy as a treatment for individuals with chronic pain through her book Cognitive Therapy for Chronic Pain: A Step-by-Step Guide, second edition. Individuals with chronic pain may experience dysfunctional thoughts and beliefs related to their experience with chronic pain that impact their engagement in treatment. They may experience avoidance behaviors, catastrophizing, or become excessively focused on a cure.

Cognitive therapy for chronic pain often begins by working with individuals to develop techniques to better identify dysfunctional or inaccurate thoughts related to their chronic pain experience. These thoughts are referred to as automatic because they happen so quickly that individuals are often not fully aware of their presence. In fact, it is more likely that individuals are aware of the shifts toward negative emotions that accompany these automatic thoughts, so they are asked to identify their thoughts that accompany strong negative emotions such as sadness, despair, guilt, fear, or anxiety. Thought records are a valuable tool for identifying automatic negative thoughts, and they are designed to be used outside of the therapy session where individuals are engaged in their daily routines. Individuals are first taught to begin by writing down their stressful events. They will then want to identify the subsequent physical and emotional changes that happen in connection to these events. Finally, they will record the automatic negative thoughts. It is important for individuals to have a reference to common dysfunctional thoughts to provide a reference for them to record their own experiences. A list of common dysfunctional thoughts and associated adaptive thoughts are listed in Table 84.2.
### TABLE 84.2 Common Pain-Related Thoughts

<thead>
<tr>
<th>Types of Unhelpful Thoughts</th>
<th>Examples of Unhelpful Thoughts</th>
<th>Examples of Helpful Thoughts</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Catastrophizing:</strong> Believing something is the worst it could possibly be</td>
<td>When my pain is bad, I cannot do anything.</td>
<td>Even when my pain is bad, there are still some things I can do.</td>
</tr>
<tr>
<td><strong>Should statements:</strong> Thinking in terms of how things should, must, or ought to be</td>
<td>My doctor should be able to cure my pain.</td>
<td>There is no cure for chronic pain, but I can use skills to cope with my pain.</td>
</tr>
<tr>
<td><strong>All or none thinking:</strong> Seeing things as “either or” or “right or wrong” instead of in terms of degrees</td>
<td>I can only be happy if I am pain free.</td>
<td>Even if I am in pain, I can still be happy. There is always something that I can do to have a better quality of life.</td>
</tr>
<tr>
<td><strong>Overgeneralization:</strong> Viewing one or two bad events as an endless pattern of defeat</td>
<td>I tried doing exercises for my back pain before, and it did not help. So, it is not going to help now.</td>
<td>Although physical therapy did not help much before, maybe this time, it will help. I might as well try.</td>
</tr>
<tr>
<td><strong>Jumping to conclusions:</strong> Making negative conclusions of events that are not based on fact</td>
<td>When I move, my back hurts, so it must be bad for me to move.</td>
<td>Hurt does not equal harm.</td>
</tr>
<tr>
<td><strong>Emotional reasoning:</strong> Believing how you feel reflects how things really are</td>
<td>I feel useless, so I am useless.</td>
<td>Even though I cannot do all the things I used to do, it does not mean I cannot do anything.</td>
</tr>
<tr>
<td><strong>Disqualifying the positive:</strong> Focusing on only the bad and discounting the good</td>
<td>So what if I am doing more, I am still in pain.</td>
<td>Doing more is important for me to live the life I want to live.</td>
</tr>

Cognitive restructuring is the next phase in this approach, and this is usually done in the subsequent visit. Once patients have better identified dysfunctional thoughts and beliefs related to their pain experience, they can begin to develop techniques to better test the reality of these thoughts and beliefs. Developing more adaptive thoughts will then lead to shifts in negative emotions and maladaptive behaviors. Individuals are asked to evaluate their thoughts to better determine the extent that their thoughts are correct or inaccurate. It is often important to note that there will likely be some degree of truth in their thoughts, although the thought becomes dysfunctional once the negative beliefs are overexaggerated. The individual can then come to a more balanced conclusion. Individuals are often encouraged to develop coping statements based on their adaptive
thoughts that might help them remember this exercise when they experience stressful situations in the future.

COMMUNICATION SKILLS
Communication style and content are important in CBT-CP, in the general management of chronic pain, and in the interactions between patients with chronic pain and their families. Much of the literature in this area focuses on physician–patient communication, but the themes conveyed in this literature apply to the management of the patient in general, including themes that may arise in CBT-CP regarding communication with and between family members and support system.

It is known that words used to communicate with people suffering with chronic pain about their pain affect their outcomes. For example, words that carry strong, negative connotations have been hypothesized to increase probability that acute pain will progress to chronic pain. It has also been shown that expressed or perceived spouse criticism or hostility can worsen chronic pain symptoms, especially among women and patients with depression. Conversely, positive communication can also be a vital component of effective pain management and relief. For example, it has been shown that improvement in communication between a patient and his or her partner can improve pain severity and relationship discord.

Approaches to improving family communication and support around chronic pain can be done formally not only through family therapy with specific feedback about communication styles and language but also through modeling provided from in-office patient–provider interactions and communication with the family member present. Modeling motivational interviewing strategies including the use of open-ended questions, questions that incite reflection, empathic statements, affirming change talk, and asking permission to share information is suggested and can be successfully adopted by family members.

It is therefore important that the provider treating the patient with chronic pain utilizes and models effective communication during treatment. It has been shown that providing clinicians with communication training in the area of chronic pain increases patient satisfaction and that improved communication predicts improved patient satisfaction more than
an actual decrease in pain score.\textsuperscript{31}

When evaluating effective components of provider communication with patients with chronic pain, it has been shown that it is vital for a provider to listen to the patient’s pain history and show empathy in order to communicate that the patient’s pain is “real” and important. It is also helpful to couple validation of the patient’s pain experience with the acknowledgment that the provider may not have all the answers for how to manage chronic pain and working with the patient to gently accept that chronic pain may be an ongoing part of his or her life (e.g., there might not be a “cure”).\textsuperscript{34}

**MAINTENANCE AND RELAPSE PREVENTION**

**Maintaining Treatment Gains**

An integral part of any CBT intervention is helping the individual maintain the therapeutic changes. This includes a strong emphasis on self-monitoring and self-management as well as planning for future difficulties and setbacks. This is especially important for individuals with chronic pain. Their struggle with a diverse and complex set of issues makes maintenance planning essential.

Whether done individually or in a group setting, there needs to be sufficient time and effort dedicated to maintaining treatment gains. For the sake of illustration, a group-based PRP is discussed. As mentioned elsewhere, a comprehensive pain rehabilitation approach includes physical therapy, occupational therapy, medication reduction, and CBT. The strength of this interdisciplinary approach is that the patient is exposed in an organized program to the elements that need to change for there to be an improvement in functioning.

One of the core elements of successful maintenance is to help the individual be as independent as possible. This can be achieved by linking the active elements of treatment with how they translate to the home environment. The schedule and intensity of a PRP cannot and should not have to be replicated when the patient is discharged. However, incorporating elements of the program in the home is essential. What follows are examples from a CBT perspective of maintenance tools.

There are three tools that are extensions of treatment goals that are
addressed during the PRP: time management, exercise, and managing symptom flares. Before dismissal, the patient is asked to establish a 2-week plan. This plan is designed to ensure continued engagement in moderation, exercise, daily activities, and self-care. They are also given a home-based physical therapy program that is a continuation of the exercises and behavioral activation done during treatment. The patient is asked to maintain this program for 3 months before advancing exercise. Finally, the patient is asked to make a plan for how to handle future symptom flares. This is done for several reasons: to normalize the possibility of flares after treatment, to have a preexisting plan and schedule to maintain functioning, and so the patient’s friends and family know what to do during the flare.

The second set of maintenance strategies are more universal CBT principles that are applied to this population: stimulus control, social support, and reinforcement strategies. The use of stimulus control is a behavioral strategy to help an individual not return to previous behavior patterns by limiting exposure to “tempting” stimuli. An example would be having an ex-smoker “pay at the pump” for gas rather than go into the clerk where there are ample smoking-related cues. For pain patients, stimulus control could include avoiding retail pharmacies, limiting internet use (no more symptom/cure searches), and not returning to practitioners who were solely focused on symptom relief.

Social support as a maintenance strategy is extremely important. Patients need several types of support to ensure ongoing treatment success. The primary support group, friends, and family are coached and encouraged to support the behavioral changes, stop symptom-focused talk, and remain neutral to any remaining maladaptive behaviors. In addition, patients are encouraged to increase community involvement, volunteering, school, work for distraction, other focus, and opportunities for new relationships. Finally, it is recommended that patients establish someone to be accountable to regarding adherence to the exercise and activity management.

Lastly, incorporating some form of reinforcement for treatment adherence is strongly recommended. Having the patient set up a reward system (e.g., weekly cash deposits to a vacation/gift account for every
week that exercise was done) can add some incentive to the maintenance process.

THIRD-WAVE THERAPIES—ACCEPTANCE AND COMMITMENT THERAPY

Third-wave interventions include such treatments as ACT, mindfulness-based cognitive therapy (MBCT), and dialectical behavior therapy (DBT), among others. As applied to chronic pain, third-wave interventions focus less on controlling pain or changing maladaptive pain-related thoughts and emotions and more on mindful awareness of internal processes and living well despite pain.

ACT, which can be considered a treatment within the family of CBT, is one of the more commonly employed and well-studied third-wave intervention for chronic pain. In general, ACT focuses on behavior change and psychological flexibility rather than symptom (i.e., pain) reduction. Psychological flexibility is broadly defined as the ability to remain in contact with present moment experiences (both internal and external) in a way that allows behavior to continue or change consistent with one’s goals and values. When applied to chronic pain, ACT aims to help individuals respond more flexibly to pain and distress, reduce unhelpful attempts to control pain, and increase engagement in behaviors that are consistent with one’s goals and values. Thus, individuals are guided to alter their expectations from pain elimination to living a “values-based” life despite pain. Important components of treatment typically include exploration of personal values, examination of the ways in which struggling with pain prevents engagement in values-based behaviors, and choosing specific behavioral goals in line with one’s values. Mindfulness practices are employed with an aim of enhancing present moment awareness of thoughts, sensations, emotions, and behaviors in order to enhance psychological flexibility. With regard to the cognitive component of treatment rather than teaching patients to challenge and change irrational thoughts about their pain or abilities, which is often difficult, patients are guided to mindfully notice and “defuse from” these thoughts in a way that allows them to engage in values-based activities anyway. In other words, the focus is less on trying to control thoughts and more on
disallowing thoughts from controlling them, whether that process involves a natural restructuring of the thought or not. Additionally, ACT typically involves less of a didactic approach and more experiential, or practice-based, components within sessions.36

A recent systemic review and meta-analysis of 11 clinical trials found that ACT for chronic pain is effective in increasing pain acceptance, improving functioning, and reducing depression and anxiety.39 Research comparing CBT and ACT is limited but has generally found few differences, suggesting that either approach is appropriate. One randomized clinical trial comparing ACT to CBT found that both treatments decreased depression, anxiety, and pain interference (i.e., improved functioning), and those assigned to the ACT condition reported higher levels of satisfaction.40

**TREATING COMORBID CONDITIONS**

Chronic pain and mental health disorders frequently co-occur,41 and it is important to manage both conditions in order to optimize recovery for patients with chronic pain.

**Depression and Anxiety**

The link between chronic pain and depression has been well established in the literature.42 In fact, chronic pain and depression are the most commonly occurring physical and psychological conditions, respectively, with co-occurrence rates of 30% to 50%.43 Their link is sometimes referred to as the depression–pain dyad, or depression–pain syndrome,44 given their frequent co-occurrence, tendency to respond similarly to medical and behavioral treatments, and overlap in neurobiologic underpinnings.42 The link seems to be particularly strong for pain conditions without a specific origin; for example, individuals with fibromyalgia are 3 times as likely to have a major depression diagnosis than individuals without fibromyalgia.45 Research has also demonstrated a link between pain and anxiety, with 35% of chronic pain patients having an anxiety disorder diagnosis compared to 18% of the general population.46 Unfortunately, depression and anxiety have historically been associated with poorer pain treatment outcomes.47–49
As discussed earlier in this chapter, CBT was originally developed and evaluated as a treatment for emotional disorders. Thus, the treatment is well suited for chronic pain patients with depression and/or anxiety, as the intervention directly targets cognitions and behaviors that influence affect. The link between physical and emotional factors is explained to patients from the onset of treatment through education about the pain cycle and is repeatedly reinforced throughout treatment. Accordingly, meta-analyses have demonstrated that CBT-CP has a significant impact on both pain outcomes as well as depression and anxiety symptoms. Aggressive treatment of both depression and anxiety to remission is important, as coping with chronic pain can be particularly challenging among patients with active mood disturbance.

**Posttraumatic Stress Disorder**

Chronic pain also frequently co-occurs with posttraumatic stress disorder (PTSD). Studies have shown that 34% to 50% of patients seeking pain treatment also have PTSD, and 45% to 80% of patients seeking PTSD treatment also have chronic pain. The conceptual relationship between PTSD and pain has been explained via the “shared vulnerability” model, which proposes that the fear of physical symptoms predisposes patients to both pain and PTSD as well as the “mutual maintenance” hypothesis, which suggests that pain triggers traumatic memories, and traumatic hyperarousal worsen pains. The link between pain and PTSD has been widely studied in the military veteran population in particular, given the physical and emotional trauma that is often endured in battle. Thus, many veterans, including those from the most recent Operation Enduring Freedom/Operation Iraqi Freedom/Operation New Dawn (OEF/OIF/OND) era, return from deployment with both physical pain and posttraumatic stress symptoms.

Given the frequent co-occurrence and shared fear-avoidance-based vulnerabilities of PTSD and chronic pain, CBT-CP can be appropriately utilized with patients who also have PTSD. Although the specific trauma is not specifically processed or targeted in traditional CBT-CP, the cognitive restructuring, emotional processing, and behavioral skills patients learn in the treatment can be generalized to aid in recovery from
PTSD along with chronic pain. Recently, integrated cognitive-behavioral treatments have been developed to concurrently address both PTSD and chronic pain among veterans, and preliminary data shows therapies incorporating behavioral activation can benefit both pain and PTSD.

COGNITIVE-BEHAVIORAL THERAPY WITHIN INTERPROFESSIONAL PAIN PROGRAMS AND PAIN REHABILITATION PROGRAMS

The broad and diverse impact of chronic pain on physical impairment, emotional distress, and social dysfunction can make chronic pain management overwhelming for individual health care providers. This phenomenon has been recognized from the earliest days of pain medicine and has led to the development of the interprofessional team-based approach as the standard of care for chronic pain management. PRPs, which employ an interprofessional approach (psychology, physical therapy, occupational therapy, medical treatment) in an intensive outpatient setting, are reviewed separately, but it is worth noting the recent renewed interest in PRPs in the midst of this nation’s opioid crisis. Historically, the number of interprofessional pain programs dramatically decreased from over 1,000 programs in the United States in 1999, when they were at their highest number, to approximately 90 programs in 2015 (this number does not include military and the veterans’ administration centers). Much of this decrease can be attributed to the rise in the use of opioid analgesics and economic forces favoring interventional pain management. The culture of diagnostic and interventional pain management at the time had as its premise, “help the patient to feel better so they can function better.” This message has inadvertently led to frustration, patient blaming, and assumptions of psychosomatics and has directly fed the opioid epidemic we are currently battling. As prescriptions for opioid analgesics are now being curbed across the nation, there is now a renewed national interest in PRPs. In fact, the CDC guidelines for pain in 2016 cited PRPs as an evidence-based alternative to using opioids for chronic pain.

Effectiveness of Interprofessional Pain Management
Programs and Pain Rehabilitation Programs
The treatment outcomes of the interprofessional pain programs and PRPs have been well documented and studied and have been shown to improve pain, mood, physical functioning, and return to work and have been shown to decrease medication use and health care utilization and costs. There have been multiple meta-analytic and systematic review types of studies summarizing the effects of interdisciplinary programs and PRPs and their effects on different chronic pain conditions and showing effects were durable on pain, mood, employment, and general health, evident even after 13-year follow-up.

COGNITIVE-BEHAVIORAL THERAPY TO PREVENT THE TRANSITION FROM ACUTE TO CHRONIC PAIN
Close to one-third of acute low back pain patients report continued moderate to severe pain 1 year later. Given the high morbidity and health care costs associated with chronic pain, identifying interventions helpful in reducing the progression of acute to chronic pain could greatly reduce burden of disease, disability, and associated health care costs. There has been appreciable literature identifying psychosocial risk factors for developing chronic pain, such as pain catastrophizing, fear-avoidance beliefs, and depression. Additionally, the complex interaction between pain and disability can be associated with additional risk factors, such as self-reported pain and disability, personality traits, and worker’s compensation or personal injury status.

The definition of acute and subacute pain varies in the literature from <6 weeks to <3 months, and the studies that have evaluated psychosocial interventions to prevent progression from acute to chronic pain focus on nonspecific back pain and vary in rigor. Physiotherapy or exercise therapy are recommended for acute and subacute back pain that is not improving with conservative treatments (heat, massage, nonsteroidal anti-inflammatory drugs [NSAIDs]) or for patients with risk factors for developing chronic low back pain (e.g., poor functional or health status, psychiatric comorbidities) and has been shown to reduce recurrence of back pain. Therefore, many of the studies evaluate the effects of adding CBT to physiotherapy in improving outcomes for acute/subacute back pain.
pain. Earlier studies showed that patients who received CBT reported significantly lower levels of pain and disability compared to those who received electromyography (EMG) biofeedback and a ninefold reduction in sickness time at 1 year when compared to information only.

In a series of studies aimed at identifying and intervening on patients with acute low back pain at high risk for development of chronic pain and disability, Gatchel and colleagues found that high-risk patients who received an early biopsychosocial intervention combining six to nine sessions of physical therapy and six to nine sessions of CBT delivered by a behavioral medicine psychologist demonstrated significantly less pain and disability (including work, health care utilization, and medication use) and improved psychosocial functioning and coping ability when compared to standard care patients at 1 year. However, when evaluating general patients (not necessarily high risk for chronic pain and disability), a trial examining exercise + CBT versus exercise alone found that despite significantly more reported exercise and self-efficacy in the combination group, there were no between-group differences in pain intensity between the exercise-only group and the exercise + CBT group. When evaluating health care utilization and work absenteeism, another study showed that CBT, alone or in combination with physiotherapy, resulted in less health care utilization and fewer missed work days for nonspecific back pain than minimal treatment (reassurance and activity advice) with a fivefold lower risk for developing long-term disability.

Because access to mental health providers to perform CBT can be limited, and physical therapists are a common provider for acute and subacute pain, there have been studies evaluating the delivery of specific cognitive-behavioral interventions (pacing, goal setting, relaxation, challenging unhelpful thoughts) by trained physical therapists. Results show that physical therapist–delivered cognitive-behavioral interventions can significantly improve both pain and disability, with the conclusion that physiotherapy interventions targeting both physical and psychological factors should be routinely employed.

Summary
As the pendulum swings away from opioid management for chronic pain in the United States, there continues to be limited access to nonprocedural, nonopioid pain management, including guideline-recommended nonpharmacologic treatments for chronic pain such as CBT and biopsychosocial rehabilitation. There is an acute need for more research on safe and effective treatments for chronic pain as well as an increased multilevel focus on improving access to these evidence-based nonpharmacologic and noninterventional treatments, so that these treatments that tend to be more time intensive and less well reimbursed can become mainstream, first-line interventions for chronic pain. CBT-CP is a first-line treatment for chronic pain and, especially when offered within an interprofessional PRP, offers a cost-effective approach to stopping the ineffective cycle of seeking an interventional “cure” for chronic pain while patients improve long-term biopsychosocial functioning by addressing cognitive distortions and pain behaviors that lead to “crashing and burning.” Essential to addressing the nation’s opioid crisis comprehensively will be improving access to these nonpharmacologic treatments and fostering their incorporation as early in the pain process as possible.

73. Grotle M, Vøllestad NK, Brox JI. Screening for yellow flags in first-time acute low back pain: reliability and validity of a Norwegian version of the Acute Low Back Pain Screening
The experience of chronic pain is upsetting, frightening, discouraging, and demoralizing and creates significant suffering for those who experience it. Chronic pain sufferers struggle with proving the legitimacy of their conditions, constructing an explanation for their suffering, and negotiating health care system. They also perceive an uncertain future and even a loss of sense of self.1 As chronic pain persists, these experiences can lead to the experience of significant anxiety and depression, among other conditions. The purpose of this chapter is to examine anxiety and depression in the context of chronic pain. It briefly describes the extent of these problems, their impact on individuals who experience them, and the processes in the interaction of these emotional experiences and pain. It also briefly reviews treatments applied to anxiety and depression, with a focus on forms of cognitive-behavioral therapy (CBT). This particularly includes the recent developments in CBT.

Prevalence of Anxiety and Depressive Disorders in Chronic Pain

Estimations of the extent and significance of anxiety and depressive disorders in chronic pain sufferers are not always consistent. Differences in the definition of chronic pain, regarding pain intensity, pain duration, and pain sites as well as differences in sampling methods, including setting and geographical location, can all contribute to variance in prevalence estimates and other measures. Nevertheless, conventionally defined anxiety and depressive disorders appear significantly more frequent among people with chronic pain than those without.

A national survey in the United States showed that among chronic pain
sufferers, 35.1% experienced anxiety disorders and 20.2% experienced depressive disorders in the past year, whereas the respective numbers in the general population are 18.1% and 9.3%. Another national survey found similar rates for anxiety, 26.5%, and depression, 17.5%. Again, these estimates are roughly 1.5 to 2 times as high as those in the general community, which are 18.1% and 9.5% for anxiety and depression, respectively, in the United States.

A large household survey in Canada also showed that the rate of depression present in people with chronic pain, 19.8%, is more than 3 times as great as in those without pain (5.9%).

Demyttenaere et al. carried out 18 surveys in 17 countries representing all five continents (N = 85,088). It was reported that "mental disorders" are more common in people with chronic pain than those without, with a pooled odds ratio (OR) of 2.7 for anxiety disorder, 2.1 for agoraphobia or panic disorder, 1.9 for social phobia, 2.6 for posttraumatic stress disorder (PTSD), 2.3 for major depression, and 2.8 for dysthymia. With further analyses of the same data, the researchers found that mood and anxiety disorders are more prevalent in people with multiple pain sites than those without one pain site and those without. Relative to people without pain, the pooled estimates of odd ratios were 1.8 and 1.9 for mood disorder and anxiety, respectively, among people with single pain site and 3.6 and 3.7 among people with multiple pain sites.

Ohayon and Schatzberg conducted a survey in five European countries, including the United Kingdom, Germany, Italy, Portugal, and Spain. It was found that 43.4% of the subjects with major depressive disorder suffer from chronic pain, which is 4 times more often than in subjects without major depressive disorder.

Another large survey representing 15 European countries suggested that the prevalence of self-report diagnosis of depression associated with chronic pain is 21%.

The results reported earlier are from population-based studies. It is perhaps not surprising that the estimates of the prevalence of anxiety and depression are higher in pain sufferers identified in clinical settings than those in the general population. A survey of patients (N = 5,808) visiting a primary care clinic showed that chronic pain is more commonly reported.
in people with major depressive disorder, 66%, than those without, 43%. In particular, disabling chronic pain is substantially more common in people with major depressive disorder, 41%, than those without, 10%.10 In a study of 1,204 consecutive adults attending a specialty pain service in London, 60.8% met screening criteria for probable depression, and 33.8% met criteria for severe depression on a commonly used, validated, screening questionnaire.11 In a literature review of depression and pain comorbidity,12 the rates for concurrent major depression in pain sufferers were identified as 18% (4.7% to 22%) in population-based settings and an average of 13% to 85% in various clinical settings. Among the 42 studies reviewed, 33 explicitly focused on chronic pain.

**Impact of Anxiety and Depressive Disorders on Functioning**

The high rates of anxiety and depression in chronic pain are worrying, particularly given that the consequences of these disorders with respect to overall health. In the most updated World Health Organization (WHO)13 report of global health, depression is ranked as the single largest contributor to global disability, and anxiety disorders the sixth. Depression was also reported to be the major contributor to suicide deaths, with number close to 800,000 per year. It was estimated that 4.4% of the global population are suffering from depression and 3.6% from anxiety.13 However, in contrast to the high prevalence and significant consequent health loss of these mental disorders, results from WHO surveys also showed that the proportion of people with access to treatment for mental disorders are far lower than that for physical disorders in developed countries, even more so in developing countries, and even for those people assessed as having a severely disablable condition.14

The association between the concurrence of depression and pain and the impairment in functioning has been well documented. In a large-scale survey representing five European countries (N = 21,425), it was reported that people with pain and depression experience decreased work productivity on more than twice as many days per month as those with either condition alone, and more than 5 times as many days per month as
those without either condition. It has also been reported that patients with pain and depression have higher unemployment rates. In a review of 22 studies on comorbidity between depression and pain, it was identified that patients with depression and pain experience impaired social functioning; functional limitations, such as limited mobility and limitation in activities; more days of illness; and more hospitalizations compared to those with pain alone.

In people seeking specialty treatment for chronic pain, those screening positive for probable depression incur 60% higher total health care costs compared to those who do not screen positive. In this study, the significantly greater costs remained for those with severe depression even after adjustment for the role of age, gender, occupational status, the presence of generalized pain, pain interference, and pain acceptance.

Although it is based on fewer smaller studies, there is also evidence showing the impact of anxiety disorders in combination with pain. In a recent survey of 80 patients with chronic neck pain, it was observed that anxiety is associated with greater functional disability. In a study of 250 chronic musculoskeletal pain patients in a primary care in the United States, 45% of the patients screened positive for at least one anxiety disorder and, as compared to those without any anxiety disorder, showed significant worse health status on a range of pain, psychological, and other quality of life–related outcomes. These patients with anxiety conditions also showed substantial functional impairment, the extent of which was strongly associated with the extent of anxiety disorders, in that higher numbers of anxiety conditions were associated with more severe pain-related interference, worse mental health, and more days of disability.

An expanding body of literature has also shown associations between chronic pain conditions, comorbidity with mental health problems, and suicide. A survey suggested that 50% of chronic pain patients had serious thoughts of committing suicide due to their pain disorder. Specific pain-related risk factors, such as pain severity and comorbidity with depression, have been suggested as accounting for the increased rates of suicidal behavior in chronic pain patients. Data from a large-scale survey of Canadian population showed that after controlling for demographics, Axis I mental disorders, and comorbidity (three or more
mental disorders), the presence of one or more chronic pain conditions was associated with both suicidal ideation and suicidal attempt. Among those with a mental disorder, comorbidity with one or more chronic pain conditions was also associated with suicidal ideation and suicidal attempt. Braden and Sullivan investigated the independent association between noncancer chronic pain conditions and the risk for suicidal behavior, using data from a national survey (n = 5,692). The results suggested that after controlling for medical, mental health, and demographic variables, the presence of any pain condition was associated with lifetime suicidal ideation, OR 1.4 (95% confidence interval [CI], 1.1 to 1.8). Data from the same survey similarly identified head pain and a summary pain score as potentially independent risk factors for suicidal ideation and suicide attempt.

The comorbidity of chronic pain with depression and anxiety has also shown association with problematic substance use (e.g., Feingold et al.). In a study including 888 individuals receiving treatment for chronic pain, depression was found present in 88% of the participants with problematic use of opioids and 46.5% of those with problematic use of cannabis, and the prevalence of anxiety was 74.5% and 41.9%, respectively. The results also revealed that any diagnosis of depression, particularly moderate to severe and severe depression, and also generalized anxiety disorder (GAD), again more so with greater severity, were significantly associated with problematic use of opioids and cannabis.

A general finding is that chronic pain sufferers with anxiety and/or depression demonstrate significantly worse quality of life compared to those without. Together with the aftermath of suicide, or problems in the wake of substance abuse, they reflect what is arguably the worst possible quality of life.

Once again, there is significant variability in the evidence surrounding rates and impacts of anxiety and depressive disorders in chronic pain sufferers. For instance, in patients suffering from pain and co-occurring depression, depression may be misdiagnosed due to shared symptoms between pain and depression (e.g., sleep disturbance and weight and appetite changes). Caution is warranted in any attempts at higher precision interpretations of these findings. Nevertheless, numerous studies generally
demonstrate a high rate of concurrence of anxiety and depressive disorders with pain as well as the additional important burden of anxiety and depression disorders on chronic pain suffers, as observed in a wide range of outcomes.

The Interaction of Anxiety, Depression, and Chronic Pain

There has been a long running debate about the relationship between chronic pain and psychopathology associated with anxiety and depression in terms of which comes first or whether one ought to be appropriately regarded as the cause of the other. Available evidence allows for contrasting interpretations. For instance, patients with preexisting depression were found to be more likely to develop chest pain and headache.\textsuperscript{27} On the other hand, in a related review of available evidence at the time, it was suggested that depression is most often a consequence and follows the development of pain.\textsuperscript{28} More than 20 years ago, a model called the “diathesis-stress model” was proposed,\textsuperscript{29,30} consistent with this view. In this model, the diatheses are conceptualized as preexisting semidormant characteristics of the individuals before the onset of chronic pain that are then activated by the stress of chronic pain condition. Bank and Kerns\textsuperscript{29} identified the experience of chronic pain itself as the stress component of the model. The researchers also suggested that chronic pain is more likely to result in depression than other chronic medical conditions due to the uniquely challenging nature of stressor associated with chronic pain.\textsuperscript{29} Dohrenwend et al.\textsuperscript{31} investigated this hypothesis with a family study for people with myofascial face pain, using psychiatric interviews. The conclusions were consistent with this hypothesis, suggesting that living with myofascial face pain contributes to the elevated rate of depression. On the other hand, a more recent study investigating the comorbidity of fibromyalgia (FM) and PTSD produced an alternative interpretation for the interaction between chronic pain and anxiety.\textsuperscript{32} In this study, surveys were conducted among community-dwelling women before and after the 9/11 attack in New York City. The odds of probable PTSD were more than 3 times greater in women with FM-like symptoms than those without,
assessed after 9/11. The OR was not reduced after controlling for FM-like symptoms before 9/11 or for the potentially confounded symptoms of PTSD specifically related to arousal. As mentioned, most of this research is now 10 to 20 years old, and some of these conceptualizations are certainly due for an update.

In some ways, it may not be important to know which came first, pain or depression or anxiety, in the early history of the events observed. Instead, an understanding of how this pattern of suffering is maintained and worsened, on a day-to-day basis, may be more practical. This effort should perhaps include identifying the circumstances that give rise to these behavioral patterns, and the most manipulable elements in the patients’ experiences, where impacts on these are most likely to lead to significant and durable improvement in functioning and well-being.

THE FEAR-AVOIDANCE MODEL
Anxiety, or its related more particular form, fear, has been integrated into what is by now a very well-known model of chronic pain and disability, referred to as the fear-avoidance model. The basic assumption of the fear-avoidance model is that the way in which pain is interpreted may lead to one of two different pathways. When acute pain is perceived as nonthreatening, patients are likely to remain engaged in daily activities, which can essentially prevent significant disability or facilitate functional recovery when some disruption is functioning has occurred. On the other hand, when acute pain is perceived as threatening, as a kind of catastrophe, this interpretation may give rise to pain-related fear, which may lead to avoidance behaviors and hypervigilance to bodily sensations, followed by disruption of functioning, including disuse, disability, and depression. In this model, processes including respondent and operant-based learning, in combination with processes of physical deconditioning (loss of physical capacity), possibly muscular reactivity, as well as cognitive processes such as, again, hypervigilance and pain catastrophizing, are proposed as entailing a cycle of mutual influence between behavioral, cognitive, emotional, and muscular processes and reduced functioning.

Numerous studies have investigated the relationships between components of the fear-avoidance model (see review). Associations were
reported for pain with disability (e.g., Boersma and Linton, Leeuw et al., Leeuw et al.), pain catastrophizing with pain disability (e.g., Peters et al., Sullivan et al.), and excessive attention with pain and pain-related fear (e.g., Goubert et al., Goubert et al.). Pain-related fear is positively associated with disability (e.g., Goubert et al., Boersma et al.) and pain intensity (e.g., Buer and Linton, Turner et al.) as well escape/avoidance behavior (e.g., Goubert et al., Al-Obaidi et al.). A systematic review showed moderate evidence for the moderating role of fear-avoidance beliefs in treatment efficacy in people with low back pain. Overall data appear to suggest the relationships between the components of the fear-avoidance models. In addition to the evidence from chronic pain, there has also been evidence for the role of pain-related fear in various stages of pain. For instance, Picavet et al. showed that both heightened pain-related fear and pain catastrophizing during the acute phase increased the risk of future chronic low back pain and disability. Heightened initial levels of pain-related fear were also shown to be related to decreased probability of returning to work and greater probability of being on sick leave and to the recurrence of low back pain and care seeking 4 years later.

A Contextual Behavioral Approach to Anxiety and Depressive Disorders

From a contextual behavioral perspective, to improve health and functioning in people who demonstrate the complex and highly varying pathologic behavior patterns in what we call depression and anxiety disorders, requires identifying functionally important factors, or processes, that contribute to the maintenance and exacerbation of these patterns. One such process proposed is experiential avoidance. Experiential avoidance refers to the behavior pattern reflected when a person is unwilling to remain in contact with particular private events, such as bodily sensations, emotions, thoughts, and memories, and takes action to alter the form or frequency of these events or the contexts that occasion them. Experiential avoidance has been proposed as a functional dimension underlying a wide range of behavioral disorders, including anxiety.
disorders\textsuperscript{53} and depression.\textsuperscript{54,55} It is suggested that experiential avoidance, regardless of its form (e.g., elaborate rituals observed in people with obsessive-compulsive disorder [OCD], or work absence observed in people with chronic pain), generally reflects the same function, avoiding or escaping from unacceptable private events, such as anxiety. This type of response, in turn, can be additionally negatively reinforced by the avoidance of related undesirable thoughts and other private events that occasion or follow these.\textsuperscript{53,55}

In depression, experiential avoidance appears to be a particularly active ingredient related to the perpetuation and exacerbation of the depressive condition, even though this is less typical to consider depression as an avoidance-related disorder. Certainly, the “social withdrawal” aspect of depression is avoidant in quality, and the irritable mood that is often present can function to drive others away, resulting in reduced contact with others. Withdrawing in one’s activities after some types of losses can be acquired from a history of avoiding further losses, such as when being withdrawn allows some prevailing threats to pass. Kanter et al.\textsuperscript{54} suggested that the core experiences of depression, the elicited emotional or affective experiences, are normal and adaptive. For instance, the capacity to experience low mood or sadness in appropriate situations can have short-term benefits such as initiating social support. So-called “clinical” or pathologic variants of depression then are simply cases of maladaptive dysregulation or overextensions of this adaptive pattern. Here, experiential avoidance is proposed to be one process by which initial emotional responses can lead to chronic and maladaptive depression in the absence of chronically maladaptive environments.\textsuperscript{54,55} In this view, the emotional experiences, once elicited and then maintained may play a role in maintaining, exacerbating and creating additional “symptoms” of depression. To say this more succinctly, when the initially elicited private responses to loss are functionally aversive, they can evoke behaviors that function to avoid or escape the private responses. The avoidance of these experiences, even when it works to keep feelings muted in the short term, can in turn produce additional long-term problems.

Indeed, a contextual behavioral analysis of anxiety and depressive disorders does not yet constitute a complete account. Even so, a complete
review of this effort is beyond the scope of this chapter. One point that should be clear in this effort is that it is somewhat unconventional, less devoted to diagnoses and disorder, and more devoted to functionally meaningful factors or dimensions that give rise to, maintain, and exacerbate the pathologic behavioral patterns. This approach is inherently transdiagnostic, applicable equally to all the people who experience these “disorders” discussed earlier, regardless of the surface symptoms. In this effort, experiential avoidance has been identified as a potential functional dimension underlying these disorders. There are others, particularly facets of what is called psychological flexibility, to be discussed in a subsequent section of this chapter.

Treatment of Anxiety and Depressive Disorders

EVIDENCE FROM PHARMACOLOGIC APPROACHES

Pharmacologic treatments are commonly used in depressive disorders. However, there have been ongoing debates about their relatively small effects as compared to placebos observed in clinical trials and whether these are clinically meaningful. A recent systematic review including 66 studies (n = 15,161) investigated the efficacy and acceptability of pharmacologic treatments for depressive disorders in primary care. Most of these studies were of short duration (up to 12 weeks). Meta-analyses suggested that more patients responded (showing at least 50% reduction in scores from depression measures) to some forms of pharmacologic treatment, including tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), a serotonin norepinephrine reuptake inhibitor (SNRI), a low-dose serotonin antagonist and reuptake inhibitor (SARI), and hypericum extracts, as compared to placebo, but effects were relatively small, with estimated ORs between 1.69 (corresponding to a number needed to treat [NNT] of 7 to 8) and 2.03. Meta-analyses of acceptability of treatments suggested that some drugs including TCAs, SSRIs, SNRI, norepinephrine reuptake inhibitor (NRI), and noradrenergic and specific serotonergic antidepressant agents (NaSSAs) were associated with significantly more study discontinuations, resulting from adverse effects, than placebo. Overall, these results are comparable with findings
from a previous review, suggesting a statistically significant but small short-term effect of antidepressants for depression, and higher risk of harm for patients in pharmacologic treatments as compared to placebo. Pharmacologic treatments may help in preventing subsequent relapse and recurrence but only for so long as one stays on them.

Medications do not appear superior to nonpharmacologic treatments for depression. For instance, a recent review including 44 trials compared second-generation antidepressants (SGAs) with various forms of nonpharmacologic treatments for adults with major depressive disorder. It was reported that SGAs and CBT lead to similar rates of response to treatment (relative risk = 0.91, 0.77 to 1.07). However, patients treated with SGAs have a higher risk of experiencing adverse events or discontinuing treatment because of adverse events, as compared to CBT, acupuncture, or St. John’s wort.

The evidence from pharmacologic treatment for anxiety disorders appears to demonstrate a similar pattern. For example, a Cochrane review of antidepressants for GAD suggested the efficacy of antidepressants in reducing anxiety symptoms, with an NNT of 5.7, indicating six patients need to be treated to lead to an additional one achieving clinical improvement. However, antidepressants were found associated with significantly more side effects such as nausea, dry mouth, constipation, drowsiness, insomnia, anorexia, sexual dysfunction, and flatulence. A more recent Cochrane review of second-generation antipsychotics for anxiety disorders suggested comparable results. Participants with GAD responded significantly better to quetiapine than to placebo (OR = 2.21; 95% CI, 1.10 to 4.45). However, they were more likely to drop out due to adverse events, to gain weight, to suffer from sedation or to suffer from extrapyramidal side effects. Again, as in depression, most of these studies were of short duration.

It is worth mentioning that antidepressant medications, typically used to treat depression and anxiety disorders, are also used as first-line analgesics, in such pain conditions as neuropathic pain. The best performance from these medications achieve a modest NNT for 50% pain relief of 6.4 (95% CI, 5.2 to 8.4) for SNRIs in these conditions. In clinical practice, there is often a presumption that these medications might
help the patient to achieve multiple improvements, in pain, depression, anxiety, and sleep, where needed. This seems certain to provide some efficiency in treatment and to be practically useful, particularly where alternative mental health services are difficult to access. We only add that the rates of response from these medications, both for pain and for depression, for example, leave many patients remaining in need of relief and support.

**EVIDENCE FROM PSYCHOLOGICAL APPROACHES**

In addition to pharmacologic treatments, psychological treatments, as well as treatment combining pharmacologic and psychological treatments, are also commonly used for anxiety and depressive disorders.

A group of researchers comprehensively reviewed the meta-analyses for the efficacy of CBT applied to a variety of problems, and CBT for anxiety disorders was identified as among those with the strongest supportive evidence, with medium to large effect sizes reported for a variety of anxiety disorders.

In a systematic review of CBT for anxiety disorders, CBT was identified to be superior to placebo with a medium effect size (Hedges’ g = .73) for anxiety disorder severity and a pooled OR of 4.06 (95% CI, 2.78 to 5.92; z = 7.26; P < .001) for treatment response. In addition, no significant difference in attrition rates between CBT and placebo was observed. When analyzed using intention to treat samples, the effect size became smaller, yet still significant. CBT was also identified as superior to active controls, such as applied relaxation and counseling. Evidence for some secondary symptoms, such as sleep dysfunction and anxiety sensitivity, also supports the efficacy of CBT. In addition, there is evidence from meta-analyses supporting the short-to-medium term effect of CBT for anxiety disorders, such as social phobia. CBT has been found similarly effective compared to medications for depression as well as for anxiety disorders.

When psychological and pharmacologic treatments are combined, meta-analysis suggest the combined treatments are superior to either treatment alone at the acute treatment stage, but not more effective than psychological treatment alone in long term, particularly considering the
harm due to medication side effects.\textsuperscript{74} These results led experts to speculate that having active medication in the system during treatment may undermine the enduring effect of CBT.\textsuperscript{75} Naturally, more studies are needed to test this hypothesis. Nevertheless, some patients did appear to respond to pharmacologic treatments, and pharmacologic treatments also showed enduring effect of preventing patients from relapse, as long as the medications are continued. Although caution against the harm to patients due to the side effect of medications should be taken, evidence for psychological treatment, CBT in particular, supports its enduring effectiveness with little risk of harm to participants.

In a relatively new set of developments, Internet-delivered therapist-guided forms of CBT, which are regarded more accessible and cost-effective compared to face-to-face treatment modality, show promise in the treatment of anxiety. A recent Cochrane review of Internet-delivered therapist-guided CBT for anxiety disorders, suggested the superiority of Internet-delivered therapist-guided CBT, in reducing anxiety symptoms at posttreatment, in comparison with a waiting list, attention, information, or online discussion group control.\textsuperscript{76} Low-quality evidence also suggests no significant difference between face-to-face CBT and Internet-delivered therapist-guided CBT.\textsuperscript{76} However, an overall low quality of evidence and short-duration investigations represent important caveats.

The evidence of CBT for depression appears less consistent. CBT for depression was reported more effective than inactive controls, such as waiting list or no treatment, with a medium effect size.\textsuperscript{77,78} However, when compared to other active treatments, such as psychodynamic treatment, problem-solving therapy, and interpersonal psychotherapy, CBT produced mixed results. Some evidence from meta-analyses suggested that CBT is equally effective as other psychological treatments.\textsuperscript{78,79} However, evidence in favor of CBT also exists.\textsuperscript{80,81} For instance, CBT was found superior to relaxation techniques at posttreatment.\textsuperscript{80} CBT was also reported to be superior to psychodynamic therapy at both posttreatment and at 6-month follow-up, although depression and anxiety symptoms were examined together here.\textsuperscript{81}
PAIN: EFFECTS ON DEPRESSION AND ANXIETY

The application of CBT to chronic pain also produces some evidence for the effectiveness of CBT in improving depression and anxiety, albeit with limited effect sizes. In a Cochrane review of psychological treatments for chronic pain, 35 studies were included in the analyses. When compared with active controls, the overall effect of CBT was significant on disability, standard mean difference (SMD) = −.19, and catastrophizing, SMD = −.18, with small effect sizes, but not on pain or mood (depression and anxiety) at posttreatment. The effect of CBT was only significant on disability at follow-up with a small effect size, SMD = −.15. When compared with treatment as usual, the overall effect of CBT was significant on all outcomes examined, including pain, SMD = −.21; disability, SMD = −.26; mood, SMD = −.38; and catastrophizing, SMD = −.53, at posttreatment. However, the effect disappeared at follow-up, except for a small effect on mood, SMD = −.26.

Developments in Cognitive Behavioral Therapy

There are current developments within CBT. One of these is called contextual cognitive-behavioral therapy (CCBT), including acceptance and commitment therapy (ACT), and often referred to as the “third wave” CBT. CCBT stems from the philosophy and worldview of functional contextualism. In this view, behavioral events are ongoing acts, having meaning only with reference to its historical and situational context. Therefore, thoughts and feelings may be related to particular behaviors, but only in historical and situational contexts that give rise to these experiences and their relation to the subsequent actions. In other words, the contents of thoughts and feelings are not problematic unless the context lends the thoughts influences on actions that undermine one’s goals and values. Therefore, CCBT as a treatment approach does not focus on creating changes in the content or frequency of one’s thoughts and feelings, rather one’s “relations” to these thoughts and feelings. CCBT specifically aims at reducing experiential avoidance and related pathologic processes in behavior. All of this means CCBT includes a very different way of looking at depression and anxiety compared to what is
usually done.

A reliable and valid measure of experiential avoidance, the Acceptance and Action Questionnaire (AAQ), was developed to assess various aspects of experiential avoidance and shows moderate to high correlations with measures of general psychopathology, such as measures of general health and quality of life, as well as standardized measures of anxiety and depression. In the domain of pain, pain-related avoidance also has been widely explored, in the form of its polar opposite, pain acceptance. For example, Vowles and McCracken found that the improvement in acceptance of pain was significantly correlated with the reduction in pain intensity, depression, pain-related anxiety, physical and psychological disability, and physical functioning, with a small to medium effect size during the treatment. The correlations remained significant at 3-month follow-up for pain intensity, depression, pain-related anxiety, and physical and psychological disability. In addition, McCracken and Gutiérrez-Martínez reported the significant associations between general psychological acceptance and pain acceptance, and depression, pain-related anxiety, physical disability, and psychosocial disability, independent from pain. Overall, these empirical findings support the association between experiential avoidance and anxiety, depression, and other aspects of functioning and well-being in pain sufferers. Again, it is beyond the scope of the chapter to provide a complete contextual behavioral account of anxiety or depression, or the pattern of concurrence of these problems and pain. Nevertheless, as outlined earlier, and shown here in evidence, experiential avoidance appears to be a relevant functional dimension related to these complex behavior patterns.

Although the specific application of CCBT to anxiety and depressive disorders is still, as we say, incomplete at this stage, evidence from a meta-analyses show that the “third wave” CBT, regardless of treatment modality, appears to be superior to treatment as usual, and as effective as other psychological treatments for depression.

Accumulating studies of the application of CCBT to chronic pain have produced supportive evidence for effects on depression, anxiety, and other aspects of functioning in chronic pain sufferers. In a systematic review of contextual, “acceptance-based,” treatment for chronic pain, 19 studies
RCTs, 5 clinically controlled studies with randomization, and 5 noncontrolled studies) were identified and included. When all studies were included in the analysis, significant moderate pooled effect sizes were found for pain, physical functioning and disability, depression, anxiety, and quality of life, SMD = .47 to .69. Pooled effect sizes from all controlled studies suggested a significant and small effect on these outcomes, SMD = .24 to .41. Pooled effect sizes from RCTs suggested a small and significant effect on pain and depression, SMD = .26. Overall, these findings suggested that CCBT is a good alternative to CBT.

In an update of the previous review, 25 RCTs were identified and included in the main analyses. Significant and small effects were found for pain intensity, SMD = .24; disability, SMD = .40; and depression, SMD = .43, and significant and moderate effects for pain-related interference, SMD = .62, and anxiety, SMD = .51, at posttreatment. A small effect was found for quality of life, SMD = .44, but not to a statistically significant extent. Improvements in all outcomes maintained or increased at follow-up with small to large effect sizes for pain intensity, SMD = .41; for pain-related interference, SMD = 1.05; for disability, SMD = .39; for depression, SMD = .53; for anxiety, SMD = .59; and for quality of life, SMD = .66.

A recent systematic review identified 11 RCTs of ACT for chronic pain. When compared to controls, ACT was favored at posttreatment with an overall large effect size for the key processes of ACT, including pain acceptance, SMD = .84, and psychological flexibility, SMD = −.87, as well as a small effect size observed for functioning, SMD = −.45; a medium effect size for anxiety, SMD = −.57; and a large effect size for depression, SMD = −.84, but not quality of life or pain intensity. The effect sizes are generally smaller at follow-ups. When ACT was compared to active treatments, ACT was favored over applied relaxation at posttreatment on pain acceptance, SMD = .84; quality of life, SMD = .40; and functioning, SMD = .70, and the effect sizes at follow-up were generally similar or smaller.

Again, overall findings from reviews show CCBT is a good alternative to conventional CBT. Perhaps more importantly, these promising findings suggest the potential of CCBT to address the complex, multiproblem,
behavior patterns observed in chronic pain sufferers, including the problems included with categories of depression and anxiety.

Summary

The suffering of anxiety and depressive disorders, as these are conventionally conceived, is evident in people with chronic pain in the community and even more so in the clinic. These conditions impose limits on the physical functioning of people who experience them, interfere with their work and social functioning, reduce quality of life, and lead to significant disability and suffering. Despite the high prevalence of these problems and the significant burden they impose on individuals, communities, and national resources, these problems are not yet adequately addressed.

In general, pharmacologic treatments and psychological treatments, including CBT, focused on reducing anxiety and depression, most consistently produce at least small benefits, mostly in the short term. Medication for depression does not appear to be superior to CBT, even though it appears more frequently applied, and in fact, CBT has fewer adverse side effects. CBT for anxiety disorders in particular produces larger benefits, medium effect sizes, or better. Psychological treatments for chronic pain, again typically CBT, can also produce benefits for depression and anxiety, again on average small in magnitude.

Over time, depression and anxiety are increasingly looked at not only as disorders or syndromes reflected as sets of symptoms but also as complex patterns of behavior that result from multiple psychological processes. Talking about depression and anxiety problems as separate categories of symptoms, separate from other domains of functioning, has clinical utility to a certain extent but may be inadequate to address the complex pathologic patterns of emotions and overt behavior observed in people with these problems. Calling a problem “depression,” for example, can create the sense of a “real entity” around the elements and a sense of a unifying cause for the whole set. On the other hand, a functional analysis of how these elements interrelate with each in other, with and in a context that is both situational and historical, can provide a different perspective.
This could include a contextual analysis of how the pattern of responses is maintained and worsened, including identifying underlying functional dimensions, and related manipulable events that can create the basis for intervention. Such an analysis could serve practical clinical purposes better. Included in this effort currently is the exploration of a process or functional dimension called experiential avoidance, for example.

The investigation of experiential avoidance is still at early stage. However, as a potentially shared functional process among these emotional experiences, chronic pain, and other related problems in human functioning and well-being, this process appears potentially important and useful for addressing suffering in people with chronic pain. It is, as implied, a fully transdiagnostic process, the kind often called for to improve approaches to treatment development.

A recent development in CBT, a functional contextual approach to human functioning and well-being, called CCBT, is producing promising results. CCBT does not focus on creating changes to one’s thoughts and feelings, or one’s moods, but rather in one’s “relations” to one’s thoughts and feelings and the contexts that support those relations. Hence, rather unconventionally, it is not focused on reducing symptoms of anxiety and depression as such and even reflects little interest in disorders named according to, and defined by, the experience of emotions. This is a defining feature of CCBT. It is focused on processes of pathology and well-being and not on diagnoses and syndromes. Perhaps most radically, in this approach, experiences of anxiety and depression are regarded as normal within the realms of being human, and it is just the impacts on behavior from these experiences that are targeted for change.

In chronic pain, CCBT has been applied and has produced promising results in a wide range of outcomes including physical and emotional functioning, work and social functioning, and quality of life, among others (e.g., Hughes et al., McCracken and Morley). The accumulating evidence appears to suggest significant potential for CCBT in addressing various problems that come with the experience of chronic pain, including the different varieties of how people suffer emotionally with it.

History of Hypnosis in Pain and Symptom Control

Hypnosis is a word derived from the Greek word meaning “sleep.” The fairly ancient practice was used by the Druids, the Celts, and by the Egyptians who frequented “sleeping temples” for relaxation and healing. In the 1770s, the Austrian physician Franz Friedrich Anton Mesmer (1734–1815) was interested in the effect of physical energy and magnetism on the body and spirit. He placed his patients in a tub of iron filings and with wide sweeps of his arm made “passes” up and down the patients’ bodies. The success of the practice, termed mesmerism, was attributed to animal magnetism, whereas the benefits were probably due to the hypnotic effect of his arm-waving ritual. In the 1830s, practical uses of mesmerism were discussed by Oliver in the United States and by the French Academy of Medicine. James Braid (1795–1860) in Scotland termed the word hypnosis in 1843, thinking it to be a stage of sleep that influenced the nervous system and distinguishing it from the state of mental concentration. Braid concluded that the relaxing suggestions diverted the patients away from critical thinking and led them into trance. Pavlov in the early 1900s also viewed hypnosis as an incomplete sleep state that allowed patients to mentally separate off from what was going on around them.

John Esdaile (1808–1859)\(^1\) began using trance inductions with surgery patients in 1845 in India, where there were not anesthetics available; he found the hypnotized patients to have increased resistance to infection, greater comfort, and quicker recovery times. In Europe, the School of Hypnotic Study was being formed in Nancy, France, where the view was that suggestion led to hypnotic trance states that were quite normal phenomena. Neurologist Jean-Martin Charcot (1825–1893) also noted that hysteria was effectively treated with hypnotism; although he brought
hypnotism into favorable light, he viewed it as a part of the hysteria process and not a normal healthy phenomena. However, there does appear to be a high proportion of patients with hysteria-related psychopathology who are highly hypnotizable.2

Pierre Janet (1849–1947) saw hypnosis as dissociation or a split away from cognitive consciousness, which was sometimes normal and healthy and other times related to dissociative states or multiple personalities. Freud in the late 1800s became interested in accessing repressed memories through hypnosis, recognizing it as a pathway to the unconscious mind. However, he was not a good hypnotist and therefore abandoned it; in doing so, he led others away as well. However, he did continue his interest in the hypnotic properties of dreams and free associations.

In the mid-1840s, the introduction of chloroform and ether into surgical practice was another reason for the apparent hiatus in the use and study of hypnosis in medicine. In the 1950s, its use in understanding the workings of the mind and its application to psychotherapy began to pick back up. In the United States, psychologist Clark Hull3 documented its use for anesthesia, posthypnotic amnesia, and pain relief. Milton Erickson conducted many of these experiments and went on to study the mechanisms of trance practices brought to him by Jay Haley and Margaret Meade. Erickson had an exquisite understanding of the mechanisms of the unconscious mind, and his personal understanding of its effectiveness for reducing physical pain, through his personal use of self-hypnosis, left him well-poised to research, practice, and teach hypnosis for symptom control and pain management. The American Society of Clinical Hypnosis (ASCH) was founded in 1957 as a spinoff from the Society for Clinical and Experimental Hypnosis (SCEH), founded in 1949. Hypnosis was endorsed by both the American Psychological Association (APA) and the American Medical Association (AMA) in the late 1950s. The British Medical Association in 1958 endorsed its use as an anesthetic in certain surgical situations.

In a way, there is a great difference between the linear and precise thinking of modern medicine and the spiritual and imagination-rich mosaic thinking of the hypnotherapist; yet, in this chapter, they come together in the discussion of pain as a psychological event and of the role of
expectancy and hope in pain management and general wellness. The early researchers and practitioners identified that the spiritual and magical element of hypnosis were somehow related to positive expectation as noted in the early practices of Mesmer with his magnets, Freud with his dream work, and Erickson with his positive mind-set of hope and respect for the patients. These men all identified the role of the unconscious mind in psychosomatic symptom formation and, in doing so, let down the Cartesian wall between the mind and the body. They also recognized that the highly hypnotizable person may be more likely to develop psychosomatic symptoms but also may be more likely to benefit from hypnotic treatment. Upcoming sections in this chapter discuss pain as a psychological event that is moderately plastic and open to suggestion. Research shows that the triggered memory of pain and the expectation of future pain can be as painful as injury-induced pain. In 1970s, there began to be an interest and upsurge in multidisciplinary pain management. Fordyce, Bonica, and many others were at the forefront of the physicians, scholars, and researchers who moved the field forward in the 1980s. Although the ideal was for patients to be holistically treated by all disciplines together, psychological management is still usually done separate from medical treatment. Turk reviewed outcome data for patients receiving care from interdisciplinary chronic pain and rehabilitation programs (ICPRPs) compared with other care. He found that pain reduction and activity level of patients in ICPRPs was as good as or better than patients receiving standard medical treatment, and that iatrogenic complications, medication use, and health care utilization was less, with more patients returning to work. Other studies demonstrate that the outcomes of psychological treatment for chronic pain compare favorably to more invasive measures and to narcotic use. A systematic Cochrane review concluded that cognitive interventions combined with exercise are recommended for chronic low back pain, and this is discussed in detail in Chapter 73. There is also strong evidence that intensive multidisciplinary biopsychosocial rehabilitation improves function when compared with inpatient or outpatient nonmultidisciplinary treatments as summarized in Chapter 90. A study reconfirms the cost-effectiveness of perioperative hypnosis when used for patients in their hospitals. Given the evidence, we
may expect that less invasive and less costly treatments may become the preferred options of patients, their providers, and insurance companies. An extensive review of the research found hypnosis to meet the APA’s criteria as an effective pain treatment for pain and superior to medication.

In the remainder of this chapter, I will explain hypnotic trance as a state of mind and describe its use in behavioral medicine in general. I will then discuss current understanding of how hypnosis works at the unconscious level in general and for pain relief, citing literature on brain mechanisms of pain. I will outline research suggesting hypnosis application to specific types and locations of pain and some commonly used hypnotic techniques to treat them. Even though some studies discuss symptom relief (tension, twitches, allergies, anxiety, rashes) as separate from pain itself, usually symptom relief leads to pain relief down the road. This chapter describes both traditional and newer practices of pain hypnosis and provides information on certification and training. I conclude with a discussion on chronic pain, where the emotional suffering related to pain, is a notable dynamic.

**Hypnosis by Definition**

Hypnosis is a process of bypassing the critical thinking cognitive mind to access unconscious processes. Without the critical thinking filters, the hypnotized person may be more suggestible and more easily influenced by the hypnotist. During hypnotic trance, a person can focus intently on just one aspect of an experience or dissociate from the experience to the point of losing track of his body and his whereabouts. Succinctly, hypnosis is simply a programmed entrance into “trance,” which is itself a perfectly normal state that we engage in whenever we are totally absorbed in a task or experience and are not reviewing the characteristics of our experience. Formally, hypnosis is “a social interaction in which one person, designated the subject, responds to suggestions offered by another person, designated the hypnotist, for experiences involving alterations in perception, memory, and voluntary action,” hopefully for the sake of some change the patient desires. Professionals should be thoroughly trained in hypnosis before practicing it and should work only in the areas of their professional
CONSCIOUS, UNCONSCIOUS, AND CONTENT OF CONSCIOUSNESS

A brief review of the conscious and unconscious minds will serve as the groundwork for discussing the mechanisms of hypnosis itself as well as the psychosomatic process of interpreting and feeling an emotional experience as physical pain.

A. Consciousness: what you are oriented toward in the present
   1. Content of consciousness (i.e., perceptions and specific thoughts): what is on your mind and in your thoughts, including what is “on the back burner”
   2. Selective consciousness: what you choose to have in the front rather than in the back or periphery of your mind

B. Unconscious
   1. Long-term memory: which you may or may not access when necessary
   2. Short-term memory: which has happened recently
   3. Automatic functioning that usually but not always bypasses your conscious mind. This is sometimes called the primary process or body language that demonstrates when you are angry, happy, or frightened. It also includes behavior such as scratching an itch or catching yourself before you fall.
   4. Programmed physiology that you have little or no access to in normal thinking state, such as your heart beating, breathing, allergic responses, healing rate, etc.
   5. Deeper processes such as the essential self, (the “essence” of you or your sense of who you are at the core). Other parts of the self are the immune system and the neurologic map or the body.

We might say that the conscious mind includes awareness and cognition, and the unconscious mind includes everything else, including your physical self. Cognition is a tool to help with survival and with the expression of your sense of yourself; it is a small part of the whole self-constellation in a somewhat figure–ground relationship. The unconscious mind is adaptive and capable of profound change, potentially with both positive and negative outcomes.

When you are “associated” to a situation, you see it through your own eyes, and you are fully present to it; an example of this is the child who is involved in a task but is not monitoring himself and who needs an adult to oversee his behavior. In reflective thinking, you are in both the conscious and unconscious minds and processes at once, contemplating an idea or
situation by looking into your unconscious mind to find new perspectives for viewing or approaching it. The conscious and unconscious processes can operate autonomous of one another, in the condition of dissociation (dis-“associated”), occurring when ideas are split off from the normal (associated) experience and when, to some extent, you are not paying attention. When dissociated, you may take a global experience of the situation and break it down into parts, amplifying one part while diminishing concentration on the other part—when, for instance, you notice one aspect of the situation and no longer notice others. You may see the situation and also see yourself in the situation, or you may see the situation differently. This can occur during trauma or during hypnosis; for instance, during surgery, you can dissociate from pain by imagining yourself at the beach and seeing the beach at the same time or dissociate from a body part during surgery and believe it to be having surgery or recuperating across the room. In an internally directed trance state, the patient may shut off pain and influence healing, immune functions, heart rate, blood flow, and autoimmune responses not commonly accessed in normal consciousness. Again, hypnosis is merely the programmed entrance into trance or dissociation at some level, and hypnotherapy is the programmed entrance into trance for therapeutic purposes.

Actually, the hypnotist or hypnotherapist is merely guiding the patient to self-hypnosis. Unless the state is induced with hypnotic medications or other psychoactive substances, the patient is the one to suspend vigilance, and his ability to do so is likely to depend on (1) the relationship that he has with the hypnotist, (2) the skill of the hypnotist inducing the trance, (3) the safety of the situation and environment, (4) the patient’s level of hypnotizability, (5) the patient’s expectancy that he will receive benefit and relief, (6) the patient’s need for the trance—pain itself can be a trance state to tap into, and (7) the patient’s past experience with trance states—ranging from dissociative disorders leading from experienced trauma to meditation and past hypnosis training.

Complementarity, the quantum physics concept of relativity, helps explain the use of hypnosis for pain control. Basically, it is impossible to be wholly in one state (fully present and focused in one perspective, such as the dissociative state) and keep another state (e.g., being in pain) fully in
mind at the same time; the difference is being in the moment versus thinking about the moment. When you are fully locked into pain, you cannot get perspective to solve the pain problem; you need to dissociate from the pain somewhat to get a better perspective on it. Once you dissociate from it, you can no longer feel it. The hypnotherapist facilitates the process. Other examples of split consciousness or going back and forth between the conscious and the unconscious minds are the rewriting the endings of dreams (lucid dreaming), remembering that the stove is on while watching television (split concentration), and accessing memories—all of which are normal functioning but also, in a way, related to hypnosis. These principles of trance and hypnotic states are important to understanding hypnotic pain management. The more access to the unconscious mind one can gain by self or guided hypnosis, to imagine or create another way of being or feeling, the more control of pain and physiologic symptoms one may have.

Central Mechanisms

CENTRAL MECHANISMS OF HYPNOSIS

Hypnosis has been viewed as magical, energy related, sleep related (Braid and Pavlov), psychosomatic, pathologic (Charcot), dissociative, and the consequence of normal suggestibility—all of which are partly true. Recent brain research using functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scans shed more light on the process. In general, the studies show that there are many brain areas involved in the hypnotic process, including simultaneous increased activities in some areas and selective shutting down of others. We can conclude that high- and low-hypnotizable people show different brain response patterns to hypnotic analgesic suggestions. However, there is no specific area of the brain that controls pain. Some studies look at performance on certain tasks (learning, verbal, auditory) and in certain situations (pain, for example) before and during hypnosis, whereas others compare high- and low-hypnotizable patients or subjects.

Clinicians as far back as Freud have known that some people are more suggestible or susceptible to hypnosis than others. About 15% of people
are highly suggestible, 65% are moderately, and 20% are not very suggestible.\textsuperscript{12} Although hypnotizability is a fairly stable trait and not related to intelligence, people can learn or improve on their ability to develop or maintain trances, use self-hypnosis, and relax vigilance. Furthermore, hypnotizability is somewhat variable within individuals depending on factors such as the situation, the hypnotist’s skill, the patient’s motivation level and expectancies, the relevance of the induction and trance to the patient, and patient’s physical and psychological state. Experienced hypnotists help patients lower their vigilance by addressing all of the aforementioned factors and, even more important, by sensing and identifying the way their patients unconsciously process information in order to help them be maximally at ease (see Haley\textsuperscript{16} and Bandler and Grinder\textsuperscript{17} or an introductory manual on hypnosis for examples of hypnotic inductions).

**HIGH AND LOW HYPNOTIZABILITY**

Over the last two decades, Gruzelier\textsuperscript{18} has been involved in numerous experiments studying high- and low-hypnotizable patient’s brain responses to experimental tasks during pain episodes and other situations. His studies seemed to show that in a hypnotic state, subjects can selectively ignore what is in their perceptual field while still knowing what is there. This is important regarding pain, in that often the patient’s focus is as much on misery and helplessness as it is on his physiology; the clinician may not be able to change the physical condition, but he may help the patient selectively disregard the pain and the suffering. Gruzelier\textsuperscript{18} found that in general, highly hypnotizable subjects exhibit more neurophysiologic and cognitive flexibility (see also Evans\textsuperscript{19}), which include “superior abilities in absorption, creativity, dissociation, attention, and vividness of imagery; these are all well-known correlates of hypnotizability.” Regarding hemisphere involvement, highly hypnotizable persons (highs) under hypnosis demonstrate more right hemispheric frontolimbic influence. Furthermore, there is more neuronal flexibility going from the right to left and from the left to right hemispheres, and, according to Gruzelier,\textsuperscript{18} “in stimulus repetitions, highs showed a shift from an initial right-sided preference, in line with the right hemisphere’s role in global orienting, to a
left hemisphere preference, in line with the left-sided involvement in the local orienting process,” indicating absorption. One study found greater informational exchange in the prefrontal areas of highs during hypnosis.\textsuperscript{20} Highs were better able to inhibit pain from their conscious awareness. fMRIs showed them to have a significantly larger rostrum area, the corpus callosum area involved in transferring problem-solving information between the left and the right hemispheres. Gruzelier emphasized another difference between “highs” and persons with low hypnotizability (lows) during an auditory attention task: Prehypnosis, highs increased event-related potential (ERP) N100 activity (engaging frontal attentional circuits), whereas lows had little activity, indicating distraction; under hypnosis, highs had little activity, indicating disengagement of the frontal process or distraction, whereas lows’ activity progressively increased.\textsuperscript{21}

Other studies involving mental tasks showed increased activity in the anterior cingulate under hypnosis in highs more than in lows (indicating that they were monitoring the task) and a decrease in the inferior frontal gyrus activity (indicating that they were disengaging from executive functioning).\textsuperscript{18} In other words, highs under hypnosis are relatively better at actively not paying attention to what they still know is in the field; they seem to let go of attending it. This seems to represent frontolimbic inhibition on the left side and a shift to the right brain, engaging the patients’ ability to feel or imagine things different than they were before. Hypnosis involves activation of the hippocampus and inhibition of the amygdala activity at the same time.\textsuperscript{22} A fractal analysis of electroencephalography (EEG) in patients under hypnosis showed dissociation of centralized activity and a loss of the normal patterns of integrated physiologic responses, which results in a trance state.\textsuperscript{23}

**CENTRAL MECHANISMS OF HYPNOTIC ANALGESIA**

Price et al.\textsuperscript{24} provided a statistical path analysis to show four necessary elements of hypnotic analgesia—relaxation; absorption; disorientation from time, space, or sense of self; and automaticity—and their relationship order. Automaticity is the condition in which the suggestion bypasses cognition and leads directly to the sensation or experience, such that the suggestion of sinking into a warm bathtub will allow you to relax your
back muscles and smile, without having to think about it or consciously relax or lower your shoulders. Studies show that imagining heat actually increases blood flow that relaxes muscles, thereby validating automaticity. The principle is similar to direct suggestion and to suggestion through expectancy and placebo. As well, those who exhibit more u brain waves, which would lead to easier visualization and creativity and relaxation, prior to introduction of hypnotic analgesia, get better pain relief.25

Some suggest that hypnotic analgesia works by activating endogenous pain inhibitory systems that descend to the spinal cord, where it prevents transmission to the brain of pain coming from nociception. One study evoked experimental pain in subjects by stimulating the sural nerve, causing the nociceptive flexion reflex (NFR).26 Hypnotic suggestion could both increase and decrease the NFR, leading the researchers to conclude that their hypnotic suggestion actually controlled the response at the spinal level by activating descending antinociceptive mechanisms. However, this does not appear to stem from the opioid system alone,27,28 in that the administration of naloxone, an opioid antagonist, does not reverse hypnotic analgesia. It would seem, then, that there are nonopiate cortical fugal or brain-to-spinal-cord descending control mechanisms.

The relationship between pain and hypnotic or dissociative faculties of the brain is made clearer in recent studies of complex regional pain syndrome (CRPS), which begins with excruciating pain and can progress to include dramatic physiologic changes and neglect or dissociation from the painful limb. According to studies, within moments of an injury or absence of sensory input, there is a reorganization of the somatosensory cortex representation of the injured limb that leads the patient to behaviorally isolate or “favor” the limb. fMRI studies show that the degree of change in the somatosensory cortex is directly related to the degree of perceived pain.29,30 Even when there is painless stimulation in the CRPS patient’s uninjured counterpart limb, there is pain-related activation all through the brain, including cerebral, motor, parietal, bilateral S2, and frontal lobe and the anterior and posterior potion of the cingulate cortex (aACC and pACC).31 When the CRPS pain lessens, however, both the cortical reorganization and impaired tactile sensation return to normal.32,33 Wobst34 summarizes the PET, fMRI, and evoked potential studies on pain,
concluding that the ACC, insular, frontal cortices, amygdala, S1 and S2, and the lateral thalamus are all involved in pain and how the body processes the pain in regard to location and duration. The studies show that the affective (cognitive and evaluative) components of pain are processed in the medial thalamus and progress back to the ACC (also see Derbyshire et al., Vogt et al., Vogt et al., and Peyron et al.).

At the same time, other areas of the brain work to calm and heal. Following awareness of physical or emotional pain, the right ventral prefrontal cortex is involved with soothing responses that are triggered by hypnotic therapeutic suggestions and messages of comfort or healing, which proceed to help the right parietal lobe to reorganize and to perceive the body intact and comfortable (see section on CRPS and phantom limb pain).

In a hypnosis study of experimentally induced pain, high- and low-hypnotizable patients responded differently. Under hypnosis, with the low-hypnotizable patients, as the pain ratings increased, so did frontal γ oscillations; however, with high-hypnotizable patients, as the pain ratings increased, the γ oscillations did not increase. The γ frequencies were noted primarily in the bilateral anterior cingulum (within the limbic system), which supports the understanding of pain being tied in with a complex of emotional responses. The midcingulate cortex may modulate and influence sensory, affective, cognitive, and behavioral aspects of nociception at least in the hypnotic state. Raij et al. used fMRI to compare brain mechanistic responses to noxious stimulation perceptions versus hypnotically hallucinated pain; they found that both real and imagined pain produced similar brain responses, although perception of hallucinated pain was less than the actual induced pain. In both cases, there was activity in the rostral and perigenual ACC and in the percingulate regions of the medial prefrontal cortex. They conclude that the medial prefrontal cortex is involved in monitoring real and hallucinated pain, which then influences how noxious stimuli are experienced and processed. A study exposed subjects to pain (1) in the waking state, (2) with hypnotic relaxation, or (3) with hypnosis suggesting depersonalization (out of body experiences). All the subjects showed somatosensory, insular, and cerebral activation with pain; however, the depersonalization group showed less activation in
the contralateral somatosensory, parietal, and prefrontal cortex; putamen; and ipsilateral amygdala. De Pascalis et al.\textsuperscript{43} have shown somatosensory event-related increase during pain, followed by a reduction when subjects were administered hypnotic analgesia. De Pascalis\textsuperscript{44} found that highs experiencing hypnotic analgesia showed smaller total, $\delta$ and $\beta$ amplitudes in the right hemisphere; they experienced more $\theta$ activity in the left hemisphere during pain and more in the right hemisphere with hypnotic analgesia, decreasing both the sympathetic activity and the overall experience of pain. Meier et al.\textsuperscript{45} showed that hypnotic hypalgesia decreased subjects’ experimental pain; when suggestions about increasing pain were made, somatosensory evoked potentials, auditory evoked potentials, and EEGs remained unchanged from the hypalgesic state, indicating that the physical response to pain and its affective component can indeed be separated. Thus, hypnotizability level certainly appears to impact on the ultimate outcome of hypnosis in general as well as for pain management.

**Pain as a Plastic Experience**

Why is hypnosis particularly appropriate for acute and chronic pain management? How can it be that Jensen and Barber\textsuperscript{46} showed hypnotic analgesia to be more effective than other analgesics, including morphine, for reducing pain? We can begin to answer this by viewing pain as a perception or conclusion derived from a complex interweaving of a real physiologic signal and psychological responses based on expectations and memories of similar past experiences; the perception itself generates feedback to the body. Physical injury and disease cannot fully predict the amount of perceived pain a patient experiences; other determining factors are anxiety and trauma, context of the injury, depression, expectation, social support, and numerous other personality factors and cognitive styles. Interestingly, as is discussed elsewhere in this chapter, those who are highly hypnotizable are often the most likely to experience psychosomatic symptoms of the overlap of psychological interpretation with nociception, but they are also most likely to benefit by hypnosis and other well-applied psychological treatment.
Chapman describes nociception as an unconscious messaging about tissue damage through the nervous system, not to be equated with pain, which is the conscious awareness of that nociception. He defines pain as “a complex, compelling unpleasant bodily awareness normally associated with tissue trauma.” One purpose of pain is to engage the cognitive problem solving part of the brain in a plan to resolve the tissue damage. Biologically, pain is a cascade of neurotransmitter and biochemical responses to nociception, involving the hypothalamo-pituitary-adrenocortical (HPA) axis and the limbic system, and causing changes in blood pressure and blood sugar, serotonin and norepinephrine levels, effecting concentration, mood, behavior, healing, and sleep. Pain can interfere with psychological and physical well-being. When the nociception is not medically treated and stopped, the body’s unconscious responses to it can continue to cause permanent change and damage in other physiologic and psychological systems. At the same time, psychological stress and suffering can lead to the same cascade of physiologic stress responses and even lead to the construction of the sense of pain where no damage exists, which helps to explain why some events, physical or otherwise, cause pain to some people more than others.

Hypnotherapy for pain aims to disengage pain from suffering and soothe both the physical and emotional stress. In the case of acute pain during surgery or procedures and after injury, the patient’s focus can be directed away from the experience, or the experience can be reframed as a beneficial and healing, and one not to be feared. Directing the patient’s focus away from the pain and back into himself is also a way to alleviate suffering, in that the pain would then be differentiated from the patient’s sense of self. Whereas pain is stressful, hypnotherapy is a relaxing and comforting experience that induces brain waves and levels of autonomic functioning that soothe the sympathetic nervous system and enhance healing and resistance to disease (see Gruzelier as mentioned in Liossi by changing the cognitive mind’s and body’s responses to nociception. Patients may simultaneously alleviate pain, promote healing, and learn to manage future pain better, all within the same cost-effective applications. For a detailed review of techniques according to medical problem, see Brown and Fromm and Hammond.
Testing Hypnotizability

Hypnotizability level does appear to influence hypnotic pain management and the outcome of hypnosis in general, although there are ways for the experienced hypnotist to work with it successfully. Researchers may be more likely than clinicians to use hypnotizability scales before engaging in subject or patient interactions. Some say that testing for hypnotizability may actually interfere with the research because testing itself is hypnotic training and subjects become more hypnotizable with practice. Nonetheless, when hypnotizability is very important, such as before attempting intraoperative hypnotic analgesia, it may be wise to use the Stanford Hypnotic Susceptibility Scale (SHSS), Form C, which is a fairly long (over an hour) and stringent test with a broad sampling of hypnotic suggestions. The Stanford Hypnotic Clinical Scale (SHCS) is a shorter version that gives scores for adults in 25 minutes; there are also versions for children. The Hypnotic Induction Profile (HIP) gives scores for adults and children in 5 to 15 minutes; it is based on a simple procedure (the eye roll) that goes beyond suggestibility to autonomic function. The Harvard Group Scale of Hypnotic Susceptibility may be read or administered by tape recording and should be used when there is a need to maintain a pool of subjects of varying suggestibility. The Waterloo-Stanford Group C (WSGC) scale of hypnotic susceptibility is a group version of the SHSS, Form C that may be best used for measuring suggestibility. The Hypnotic State Assessment Questionnaire (HSAQ) assesses patients’ hypnotic state at one point in time and may be used during clinical or experimental sessions. The Elkins Hypnotizability Scale takes 25.8 minutes, identifies four factors, and has good clinical and research correlation with the Stanford Hypnotic Susceptibility scale. Weitzenhoffer points out that suggestibility and hypnotizability are different and that some research has failed because subjects were not really hypnotized but rather merely followed suggestions. To be sure of hypnotizability, he recommends administering the Stanford Profile Scales of Hypnotic Susceptibility, Forms I and II, or at least one of them, and the next best assurance that the patient is in a hypnotic state would be to use a score of 10 as a cutoff on SHSS, Form C.
Lynn et al.\textsuperscript{60} outline various hypnotherapists’ views on assessing hypnotizability levels. Many (see Yapko\textsuperscript{51}) object to the use of such tests, stating that they are obtrusive, undermine the therapeutic relationship, and do not adequately measure hypnotic capacity or take into consideration change in hypnotizability over time. Other options to using tests are to assess the patient’s success with the first induction\textsuperscript{61} or to use a conversational assessment of hypnotizability.\textsuperscript{62} A series of questions can give the clinician a good idea of how easy it will be to get a patient into a hypnotic state (i.e., questions about past hypnotic states or trauma, dissociative tendencies in various realms of life, and right/left brain characteristics).

A scale that may be informative to a psychologist treating pain patients is the Tellegen Absorption Scale,\textsuperscript{63} a 34-item true–false test that correlates well with hypnotic susceptibility. Wickramasekera\textsuperscript{64} found that patients scoring high on absorption scales or tests of hypnotic susceptibility and also scoring high on neuroticism as measure by the Marlowe-Crowne Social Desirability Scale\textsuperscript{65} were more likely to develop psychosomatic pain or symptoms, by dissociating traumatic or undesirable experiences and converting them into somatic symptoms or pain, creating what Damasio termed “psychological markers.” Wickramasekera developed a 25-item scale to be used to identify patients who were more likely to somatize. He points to the neural flexibility and “ideational fluency” that Gruzeleir\textsuperscript{18} suggested was related to a propensity to dissociate that can leave one vulnerable to schizotypy, affective distress, mood disorders, and somatic markers or memories that stay beyond conscious awareness. In simpler terms, highly hypnotizable patients are more likely to create a somatic marker for a psychological event and are more likely to trigger a memory of previous pain when they experience a new pain (see Chapman\textsuperscript{47}). A meta-analysis\textsuperscript{66} shows classic, modern, and mixed forms of hypnosis to be effective for treating psychosomatic disorders (those which meet the criteria for somatoform disorder), which would include both hypersensitivity to pain, hyperawareness of symptoms and to body processes in general, and the transduction or conversion of emotions and memories into somatic markers. This is remarkable given the range of disorders and symptoms included: tinnitus, duodenal ulcers, asthma,
irritable bowel syndrome (IBS), osteoarthritis, chronic pain, and dyspepsia. Also, DuHamel et al.\textsuperscript{67} found that their high-hypnotizable burned patients had significantly more intrusive avoidance and arousal symptoms with their injury-related trauma. Roelofs et al.\textsuperscript{68} showed that they could use hypnosis to induce catalepsy and altered perception of the cataleptic limb in high-hypnotizable subjects, suggesting the formation of conversion disorders or psychosomatic illness. Younger et al.\textsuperscript{69} show a linear correlation between hypnotizability and somatic complaints commonly assumed to be of a psychosomatic nature.

**Current Research and Applications of Medical Hypnosis for Pain**

The applications of hypnosis to medicine are numerous and go beyond the scope of this chapter because not all involve pain; Table 86.1 outlines common applications of hypnosis in medicine in general. Information on the effect of hypnosis on emotional pain and on physical pain, related or not to medical conditions, is undoubtedly not best found in the medical research but rather in books, articles, and trainings offered by the clinicians who regularly use it but who are not researchers. This is in part because every effective hypnotherapy session is, in research terms, an N of 1. However, research in hypnosis and its clinical use in medicine are increasing due to the recent surge in brain research and the increased understanding of what pain is and due to increased attention to the number of the people in chronic pain and in health care utilization and costs. Hypnosis research is important, for without published results, it is difficult for hospitals and insurance companies to justify reimbursing and endorsing its use in medicine.

Earlier research on psychological treatment of medical conditions often compares such treatment to standard care practices with and without the addition of cognitive-behavioral therapy (CBT). CBT often consists of a standardized program that is more applicable to research than hypnosis. CBT differs from hypnosis in that the therapist intends to speak directly to the patient’s cognitive conscious mind, without deliberately sending any direct or indirect messages to his or her unconscious mind. A hypnosis session may likely include behavioral suggestions in and out of trance and messages to the conscious and the unconscious mind at the same time. Both may include homework. Kirsch et al.\(^6\) looked at 18 studies of CBT with and without additional hypnosis. The addition of hypnosis to CBT substantially enhanced treatment outcome, such that the patients who received additional hypnosis did better than 70% of those with just CBT treatment. In most cases, the authors mean CBT administered in the medium of hypnosis.

As we go on to discuss the research on medical hypnosis, there are some points to bear in mind. First, we expect there to be quite a difference between the methods and benefits of hypnosis in clinical practice and the process of studying it in research. We must assume that a clinician in his or her office would not exactly follow a research protocol and that he or she would modify even a hypnotic script to fit his or her patient’s situation. Also, pain hypnosis is used primarily for chronic pain, less often for procedural and least for surgical pain, where hypnosis is usually used as an adjunct to medicine. Under strict standards, for hypnosis to be considered the dependent variable in research, it must deliver suggestions that could not be just as well delivered to the patient cognitive behaviorally (as in telling the patient what to do). However, some highly hypnotizable or well-trained patients have ready access to the unconscious mind and absorb even a CBT message quite deeply or literally; a good example of
this is the patient who testifies that he always gets all the side effects mentioned on the inserts of his medications. Finally, most patients in severe pain or in traumatic conditions are already in a trance and in a manner of speaking hypnotized, so that the comparison between CBT and hypnosis is muddy at best. A recent study found that multiple sclerosis (MS) patients who tried hypnosis for pain relief had more success than did those who tried opioids, benzodiazepines, or nerve blocks. But in general and in effect, the strict standards of the research may dilute the power of hypnosis. Fortunately, clinical success with hypnosis does not depend wholly on the results of research studies.

**EFFICACY AND EFFECTIVENESS**

To move the practice of hypnosis in medicine along, research on effectiveness—how hypnosis works in the real world, in quasi-experimental design—should be as methodical as the research on efficacy—how a technique works within the controlled research situation (see Wild and Espie, Nash, Chaves and Dworkin, and Gay et al.). A 1982 article reported skepticism about the effect of hypnosis on pain due to the lack of controlled studies comparing hypnosis with credible placebos or other treatment methods. Hawkins updated that article with a review of research articles up to the year 2000 and was able to conclude that hypnosis is effective for pain related to cancer, burns, gastrointestinal problems, and for invasive medical procedures. He also noted that poor-quality reviews were not more likely to produce positive conclusions about efficacy and that there was a paucity of good studies in the areas of obstetrics, headache, and chronic pain. Montgomery et al. did a meta-analysis of pain analgesia studies using healthy subjects and patient samples and taking into consideration hypnotizability levels; they concluded hypnosis to be effective in both areas for 75% of their population. Hypnotic analgesia compared favorably in effect to standard care and to attention. Hypnosis has compared favorably to empathic attention and to autogenic training (AT) for psychosomatic and medical disorders. Yapko, however, suggests that AT is in itself a hypnotic induction and that the comparison of the two treatments presents a problem.
The research process itself raises some concerns. One is that research studies focus on the precise content of the intervention, not how it can be flexibly adapted to the real-life patient situation. Another concern is the outcome measure itself: We intend for patients to be noticing pain less, but then we ask them to tune into it and rate it at the end of the study. Also, many studies do not account for hypnotizability, which would color research results and which in clinical practice that therapist could address. Another issue is expectancy—the patient’s expectation that hypnosis will resolve his pain, which seems to predict pain relief. Jensen and Patterson\(^8\) suggest that most of hypnosis studies lack adequate controls for expectancy and placebo effects, even though the studies find that hypnotic analgesia is effective in treating chronic pain. Clearly, raising the patient’s expectancy is a good thing, as are raising his levels of self-efficacy and curiosity about finding new ways to cope and encouraging the placebo effect. A study looking at changes in various psychological responses to pain postoperatively and after 3 months found hypnosis to be effective. The positive effect was not significantly related to hypnotic ability, concentration of treatment (e.g., daily vs. up to weekly), or initial response pattern to treatment, but it was moderately related to the participants’ expectancy ratings of treatment after the first session.\(^8\)

All of this being said, Amundson et al.\(^8\) point out that research probably underestimates the effectiveness of clinical hypnosis. Many are concerned about the randomized controlled trial (RCT) approach to hypnosis research that is so distinct from the patient-centered and cooperative relationship–based nature of clinical hypnotherapy.\(^8\),\(^\) Clinical one-on-one hypnotic sessions take patient’s unique issues and personal variables into consideration, and scripted or standardized protocols cannot address the psychological and emotional issues intertwined with the pain. Spiegel and Kahn\(^8\) discuss the difficulties inherent in using an outside hypnotherapist as the interventionist in research or therapy, which lacks the all-important therapeutic relationship; they also point out that the relationship between the hypnotherapist and the treating physician is important. It would seem that hypnotic protocols would be most effective when designed for each patient by a therapist who is interactively responsive to the patient, for according to one extensive
study, 30% of therapy outcome is based on the therapeutic relationship, even when the treatment is medication; another 15% is due to expectancy. Nonetheless, research showing the effectiveness of hypnosis must be stringent if it is to be widely available in medicine and adequately reimbursed by insurance companies. In fact, when comparing the delivery of hypnotic analgesia by sessions with the hypnotist present, manualized protocols, standardized audiotapes, or individualized audiotapes (as would be prepared for patients in clinical practice), a meta-analysis indicates that any delivery is better than none; however, since clinicians understand the importance of being fully present and flexible in a hypnotic session, more research in this area is needed. Interesting delivery formats are now on the horizon. Patterson et al. have attempted to improve absorption that may be missing with audiotapes by creating virtual reality (VR) computer-based presentations that immerse patients in a three dimensional computer-generated environment to absorb the patients’ attention and divert it away from the pain experience. VR induces and sustains a hypnotic state without a therapist. Questions arise as to whether this intervention satisfies the research definitions for hypnosis and whether the same effect could be accomplished by naturalistic absorption or with audiotapes alone.

Here is an example of a clinical application of hypnosis that is distinct from research protocol. A female patient in her 30s had been extensively evaluated for her deep, sharp right-side pelvic pain that came on for 15 to 20 minutes as often as every hour, even during the night. She rarely has pain when she was on birth control pills, other than after sexual intercourse. There was a small area of endometriosis, successfully removed, and one cyst that ruptured, but otherwise, no diagnoses explained the pain. She and her husband were anxious to be off birth control pills in order to conceive. She also exhibited generalized high vigilance. She asked a hypnotherapist to help find any unconscious motivations for the pain. She was highly hypnotic and motivated, with high expectancy. The therapist worked interactively with her on a wide range of techniques to find what worked uniquely for her in managing and accepting the nerve pain, which she practiced self-hypnotically at home. Hypnosis helped with vigilance, and therapy helped other issues about trust. The therapeutic relationship supported the work with hypervigilance.
and trust, and specific fears that related to pregnancy.

Clinically and in research, even when patients do not receive pain relief with hypnotic analgesia, they seem to receive satisfaction from the sessions. Jensen et al.\textsuperscript{89} reported that out of the benefits listed by subjects in their pain hypnosis study, 23% reported pain-related benefits as the reason for satisfaction, 58% reported other than pain benefits, 13% were neutral, and 8% reported a negative experience. Subjects cited increased sense of control and positive shifts in perspective, with no subjects reporting dissatisfaction. Dawson et al.\textsuperscript{90} have said that pain treatment satisfaction in general has more to do with the provider–patient relationship than pain-related outcome.

We will briefly mention two other variables. Direct versus indirect hypnotic suggestions for pain or symptom relief (e.g., to progressively relax muscles vs. imagining lying on a beach at a peaceful island, which would warm and relax muscles) both seem to be effective. In regard to whether hypnosis is more effective when labeled as hypnosis or introduced using other terms, Jensen and Patterson\textsuperscript{80} concluded that in the short term, there is probably no difference, but over time, there may be a benefit for the patient in attributing improvement to hypnosis or self-hypnosis.

**REVIEW OF RESEARCH STUDIES ACCORDING TO PAIN PROBLEMS OR SITUATIONS**

Research on hypnosis has waxed and waned over the years and varied in focus. Many of the new studies are physician driven and are looking for nonmedicinal, noninvasive self-management treatments that improve medical outcome. Even though pain is common to most medical disorders and procedures, each carries a unique cluster of symptoms that might indicate a different psychological or hypnotic approach for healing and management, differing lengths of treatment time and varying depths of trance. Research and clinical reports show the importance of matching the appropriate protocol to the type of pain experienced.\textsuperscript{91} The following sections will outline recent research on hypnosis when used as one of the treatment modes, grouped according to medical condition. Under each heading, research findings, primarily since the year 2000, will be followed by some suggestions and techniques for use in clinical practice. Most of
the articles address acute and procedural pain. Hopefully, the sections will serve as a background and a resource for hypnotherapists and clinicians and for those planning to embark on such medical research.

**Perioperative and Procedural Uses**

As described earlier, hypnotic analgesia was first reported as successful in surgery before there were any chemical anesthetic alternatives. In this century, although there are sporadic reports of its successful use as the only anesthetic, it is now most often as an adjunct to chemical anesthetics or to analgesics. Studies have looked at improved well-being or enhanced healing and recovery time after surgery or procedures and reduction in hospital costs. Hypnosis successfully targets a number of surgical and postsurgical variables, such as anxiety, blood pressure, and patients’ sense of control over their feelings; pain, nausea, vomiting, blood loss, and wound healing; pain, knee strength, edema, inflammation, and postsurgical anxiety after anterior cruciate ligament (ACL) surgery; both objectively and subjectively rated healing, when level of hypnotizability was controlled; postoperative anxiety and pain level, even after a single session of hypnosis before surgery; pain and distress, where the effects were mediated by patient expectancy; and shorter hospital stays and less parenteral narcotic use. A study showed hypnosis to lessen procedural pain and result in a speedier medical procedure; positive results did not correlate with hypnotizability, possibly because the hypnotist facilitated self-hypnosis before and during the procedure, such that subjects received individualized treatment.

Three studies used hypnosis because it might be used clinically. Enqvist and Fischer aimed to reduce preoperative stress that might influence healing and recovery from a surgery, specifically to reduce medication use, inflammation, infection, postoperative pain, and edema. Using one surgeon, who was blind to the grouping, patients were given a 20-minute tape containing an induction and suggestions of finding a safe place, having control of bodily responses to surgery, dissociating, and alleviating pain. Subjects were also asked to use their chosen way of relaxing for 2 minutes and to let soft music bring them back to awareness. In a controlled study, Dyas used a conversational induction containing positive
language patterns and suggestions that included counting down (into trance), relaxing breathing, finding a safe place, and dissociating from the surgical procedure; reinforcing words were used during surgery, and posthypnotic suggestions addressed continued relaxation and comfort. Another controlled study used music with or without the audio taped voice of a hypnotherapist during surgery under general anesthesia; the addition of hypnosis was beneficial, and the author suggests the results would be even more significant using individualized tapes and in situations where less anesthesia is used.

Obviously, both physical and emotional pain during surgery can present a problem because pain is both traumatic and stressful and relief from it can improve healing, save money, and make for happier patients and surgeons. The most important patient variable to consider for use in surgery as the sole or primary anesthesia seems to be hypnotizability. To be sure the patient is highly hypnotizable and can go into a deep state, stringent testing should be done (see Weitzenhoffer and Hilgard and Lynn et al.). The sole use of hypnosis should be reserved for the patient who is highly hypnotizable, experienced with hypnosis, and for whom the payoff is likely to be great. Preoperative preparation for surgery described by Kessler and Dane is also effective and satisfying to many patients. Kessler also found that the most significant variable related to the anxiety in surgery that can affect the surgical outcome variables related earlier was the expectation of negative surgical outcomes, coming either from patients’ previous experiences or to those close to him or her. He designed a short screening questionnaire to identify patients who are in most need of hypnotic preparation (Kessler, personal communication, 1996).

Subsequent perioperative hypnotic treatment can be done with any level of trance, even conversational, to assure that the anxiety level regarding the procedure is optimally low and that the mind-set is positive; this can speed up healing and recovery and allay concerns about procedure and recovery processes. During such perioperative preparations, I have twice discovered male patients who fully expected to die because they were grieving the death of fathers who died during the same procedure or at their like chronologic age; we took the time to work through those issues before surgery took place.
Perioperative hypnosis to lower anxiety and its related biologic components should address positive expectancy of the surgical outcome and the positive interpretation of the surgical events and sounds the patient may unconsciously notice. The optimal protocol will include some critical details of the surgery that the patient can interpret positively, such as

When you feel the surgeon touch your stomach with a knife, that will be an indication that he is finding the best place on your belly for the smallest opening to allow him to remove the part of your intestine that needs to come out so that he can reattach the healthy tissue and allow your intestines to work normally again, or

When you feel a little tugging, that will be an indication that he is closing the opening with a nice line of little stitches, or

Since you will be hungry after not eating before surgery, you can begin to look forward to your favorite food soon after surgery, and

You can let your thoughts be on that beach you love so much, and you can listen only to sentences from your own doctor and that begin with your first name.

In that way, the surgeon can request the patient to lower his blood pressure and divert blood away from the surgical site, and he can prepare the patient for any changes in the surgical plan and even imbed suggestions to lose interest in unhealthy food or cigarettes. For a review of other “patient-friendly” terms, see Bennett and Disbrow.105

Complex Regional Pain Syndrome
CRPS is one of two pain syndromes responsive to hypnosis that are particularly interesting because they demonstrate the brain mechanisms of pain. CRPS is a complicated condition wherein pain persists after injury and is disproportionate to the injury or level of stimulus following healing of the injury; the continuing severe pain has no confirmed mechanism. Even when there is neuropathology, which can lead to muscle atrophy and bone demineralization, the symptoms can be sympathetically driven. Treatment usually includes some psychotherapy to manage anxiety and often to disclose a series of emotional events that trigger a flight-or-flight
or psychophysiologically defensive response. The psychological meanings
attached to a nociception or to perceived pain may trigger the brain to
temporarily rewrite the neurosensory map of the pain area. This in turn
leads to a relative neglect syndrome of that limb, which can establish, in
lay terms, a “cry for help” in the form of pain and distress
symptoms.\textsuperscript{29,107,108}

Psychosomatic treatment should include psychologically working
through the incidents in the patient’s life that led to the need for the
defensiveness,\textsuperscript{109,110} addressing anxiety and stress management, and
counteracting the neglect of the injured limb in order to reintegrate it back
into the body. This can be done using mental imagery,\textsuperscript{111} desensitization
training,\textsuperscript{112} or hypnosis, which can accomplish all of the aforementioned at
the same time. The process of neglect is a dissociative process beginning
at a deep level. Given work on hypnotizability and psychosomatic
disorders, we can hypothesize that highly hypnotizable people may be
more likely to develop CRPS under the right conditions and also assume
that hypnosis would more readily help them resolve the complex
syndrome. Using hypnosis while undergoing physical therapy for CRPS
showed improvement in pain, stiffness, and strength, as well as patient
satisfaction.\textsuperscript{113}

\textbf{Phantom Limb Pain}

The other pain disorder responding to psychologically addressing brain
mechanisms is phantom limb pain. Pain in an amputated limb can come
from damaged nerve endings that are at the stump or that connect with the
neurons in the spinal cord. It can also come from a change in the
somatosensory cortex map of the body that results either from lack of
sensory input from the missing or paralyzed limb or from a peripheral
nerve injury that leads to lack of sensation.\textsuperscript{114} This may lead to a
neurologic need or a cry out to find the missing limb that takes the form of
pain sensation.\textsuperscript{115}

Long before there were fMRI studies, Erickson said, “If you can have
phantom limb pain you can have phantom limb pleasure,” implying the
power of the unconscious mind to change the interpretation of information
from the periphery or the somatosensory cortex, from negative to positive.
The patient can do this with self-hypnosis or with deep trance hypnotherapy to resolve pain by creating a more positive mind/body messaging system (to counteract pain) and a better transfer of information between the cognitive and the unconscious areas of the brain (this may counteract neglect due to changes in the somatosensory mapping). Giraux and Sirigu\textsuperscript{116} have patients imagine that they are still using the missing or paralyzed limb to relieve pain. This is similar to the positive rehabilitative effects found when asking patients to imagine doing the physical therapy if they are not yet ready to actually do it. Flor et al.\textsuperscript{117} had patients touch the stump for sensory stimulation; both studies\textsuperscript{16,17} demonstrated pain relief. This works along the same lines as having CRPS patients gently stroke and soothe (desensitize) their limbs that were previously too painful to touch in order to restore the somatosensory map that was altered due to excruciating pain (J. Hernandez, unpublished data, 2008). Evidence for the relationship between the somatosensory cortex and pain comes from research where the somatosensory map was reorganized back to the original somatosensory map by using an electrical prosthetic limb\textsuperscript{118} or by use of a mirror image of the remaining limb to “trick” the mind to thinking there were two functioning limbs.\textsuperscript{119} Hypnosis may also be used to accomplish the end goal of resolving the need to find the missing limb. Older and more traditional hypnotic trances for phantom pain may be found in Hammond.\textsuperscript{50} However, a recent systematic review of the literature including RCTs showed limited research and hence limited evidence supporting the effectiveness of hypnosis.\textsuperscript{120}

Case Study: This author used hypnosis to assist a young college student patient who had lost his leg in an automobile accident. He felt positional pain leading him to believe that his leg was bent in a painful position under his body. First, we discussed the actual cause of the pain as a somatosensory reorganization that was his mind’s first attempt to help him survive that he could now revise; this mini-lecture was partly informational and partly a hypnotic confusion technique and an induction into trance. He was guided to imagine moving the leg to a more comfortable position and then soothing it so that it would recover from the bent position. This reduced some but not all the pain. In the next session, we used a technique of
connecting spiritually with the limb as a valuable part of himself (J. Hernandez, unpublished data, 2008) for further description of this technique. He was hypnotically guided to bring his attention into his leg (“go down your leg to the injury”) and gently nurse and soothe the injury. He was guided to recognize that his leg was a valuable part of himself that he could always have relationship with (as he did with elders who had passed on) and he was guided to watch his leg go to a spiritual place to rest outside of his body where he knew it would be safe in the universe and would wait for the rest of his body in the future at the end of his life. He was then guided to visualize the perimeter (the map) of his body at present (without the leg), and to see and feel the body moving without the leg, and to practice this in his mind, free from pain. His guided imagery had him sensing himself going to class and doing in the future the things he had done in the past. This lengthy set of sessions helped with the majority of his pain; his keen focus on getting back to his life, and on to his active career certainly helped him to take positive suggestions. The treatment is in line with the research on the brain mechanisms discussed earlier and in line with trends toward success reported by Oakley et al.\textsuperscript{121}

**Burns**

There is relatively long history of using hypnosis for burn pain, which can be very intense for an extended period of time. Wound care procedures necessary for recovery from burns is painful as well, and pain medication usually does not cover all of the pain. Burn pain is often severe enough to evoke a negative trauma-related trance state in itself, if not shock, at the very same time that a positive mind-set is important for recovery. As mentioned earlier, distraction is a useful pain management technique for certain situations, but hypnosis appears to afford more pain relief than distraction alone during dressing changes. Frenay et al.\textsuperscript{122} also found it more effective for pain reduction than stress reducing strategies for decreasing pain and anxiety during wound care; in that study, the wording was individualized according to the hypnotherapist’s observations and her judgment of the patient’s clinical needs. One case study has experimented with immersive VR (mentioned earlier in this chapter).\textsuperscript{88} In that study,
patients engaged in the VR during wound care; those who remained with the program enjoyed the experience and had no medication side effects, and their pain and anxiety significantly dropped with the VR.

Clinicians will appreciate the work of Ewin,\textsuperscript{123–125} a teaching surgeon and psychiatrist who, in addition to using hypnosis during procedures and surgery, also used hypnotic imagery to prevent the symptom formation after skin is burned. He would immediately give suggestions to counteract the body’s response to a burn (reddening and blisters), such as swimming in a cold stream in the evening, and he took advantage of the trauma-induced trance state after a burn incident.

Case Study: I used the technique for a hand burn resulting from picking up a frying pan that had been on the stove. I imagined moving my hand in a cool mountain stream visited during childhood, and when that cold was fully reexperienced, I imagined a sequence of events to include swimming pool that day, on through time to the very near future (watching TV in the next room), skipping the episode of the burn completely; I rehearsed the sequence a few times, letting the unconscious mind do the work of deleting the burn experience. Also, to regain my body’s trust and prevent avoidance or resistance in the future, I immediately telepathically sent my hand an apology and an assurance about taking better care of the hand from then on.

For débridement and healing of burns, good techniques might include imagining anesthesia or numbness in the area and displacing the limb or area of the body that is in pain to another side of the room or to a special imaginary healing place, so that the body can rest easy and be ready for its return after trance; trance can be extended by posthypnotic suggestion to last as long as is necessary. There may be a place as well for amnesia for the more painful and traumatic events of the accident, which would have to be addressed in trance individually. Trance phenomenon will allow for the conscious and unconscious minds to work together to know that an accident occurred while conveniently forgetting about parts of it, both at the same time; it is also possible for a patient to know he is being treated for a pain injury and to forget the pain, both at the same time.

\textbf{Dentistry}
Hypnosis has been successfully resolving pain and anxiety surrounding dental work for over 80 years and was arguably used as much for dental work as for other purposes through World War II. Kay Thompson, a dentist who was also an Ericksonian hypnotherapist, pointed out potential psychosomatic element of pain in the oral cavity, as the mouth is the first infant connection to the mother, the first source of gratification, and the first experience of getting attention to one’s needs (through crying). For whatever reasons, pain in or near the head may be more likely to result in anxiety and a loss of self-control and efficacy, and patients are relatively quick to appreciate caring support and attention.

A study comparing Ericksonian hypnosis to progressive muscle relaxation tapes, education about procedures, and a control group showed the Ericksonian hypnosis group to have less anxiety about dental procedures; in the protocol, negative thoughts were restructured (the sound of the dentist drill as a suggestion to go deeper into trance) and patients were to visualize success over pain and to use age regression to a painless time in the past. A study comparing patient’s pain before and after dental work offered five hypnosis sessions which included relaxation imagery, catalepsy, analgesia, and anesthesia, with posthypnotic suggestions to patients; they were also given self-hypnosis tapes. The patients showed less pain frequency and duration and an increase in daily functioning compared to baseline, even at 6-month follow-up. A study comparing educational sessions or occlusal appliances to hypnorelaxation for temporomandibular joint (TMJ) pain showed that the hypnosis group reduced current and worst pain significantly more than the control groups did. Hypnosis has been shown to be an effective adjunct in dental surgery to reduce pain, pain medication use, and anxiety, and pre- and intraoperative hypnosis audiotapes used for third molar extraction with anesthesia reduced anxiety and pain medication use.

For surgery and procedures, a depth of hypnosis is often used wherein the patient is responsive to the dentist’s requests (to open wider, close, etc.) but does not feel the procedure itself. Hypnotic suggestions may be for relaxation, for creating numbing, for going by trance to another place while safely leaving the tooth with the dentist, and for feeling pressure rather than pain. In addition to dental procedural pain and anxiety, many
dentists learn hypnosis for needle phobia, gagging, bruxism, saliva control, and TMJ, all of which will necessitate specific suggestions.

**Pediatric Pain**

Children are, in general, more hypnotizable than adults for a number of reasons. They have much richer fantasy lives, are relatively more curious, and are encouraged to use imagination in play; there are fewer parameters and fixed interpretations of the world in general, as they are still learning and are relatively trusting of adults and authority. Critical thinking develops as the brain matures, and it is only in adolescence where society demands more realistic and responsible thinking. In general, peak hypnotizability may be as late as latency (8 to 12 years of age), when children are the most open-minded, curious, imaginative, and willing to suspend judgment and when they are reasonably knowledgeable. Learning pain management and self-control early can help children tolerate medical procedures (shots, fracture settings, etc.) and eliminate negative associations to pain that may remain with them as adults. Children are not reflective thinkers, and so they are more likely to be psychosomatic in presentation of emotional or situational problems; the bank of literature on childhood stomach aches tells us that for them, stomach aches may be a benchmark for distress that may otherwise go unexpressed.

Training in self-hypnosis improved children’s functional abdominal pain by 80%, and self-hypnosis tapes improved the respiratory functioning of anxious children in a pulmonary center by 95%. A prospective controlled trial explored the efficacy of adding self-hypnosis training to the use of analgesic cream for lumbar puncture-induced pain and anxiety in 6- to 16-year-old cancer patients; the additional hypnosis led to a decrease in anticipatory and procedure-related pain and anxiety. A retrospective study found a significant decrease in self-reported pain intensity, duration, and frequency of headaches, with no adverse effects, after adolescents were taught self-hypnosis. An hour of self-hypnosis training given to children, along with instructions to practice several times a day, led to less stressful and speedier urologic procedures, by both parental and staff report. Manual-based clinical hypnosis has been found more effective than distraction, cognitive-behavioral...
treatments, and play and distraction. Hypnosis can also help children undergo acupuncture. However, reviews of the research still found hypnosis to be not robust enough to fall within best practice guidelines for managing procedure-related pain in pediatric oncology; several researchers call for more RCT for the clear-cut benefits of hypnosis and other psychological interventions to be shown, although no studies refute the likelihood that it is beneficial and shows a better side effect profile.

Designing trances or trance experiences for children will of course involve taking their developmental age into consideration as well as the degree of trauma and fear involved in what they will be experiencing. First, it is important to remember that children are highly suggestible and are still vulnerable to trauma long before they can understand its context or verbalize their problem. On the other hand, even babies can be lulled or stroked into a soothing situation and be spoken to in reassuring words, songs, and sounds. Olness and Gardner suggest framing therapeutic suggestions and stories in the context of what they know, such as bubbles, pop-up books, dolls, and stories, and utilizing storybook figures as the characters of the stories. Nature, favorite pleasant places, cars, magical travel, music, and repetitive action such as ball bouncing or yoyo tossing can be used in inductions. For adolescents and older children who are more interested in relationships, stories and images could include peer groups. All aged children may be quite intrigued with some of the classic induction techniques such as the pendulum, arm levitation, and the coin drop. It is particularly important to speak to the child in language he or she can understand, to consider play as a way to make the experience more pleasant, to speak with a tone of voice that allows the child to feel supported and respected, and to add suggestions about self-control and self-efficacy and safety. For detailed discussion of hypnosis with children, see Olness and Kohen.

Case Study: A case example is a 13-year-old patient who broke his nose while playing baseball; his mother brought him to a facial trauma doctor I was working with at the time. Concern for his anxiety was relatively great since the same surgeon in the same hospital had previously done surgery on the youngster’s throat after a near-fatal
small airplane crash. Before trance, any fears or discomfort was discussed so that he would be safe in the procedure room. As the room was being set up for him, we discussed any of his concerns and his baseball game. I hypnotically coached him to go back in his mind to complete the game as he wanted it to end, and along the way, I suggested to him that he could forget about whatever parts of the whole afternoon that would make him more comfortable and that he did not need to remember. I gave him permission to suggest to me how to make the experience safer and more comfortable for him. He proceeded to ask one resident to leave because she was talking about trivial personal issues and not paying attention to his procedure. To our surprise, when the patient woke up the next morning, he removed all the bandages and packing and went down to breakfast without mentioning or questioning the bandages or the hospital experience, but he did remember some pretty girls he saw on the way there. Since that incident, the author includes suggestions to follow his doctor’s instructions, so that any necessary aftercare does not also go by the wayside!

Irritable Bowel Syndrome
Most IBS patients have low thresholds of pain in their bowels, along with abnormal autonomic nervous system functioning and considerable symptom discomfort. Hypnotherapy has been shown to improve pain, autonomic symptom dysfunction, and well-being, even at follow-ups beyond 5 years. A recent study shows hypnosis to reduce short-term and long-term IBS symptoms themselves in 50% of patients even a year after treatment. The Manchester Model hypnosis protocol has been consistently effective for treatment of bowel and other physical symptoms, depression, and anxiety; improvement in symptom scores is associated with improvement in IBS-related thoughts. When Palsson’s North Carolina hypnotic protocol is administered to IBS patients, their daily diary reports show an approximate 50% reduction in pain. In a study comparing the North Carolina protocol administered with the manual presentation versus with individually tailored presentation, the manualized induction group had less emotional stress after the treatment,
but the individualized induction group continued to improve and did better at 10 months than the group who received the scripted trance and showed less emotional distress. Recently, a study showed that home-based gut-directed hypnotherapy with an audio recording for treatment of pediatric abdominal pain and IBS was as effective as therapist-administered hypnotherapy.

Hypnotic suggestions to improve gut symptoms and IBS pain can include those to warm hands, progressively relax, move attention away from gut symptoms, and to calm and comfort the gut, in addition to suggestions for enhanced over-all well-being, self-efficacy, self-management, and control. The North Carolina protocol is lengthy; it includes all the aforementioned and also suggests dissociation away from the pain and to a carefree place. This appears to break the cycle of pain, and patients reset their perceptions of pain. The protocol includes seven scripted, therapist-guided sessions and an audiotape for home use. The Manchester Model now has 12 scripted sessions and an audiotape for home use; the scripts include suggestions to warm the hands and transfer the warmth mechanically to the gut, for control and normalization of gut functions, as well as suggestions for ego strengthening and self-control in handling IBS symptoms.

**Headaches**

In general, migraine, tension, and mixed headaches respond to hypnosis. Migraine headache frequency, duration, and severity decreased in one study when patients were given one group hypnosis session and 12 weeks of follow-up with hypnosis audiotapes. Tension headache pain, vitality, and mental health improved when patients were offered guided imagery audiotapes. There have been many comparisons of AT to hypnosis for headache control. AT focuses specifically on relaxing muscles, which is in part what hypnosis would address, so that similar effectiveness is expected. Studies show AT to be more effective, less effective, or equally effective for headache pain. Both treatments seem to help patients perceive more self-control of pain; improvement in pain scores seems to be related to hypnotizability, and formal hypnosis with a formal induction seems to improve the chances of success.
To treat a headache, it is usually important to know whether the patient has tension, migraine, or cluster headaches. For tension headaches, direct suggestions could be to breath in and out through the skin in the head and neck, to loosen the scalp, to let the hair fall naturally directly from the scalp, or to cool or warm the inside of the head (depending on the type of headache). Indirect suggestions might be to imagine being in a relaxing place or in a cold place, with cool wet rag at the neck. For migraines, Gibbons\textsuperscript{164} suggests diving into water, because this lowers blood pressure and heartbeat and may alleviate circulatory congestion in the head. Suggestions for cold (skiing, hiking in the snow) may also be helpful. Patients may also constrict blood vessels by imagining them to become tight, cool, and narrower. Tension headaches may respond to suggestions that help to open the blood vessels, such as warm climates, relaxation, or warm water. Hammond\textsuperscript{157} finds self-hypnosis effective for tension headache management; he suggests that patients who report daily morning headaches may respond well to the use of self-hypnosis tapes at bedtime, which aim to allay tension while they are sleeping.

Cancer
Cancer pain may be distinct from other long-term or chronic pain, in that changes or increases in pain may trigger end-of-life concerns, grief, depression, and anxiety. In addition, there are very often painful and bothersome side effects to cancer treatment, such as nausea, vomiting, tissue or nerve damage, weakness, and fatigue, many of which respond to hypnosis quite well. The feedback loop between diseases such as cancer, negative cognitions, and suffering are discussed elsewhere, as is the effect of stress and distress on immunosuppression, which can compromise patients’ recovery times and resistance to secondary illnesses.

Hypnosis is particularly effective in reducing stress through direct and indirect suggestions to relax and through enhancing patients’ sense of self-efficacy and self-control. Spiegel and Bloom\textsuperscript{165} showed positive effects with hypnosis in terminal cancer patients, possibly including giving patients a slightly longer life span; the latter benefit was not replicated in the recent study, possibly due to the improved medical treatments that extend the lives of all patients who were subjects.\textsuperscript{166} This does point out
the importance of alternative medicine therapists ensuring that patients are not discounting or ignoring medical care.

A number of studies compared hypnosis to CBT for control of cancer pain. One showed bone marrow transplant patients to benefit more from hypnosis than from CBT or attentional control because they had less pain at worst times and for shorter durations.\textsuperscript{167} Other studies show the benefits of hypnosis over CBT for pain, anxiety, and overall distress.\textsuperscript{98,137,168} A prospective randomized study with advanced-stage cancer patients showed that a manualized presentation of four weekly hypnosis sessions with addition of audiotapes for home use significantly decreased pain; suggestions were comprehensive, including relaxation, comfort, dissociation, and more specific pain control techniques.\textsuperscript{169}

Quality of life is particularly important with cancer because for end-of-life patients; there may be grieving to do as well as personal, relationship, and spiritual business to tend. To address this, one study randomly assigned patients to 10-minute self-hypnosis audiotapes teaching either progressive relaxation (a passive coping strategy) or breathing exercises (an active coping strategy) to be used three times a week.\textsuperscript{170} Positive attitudes increased and negative attitudes and anxiety decreased in both groups, with more improvement shown with the active coping strategy; this may have had to do, again, with perceived self-control. Quality of life, particularly vitality, improved for metastatic breast cancer patients who were given 4 weeks of self-hypnosis training, in comparison to those offered 4 weeks of training in a Japanese healing method called Johrei and to wait-list controls\textsuperscript{171}; both treatment groups improved in mood and anxiety scores. Other studies have shown quality of life improvement for cancer patients using hypnosis.\textsuperscript{172,173} The latter study’s protocol looks similar to what might occur in a clinical setting; it offered four 30-minute sessions of hypnosis weekly, using traditional inductions and individualized suggestions for symptom management and ego strengthening. Hypnotic suggestions that foster or support existential, religious or other beliefs about life after death for patients, and for those who socially support them, might be given early in treatment (see Spira\textsuperscript{174}).
Osteoarthritis

The research literature on the use of hypnosis with arthritic pain is sparse. One study found Erickson hypnosis to compare favorably to Jacobson relaxation and control conditions for treatment of osteoarthritis pain. Pain relief was directly related to imagery and hypnotic susceptibility but not to expectancy. Hypnotic suggestions addressed relaxation, positive imagery, and age regression to a more comfortable time; the authors used the words of mental imagery rather than hypnosis, and the words pain and analgesia were not used.

Clinically, suggestions to alleviate arthritis pain may include warm water, warm blankets, warm sun, and stroking the area with arm hands. Also, suggestions to initiate moving arthritic parts or walking while exhaling and to keep the breath flowing can alleviate unnecessary tensing. The patient may self-hypnotically rehearse moving the arthritic area, thereby limbering the body before actually moving, to help the mind and body work together. Patients might move around while keeping in mind the image of themselves at a much younger age and at pain-free times. They might also focus more intently on the goal for moving (specifically what they will do on the other side of the room once they get there) rather than on the sensation of moving. Time distortion to a pain-free time in the past or future, and getting involved with increased focus on what they are doing, may also distract them from physical feelings. Other suggestions might be to let go of the sensation of gravity in the body and to lighten their steps.

There are references to anger as a psychosomatic link to some arthritis pain. As with other emotional links to pain, hypnotic treatment is likely to be even more successful when such psychological or emotional components are addressed. Often, defensiveness or fear underlie the anger and can lead to body tension; the extent of this would be relatively easy to discover during the very important pretreatment assessment.

Medical Hypnosis Techniques

PRINCIPLES OF PREPARATION, INDUCTION, AND SUGGESTIONS
The traditional hypnotherapy session may be divided into four phases: induction, a period of deepening involvement of the unconscious mind while lessening involvement of the conscious mind, the therapy itself, and then a gradual transition back to conscious awareness. Beforehand, a pretreatment assessment should include learning the patient’s analogies or metaphors about the pain (stabbing, slicing, cold, daggers, or tingling) and learning what the pain means to the patient in terms of suffering; insult; guilt; religious beliefs; associations to past traumas; future expectations and fears; and social, cultural, or familial losses. That information will help the therapist know the extent of the patient’s fears and concerns and the nature of his suffering and determine the appropriate therapy and support that is needed. It will also tell the therapist what specific words or metaphors to use in his messages and suggestions to the patient and what overall approach to use. The better the therapist understands the mechanisms of the unconscious mind, particularly where pain, stress, and memories are concerned, the easier it may be to do effective pain management work.

Ethics for using hypnosis are even more stringent than when using other psychological techniques, in that trances allowing access to unconscious processes can potentially leave the patient more vulnerable. ASCH guidelines also include preparing the patient for hypnosis by dispelling myths about what hypnosis is and is not, advising them of what they might experience, and ensuring that hypnosis is not against their religious beliefs or that it will not violate safety boundaries; this protects both the patient and the clinician. They should know that the therapist will not shield them from any pain they should keep in order to protect themselves; it is sometimes best to allow patients to keep a certain small percentage of their pain and to recognize any pain that they might need to address. Patients should be advised and comforted to know that the therapist is guiding them into a condition of self-hypnosis and is not doing hypnosis to them. They should also be advised that everyone has his own level of susceptibility that is independent of intelligence and emotional or moral fortitude and that can vary according to day or time. They should also be given permission to stop the session and to talk to the therapist whenever they need to do so.
One variable to consider is the level of involvement in treatment the patient desires. Some patients are proactive in their treatment and cope best by knowing everything there is to know about the process and prognosis, whereas others avoid knowing the clinical details. Giving the patient the amount of detail he wants to keep him comfortable will help in keeping good rapport. In one study, researchers found that over time, patients who attributed the pain control to themselves did better with pain.\textsuperscript{163} For the benefit of positive expectancy, using the word hypnosis may benefit the patient outcome because some patients prefer handing over the pain management to the clinician, as in the often heard phrases “Just hypnotize me and make me stop (smoking) or (eating) so much.” That mind-set signifies an external locus of control, which is not a good indicator of pain management in general or for therapeutic success; however, it may indicate success with hypnosis in that the patient may be willing to suspend vigilance with little resistance.

It is best to provide a quiet, pleasant, and emotionally safe space for the hypnosis sessions, which, of course, may be compromised in many clinical, surgical, and emergency settings. Again, the most important element is the patient–clinician relationship, and there are techniques health care providers can use to gain rapport and help anxious and traumatized patients relax in emergency rooms (ERs), operating rooms (ORs), and busy clinics (see \url{http://www.anodyne.net}). In the clinical setting, proper posture helps patients truly “let go” and relax; they may do best when sitting with both feet on the floor and with hands resting on the knees, so that they are not likely to fall asleep but they do not have to work at balancing. An emotionally safe one-on-one session would facilitate the patient’s recovery of memories and hidden associations to the pain. Setting up positive expectancy, including the clinician’s and the rest of the treatment staff’s positive belief in success, also improves the success of hypnosis; this is the variable that confounds many research studies, according to Jensen and Patterson.\textsuperscript{80}

Styles of hypnosis vary depending on the preferred approach of the therapist, the context, and the needs of the patient. Research indicates that all therapy techniques work more or less equally well, and that the most effective is the one the therapist feels most comfortable using, as he directs
his attention toward the patient’s chosen outcome and remains flexible about changing approaches as the patient’s needs change. In hypnosis, the patient is suspending vigilance and giving over access in his unconscious mind, so that the onus is on the therapist to choose words carefully and to maintain the safe therapeutic space. That being said, the inductions, certainly the messages, and the length of the sessions will necessarily differ according to the circumstance of pain—chronic, acute, surgical, or trauma-induced pain. Emergency situations are often best handled with a very direct authoritarian approach. In emergencies and where pain is suddenly acute, the patient may be anxious and may want someone to take charge, and he may need suggestions for quick relief; indeed, the pain and trauma involved may already have induced a trance state. Depth of trance is not necessarily related to outcome; the purpose of the trance is to get suggestions to the unconscious mind efficiently, and hypnosis aims to facilitate that at whatever level. Hypnotic anesthesia for surgery demands a deep trance and a longer induction. For other medical procedures where the patient is to be conversant (such as with epidural injections or spinal cord stimulator placements or brain surgery), a lighter trance may be in order. Light trances may allow patients to observe and learn self-hypnosis, whereas the therapist can gain information on how the work is going and even explore sensations in the pain area to gain more diagnostic information. Conversational trances can occur when the therapist establishes very good rapport with the patient, when the patient is already in an altered state of mind, and when the therapist talks directly to the unconscious mind using hypnotic language and techniques (e.g., the Ericksonian techniques described in the following discussion). Hypnosis may bring up unexpected memories or associations that should be addressed and resolved when they occur or when they are recognized; this might necessitate varying levels of trance during the session.

COMMON INDUCTION PROCEDURES

Inductions can be done conversationally, naturalistically, using rituals or chanting, by directing the patient inward, or by using objects such as a coin or crystal on a chain. In general, the induction involves fixating or narrowing the patient’s attention and deepening his involvement while at
the same time suggesting dissociation from conscious awareness of the field. Good rapport-building skill and the use of hypnotic phrasing and words allow a seamless transition from induction into therapy. Therapy can begin during induction or after the patient is at the necessary level of trance.

A number of classic induction procedures are often taught in hypnosis training:

- Chiasson induction: The patient is asked to hold his hand out in front of him and to notice his arm or hand move slowly toward his face. The therapist suggests that the patient’s eyes feel so heavy that he wants to close. When the hand comes closer to the face and as the fingers open, trance will also occur.

- Reversed arm levitation induction: The patient starts with his arm out in front of him, and as it slowly drops to the table (lap, chair arm) and rests there, he will go deeper into trance.

- Catalepsy induction: The patient holds the arm out in front of him and is given the suggestion that he will lose the feeling of it being there and that he will not be able to move it.

- Chevreul pendulum technique: The patient holds a shiny object in front of him at eye level and has his eyes follow the swinging movement; the therapist suggests that the arm is getting tired and will slowly sink to the table. The moment the pendulum hits the table, the patient will go deeper into trance and may close his eyes for comfort.

- Coin technique: The patient holds a coin in his fist out at arm’s length. The therapist may suggest that the coin is a balloon that expands, so that the hand opens; eventually the coin drops, which the patient knows is the signal to enter into trance.

- Magnetic hands: The patient holds his two hands out in front of him, with the suggestion to watch how they slowly come together like magnets, eventually touching one another, which is the invitation into trance.

- Imagery induction: The patient is asked to go in his mind to a personally ideal, specific place or location, and to hear, sense, smell, and totally be in the setting.

- Going down a staircase: The patient is guided to walk slowly down a
flight of stairs (often 20); as the therapist talks, inducing trance, he
imbeds a countdown of the number of stairs until the patient gets to
the bottom, when he will drop into trance. The lead out of trance will
be to reverse the numbers (from 0 to 20) as the patient walk back up
into the conscious mind.
• Progressive relaxation: The patient is guided to relax muscle groups
progressively, starting at his feet and working upward or starting at
his head and working down. The advantage of this technique is that it
is easily used self-hypnotically.
• Eye fixation: The patient is asked to watch something intently until he
cannot anymore, and when the eyes decide to close, he may go into
trance.
• Rapid eye roll: The technique is also an indicator of
hypnotizability. The patient is asked to take a deep breath and hold it,
then to roll the eyes upward to look into the top of the eye sockets,
then to close the eyes, and as he slowly breathes out, he will relax into
a trance.

When there is a sufficient level of trance, therapy can continue to help
the patient feel better and give him tools to forget pain, change the
perception, put it into perspective, or view the sensations constructively.

SUGGESTIONS AND IMAGERY
The link between thoughts, feelings, behaviors, physiologic state, and pain
can allow any of them to change when any of the others does. Curiosity
and imagination can be essential keys to change, and change can happen
for the patient when he imagines that he is in the state of mind or body that
will allow the change to occur. For instance, when I want to be relaxed, I
can imagine being at the beach, to put me in the right frame of mind, or I
can go to the beach. If I want someone to like me, I can imagine that they
already do to show them how to treat me. If I want to dance gracefully, I
can imagine myself gracefully gliding across a dance floor to access body
memories. Body states, behaviors, and feelings are modified more easily in
trance than out of trance. When patients use their his or her own images,
they are more likely to be relevant to them and more likely to be
successfully used in future self-hypnosis sessions. To encourage
dissociation away from the body, the suggestion may be a very detailed trip up in the air in a balloon, off into the clouds, on a rowboat in a magical lake, on a magic carpet over a peaceful place, up on a mountain top, or down on a beach. Any of these can help move the focus out of here and now and out of the body. Turning inward, but still dissociating away from pain, suggestions might be to take a journey from the top of the spine all the way down the back to the sit bones, to go inside the organ or area of the body that has pain, and do something soothing (expand the space, add a healing potion, stroke the inside walls of the area) according to the patient’s image of the pain problem or to go into (working with) the inner workings of the brain to change the interpretation or sensation of pain. All these use the complementarity principle, to be discussed in the following text.

For hypnosis to be effective, the message or suggestion needs to go (1) from the conscious to the unconscious mind, reflectively or by self-hypnosis; (2) directly to the unconscious mind while the conscious mind is in deep trance; or (3) indirectly to the unconscious mind by confusing the conscious mind or by some otherwise subliminal technique. Techniques to do the latter include (1) imbedded commands (“If you are like me, you will feel that the couch is better than the chair for going into trance.”)—here, the italic words are said a bit louder and will be heard by the listener, at an unconscious level, as the dominant or “take home” message; (2) suggestions of dissociation (“While you are aware of the pain at a conscious level, your unconscious mind is already beginning the healing process all by itself without you having to do anything.”); (3) the “yes” set, wherein the therapist says a series of truisms the patient will endorse and then presents the therapeutic message that the patient may have otherwise doubted (“You did well last week, and you did well yesterday, and you are doing well now, and you will continue to do well tonight as well.”); (4) implied causatives, which assume that when the patient does A, B will follow (“Whenever you begin the healing, you will probably notice the pain that leads to the automatic healing responses in your unconscious mind that know how to resolve pain all on their own.”); and (5) confusion, which forces one to suspend the conscious mind so as to think through and resolve the cognitive conflict the confusion created (see section on
Erickson). Direct versus indirect style of suggestion is exemplified by whether the patient is told, for instance, to “Lower your shoulders” or “Take the creases out of your forehead” as opposed to “You may remember the pleasure of a very warm shower on your back and shoulders at the end of a winter day” or “If you have ever had a soothing massage, would your shoulders remember that now?” and “Does your forehead remember how it was so smooth when you were a baby, sleeping peacefully in your cradle?” or “As your eyes slowly begin to close, it is as though you can feel the day’s tension roll right down your face, from your hair and all down over your chest and onto the floor in front of you.”

The unconscious mind operates more in machine language than the sophisticated conscious mind, so keeping language extremely simple, using metaphors and sparing words, is usually more effective, unless you are accessing the patient’s unconscious mind by using a confusion technique, imbedding two conversations and hidden messages at the same time, or creating a state of boredom so that the patient will go deeper into unconsciousness. Whatever the purpose for the trance, it is usually a good idea to add in suggestions to enhance self-esteem and self-efficacy. Convincers can assist the effect of therapy by raising the patient’s level of positive expectancy that hypnosis works. Traditional ways to do this might include glove anesthesia, wherein the therapist guides the patient to create numbness in one hand, catalepsy or the arm raise as discussed earlier, or simply calling attention to the lost sense of time that occurs during trance. Finally, fractionation involves changing the patients’ depth of trance, coming out and back into trance, which effectively deepens the trance, may make the trance more effective and may show the patient that he is an interactive partner in the process.

For surgical and procedural anesthesia or analgesia and for trauma situations, acute pain relief is the primary concern. However, the suggestions made for trust and emotional comfort during and after surgery, speedy recovery, ease with the hospital and healing processes, reduction in anesthetic and pain medications, self-confidence, amnesia for presurgical pain, and future well-being can be posthypnotic and address postsurgical issues. With chronic pain, posthypnotic suggestions can help the patient process and reframe nociception that continues to occur after the hypnotic
session. The suggestions can be general or specific, suggesting that whenever the patient feels x, he can automatically do y (“In the future, whenever you feel tension in your head, you can automatically say your special releasing words to yourself, release, and relax,” or “Whenever you want relief from daily tension, you can say the word “ease” to yourself, and you will automatically feel the wave of release throughout your neck area.”).

Finally, the patient can be guided out of trance with suggestions that encourage more cognitive thought and less unconscious processing. References to recognizing time, temperature of the room, the therapist’s voice (“as distinct from your own”), or feeling the heartbeat, as the therapist picks up the pace and volume of his speech, can all guide the patient back to conscious awareness. There may be side effects to trance which are not convenient, such as foggy thinking, lethargy, disorientation, slow heartbeat, lack of vibrancy, and a temporary amnesia for what was going on before the trance. They may be erased with another brief series of suggestions so that the patient feels refreshed and in control at the end of trance.

Chronic Pain Management

Jensen and Patterson\textsuperscript{80} reviewed 19 studies on the efficacy of hypnosis for chronic pain and outlined the control conditions used for comparison. Eight studies involved headache pain alone and others included cancer; sickle cell; low back, temporomandibular, and mixed chronic pain problems. There were six types of control conditions: measuring change from baseline; hypnosis versus standard care; hypnosis added to another treatment, including physical therapy, medication, education or advice, or an occlusal appliance; hypnosis versus biofeedback; an attentional control condition; and minimal effect control conditions (this allows for passage of time and patient expectancy that a change could occur). They also addressed conditions (or independent variables) that effect success with hypnosis, namely, suggestibility, frequency of treatment sessions, frequency of self-hypnosis practices, patient-rated outcome expectations, initial treatment response, and diagnostic group. The overall conclusion
was that hypnotic analgesia was significantly more effective than no
treatment and other standard care conditions, although other hypnotic-like
treatments, such as progressive relaxation and AT, produced similarly
effective pain control.

We have mentioned chronic pain as distinct from acute and procedural
pain throughout this chapter, although almost all the techniques mentioned
also may apply to chronic pain. Chronic pain carries the expectation that it
may never go away and the extra burden of itself as a prolonged
physiologic stressor. In addition, its emotional suffering component may
magnify with time. To that aim, Hilgard et al. asked their patients
to rate their suffering and pain separately so that they might learn to
differentiate them. Chronic pain is of the type that the patient can well
afford to disregard, forget, or modify; there are hypnotic techniques for all
those possibilities. Treatment may include dissociation from the
nociception and from the awareness of pain; time distortion, which allows
the patient to mentally “be” in the future or in the past when he does not
feel good; selective amnesia for the original injury that cause the pain;
displacement of the pain to a place outside the body; imaginary numbing
of the pain; and altered perception of the pain that recognizes nociception
as just a signal and nothing more.

Brown and Fromm outline group pain therapy sessions, which may be
done in 8- to 12-week formats. The techniques are taught to the patient
through personal experience during sessions and then the patients practice
them for home use. Brown classifies pain management techniques in four
categories—alleviation, alteration, avoidance, and awareness.

1. Alleviation of the sensations or symptoms involves making direct or
   indirect suggestions to make the pain go away, to substitute pain
   sensations for other sensations or for different ones, to create
   numbness, or to imagine analgesia.

2. Alteration involves changing the overall experience of pain by
temporary forgetting it or losing sensation of it, by altering the
   meaning of it, such as aching after winning a sports event, or
   changing the sensation (from pain to pressure or tingling), or by
dissociating from the pain, or by depersonalizing from the body.

3. Avoidance involves taking pain away using distraction, engaging in
fantasy, distorting time, age regression or progression, by getting
absorbed in a mental task, or by imagining the pain somewhere else
in the body.

4. Awareness techniques include focusing the conscious mind on the
component parts of the pain, and studying the component parts of
one’s pain awareness, or the component parts of the mind and body’s
nociception process itself. Brown’s awareness techniques also
highlight complementarity, in that when a patient thinks about his
thinking, he tends to go into trance and cannot pay attention to pain.

Brown suggests having patients pinch the skin between the thumb and
the forefinger to induce just enough pain to test out each of the
aforementioned techniques and to find out which ones work best; in
subsequent practice sessions, each patient will hone the techniques that
worked best for him personally. Brown suggests beginning with secondary
pain areas (for instance, the leg pain that accompanies back pain or
compensatory pain) before working with the primary one.

Finally, pain management training should include relapse prevention, to
help patients come back from handling occasional relapses in pain or in
personal pain management as well as the more challenging times when
patients’ pain feels more intense due to stress. Patients do best when they
are prepared to manage the psychological and behavioral triggers in their
lives that exacerbate pain and when they have a variety of techniques to
use for different situations, types, and levels of pain.

Spira and Spiegel discuss practical ways hypnotherapists can work
with patients’ varying levels of hypnotizability, presenting a tabular
outline of techniques to use according to the patients’ hypnotizability (low,
moderate, and high) and pain levels (mild, moderate, or severe). The table
shows strategies that help low hypnotizable patients, who will do best
learning to release tension for mild pain, differentiate pain from their
responses to moderate pain and distract themselves during severe pain
bouts. Moderately hypnotic patients may best attend to their own positive
coping resources to managing pain and other problems; as pain increases,
they may imagine themselves to be in a positively resourceful state.
Patients who are highly hypnotizable can alter mild pain directly by
triggering memories of past successful alterations to go directly to that

4428
state; as pain progresses, they may dissociate from the experience.

**ERICKSONIAN NATURALISTIC APPROACHES TO PAIN AND SYMPTOM MANAGEMENT**

Erickson was an expert at pain management from personal and professional experience; his techniques and philosophies are taught worldwide and through The Milton H. Erickson Foundation. Neurolinguistic programming (NLP) developed as an attempt to understand how and what Erickson knew about the unconscious minds of his patients; a good part of NLP’s focus is on getting into rapport with the patient’s unconscious processes to help him make changes that other parts of his mind are resisting (see [http://www.NLPU.com](http://www.NLPU.com) for more information on medical and pain-related applications). Erickson believed that hypnotic trance should be cooperative and interactive and that induction should guide the patient inside himself or herself. He believed patients were unique and resourceful in resolving their own pain and suffering, if they could become “unstuck” and open up to doing so. He oriented patients toward positive change, and his rapport with patients was a study in and of itself. He spoke directly to the patient’s unconscious mind (or body processes) and bypassed conscious and unconscious resistance by utilizing the patient’s language, posture, mood, words, and thinking patterns; this requires the attentive listening and observation skills. To treat pain and symptoms, particularly psychosomatic pain, he stressed the importance of seeing the symptom as a valid part of the patient’s experience with some positive purpose that the therapist must welcome in order to work with it.

Erickson managed his own pain by absorbing himself deeply into the awareness of his pain and verbalizing his perceptions of it; this advanced technique diverted his attention away from the sensation itself. His other pain management techniques included altering or reinterpreting the signal, reframing it as a positive thing, eliciting positive early memories to replace the present feelings, or disregarding conscious awareness of pain signal. He was also a master at introducing confusion at the cognitive level, to send the patient into trance, and then confusing perception of pain signals. He disengaged the conscious mind with techniques the conscious mind could not follow. Examples of confusion techniques include the following:
Lankton and others\textsuperscript{184–186} use a number of Erickson’s tools for treatment of pain that include metaphors, stories and anecdotes, or jokes to pull attention away and disconnect from cognitive control. Lankton and Lankton\textsuperscript{184,185} devised the triple imbedded metaphor technique that begins with a naturalistic trance induction and then progresses deeper with the use of three concurrent stories. The technique relies on excellent rapport and the design of stories and language specific to the patient and imbeds suggestions for cognitive, behavioral, emotional, and physiologic changes at deep levels. The use of metaphors fosters a shift to the right side (more
hypnotic and feeling) of the brain. Lankton’s hypnotic trances for treatment of physical pain highlight confusion of the pain perception, time distortion, humor for distraction and rapport, and posthypnotic suggestion.\textsuperscript{186}

Kay Thompson,\textsuperscript{187} an Ericksonian who was also a dentist, used distraction techniques with children and played many word games, such as “panes” of glass that could shatter and be disposed of, seeing through a pain of glass, “untying the knots to not feel” pain, and her famous phrase to start the process of pain management, “When everything that can and should be done about the pain has already been done, you can forget about the pain now.”

Obviously, there is overlap in the pain management tools that practitioners use; what differs is the style of presentation, the particular suggestions for physiologic healing according to the specific type and site of pain. Above all, the patient needs to know that his or her pain and suffering are acknowledged by the therapist; trust, rapport, safety, confidence, and expectancy are all beneficial to the outcome.

Conclusions

Trance is a natural phenomenon, and health care providers have been using hypnosis to guide the patients into pain relieving trances for over 200 years. Recent research on the central mechanisms of pain and of hypnosis has highlighted a role for hypnosis in many medical disciplines, concluding that patients prepared hypnotically for surgery do better than 89% of other patients, and that 75% of both healthy subjects and patients respond positively to hypnotic analgesia, even when hypnotizability is not controlled. Ongoing efficacy and effectiveness studies on hypnosis have improved techniques such that even in the wake of the improved medicines and procedures that modern pain clinics have to offer, hypnosis is still poised to take a respectable role in interdisciplinary pain medicine.

Group therapy continues to be an appealing and common method of chronic pain treatment delivery both in clinical and research settings. First appearing over three decades ago in the pain management literature, case reports and open clinical trials began reporting on adapted individual treatments applied in small-group settings that explored the patient acceptability of a group format. Since that time, controlled trials have demonstrated the utility, efficacy, and cost-effectiveness of this mode of delivery, and the group format is commonly used in interdisciplinary pain management clinics for helping patients manage heterogeneous chronic painful conditions.

Although there are multiple levels of evidence, and each has advantages and disadvantages, in an evidence-based practice, randomized controlled trials (RCTs) provide stronger support. Therefore, the primary findings presented in this chapter are based on evidence emerging from searches of the scientific literature that were performed as recommended within the practice of evidence-based medicine. Specifically, the search implemented in the prior edition of this chapter that searched the literature dating back to 1980 until 2007 was extended to identify literature published between 2007 and August 2017. As per the prior edition, combinations of controlled vocabulary terms, keywords, and methodologic filters were used in an effort to identify the highest level of evidence currently available on group treatment of chronic pain. Details of these searches may be found in Appendix 87.1.

These literature searches revealed that RCTs have primarily evaluated five different types of groups: (1) cognitive-behavioral therapy (CBT) groups that focus on teaching pain self-management skills; (2) mindfulness-based interventions (MBIs) including mindfulness-based
stress reduction (MBSR) and mindfulness-based cognitive therapy (MBCT); (3) acceptance-based approaches, primarily acceptance and commitment therapy (ACT); (4) education groups; and (5) supportive/expressive groups. Although the evidence has rapidly evolved to add further support to mindfulness and acceptance-based approaches since the last edition of this chapter, the vast majority of well-controlled trials of group-delivered treatments for chronic pain continue to be dominated by CBT, which has been shown to be an efficacious treatment of chronic pain; as a result, the focus of this chapter is on group CBT for the management of chronic pain conditions.

Rationale and Basic Considerations of Group Treatment for Pain

EVIDENCE FOR EFFICACY OF GROUP TREATMENT FOR CHRONIC PAIN MANAGEMENT
The highest level of evidence from an evidence-based practice viewpoint is meta-analyses and systematic reviews that quantitatively synthesize the evidence. To our knowledge, no meta-analyses or systematic reviews specifically of group CBT for chronic pain management have been published to date, although reviews of both individual- and group-delivered CBT (combined) have been published. Our literature search revealed numerous controlled studies (both RCTs and non-RCTs) of cognitive and behavioral approaches that have compared (1) group treatment to individual treatment; (2) group treatment to wait-list controls, to treatment as usual, and to other kinds of group treatment (e.g., relaxation or education/support groups); and (3) behavioral group treatments to group exercise and physical therapy treatments. These are reviewed in the following text, followed by a description of the current evidence for group mindfulness- and acceptance-based approaches.

GROUP VERSUS INDIVIDUAL TREATMENT
Table 87.1 summarizes the controlled studies that have directly compared the efficacy of group-administered treatment to individually administered treatment for chronic pain. Relatively few studies have compared
group to individual treatment, and we found only one further RCT specifically addressing this question since the prior edition, and one further RCT that compared group in-person delivered CBT to individually delivered CBT via the Internet. These studies have consistently demonstrated few meaningful differences in outcome between the two treatment modalities, and no differences were observed in the one study comparing in-person group therapy and online individual therapy.

\(^a\)Information obtained from English abstract only.

CBT, cognitive-behavioral therapy; ITT, intention-to-treat; NRS, Numerical Rating Scale; OTC, over-the-counter; PCS, Pain Catastrophizing Scale; QOL, quality of life; RCT, randomized controlled trial; TAU, treatment as usual; VAS, visual analog scale.

One of the earliest RCTs comparing group to individual treatment\(^\text{14}\) found no differences in outcome between the two modes of treatment for headache patients with the exception that at the 6-month follow-up, participants in the group condition showed less of a tendency to drift back toward baseline levels of pain ratings. Because participants knew prior to treatment that they would be randomly assigned to group or individual treatment formats, posttreatment interviews queried their perceptions regarding the treatment modality to which they were ultimately assigned. Patients in group treatment highlighted the benefit of being able to share...
openly with other headache sufferers and to discuss their progress with others in the group. Patients in individual treatment valued the personalized attention given via the dyadic therapeutic relationship and expressed concern that group treatment would not have offered sufficient therapist time for each individual. Thus, patients who participated in each treatment modality seemed to highlight the positive aspects of the treatment modality to which they were assigned as the reasons why this would be the preferred mode of treatment.

Another early RCT focusing on patients with pain in the upper extremities also demonstrated minimal overall differences between individual and group treatment. At 6-month and 2-year follow-up, those who received the group treatment reported less pain-related interference than those who were treated individually, and treatment outcome was otherwise equally efficacious. It is interesting to note that posttreatment satisfaction ratings were higher for individually treated patients, and individual treatment was more effective than group treatment on the outcome measure of self-reported coping strategies. One limitation of these early RCTs, however, was the relatively low number of participants in each condition, which limited the statistical power. A benefit of the studies was the collection of patient satisfaction data.

Several later trials confirmed these general findings. In patients with chronic low back pain, Rose et al. reported few differences in an RCT comparing patients treated individually and those treated in groups. Another RCT by Kääpä et al. examined group-delivered multidisciplinary treatment compared to individual physiotherapy for chronic low back pain and found few differences in outcome immediately following treatment and at 6-, 12-, and 24-month follow-up; however, this study was limited by design features with the two conditions receiving different treatment doses and intervals. In a sample of patients with mixed chronic pain, Frettloh and Kröner-Herwig also found few statistically significant differences in treatment outcome between individual and group modalities, although the effect sizes in improvement at follow-up suggested that group treatment may have been superior to individual treatment.

In another RCT of individuals with mixed chronic pain, Turner-Stokes
et al.\textsuperscript{11} compared outpatient group and individual therapies and found that both treatments resulted in improvements on measures of depression, anxiety, medication consumption, general activity, and pain severity. Those treated in a group showed greater initial gains than those treated individually, but these treatment differences were not sustained over time. Patients treated individually showed slower initial gains but evidenced the same benefits as those who had been treated in a group at the end of treatment. These authors also reported less of a tendency for the treatment gains made by individually treated patients to drift back toward baseline over time. In this study, however, group treatment was delivered for more hours at a time and over a shorter duration (8 weeks) than individual treatment (spread over 16 weeks), and this difference could explain the slower treatment gains witnessed with the individually treated patients.

Finally, one recent RCT compared group-delivered, in-person CBT to individual, Internet-delivered CBT.\textsuperscript{9} The results showed that both formats resulted in significant improvements across a number of important pain-related outcomes, with the Internet-delivered condition outperforming group therapy on some domains in the completer analyses, although the longevity of these effects was not fully examined. Other research now in progress is examining the utility and efficacy of group-delivered telepain management programs that implement videoconferencing interfaces; these innovative delivery platforms have the potential to improve access to CBT in the future.\textsuperscript{17} Overall, the research comparing group to individually delivered treatment has generally concluded that there are very few meaningful differences between outcomes resulting from group and individually administered treatments for chronic pain.

**GROUP COGNITIVE-BEHAVIORAL THERAPY VERSUS WAIT-LIST, TREATMENT AS USUAL, OR OTHER GROUP TREATMENTS**

Table 87.2 summarizes the controlled studies that have compared the effects of group-administered CBT to wait-list control conditions, treatment as usual conditions, or other group treatments such as relaxation, education, or supportive/expressive group therapy.\textsuperscript{18–64} Trials comparing CBT to MBIs and ACT are reported in Tables 87.3 and 87.4, respectively.
There are an impressive number of controlled trials that have been carried out by different research groups focusing on different populations of individuals with pain that together establish the efficacy of CBT for chronic pain. Systematic reviews of these trials have been conducted that include both individual and group-delivered CBT formats across pain types and in children and adult populations; due to space limitations, not all of the studies reported in these reviews are included here. In most cases, RCTs that compared group CBT to other types of group treatments also included a wait-list condition to control for the natural progression of the chronic pain disorder. In the following text, we highlight findings from select studies reported in Table 87.2 comparing group CBT to other types of group treatment because they have played an important role in identifying the effects of CBT; later in this chapter, we also describe a selection of studies that have examined the mechanisms underlying CBT treatment efficacy.

</table>
CBT is a generic term used to describe a complex and multifaceted treatment, and the included treatment components within group CBT protocols vary across studies and research groups. However, the general principles associated with CBT are typically consistent across studies (i.e., that one’s thoughts and feelings influence one’s ability to cope with pain and teaching pain self-management strategies). An overarching component of CBT includes strategies to educate patients about how the brain processes pain and psychological factors affecting pain perception. Furthermore, training in specific pain management skills almost always includes one or more modules on recognizing and modifying maladaptive or distorted pain-related automatic cognitions and beliefs, enhancing cognitive coping, learning relaxation strategies (including one or more types of relaxation techniques such as biofeedback, autogenic relaxation, progressive or passive muscle relaxation, meditation, and/or self-hypnosis), and completing regular homework assignments such as thought records or guided relaxation for skills acquisition. Frequently, but less consistently, CBT includes modules focusing on stress management (sometimes referred to as stress inoculation), paced physical activity, assertive communication, pleasant activity scheduling, and coping self-statements.

Because of the varied approaches that have all been subsumed under the label of CBT in the literature, it has historically been difficult to identify the specific treatment components that account for treatment efficacy, and this continues to be the case. There are a limited number of dismantling studies that have evaluated specific CBT components for pain management. However, controlling for nonspecific treatment effects (e.g., attention from therapist, expectations of health care provider and patient)
is an important step toward determining the specific components of treatment efficacy as well as for elucidating specific and shared treatment mechanisms. Comparing patients receiving group treatment for chronic pain to those on a wait-list does not allow for this type of analysis, although wait-lists do control for the natural progression of the disorder over time and potential reactivity associated with self-monitoring or keeping pain diaries (if included as part of the study). The social context in which the treatment is administered is of particular relevance for the study of the active components of group treatment approaches. Therefore, studies comparing one type of group treatment to another type of group “attention control” treatment (e.g., support group) provide better evidence for disentangling the specific versus nonspecific treatment effects of CBT. Furthermore, comparing CBT to other active treatments demonstrates the relative effects and also allows for examination of whether the treatments exert benefit for the reasons proposed by the respective theory.

Although there is strong evidence for CBT delivered in nongroup formats in nonadult populations, most of the group CBT research to date has been conducted within adult populations with chronic back pain, headache, orofacial pain, or arthritis-related pain and to a lesser degree across an array of other pain conditions. Systematic reviews of the CBT literature typically collapse across most pain types (indicative that the treatment approach and effects are sufficiently similar across these conditions to do so); however, headache and migraine are usually reviewed separately due to differences in the overall approach as well as history. More recently, the treatment of neuropathic pain was isolated within a systematic review and results showed that compared to nociceptive pain, neuropathic pain is particularly recalcitrant to treatment. The primary focus here is on adult populations; the specific type of pain investigated in each study is reported in the corresponding Table 87.2. There continues to be a limited number of studies in which one group treatment for pain has been compared to another. One study in patients with fibromyalgia, for example, compared group education plus CBT versus group education plus group discussion (which controlled for the effects of attention). These authors found that both groups showed equal improvements in pain coping and knowledge, and both were superior to a
wait-list control condition. An economic evaluation of the treatments resulted in the authors’ suggestion that the extra health care costs associated with the addition of the CBT modules were not warranted based on the outcomes. It is important to note that the education modules that were offered to all participants included structured physical fitness training after each of 12 sessions, and this behavioral component may have served to increase the overall outcome efficacy of both groups. Furthermore, the discussion modules (attention control) included weekly homework assignments, which is typical of CBT groups but atypical of control conditions. The authors suggest that the homework assignments may have served as a form of graded exposure for the fearful participants, thereby resulting in treatment gains in the control group. It is also important to mention that both treatment groups in the mentioned study used limited therapist time in an effort to reduce treatment costs. It may be that the principles associated with cognitive-behavioral change require some threshold amount of therapeutic intervention in order to be successfully implemented. These findings and others led Vlaeyen and colleagues raise the important point that the active components of group treatment need further careful study.

Another study assessed the efficacy of group CBT for pain using education booklets as the control condition and found significant pre- to posttreatment differences in favor of the CBT self-management groups. Although the use of education booklets does not control for the nonspecific treatment effects of group interaction or support, this study suggests that merely offering facts about pain and pain management outside a therapeutic context does not appear to be efficacious. However, another study that compared cognitive-behavioral pain self-management to a condition that was assigned a book to read on managing chronic pain found that both conditions similarly showed clinically significant changes over time. A limitation of such an approach is that to read a book requires a certain level of literacy, as does participating in a traditional CBT program.

Thorn and colleagues addressed the literacy treatment barrier via developing literacy-adapted CBT and education programs and tested their relative efficacy in a series of two RCTs within low-literacy, low-
socioeconomic status (SES), predominantly minority populations. Results of the initial RCT showed that delivering education within a therapeutic context (i.e., that included factors such as therapeutic rapport and group support, as opposed to bibliotherapy) was particularly beneficial and both groups improved significantly across a number of outcomes; no significant differences between the literacy-adapted CBT and pain education treatment were observed in the intent to treat sample. In Thorn and colleagues’ most recent trial that included a larger sample size and several methodologic enhancements, again, both the literacy-adapted CBT and education interventions performed similarly on the primary outcome of pain intensity and the secondary outcome of pain interference, with both significantly outperforming the treatment as usual control. Maintenance of gains in pain interference was observed in both groups; although benefits in pain intensity were maintained in education at follow-up, this was not the case for CBT. However, participants in CBT were less likely to be depressed at follow-up. Comparison of effect sizes and clinically meaningful improvement (>30% reductions in pain intensity, pain interference, and depression) suggested a slight advantage of CBT over education, but overall, these findings suggest that both literacy-adapted CBT and pain education are suitable for implementation in highly disadvantaged populations. Patient workbooks and therapist supplements for these literacy-adapted treatments are freely available at pmt.ua.edu/publications.html.

Several other studies have compared group CBT to relaxation training or another group condition. In one study of patients with low back pain, patients receiving group CBT and those receiving relaxation training improved compared to wait-list controls, although at follow-up, those who received CBT showed greater treatment gains than those receiving relaxation training. In a similar study with individuals with fibromyalgia, those who received group CBT showed greater improvement in pain ratings than those who received autogenic relaxation training. Focusing on high school students with migraine and tension-type headaches, Larsson et al. compared self-help relaxation groups to problem discussion groups and untreated self-monitoring groups and found self-help relaxation to be superior to the other two conditions. Contrary
findings were reported by Mishra and colleagues\textsuperscript{36} who compared CBT versus biofeedback versus CBT + biofeedback versus no treatment in a temporomandibular disorder population and found that although all three active treatments significantly outperformed the no treatment arm, there were no significant differences in outcomes across the active treatments. Together, these studies suggest tentative evidence supporting CBT groups as conferring greater benefit than relaxation-only groups and that relaxation groups alone may be superior to groups offering only education or discussion in some settings.

A specialized subset of studies comparing one type of group treatment to another are those that have compared group CBT offered only to the patient, to group CBT offered to both the patient and his or her partner. Moore and Chaney\textsuperscript{61} found that among patients with mixed chronic pain syndromes, couples group therapy and patient-only group therapy were both superior to a wait-list control group, but the patient-only groups showed significant improvement on more outcome variables than did the couples groups. Another study found similar improvements in physical and psychological functioning, cognitions, and coping among both couples groups and patient-only groups, although at 6-month follow-up, patients in the couples groups reported greater improvement in communication with their spouse than did patients in the patient-only groups.\textsuperscript{33} Patients with chronic headache differ in some ways from those with other chronic pain syndromes, and therefore, it is interesting to note that one study found that partner involvement in chronic headache management groups actually reduced efficacy compared to nonpartner involvement.\textsuperscript{48} Further research is necessary to determine whether this finding is unique to individuals with chronic headache pain or if other variables are associated with this outcome.

Another line of research has examined potential algorithms for tailoring CBT to the specific baseline symptom profiles of individuals entering treatment. van Koukil and colleagues\textsuperscript{26} conducted an RCT within a fibromyalgia sample and compared tailored CBT + exercise to a wait-list control. Specifically, patients were classified at baseline into two groups, (1) pain avoidance (i.e., individuals who avoid activities due to fear of pain) or (2) pain persistence (i.e., individuals who persist in activities
despite pain), and were then randomized. Those in the intervention condition received treatment that was tailored to their cognitive-behavioral pattern. Specifically, individuals with a pain-avoidance profile received group-delivered treatment theorized to explicitly target increasing daily activities, reducing pain and avoidance behaviors, and increasing physical condition. Whereas those individuals with a pain persistence profile received group treatment targeted toward regulating daily activity, increasing activity pacing, restructuring pain-persistence cognitions, and increasing physical condition. Results showed that the tailored treatment resulted in large effect sizes and significantly greater improvements across all primary outcomes as compared to the wait-list control. Unfortunately, this study did not include a “mismatched” arm; hence, the utility of matching patients to these tailored treatments is not fully known. However, in a recent study by Kerns et al. that examined individually delivered tailored CBT to standard CBT, no significant outcomes were observed; to the best of our knowledge, no research has examined similar research questions in a group setting. Future research identifying the optimal approach to tailoring group-delivered CBT to specific profiles is needed as this has the capacity to more efficiently and effectively engender positive changes.

Finally, one promising study by Seminowicz and colleagues showed that group-delivered CBT resulted in increased gray matter in several areas of the brain related to pain processing following an 11-week treatment. Many of these increases were correlated with treatment-related reductions in pain catastrophizing, suggesting that successfully targeting this cognitive mechanism may be a powerful way to harness neuroplasticity and potentially reverse a selection of brain-related changes associated with central sensitization and worse pain outcomes. Although the sample size was small and the design lacked randomization and follow-up, these promising results provide preliminary evidence to support CBT as an intervention that effectively retrains the brain to enhance top–down control of pain and cognitive reappraisal of pain as well as alters the perception of noxious signals. Although reduced pain catastrophizing was found to be a critical correlate of these changes, it is not clear if cognitive change in catastrophizing is a mechanism specific to CBT.
BEHAVIORAL VERSUS EXERCISE AND PHYSICAL THERAPY GROUP TREATMENTS

Physical therapy has long been considered an essential component of chronic pain management, and as a result, it is important to consider its role in treatment groups for chronic pain. Although most studies have focused on the efficacy of physical therapy and exercise in an individual context, we located two RCTs specifically comparing group behavioral approaches to group physical therapy. In one study, individuals with chronic low back pain who received group behavioral treatment and those who received group physical therapy both showed significant decreases in activity limitations, anxiety, and depression. In another study, Turner et al. examined the differential efficacy of group behavioral therapy alone, group aerobic exercise training alone, group behavioral therapy plus group aerobic exercise, and a wait-list control group. The three treatment groups showed greater improvement than the wait-list control group, and all groups showed increasing improvement over the 6- and 12-month follow-ups. It is important to note that in this study, the combined behavioral plus exercise group treatment showed the greatest improvement overall, suggesting that physical activity may be an important component to incorporate into group treatment for chronic pain.

However, in another study by van der Roer et al. that compared a combined exercise therapy, back school and operant-conditioning behavioral principles condition to physiotherapy, no significant differences in outcome were observed on any outcome measure during the complete follow-up period. Similarly, in an RCT by Smeets and colleagues, the advantage of combining cognitive and behavioral interventions (primarily graded activity) with active physical therapy was also not observed; this study found no significant differences in outcomes between the combined treatment and the individual components, but all three significantly outperformed the wait-list control. The van der Roer et al. study and research by Smeets et al. was not included in Table 87.2, however, as the treatments compared in these studies entailed both individual and group delivery components.

To summarize, converging lines of evidence described earlier and in Table 87.2 provide strong evidence that individuals with chronic pain
benefit significantly more from group CBT than from being on a waiting list or receiving medical treatment as usual. The specific mechanisms of treatment efficacy have yet to be clearly identified, but studies to date have shed some light on these mechanisms, which are described in more detail later in this chapter. As efficacy research moves from open trials to RCTs designed specifically to compare group CBT to other active group treatments, future studies are likely to emerge that will help identify the active components of CBT treatment.

**MINDFULNESS-BASED APPROACHES TO PAIN MANAGEMENT**

The past decade has witnessed an exponential growth in the amount of research directed toward understanding the effects of MBIs for chronic pain management. Although this body of research continues to be limited due to common methodologic issues such as small sample sizes, and lack of randomization and comparison conditions, the number of quality RCTs on mindfulness-based pain and stress reduction or other meditative therapies for chronic pain is steadily increasing. A recent meta-analytic review by Veehof and colleagues examined the evidence of mindfulness- and acceptance-based interventions for pain. Nearly all of the studies reporting on the effects of MBIs for various chronic pain conditions that were included in this review involved group-delivered treatment, except for a small selection that examined modes of online delivery in an individual format. Regarding group meditation treatments specific to chronic pain, we were able to locate 17 RCTs and 3 non-RCTs (see Table 87.3 for a summary). Most of these studies compared group meditation (usually in integrated packages such as MBSR and more recently, MBCT) to standard care and found meditation to be more beneficial with respect to pain interference, pain perception, pain coping, and measures of affect immediately posttreatment and also at follow-up. However, most follow-up periods were relatively short (i.e., 3 to 6 months), and although pain interference is the recommended primary outcome for MBIs, a number of studies did not include a measure of this outcome. Furthermore, there is a large range in the size of the groups examined in the MBI for chronic pain literature, ranging from as small as 4
all the way up to 25 group members; although yet to be empirically examined, this variability in group size is likely an important factor influencing potential differences in outcomes observed across studies.

Given the promising preliminary evidence of group-delivered MBIs for chronic pain as compared to inert comparison conditions, a more recent focus has been on comparing MBIs to attention control conditions (such as social support), psychoeducation, and to other active treatments—primarily to CBT, given this is the “gold standard” treatment in the field. In one of the largest RCTs conducted to date, Cherkin and colleagues compared MBSR versus CBT versus usual care in a population with chronic low back pain. The results found that MBSR was as effective as CBT (both of which were significantly better than the control) for improving back pain and associated functional limitations, and the benefit in both active treatment conditions was maintained at the 52-week long-term follow-up. In a 2-year follow-up, participants in CBT compared with usual care showed greater improvement in function, whereas MBSR did not differ from usual care at 2 years. Clearly, further well-controlled trials comparing MBIs to other active treatments with adequately powered samples and long-term follow-up assessment time points are needed. However, the literature to date suggests that group-delivered MBIs are efficacious approaches for chronic pain management and, although not typically superior to CBT, do provide a viable alternative.

ACCEPTANCE-BASED APPROACHES TO PAIN MANAGEMENT

As with MBIs, the body of research devoted to acceptance-based interventions such as ACT and contextual cognitive-behavioral therapy (CCBT) has rapidly increased since the prior edition of this book. In the
aforementioned review by Veehof and colleagues, several of the included ACT studies entailed group treatment delivery; in total, we identified six RCTs that examined group-delivered acceptance-based approaches for heterogeneous chronic pain conditions (see Table 87.4 for a summary). Across these studies, the most consistently reported benefits of group-based ACT applied to chronic pain include improved physical and emotional functioning and increased pain acceptance, and although follow-up periods were short, the benefits observed were maintained.

Several other nonrandomized trials of interdisciplinary treatment outcomes where the orientation was ACT-based have also found support for this approach; these studies were not included in Table 87.4 as it was not possible to determine the effect of group-based ACT as a standalone (i.e., ACT in the absence of combined physiotherapy, activity/exercise, nursing and anesthesiaology, etc.). However, these studies do provide further preliminary evidence for the potential efficacy of group-delivered ACT across a range of chronic pain conditions. To summarize

these findings, results generally found interdisciplinary ACT resulted in significantly improved physical performance and quality of life; fewer sick days; and reduced pain intensity, disability, medical utilization, daytime rest, distress, depression, and pain-related anxiety, with these benefits typically maintained at follow-up.

Similar to the mindfulness literature, the research examining group-delivered ACT approaches for chronic pain has more recently transitioned to comparing ACT to other active treatments. Within a fibromyalgia sample, Luciano and colleagues reported that ACT resulted in significantly greater improvements across a number of pain-related outcomes in comparison to both the recommended pharmacologic treatment for fibromyalgia, as well as a wait-list control; these effects were maintained at 6-month follow-up. One RCT by Loebach-Wetherell et al. compared ACT to CBT in a mixed chronic pain sample and reported similar significant benefits for both treatments across physical and emotional functioning outcomes immediately following treatment and at 6-month follow-up; however, ACT outperformed CBT in terms of client satisfaction, whereas treatment credibility ratings were significantly higher for CBT than ACT. Moreover, in a secondary analysis, it was found that although older adults were more likely to respond to ACT, younger adults were more likely to respond to CBT, both immediately following treatment and at follow-up. Across the group-delivered acceptance-based literature as a whole (including open trials), there is a large amount of variability in the number of sessions delivered, and the frequency and length of sessions per week, and much of the research has examined ACT-oriented interdisciplinary programs as opposed to ACT as a stand-alone psychosocial approach. However, the evidence to date is particularly promising and suggests that group-delivered ACT (especially as delivered within an interdisciplinary context) may perform as well as CBT for chronic pain management.

Factors Affecting Psychotherapeutic Outcome

Although evidence for the efficacy of a number of group-delivered psychosocial treatments is accumulating, the approach with the most well
developed body of research to support its use continues to be CBT. Thus, here, we focus on examining the literature that has investigated the mechanisms underlying the well-documented effects of CBT for chronic pain. Although there are many potential factors affecting group CBT treatment outcome for pain management, we have chosen to highlight four: the importance of changing cognitions, the importance of practicing skills to maintain treatment gains, the need for sufficient therapist contact to promote change, and the role of the group process itself.

THE IMPORTANCE OF COGNITIVE CHANGE

The CBT approach is based on the underlying theoretical assumption that emotions and behavior are largely determined by cognitive perceptions of the world. Based on this premise, although there is no “standard” CBT protocol, a critical component of CBT for chronic pain is promoting more adaptive and realistic appraisals of pain and stress. Specifically, the basis of cognitively focused CBT for pain is on helping patients become aware of, examine, and gain control over the thoughts that influence their feelings, coping behavior, and physiology. Given the plethora of research that has consistently found that pain catastrophizing is a robust predictor of a range of negative outcomes (above and beyond other factors such as disease severity, pain intensity, anxiety, and neuroticism), this construct represents a key cognitive mechanism targeted in many CBT programs. Research has found that treatment-related reductions in pain catastrophizing during CBT-oriented interdisciplinary treatment correlate with improvement in pain-related outcomes. In another study by Thorn and colleagues, it was found that tailoring CBT specifically toward the reduction of catastrophizing is particularly effective for headache pain, with treatment-related reductions in pain catastrophizing correlating with improvement in several treatment outcome variables. Furthermore, Burns and colleagues used lagged and cross-lagged analyses and found that early treatment reductions in pain catastrophizing predicted late-treatment improvements in pain-related outcomes, but not vice versa during CBT-oriented interdisciplinary treatment programs. Additional cognitive variables that have been found to correlate with improved outcomes during CBT include self-efficacy,
perceived pain control,\textsuperscript{120,125} pain helplessness,\textsuperscript{126} and other pain-related beliefs.\textsuperscript{120} Other research has also shown CBT to shift implicit pain self-associations, and this shift was correlated with improved self-esteem.\textsuperscript{127}

More recent research has identified that changes in cognitions, such as pain catastrophizing is likely not a mechanism specific to group CBT for pain, however. For example, Thorn and colleagues conducted secondary analyses of the RCT described earlier\textsuperscript{128} (within the low-income population with low health literacy skills\textsuperscript{24}) and found that the observed similar efficacy between group CBT and education might have been accomplished through similar mechanisms, with pain catastrophizing found to account for pre- to posttreatment differences in outcomes across both conditions. Smeets et al.\textsuperscript{129} found that treatment-related changes in pain catastrophizing similarly mediated outcome across both CBT as well as physical treatments for chronic low back pain. Turner et al.\textsuperscript{130} also found that pain catastrophizing similarly improved across both group-delivered CBT and MBSR.\textsuperscript{130} Moreover, this same study by Turner’s group identified similar effects on mindfulness, acceptance, and pain management self-efficacy for both CBT and MBSR. Consistent with this, other research examining group CBT-based multidisciplinary pain programs has found that pain acceptance (which is a treatment target theoretically specific to acceptance-based treatments) was correlated with improvement in pain outcomes,\textsuperscript{131,132} and another study showed CBT-related changes in mindfulness was associated with improved pain outcomes.\textsuperscript{133} Taken together, this research suggests that beneficial outcomes during group-delivered CBT (as well as other psychosocial treatments) might be due to widespread changes across a range of both theory-specific and theory-nonspecific, as well as adaptive and maladaptive, pain-related cognitions of which pain catastrophizing is just one (albeit potent) factor.\textsuperscript{134} These findings have led some researchers to posit that global changes in cognitions associated with CBT (e.g., the way one relates to and conceptualizes chronic pain, appraisal processes, confidence in one’s ability to cope, altered pain self-associations) may be more important to positive outcome than increases in the performance of specific skills taught in CBT per se.\textsuperscript{135,136} However, this view is yet to be empirically tested, and as discussed in more depth in the next section, it is
more commonly theorized that skills practice is a necessary but perhaps not sufficient factor (i.e., cognitive change is also needed) for improving outcomes.

**COMPLIANCE WITH HOMEWORK AND SKILLS PRACTICE TO MAINTAIN TREATMENT GAINS**

The CBT approach is designed to be an empowering intervention that teaches patients skills that they themselves can continue to use to self-manage pain, long after completion of treatment delivery. Thus, when considering whether a valid clinical trial of CBT has been conducted, there must be some demonstration that patients are independently practicing these coping skills at an adequate level as this is theorized to be a key precipitating factor in engendering the earlier described cognitive changes. Treatment enactment refers to the extent that clients actually apply what they have learned out of the treatment session. Homework or practice of skills learned in treatment is one way to measure treatment enactment. Scharff and Marcus\(^{137}\) found that individuals with headache pain who practiced the skills taught in treatment (which included physical therapy, headache-free diets, and relaxation) were more likely to maintain their treatment gains when measured at follow-up. Likewise, completion of homework assignments were significantly related to treatment outcome in patients with irritable bowel syndrome (IBS) participating in group CBT.\(^{35}\) Vlaeyen et al.\(^{44}\) compared group education plus CBT to group education plus attention control (group discussion) and noted that in the CBT group, compliance with completion of homework assignments was quite low, which might increase risk for relapse long-term.

Indeed, research underscores the problem of relapse following CBT and other psychosocial pain interventions.\(^{138}\) Although it has been assumed that posttreatment variability in maintenance trajectories depends at least in part on the maintenance of coping skills practice, few studies have empirically examined if this is the case. One important study comparing individually delivered CBT to treatment as usual that examined a 2-week posttreatment epoch identified that on average, continued use of active cognitive and behavioral coping, positive affect, self-efficacy, and perceived control over pain was associated with maintenance of gains, and
pain catastrophizing and negative affect were associated with loss of gains.\textsuperscript{139} Although innovative approaches to enhancing skills practice have been applied, the beneficial effects of these maintenance model approaches has been somewhat limited.\textsuperscript{140,141} The less than optimal efficacy of these relapse prevention interventions may stem from a lack of understanding of the mechanisms of posttreatment improvement, maintenance, and relapse, and future research in this area is critically needed.

**IMPORTANCE OF THERAPIST SKILL AND ADEQUATE TIME WITH THERAPIST**

Given the lack of compelling evidence to date in regard to change in cognitions being specific to CBT, it has been postulated that beneficial effects may be wrought via change in nonspecific factors.\textsuperscript{134,142} From the inception of CBT, Beck and colleagues\textsuperscript{143} ascribed importance to the presentation of a convincing treatment rationale in the first CBT session. In this context, it has been argued that more experienced/skillful therapists will deliver a more credible and persuasive rationale and will more likely be perceived as “experts.” Importantly, this treatment rationale also functions to foster a collaborative therapeutic alliance and generate positive expectations—factors which have repeatedly been demonstrated to influence outcome across a range of studies and population types.\textsuperscript{69,144,145} Furthermore, although trials specifically designed to evaluate the contribution of therapist expertise/skill in group CBT for chronic pain in relation to outcomes are lacking, in the CBT for depression literature, it has been found that compared to those treated by less experienced clinicians, patients of experienced clinicians tend to show more improvements.\textsuperscript{146}

Within the group CBT for chronic pain literature included in Table 87.2, there was a large amount of variability across studies regarding the professional discipline of the delivering interventionist (i.e., psychologist, nurse, physiotherapist, etc.), the length and form of therapist training procedures specific to the study protocol, the degree of therapist expertise/experience (i.e., graduate student, postdoctoral student, licensed clinical psychologist), and the amount of time therapists spend with patients (i.e., treatment dose) as well as in the number of therapists in the
room leading any one group. Moreover, treatment fidelity (also known as treatment integrity) was not routinely reported, and when fidelity ratings were reported, there was also variability in what precisely was coded and described (i.e., adherence, appropriateness and quality, or any combination of the three). Thus, the specific role of therapist factors along with the “dose” of time a patient spends with the therapist is not well quantified in group CBT for pain research. However, available evidence across other population types suggests such therapist factors play a critical role in outcomes, and it will be important for future research to establish the size of these effects in the context of group CBT for chronic pain.

**IMPORTANCE OF GROUP PROCESS**

Research across various populations (i.e., not specific to pain) has shown that group processes developed during treatment, such as cohesion and social learning, have the capacity to become agents of change in and of themselves. In our review of the group pain management literature, we located one open clinical trial and one RCT that offered interesting qualitative information regarding the importance of group process. Moore et al. identified that failure to improve during a multidisciplinary treatment depended in part on whether other members of the same treatment group also failed to respond (or left the program prematurely due to dissatisfaction). In another study by Day et al., qualitative data from recorded semistructured interviews with participants who completed either group CBT or pain education (as a component of Thorn et al.’s earlier described RCT among low-income patients who generally had low health literacy) were thematically analyzed. Group cohesion emerged as one of the most robust themes identified across both CBT and education, and within this overarching theme, subtheme processes of “learning together/sharing” and a “feeling of not being alone” were identified as exceptionally valued aspects of both treatments. A sense of “feeling like a family” was a further subtheme reported by participants who completed CBT but not education. More research is needed to clarify the role of such nonspecific treatment factors in treatment outcome. However, the earlier studies highlight the importance of social factors in chronic pain and underscore the caveat that group treatment should be designed to capitalize
on these social influences.

**Advantages of Group Treatment**

**EFFICIENCY AND COST-EFFECTIVENESS**

Given the general lack of difference in treatment outcomes between group and individual CBT, it could reasonably be argued that group treatment is a more efficient modality of therapy for chronic pain disorders. Certainly, group treatment is cheaper in terms of practitioner time and patient expense. Indeed, in a study by Bruns and colleagues\(^{150}\) that used Medicare reimbursements rates to compare the cost of a typical lumbar spinal fusion to the cost of a 10-session group-delivered CBT program, it was found that the surgical costs alone were 168 times greater than the costs of delivering the CBT program. However, cost-effectiveness depends not only on cost but also on relative effects.

Reviews of the literature have identified that psychosocial approaches such as CBT are at least as efficacious as surgery and medication management for pain.\(^{151,152}\) Other research\(^{153}\) has examined the cost-effectiveness of adding CBT to an inpatient rehabilitation program compared to standard rehabilitation without CBT; there were no significant differences between direct medical or nonmedical costs, and CBT showed lower indirect costs. Furthermore, 6 months following treatment, those who additionally received CBT were absent from work an average of 5.4 days less than those who received standard care.\(^{153}\) Similar results were reported in an outpatient setting by Lamb and colleagues\(^25\) who examined the cost-effectiveness of adding six sessions of group CBT to a standard active management advisor consultation versus the consultation alone; over 1 year, the group who had additionally received CBT had a sustained benefit in pain-related disability at low-cost to the health care provider. However, “more is not always better,” as described by Smeets and colleagues\(^{154}\) who compared the cost-effectiveness of active physical treatment versus graded activity and problem solving versus a combination of these treatments; the combination treatment did not result in significantly greater improvements in quality adjusted life years or disability as compared to the single treatment modalities, and it
was not deemed cost-effective.

**SOCIAL PROXIMITY AND SUPPORT**
There are several other advantages to using a group modality with patients who have chronic pain-related conditions: A group approach provides social interaction and support from others who share common distressing experiences including the pain itself as well as secondary stressors associated with the pain such as frustrating interactions with the health care system, economic hardship, and deteriorating family relationships. Individuals struggling with chronic pain often feel isolated and misunderstood. Disclosing thoughts and feelings to others who share similar concerns offers patients a greater sense of legitimacy than might be experienced by sharing thoughts and feelings with a therapist or significant other who does not experience pain. More times than not, other patients in the group will have had similar experiences that they also share, which is validating to the person who originally disclosed their concerns, leading to a sense of “not being alone.” Qualitative studies of people who have previously completed group-delivered CBT have found that sharing experiences and learning together, as well as being listened to, understood, accepted, tolerated, and affirmed, were highly valued perceived benefits of the group approach for pain management.\(^\text{149,155}\)

Beyond the social support provided by others who share similar concerns (which is considered a nonspecific treatment factor), group CBT seems to offer additional benefits. Studies have shown group CBT to be superior to group relaxation sessions\(^\text{64}\) and to group discussion sessions,\(^\text{57}\) both of which offer the type of social support received in group CBT. Maunder and Esplen\(^\text{156}\) reported that a supportive-expressive group for patients with inflammatory bowel disease did not improve symptoms of gastrointestinal (GI) distress/pain, patient quality of life, anxiety, or depression, and they concluded that, at least for this population, supportive-expressive group therapy alone is not efficacious.

**VICARIOUS LEARNING AND MODELING OF COLLABORATIVE APPROACH**
Group treatment provides clinicians with multiple scenarios to choose
from and build on during group discussions, which is helpful when illustrating a particular teaching point. Taking advantage of a salient example and using it for the benefit of the entire group maximizes the likelihood that patients will understand the intervention through vicarious learning (i.e., other group members observing a therapeutic interaction between an individual patient and the therapist).

Moreover, group treatment provides a fertile venue for modeling a collaborative approach to treatment between the patient and the practitioner. Early in the group process, the leader establishes the expectation that patients will actively participate in group discussions, self-monitor their activities, and complete homework assignments. Through selective reinforcement of patients who actively engage in their treatment by participating in the group and completing the homework assignments, the leader can strive to increase active coping in all of its members. A qualitative study of group CBT treatment with women suffering from chronic pelvic pain revealed that this collaborative approach facilitates a therapeutic progression beginning with developing self-knowledge, followed by assuming responsibility for self-management, and ending with increasing self-control and personal mastery of emotions.¹⁵⁷ Similar results were found by Day and colleagues¹⁴⁹ in their qualitative analysis of literacy-adapted CBT versus pain education in a rural, minority population. Participants reported valuing the collaborative rapport and group learning environment, and many found that working through thought record homework activities in session on a flip chart with the therapist was particularly important for acquiring the cognitive restructuring skill set.¹⁴⁹

INTERPERSONAL GROUP PROCESS
A final potential advantage of group treatment is the use of group process to facilitate treatment gains (i.e., utilizing the interpersonal exchange between group members in addition to the exchange between therapist and the patient). A group of patients provides an opportunity to capitalize on the moment-by-moment interchanges among group members as well as the interpersonal relationships that develop over time. It is noteworthy that group members will often accept positive feedback, negative feedback,
and confrontation from other group members better than from the group leader. This may not only be due in part to feeling more understood by a fellow patient (someone who has “walked in my shoes”) but may also be due to the power of the interpersonal process that occurs in group settings.

Practical Issues

OPEN VERSUS CLOSED GROUPS
Most controlled studies in the literature have focused on time-limited, closed groups. In research, this is a necessity to control for a number of confounding variables that ongoing, open groups would introduce into a research design. There are also clinical advantages to running a closed group where all members start and end group treatment at the same time. From a practical perspective, however, running closed groups can prove difficult in some clinical settings because new patients would be required to wait until a new group starts to begin treatment. In response to this concern, Thorn adapted her 10-session CBT manual so that the modules were less dependent on each other, with an introductory session provided to any patient just starting out (i.e., before he or she joins an ongoing group). The feasibility and effectiveness of such an approach has not been tested but may hold particular importance for patients such as injured workers, who are under pressure to return to work. Furthermore, such practical adaptations, if found to be effective, would also increase the probability of implementation in real-world settings.

LENGTH OF GROUP
The length of the groups varied in the RCTs reviewed for this chapter, ranging from 5 to 12 sessions, with a modal number of 10 sessions. Most RCTs reported meeting weekly for 90-minute sessions. Time-limited groups are the accepted standard in research trials because treatment manuals are usually highly structured, and demonstrating fidelity of treatment through therapist adherence to the protocol is an important component of treatment implementation. Furthermore, treatment groups of varying lengths would introduce variance that would reduce the statistical power required to detect real differences between treatment and
control groups. On the other hand, clinical realities often necessitate varying the length of a particular treatment component based on whether or not the intervention has been understood by the group members. In clinical settings, there may indeed be some situations in which it would be well advised to repeat a particular unit, continue coverage of a particular topic, or adapt the treatment protocol in some other way. An example of this is Thorn’s research described earlier, where the CBT and pain education materials were adapted for patients attending low-income clinics, many of whom also had low health literacy.18,24

NUMBER OF PARTICIPANTS
A group composed of approximately five to six members is of sufficient size to facilitate interaction among group members, accommodate the absence of a member without jeopardizing group cohesiveness, and provide enough time to attend to each patient during the individual sessions. Most CBT groups will have more women than men because women have more chronic pain problems, present more frequently for pain treatment than men,159 and may be more receptive to group interventions based on their tendency to cope via a communal support process.160 Indeed, one study found that women improved more than men on a number of pain-related outcomes during a multimodal pain management program that included both individual as well as group therapy components.161 Differences in age, ethnicity, and cultural background do not appear to jeopardize the group process perhaps because chronic pain serves as a unifying factor, making other potentially divisive issues less important. We were unable to identify any studies addressing the issue of whether it is important to racially match group leaders with participants. In an unpublished follow-up qualitative study using posttreatment key informant interviews with African American members of a CBT headache management group 2 years after the RCT had been completed,29 those interviewed thought that including therapists of different racial and ethnic backgrounds as group leaders would enhance the comfort level of participants and thus increase both their willingness to participate and their chances of treatment completion. In mixed race groups, it is probably preferable to have at least one of the cotherapists be a person of different
INDIVIDUALS WHO MAY BE INAPPROPRIATE FOR GROUPS

Almost anyone deemed appropriate for individual CBT for pain management is appropriate for group treatment, but there are a few exceptions. Patients with moderate to severe dementia or other cognitive impairment, psychosis, or chronic interpersonal relationship problems have typically been considered inappropriate for group treatment. However, a published protocol by Kennedy et al. described a mixed methods controlled trial that they were conducting to investigate an adapted group CBT program for women with mild to moderate intellectual disabilities and menstrual pain; to the best of our knowledge, although the trial is listed as completed on the trial registry, the results have not been published. Further research to examine modified CBT programs to reduce the cognitive load and needed literacy level for effective participation is needed.

In addition, it is not unusual for individuals with chronic pain to have problems managing anger, and in some cases, the degree of anger and hostility may be a contraindication for group treatment. In these cases, however, it is often possible to help the patient learn to regulate his or her anger and hostility in individual treatment and then invite him or her to participate in a group at a later date. Keefe et al. noted that they sometimes use a “time-out” strategy for group members whose anger is disruptive or in other ways countertherapeutic, in which patients meet individually with group leaders while continuing to attend the group but remaining silent for two to three sessions. Clearly, if a patient expresses a strong preference for individual treatment or if his or her schedule prohibits involvement at the prescribed group time, an individual approach will need to be employed.

Summary and Conclusions

Group treatment approaches for pain management have been clearly established as efficacious. Although the evidence for MBIs and ACT has
grown exponentially over the past decade, the vast majority of controlled research studies continue to be focused on CBT group approaches. The available research suggests that there are few differences in treatment outcome between group and individual CBT for chronic pain. Thus, because group treatment is more efficient in terms of therapist time and more economical for patients, we suggest that group treatment is generally the favored modality. Certainly, not all patients are appropriate for group pain management, and logistical difficulties in organizing and running a group prevent the universal adoption of group treatment as the only method of appropriate treatment. Relatedly, some patients may need more intensive psychotherapy than what the typical group approach has to offer. It is therefore quite appropriate to refer certain patients for individual treatment after the completion of group treatment.

Future Directions

It is important to note that although the extant research literature has established the efficacy of group CBT for pain management, the external validity of research-based efficacy trials has yet to be studied (i.e., effectiveness studies). Because the efficacy studies cover a wide range of pain problems and come from a variety of research laboratories both inside and outside the United States, we may feel more confident in the generalizability of the results. Methodologically, an important next step would be to move toward pragmatic randomized controlled trials (pRCT), which would help provide information necessary for implementation in routine clinical practice. Furthermore, future research such as that initiated by Thorn and colleagues exploring appropriate adaptations for local populations with special needs will help establish the effectiveness of group approaches for real-world settings. Other important issues include enhancing access, durability of treatment effects, and identifying and facilitating reliable mechanisms for reimbursement.

Recently published national clinical practice guidelines stress nonpharmacologic evidence-based alternatives to pain medications and specifically list CBT as one of those options. Notably, the 2017 MD Chronic Pain Guidelines reviewed all available high-quality research on
364 treatment × condition pairs. Of these, CBT and only seven other treatments are listed as having consistent evidence of efficacy, no risk of mortality, limited or no side effects, and low cost.\textsuperscript{166} Although other formats for treatment delivery of CBT have been developed to increase accessibility (e.g., online resources), the power of group participation in patients who are socially isolated cannot be underestimated.

Two other areas in need of more research are cost-effectiveness studies and research examining the specific mechanisms associated with treatment efficacy. Regarding cost-effectiveness, such research is particularly difficult to carry out in health care settings without readily available (electronic and universal) health care utilization information. Regarding the identification of specific treatment factors responsible as the agent of change, the research conducted up to this point offers a promising start that efficacious group CBT is more than simply therapeutic and social support. However, the mechanisms that may be specific to CBT versus shared across all active treatments for chronic pain need further investigation. Also lacking is well-formulated algorithms for tailoring CBT to the specific baseline cognitive and behavioral profiles of patients in order to most effectively and efficiently target change mechanisms to optimize outcomes. Although yet to be empirically tested a priori, the limit, activate and enhance model recently proposed by Day et al.,\textsuperscript{167} provides a theory-driven moderation model for guiding the matching of patients to the evidence-based treatment mostly likely to be of benefit on the basis of key baseline characteristics. The determination of the need for preparatory-oriented interventions (i.e., such as motivational interviewing to prepare readiness to change) is also integrated into this framework. This model provides the first theory-driven framework for algorithm-based interventions within the pain management context; further research testing this model is needed to further refine and optimize its tenets.

Finally, there is a clear need for improvements in the reporting of group-delivered treatments across the chronic pain literature. Current reports often omit details regarding theory, design, and delivery features that have been shown to be of importance in the group setting. Indeed, a recent review identified that only 12% of studies investigating group-based behavioral change programs for chronic musculoskeletal pain reported a
theoretical basis for the intervention(s) delivered.\textsuperscript{168} The insufficient reporting of critical design, implementation, and evaluation processes impedes efforts to compare group-delivered psychological treatments across studies, reduces the capacity to replicate effective treatments, and limits the capacity to synthesize the evidence of effects.\textsuperscript{169} Although systematic reviews and meta-analysis of group treatments for chronic pain are lacking, to assist in the future conduct of such studies, it is recommended that future RCTs of group-delivered treatments follow the reporting guidelines for group-delivered interventions proposed by Borek et al.\textsuperscript{169} As health care practitioners of all disciplines become more and more reliant on systematic reviews to support evidence-based practice, comprehensive reporting of design and delivery features and a thorough systematic review and meta-analysis of group treatments for chronic pain would represent certain contributions to the literature.

Appendix 87.1: Search Strategies

The search strategy implemented in the prior edition of this chapter was extended to search the updated literature published since the end point of the prior review (March 2007, dating back to 1950) until August 2017. Specifically, the Cochrane Database was searched along with MEDLINE, PsycINFO, PsycARTICLES, CINAHL Complete, and Academic Search Complete using EBSCOhost as an interface to search for group treatments for (1) gastrointestinal disorders; (2) back, facial, neck, neuralgia, and intractable pain; (3) pelvic pain, dysmenorrheal, and vulvar diseases; and (4) headache disorders. The search was limited to “human” studies published in “English.”

1. Search strategy
   1. exp psychotherapy, group (15,111)
   2. exp colonic diseases (208)
   3. 1 and 2 (7)

2. Search strategy

Motivation is a primary determinant of human behavior, influencing its initiation, direction, intensity, and persistence. \(^1\) Historically, motivation has not been a central issue in health care as the modal approach to treat illness was believed to require very little active participation from patients beyond complying with advice. However, as our appreciation of the growing number of chronic diseases for which there are no cures, the importance of helping patients become active in a treatment has been increasingly noted. Patients have described the importance of motivation and accountability, particularly when they become discouraged or have difficulty with treatment adherence. \(^2,3\) This realization has led to motivation and motivation enhancement being given greater attention. Self-management approaches for managing health have gained in importance as potential methods to increase motivation for self-management and to facilitate long-term health-relevant behaviors. There is a large volume of literature indicating that even relatively simple behaviors, such as taking medication in the prescribed manner, can be problematic. Studies have reported that depending on how it is defined and measured, the rates of nonadherence to medication in adults range anywhere from 8% to 62%. \(^4,5\) In general, one-third of patients can be expected to be nonadherent. \(^6\) Treatment nonadherence is also a significant behavioral health problem and public health concern in pediatric populations. Approximately 50% of children \(^7\) and 65% to 90% of adolescents \(^8,9\) are nonadherent across pediatric conditions.

For patients with chronic pain, rehabilitation rather than complete cure is most realistic. One of the critical requirements for successful
rehabilitation is that patients adopt an active, participatory role in their treatments, coping with symptoms and life changes, and adjustment to their circumstances. Literature consistently acknowledges that multidisciplinary pain care, which includes an activating therapy, is helpful for restoring functioning and improving quality of life, without complete elimination of pain. However, such a treatment requires patients to make significant lifestyle changes including the incorporation of various functional activities in their daily routines. Maintaining these changes over long periods of time is often difficult even for healthy individuals. For example, two-thirds of those who sign up with gyms never use the facility, and 50% drop out of physical activity programs within the first 6 months. Thus, it is hardly surprising that patients with chronic pain find it difficult to adhere to regular physical activity regimens, use of coping skills, engaging in problem solving, and modifying communication patterns with family, friends, and coworkers as well as health care providers. In the one study that directly examined the issue of adherence to pain rehabilitation recommendations, Lutz et al. followed patients 8 months after they had been successfully treated at pain rehabilitation and found that, based on self-report, the rates of adherence with each of the specifically recommended behaviors (e.g., progressive ambulation and stretching exercises, regular application of ice and heat, relaxation) averaged about 42% and with all of the recommendations proscribed by the treatment program was only 12.2%.

Another dilemma for successful implementation of activating therapy is that it can be contrary to the very nature of pain where the motivational drive is to avoid or escape from any activities that might increase pain. Furthermore, most people including many health care providers have learned “if something hurts, don’t do it.” This approach may be appropriate for acute pain care where may pain serve a protective role. However, for chronic pain, equating hurt with harm often becomes a barrier for successful rehabilitation and even increases disability following loss of mobility, strength, and endurance from inactivity. Thus, clinicians are frequently faced with the challenge of how to motivate patients to actively engage in the treatment recommendations that may seem counter to patients’ acquired beliefs. Long-term treatment success, in particular,
depends on regular adherence to recommended self-care regimens, although how close to the recommendations is an open question. Historically, clinicians have invested less energy in patients who show little commitment to follow through with recommended therapies. “You can lead a horse to water, but you can’t make it drink” was a typical way of conceptualizing the issue. However, as noted earlier, motivation to commit to the treatment plan and adherence with regimen are essential in successful pain rehabilitation (pharmacologic as well as rehabilitative). Thus, motivating patients for behavioral change is essential and a critical clinical issue in successful pain management. In this chapter, we review the two approaches to optimize motivation and engagement of patients: motivation enhancement therapy (MET) and implementation intentions (IIs).

Neural Mechanisms of Motivation

Neural mechanisms of motivation are complex, involving multiple brain systems. Although motivation is a critical component of recovery from chronic pain, how specific neural factors underlie the motivational factors relevant to people with chronic pain is not well understood. However, we may consider how chronic pain itself as well as comorbid dysfunctions could contribute to the motivational state of chronic pain patients to adhere to specific recommendations.

Chronic pain commonly outlives peripheral tissue injury or actual neural damage; yet, long-lasting changes in the modulations of pain due to neural plasticity and central sensitization have been well documented in various chronic pain conditions. Neuroimaging studies in humans have demonstrated alterations in the reward, motivational, emotional, and cognitive brain centers that may play a role in establishing and/or maintaining chronic pain. In addition, it has been hypothesized that some chronic pain syndromes may be maintained by dysregulation of homeostatic reward processes similar to those described in addiction neurobiology. Addiction and chronic pain disorders may share central reward deficiency and motivational maladaptation patterns secondary to hypodopaminergic states in the nucleus accumbens core (NAc) and medial...
prefrontal cortex (mPFC) and alterations in endogenous pain transmission pathways.\textsuperscript{26–28} Furthermore, a study in mice by Schwartz et al.\textsuperscript{29} suggests that chronic pain induces synaptic changes within the NAc, which plays a central role in the neural circuitry that modulates motivation.\textsuperscript{29,30} Such pain-induced synaptic changes can have a negative impact on patients’ motivation,\textsuperscript{29,31,32} which in turn could lead to difficulty in adhering to a treatment plan for their chronic pain.

In addition to the painful symptoms, individuals who have chronic pain often experience a multitude of quality of life–altering symptoms such as anxiety, depression, fatigue, sleep disturbance, elevated stress levels, activity reduction, and cognitive deficits.\textsuperscript{31–34} Such comorbidities can further decrease motivation to initiate and complete goal-directed and higher order mental and physical tasks.\textsuperscript{29} Thus, individuals can experience a twofold impairment of motivation secondary to both chronic pain itself and its comorbidities.

**Concept of Readiness to Change: Transtheoretical Model of Behavior Change**

The transtheoretical model of behavior change was developed in an attempt to understand motivation to adhere to health care regimens. The model offers an integrative framework describing the process of behavior change.\textsuperscript{35} It was originally developed to understand how people change their addictive behaviors. The model, however, has been extended to many medical problems including chronic pain.\textsuperscript{36} The basic assumptions underlying the model are the notions that people differ in their readiness and willingness to take on behavioral change and that there are certain processes of changes that facilitate the advancement of one’s readiness. The model is organized around a major construct: stages of change.

According to the model, patients attempting to change health-related behavior move from one stage to another, often in a cyclic fashion (Fig. 88.1; description of each stage is in Table 88.1), although the movement through these stages is not necessarily linear or unidirectional. Some behaviors are easier to change than others; it is reasonable to assume that several attempts may be necessary to achieve significant behavioral
change. A good example of the nonlinear change of stages may occur in smoking cessation where average smokers take seven to eight attempts to quit before succeeding. The description of each stage as well as typical patient behavior seen at each stage point is listed in Table 88.1.

![Figure 88.1 - Stages of changes.](image)

**TABLE 88.1 Stages of Change**

<table>
<thead>
<tr>
<th>Stages</th>
<th>Descriptions</th>
<th>Patients’ Behaviors</th>
</tr>
</thead>
</table>
| Precontemplation | Patient does not perceive a need to change and actively resists change. | • Unwilling to discuss  
• “Who? Me?”                                   |
| Contemplation    | Patient begins to see a need for change and may consider making a change in the future. | • Somewhat ambivalent or fearful of change  
• “Yes, but…”                                    |
| Preparation       | Patient feels ready to change and takes a first concrete (behavioral) change. | • Sees more pros for change than cons  
• “I’ll start this on Sunday!”                      |
| Action            | Patient actively engages in behaviors consistent with regimen.               | • Feels more confident                                    |
| Maintenance        | Patient executes plans to sustain the changes made.                         | • Feels comfortable with the change  
• Identifies self as the changed entity              |
| Relapse            | Some patients fail to sustain the effort.                                    | Variable                                                   |

The model has been adapted to chronic pain. Kerns and colleagues developed a self-report inventory “Pain Stages of Change Questionnaire” to assess the level of readiness to adopt self-management approach in chronic pain patients. Research has found the significant association
between the stages of change and coping as well as disability of chronic pain patients. Furthermore, improvement of the stages corresponds with better outcomes of pain rehabilitation.

There are three critical parameters of the model that determines the likelihood of advancing one’s readiness.

1. **Processes of change** are one of the dimensions of the transtheoretical model that enables understanding of how shifts in behavior may be achieved. Change processes involve both covert and overt activities and experiences that patients engage in when they attempt to change their behavioral patterns. Each process is a broad category, and an eclectic collection of techniques, methods, and interventions can be recommended to facilitate the change process. Ten processes are cluster into two groups: the cognitive-experiential cluster of processes and the behavioral processes (Table 88.2). As can be seen (right-hand column of Table 88.2), there are various strategies that come from the disparate theoretical orientations to target each process.

2. **Self-efficacy** is defined as personal confidence in one’s ability to change problematic situations. If people think that there is no way that they can perform the prescribed activities, it is highly unlikely that they will initiate or persist in the desired behaviors and that the treatment will be successful.

3. **Decisional balance** is defined as a personal “balance sheet” of gains (benefits) and losses (costs) for changing and not changing their behaviors. People are likely to advance their change stages when they (1) perceive themselves to have adequate skills to cope, (2) feel confident in executing those skills (i.e., high efficacy belief), and (3) perceive more gains of changing and losses of not changing than more losses of changing and gains of not changing (decisional balance). We discuss the decisional balance process later in this chapter as a part of reviewing some motivational enhancement techniques.

Some of the behavioral strategies such as counterconditioning and stimulus control are generally a major part of the rehabilitation for chronic pain. The cognitive-behavioral self-management skill training that is typically a part of the pain rehabilitation also improves self-efficacy\(^{42}\); however, baseline levels of self-efficacy vary across patients, and there is a linear relationship between the baseline level of self-efficacy and posttreatment level of self-efficacy and subsequent treatment benefit self-management skill training.\(^{43}\) Strategies targeting experiential processes are recommended as the primary approach to help people with low level of treatment readiness and self-efficacy.\(^{44}\) Thus, using the concept of the
change process seems a promising way to optimize the clinical outcomes of pain rehabilitation.

**MOTIVATION ENHANCEMENT THERAPY**

MET, developed by Miller, is one of the therapeutic methods to target motivation and patient engagement with therapy. This approach is based on the transtheoretical model that people vary in their readiness to adhere to treatment regimen and provides a problem-focused, patient-centered, clinician-directed approach with the aim of helping patients move through the stages-of-change readiness. Although some of the techniques and approaches overlap with those of cognitive-behavioral therapy (CBT), one of the most prevalent behavioral medicine approaches in treating chronic pain patients, the two therapy approaches have some distinct characteristics. The nature of the therapy course is no doubt variable depending on the personal styles of the clinicians, and there is a danger of oversimplification of complex therapy modalities; however, for the sake of comparison and contrast, we summarize the characteristics of MET as compared to CBT in Table 88.3.

| TABLE 88.3 Motivation Enhancement Therapy (MET) Versus Cognitive-Behavioral Therapy (CBT) Approaches |
|-------------------------------------------------|---------------------------------|---------------------------------|-----------------|
| Orientation                                    | MET                             | CBT                             |                 |
| Therapist–patient relationship                 | Patient-centered                | Goal-oriented                   |                 |
| Focus                                          | Collaborative                   | Top-down                        |                 |
| Therapist’s task                               | Stage change                    | Action                          |                 |
| Dealing with ambivalence                       | More listening                  | More talking                    |                 |
| Approaches to reasons for change               | Explore ambivalence             | Direct persuasion               |                 |
|                                                | Elicit reasons for change       | Give reasons for change         |                 |

MET is nonconfrontational and patient-centered, exploring and reaching resolution of ambivalence toward behavior change. A MET clinician helps patients explore their inner phenomenology that is explored without judgment or criticism. In order to facilitate this process, MET encourages a clinician to exercise empathetic listening and to ask open-ended questions.

Asking open-ended questions helps the clinician to better understand the individualized phenomenology of the patient regarding the problem that is the target of behavior change in a nonthreatening manner. It also aids the
patient to achieve a clearer view on the issue. Asking open-ended questions, however, is not time-efficient; asking questions that can be responded with a short “yes” or “no” answer can save time. As you can see in the following sections describing the MET techniques, however, asking open-ended questions is vital in successful implementation of MET. Some examples of open-ended and close-ended questions are listed in Table 88.4.

**TABLE 88.4 Close-ended Questions Versus Open-ended Questions: Examples**

<table>
<thead>
<tr>
<th>Close-ended Questions</th>
<th>Open-ended Questions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Are you having a problem exercising?</td>
<td>Tell me about the problem you are having about exercising.</td>
</tr>

</tr>
<tr>
<td>Would you be able to come to the clinic every week for trigger point injections?</td>
<td>How would you feel about coming to the clinic for trigger point injections?</td>
</tr>
</tbody>
</table>

The MET offers a collection of therapeutic techniques to help patients (1) clearly recognize their problems, (2) perform decisional balance work, and (3) produce self-motivational statements and internalize those motivational statements by means of improved self-efficacy. MET also provides the guidance for how to handle resistance and setbacks. In the following section, we describe the basic MET methods, including how to deal with resistance and what not to do while engaging in MET. Although MET might be a treatment within itself, it may also serve as a complement to CBT and set the stage for patients to benefit from the skills included in CBT.

**Help Patients Recognize the Problems and Goals**

Patients come to clinics with various expectations and goals. Some patients expect to be pain-free, whereas some patients focus on improving the quality of life even if pain is not totally resolved. However, many patients are often unaware of what should happen to achieve their goals and what their role should be for meeting the expectation. The next step to help patients become more aware of what needs to happen is to delineate
the gap between where they are now and where they want to be when they get better. For example, the discussion may start with questions such as:

- How is your life different from your life before pain began?
- How has your pain stopped you from doing what you want to do?
- What are you now doing to cope with your pain problem? How is that working for you?
- How do you think your pain and disability impact your relationship with your spouse/family?
- What do you miss most about your life before the pain began?

Then, the discussion should be turned into what patients want to see happen through treatment. For example:

- What would your life look like with better pain management?
- What change would you like to see most?
- What are you doing now that is helping you to make these things happen?
- What other things could you do, or do more of, to help achieve your goal?

This line of discussion can also help identify specific discrepancy between what a patient wants from therapy (e.g., “I want to get well”) and what he or she is doing (e.g., “I can’t do my exercise because I am not well”). The process facilitates the realization of the possibility that patients’ own behaviors contribute to the maintenance of pain and prevent them from obtaining their goal of “getting better.” Such realization in turn can form a background on which motivation for behavioral change can be built.

Not only can clarification of the gap between a present state and a goal state help drive the motivation to change but it also serves to create the opportunity to move to specific plans. A clinician and patient can start “brainstorming” as to what possible ways there are to make the change probable. Plans can be prioritized by patients’ preference and practical concerns as well as perceived effectiveness of the actions. Possible problems and obstacles should also be thoroughly explored to better prepare the patient.

It is common to find that the patient, after years of functional impairment and other related problems, feels very helpless and convinced
that there is nothing they can do to manage their plight. Such resistance can seriously arrest the process of behavioral change. We discuss some ways to deal with resistance later in this chapter.

**DECISIONAL BALANCE**

Motivation for behavioral changes is rarely linear. Often, we may understand the need for behavioral change but remain reluctant to commit ourselves to do the things needed for the change. People experiencing persistent pain are no exception. Nearly all pain patients would want to improve, and many of them may intuitively understand how behavioral changes can help their pain. Despite this, many patients may remain feeling ambivalent or conflicted about committing themselves for behavioral change. One often hears comments like “I know I need to be more active, but . . . .”

To a large extent, activating rehabilitation and self-management pain care requires daily practice of the learned skills and modification of lifestyle, aiming at the long-term, gradual improvement. Thus, activities required for these approaches typically do occur immediately despite substantial effort involved. This tends to lead patients to focus more on immediate “cost” of self-management activities, such as postexercise soreness and time commitment. Decisional balance helps people explore all sides of the story on the consequences of not only “doing” but also “not doing” activities that they think need to be done.

The decisional balance procedure involves creating a personal “balance sheet” of both advantages and disadvantages of committing to change compared to not committing. For example, suppose that a clinician would like to facilitate a more active lifestyle for a patient who has dealt with pain by remaining sedentary and resting for years. The patient will be asked to list what they think are good things and not so good things about maintaining the status quo, in other words, not changing and keeping doing what they have been doing. The patient will also be asked to list good and not so good things about changing their way to be more active and keep functioning despite pain. An example of a “balance sheet” is shown in Table 88.5. The clinician can help patients explore the impact of the change and no change on various life domains and the emotional and
cognitive consequences of their action (or nonaction). The sheet will help facilitate the resolution of the potential “I want to, but . . .” conflict. The section of “not so good” things about change can also help the clinician see what areas of coping and other supportive care can be implemented to increase the sense of self-efficacy for the change.

**SELF-MOTIVATIONAL STATEMENTS**

Self-motivational statements or “change talks” by patients represent an important step toward better readiness for behavioral change. In MET, it is critical that thoughts reflecting their intention to change are discussed and help them internalize such thoughts. There are three steps in this phase. First, such thoughts should be elicited and verbalized. Then the thoughts need to be elaborated, as such thoughts, if remaining abstract, may result in perpetual wishful thinking with no actual behavioral change. And finally, elicitation and elaboration of such thoughts need to be reinforced. Going through this process helps patients identify problems and goals, and they then explore what it would mean to change versus not change. At this point, the patients may spontaneously come up with statements reflecting their willingness and intention to commit themselves for behavioral changes. If so, the therapy can start with the second step. However, for
many chronic pain patients whose maladaptive habitual patterns are so ingrained in their lifestyles, some time may be devoted to help patients feel comfortable with change talks.

In order to guide a patient through this process, the clinician may ask questions such as:

- What encourages you that you can change if you want to?
- What do you think would work for you, if you decided to change?
- What will make (engaging in exercise program, etc.) it easier for you?

One of the supportive yet effective methods for the elicitation of self-motivational statements is to review past success. By recognizing that they were able to commit to change and were successful in doing so, it breeds the ground for optimism and improves the sense of self-efficacy. For example, in the earlier phase in treatment, the clinician may ask patient to list what and how they were able to change something in their lives, and guide the patient by asking

- What do you remember when you were able to . . . ?
- What was it like when you changed . . . ?
- When else in your life have you made a significant change? How did you do it?

Some patients may have a tendency to disregard past success and instead focus exclusively on past failures. It is also common to encounter the extremely negative cognitive style in which patients generalize past failure to all or many future actions. In a case like this, it is helpful to explore their previous failures and help them reframe the experience. Provision of education regarding outcome literature and how certain behaviors increase their probability of recovery may also be beneficial as serve as a means of encouragement and facilitate persistence even when initial positive effects may be modest.

It is extremely important for a clinician to recognize and acknowledge self-motivational statements. Typically, initial self-motivational statements are rather only vaguely directed toward the perceived needs (e.g., “I know I really need to take the home exercise program more seriously,” “I am wondering if I should start thinking of how I can manage my anxiety better,” “It may not be a bad idea for me to go back to work”). How such statements are responded to by the clinician can determine whether they
can be transformed to more concrete motivation and actual behavioral actions. Basic responses by the clinicians should clarify the issue at hand in terms of how the change can be made based on what concerns. The statements can further be elaborated with responses like:

- Tell me in what ways you think you can do that.
- Sounds like you have some thoughts about it. What other concerns have you noticed about this problem?
- What are some reasons why you want to do this?
- How do you think you can enjoy this change?

Note that these statements focus on the patient’s thoughts and not the clinicians. They are designed to engage the patient in the process of exploration.

The clinician must remain cautious during the process of elaboration. It is common to see that premature or presumptuous encouragement by the clinician can result in undue pressure for the patient. A discouraged patient is likely to become resistant to change. It is important to remember that MET is clinician-directed but patient-centered.

The attempts at self-motivational statements and subsequent elaborations should be positively reinforced. The clinician’s encouraging responses can significantly impact the patient’s frame of mind about the change. Simple comments such as “I think it’s a wonderful idea,” “I see how important this is to you,” “You have a point there,” and “You seem to have some useful insights” can help the process of eliciting self-motivational statements conclude in a positive and productive manner.

**What Not to Do in Motivation Enhancement Therapy**

One of the important aspects in MET is to avoid placing a patient in a passive role in the clinician–patient interaction. This is a very easy trap for the clinician to get in. For example:

**Clinician:** How long have you had this pain?
**Patient:** Seven years.
**Clinician:** Where does it hurt?
**Patient:** My back.
**Clinician:** Are you working now?
Patient: No.
Clinician: Are you receiving disability?
Patient: Yes.

The process like this is counterproductive for activating rehabilitation because it sets a tone of the treatment where the clinician is the expert who can tell what to do, whereas the patient is the passive recipient of the treatment.

We are not saying that a clinician should never provide advice. As an expert, a clinician can provide options and choices. What is important here is to emphasize that there are options and to help the patient achieve their own conclusion of what would work for him or her. Ultimate responsibility of behavioral change lies with the patient, and it should be communicated clearly through the MET process.

Value judgment by the clinician can also be detrimental in helping the patient increase motivation for behavioral change. Consider the following interaction:

Clinician: It seems that you are only interested in getting medications from us. You have not done anything we asked you to do such as exercise, habit change, and mood monitoring; no wonder you are not doing so well.
Patient: Well, I need my medicine because it takes some edge off my pain. I am not doing that badly. I am doing fine.

Value judgments by clinicians can elicit defensiveness, often leading patients to discount the very problem that needs to be addressed. “Oh, it’s no big deal,” and the change stage could return all the way back to the precontemplative stage (see Table 88.1 for the description of the stage). When the patients consider the problem “no problem,” it is very hard, if not impossible, to motivate them for behavioral changes.

**Dealing with Setbacks and Resistance**

Changes are hard to make. As noted earlier, patients are likely to hold some ambivalence about committing to change, particularly when the change involves the fundamental part of their lifestyle. Resistance should be anticipated and is expected. It can occur at any phase of MET and may
take various forms such as arguing, interrupting, denying, ignoring, challenging, minimizing, and sidetracking. Some example behaviors of these resistance forms are listed in Table 88.6. One of the hallmarks of MET is that a clinician does not fight resistance but works with it. Too often, an eager clinician gets overdriven to argue for the change, only to find that the patient backs off from the previous self-motivational stance and becomes reluctant to commit. MET requires a clinician to direct a patient to move toward the behavioral change without imposing, ordering, or arguing for it. How do we do this? The approach here is to stay on the same side with patients yet help them to argue for change themselves. There are several specific techniques that a clinician can employ to work with resistance.

**TABLE 88.6 Examples of Resistance**

<table>
<thead>
<tr>
<th>Resistance</th>
<th>Behaviors</th>
</tr>
</thead>
<tbody>
<tr>
<td>Arguing</td>
<td>Contests the accuracy of information or the clinician’s expertise</td>
</tr>
<tr>
<td>Interrupting</td>
<td>Interrupts the clinician in a defensive manner</td>
</tr>
<tr>
<td>Denying</td>
<td>Shows unwillingness to admit/recognize problems</td>
</tr>
<tr>
<td>Ignoring</td>
<td>Does not follow the discussion or conversational direction</td>
</tr>
<tr>
<td>Challenging</td>
<td>Challenges the accuracy, effectiveness, or applicability of what the clinician says</td>
</tr>
<tr>
<td>Minimizing</td>
<td>Minimizes the risk of problem behaviors (or not doing something) or minimizing the benefit of change</td>
</tr>
<tr>
<td>Sidetracking</td>
<td>Changes the direction of the conversation away from the direction that the clinician was pursuing</td>
</tr>
<tr>
<td>Blaming</td>
<td>Blames others for the problem and does not acknowledge any responsibility for him or herself</td>
</tr>
<tr>
<td>Nonanswering</td>
<td>Gives a response that is no answer to the question asked</td>
</tr>
<tr>
<td>Disagreeing</td>
<td>“Yes, but . . .”—disagrees with a suggestion without offering any constructive alternative</td>
</tr>
</tbody>
</table>

**SIMPLE REFLECTION**

In simple reflection, clinicians express their acknowledgment of the patients’ comments that reflects resistance in a nonconfrontational manner. For example, patients may argue that they are too exhausted and sore to do the home exercise program after taking care of the household chores; the clinician may respond:

- I see that you are frustrated for not being able to make the change you want.
• It is hard for you to work out after a long day.

The simple reflection method is to provide the sense that the patient is heard and understood. Notice that the reflection does not have any hint of value judgment (e.g., “It is really too bad that you cannot save any energy to exercise because we are not asking you to do that much, you know”), which would defeat the purpose of the simple reflection technique that is to be used to signal that the patient’s concern was heard and taken seriously.

AMPLIFIED REFLECTION

Amplified reflection is an applied variation of simple reflection in which the clinician reflects back the patient’s comment in an overexaggerated manner. With the example of not being able to do the home exercise earlier, the clinician may respond, “You feel/believe that it is absolutely impossible for you to do the exercise.”

The amplified reflection adds the core meaning or intensity of the emotion associated with the patient’s statement. By doing so, it helps patient better see the balance of their ambivalence. Facing the exaggerated form of their own statement often helps them focus more on the other side of their original comment. Consider a case where a patient complains of postexercise soreness.

Patient: I am so sore after doing those exercises that I cannot do anything but lay in bed for the rest of the day. The house is a mess and I do not feel better.

Clinician: There is absolutely no way that the exercise can help you get better.

The amplification must be done in an empathetic manner. There can be a fine line between empathetic amplification and sarcasm. The same statement earlier, with a slightly different tone, can be delivered as a sarcastic criticism. If the patient feels that the clinician is being sarcastic or inpatient, the reflection will likely encourage further resistance and retard the process of change.

DOUBLE-SIDED REFLECTION

Double-sided reflection is used to highlight the ambivalent feeling that the
patient has expressed. With the example earlier, the clinician may respond, “On the one hand, you find it very difficult to incorporate exercise in your life, and at the same time, it is frustrating because you really want to do it.”

Miller and Rollnick\textsuperscript{46} recommend the use of “and” rather than “but” to bridge the two sides of the ambivalence. It also seems advisable that one ends the reflection with the motivational side, perhaps reflecting the motivational statement the patient has previously used.

**AGREEMENT WITH TWIST**

This is another variation of the reflection in which the clinician initially reflects and then reframes the patient’s statement. Initial reflection is typically presented as an empathetic agreement, affirming that the patient was well heard. Then, the clinician offers a reframed perspective on the same subject in a nonthreatening manner. For example:

Patient: I know I do not do all the stuff the physical therapist wants me to do. But it is so hard, and I don’t think she [the physical therapist] understands how hard it is for me to do the program every day.

Clinician: You have a point there. It is so frustrating for you not to be able to do the exercise, even though you are so anxious to find a way to do it and move forward with your program.

This subtle change in the direction can help the patient move further toward change while maintaining the therapeutic relationship.

**PERSONAL CHOICE AND CONTROL**

The psychotherapy literature suggests that one of the conditions in which resistance tends to arise is when a patient perceives a loss of, or a threat of losing, personal choice and control.\textsuperscript{47} Typically, resistance is stronger when the importance of the threatened freedom is greater, often resulting in people asserting their option by doing something counteractive to the required behavior. In MET, it is essential that the affirmation of personal choice and control be reminded throughout the course of treatment that it is ultimately their choice to follow through the treatment recommendation. For example:

Patient: All of you keep telling me to do the home program, even though I
keep telling you I do not want to do it.
Clinician: It is your choice, of course. It is your health after all. We can only make the recommendations and the rest is up to you.

Such an interaction can help the patients understand that the choice is theirs; at the same time, it fosters a sense of responsibility for the patients to commit to the treatment regimen.

**SHIFTING FOCUS**

Some patients, particularly those with tendency to “catastrophize” (i.e., a cognitive and emotional process that involves magnification of pain-related stimuli, feelings of helplessness, and a negative orientation toward pain) and use the black–white cognitive styles, tend to get trapped into the mode of “cannot do because . . . ”; there is always a reason why they cannot do what they need or want to do. For them, obstacles and barriers to advance behavioral changes can become so great that such barriers could be the only thing on which they focus. This may become even more pronounced in the time of flare-up. Once they feel very discouraged by the flare-up episode, motivation to apply coping skills may dwindle. A clinician can defuse such intense focus and help the patient move out of the trap and onto the step necessary to make the desired change. For example:

Patient: I can’t believe this! I thought I was doing so well with this program, but it must have been just all illusion! There is absolutely no way I am getting better. Pain always wins! I just should give up.

Clinician: I see your frustration. Having a bad day feels like such a setback. It sounds like pain really influences your life. Tell me more about the kind of things you would like to do in your life.

Shifting focus can help defuse the resistance and instead shift attention onto something that can be workable and supportive for behavioral change.

**Research Outcomes**

A growing body of research supports the conclusion that MET is effective
in promoting healthful behaviors. Past research has shown that MET has been effective for facilitating change to reduce problem behaviors, such as smoking, alcohol abuse, problem gambling, behaviors related to eating disorders, and high-risk sexual behaviors. MET has also been shown to increase wellness behaviors such as promoting exercise in myocardial infarction patients and cancer survivors, adherence with self-management regimen in diabetics, and attendance for mammography screening. MET has become a popular method to address obesity and research shows its efficacy for children as well as adult diabetic patients. MET has been shown to help normalize the lipid profiles of hyperlipidemic individuals via increased fitness.

MET can easily be integrated in various clinical settings and with pain-oriented treatments such as CBT and physical therapy. Brief MET counseling in a primary care setting may reduce substance use among high-risk adolescents. In a busy clinical setting, clinicians may regard a full course of MET difficult to implement. There is some evidence, however, that implementing even a small part of MET can be efficacious in promoting behavioral change. A recent study has reported that a brief MET provided at the emergency room setting significantly decreased aggressive behaviors in high-risk adolescents. MET can also be implemented through phone counseling. Phone-based MET has been shown to help medication adherence and promote healthy lifestyle in diabetics.

Unfortunately, MET has not been extensively tested for pain patients, although there are some excellent chapters describing MET, reflecting the growing awareness of the importance of motivation in pain treatment. Available evidence strongly suggests that the state of motivation for change is critical in better treatment outcomes for pain patients. Furthermore, a recent study suggests that implementing MET prior to the initiation of the CBT-based self-management skill training for pain patients may enhance the treatment attendance. A single-group study shows significant symptom reduction in fibromyalgia patients undergoing a brief exercise program with phone-based MET. A recent case series for back pain patients also showed significant pain and medication reduction following MET combined with CBT.
Volitional Approach: Implementation Intentions

The idea of IIs aims to address the imperfect relationship between intentions to perform a certain behavior and actual behavioral engagement. IIs involve practical action plans to deal with a range of contingencies; they require construction of “if-then” plans for foreseeable barriers and problems that may interfere with attaining the behavioral goal. Thus, IIs encompass a process of identifying potential barriers and situations and planning potential responses by means of resource findings and problem solving. IIs typically involve two types of planning: action and coping. Action planning involves determining when, where, and how to execute the target behavior, whereas coping planning offers a series of problem-solving exercises to handle potential barriers.

Suppose that one of the therapy goals is to help a patient become more physically active. The patient is well aware of the importance of activation and would very much like to be able to tolerate a greater level of activities so she could enjoy her life with her family. In this case, her intention to be active is strong. What IIs can do for her is to fill a gap between her strong intention and actual implementation of the behavior.

As suggested previously, IIs approaches have two phases: action planning and coping planning. For the action planning, all parameters of behaviors will be determined, including when, where, and how the target behaviors are executed. Action plans should be detailed, feasible, and practical. It should not be overly ambitious; starting out at the level that the patient can easily experience initial success may help foster a sense of self-efficacy.

Coping planning involves identification of potential barriers and preparation to address them. A portion of the session should be spent on identifying specific barriers that may keep the actualization of the behavior from happening. Barriers in various areas need to be considered, such as pain-related issues (e.g., actual or anticipated postactivity flare-ups), lack of time or resources, or interpersonal issues (e.g., family/friends support).

In order for effective coping planning, patients may benefit from acquiring basic problem solving skills. Typical problem-solving skill training begins with the identification of specific problems; for each
problem, the patient is asked to generate as many potential solutions as they can, no matter how implausible impossible they may seem. Then, the patient in collaboration with the therapist can systematically evaluate the feasibility and potential consequence of each approach. Based on the evaluation, the patient rank-orders the options and is encouraged to start trying one at the time from the highest ranked solution.

Similarly, acquisition of specific behavioral or cognitive skills that are typically included in a multimodal self-management rehabilitation for chronic pain may also be helpful. For example, self-management skill training for pain flare-ups, effective communication and social skills training, relaxation, and time management can be incorporated in the IIs coping planning to help address specific barriers. Applications of these skills should be well integrated in the coping planning by developing if (barrier)–then (coping) scenarios. For some barriers, behavioral rehearsal may be applied to help patient gain confidence for carrying out the planned behavior.

Each person likely has unique barriers to his or her situation. Those unique barriers also need to be identified and addressed in advance, anticipating the most likely difficulties they will encounter in trying to implement planned behavior. Clinicians should work collaboratively with patients to explore emotional, cognitive, and physical cues that are associated with barriers. Examples of IIs outlines are described in Table 88.7.

| TABLE 88.7 Examples of Implementation Intentions Outlines for Specific Barriers to Activation Therapy |

    ● Develop action plans |
| Flare-ups | ● Flare-up management  
  ● What can we do |
IMPLEMENTATION INTENTIONS: OUTCOMES

The IIs approach has been used to promote the patients’ active involvement in modifying their own health behaviors including better eating habits, addictive behaviors, smoking, weight loss, medication adherence, cancer screening, vaccination, and dental flossing. A meta-analysis of 94 studies found that II formation had a medium-to-large effect on goal attainment (d = .65). IIs have also been incorporated in a number of trials aiming to activate people with or without health concerns. A recent meta-analysis review also showed a large effect of IIs (d = .99) for achieving the goal behaviors among those with psychiatric conditions. IIs may be particularly useful adjunct for activation therapy; IIs have been shown to be effective for improving physical activity levels in healthy young adults, sedentary women, obese elderly people, cardiac patients, and diabetic patients. The meta-analytic review of the IIs on physical activity from 24 studies shows encouraging results with a pooled effect of .31 at posttreatment and .24 for follow-up visit with a higher effects shown with a program involving specific barrier management. Interestingly, the coping pattern acquired through the IIs approach appears to generalize over and beyond the target behaviors, likely helping patients become proficient to handle a range of challenges on their own. Although there is no study yet to show the
effectiveness of the IIs approach for patients with chronic pain, the available evidence strongly suggests that the approach should be beneficial for improving their ability to actively engage in the treatment and maintain their effort to perform self-management skills and is worth systematic investigation.

Conclusion

In this chapter, we have described and reviewed the approaches to address patients’ motivation and engagement for treatments. Effective pain management often requires active engagement and adherence to prescribed regimens over long periods of time. We reviewed the theoretical basis of behavioral change and the basics of the therapeutic approaches to enhance motivation for change, MET and IIs. There are multiple areas of treatments that require significant behavioral, cognitive, and emotional changes for pain patients. Pain clinicians, across disciplines, often face behavioral issues, such as maladaptive behaviors related to medication use and resistance and nonadherence to exercise and other self-management behaviors, all of which become a significant hindrance for optimal treatment implementation. MET and IIs are two approaches that are designed help patients achieve behavioral goals and optimize treatment benefit. Although there is limited empirical evidence for MET and IIs in pain medicine, there are a growing number of studies in other areas demonstrating the efficacy of MET and IIs in reducing maladaptive behaviors and increasing wellness behaviors, suggesting that these approaches can be a powerful tool for pain clinicians as well. Although we present MET and IIs as stand-alone treatments, the concepts and strategies can be used to complement more traditional rehabilitation treatments.

Clinical pain training has historically focused on the following categories: type, location (usually tied to a specific offending joint), and psychological components of pain. Musculoskeletal pain generators do not neatly fit into these categories. These pain generators are often regional, a consequence of the body’s biomechanical function against Earth’s gravitational pull, and subject to the will and desire of the individual person. For example, the pain generator in medial compartment knee osteoarthritis can be viewed as the knee joint complex in which targeted treatments such as medications, injections, or surgery can be considered. Alternately (or perhaps ideally, simultaneously), the pain generator could be viewed as all the biomechanical considerations of strength, flexibility, and gait which lead the patient to place increased mechanical stress on the medial knee compartment, therefore worsening pain and joint pathology. In that light, a combination of exercise, weight loss, and specific gait training can decrease medial knee joint loads and therefore treat the painful area.\(^1\)

By emphasizing biomechanical principles, the contents of this chapter represent a fundamental change from the customary emphasis on the use of passive physical therapy and physical modalities in treating musculoskeletal pain. Patients are often treated for musculoskeletal disorders with passive modalities such as hot packs, cold packs, massage, electrical stimulation, and deep heat. Unfortunately, these passive
therapies are overused. Although they certainly can play an important role in providing symptomatic relief of musculoskeletal pain, passive modalities should be used only as methods to facilitate active rehabilitation. The patient most needs to become actively involved in a therapeutic exercise program specifically designed to improve musculoskeletal functioning.

Musculoskeletal rehabilitation is a process whereby poor posture, muscle imbalances, and other biomechanical deficits are corrected using specific exercises to gain better static and dynamic control of the musculoskeletal system. The physical restoration process may involve passive therapeutic modalities to facilitate the exercise program. Clinicians treating musculoskeletal pain and dysfunction must identify and work to correct deficits in the patient’s biomechanics.

The goal of this chapter is to provide an overview of a biomechanical approach to assessing and managing patients with musculoskeletal pain. This chapter reviews basic concepts in biomechanical assessment, followed by examples of common painful syndromes and their biomechanical considerations. Clinical applications of physical modalities are outside the intention of this chapter and are discussed elsewhere in this book.

Basic Considerations

Key considerations in musculoskeletal rehabilitation include but are not limited to the following concepts: kinetic chain theory, adverse neural tension, and neuromuscular control. In addition, biomechanical considerations in the setting of common physical examination techniques can aid the clinician in evaluating ineffective movement patterns which can precipitate or reinforce pain. As the patient is an active participant in the examination, he or she too is made aware of his or her alternate movement patterns which may positively reinforce the process for correction.

**KINETIC CHAIN THEORY**

The underpinning of modern kinetic chain theory was pioneered by Franz Reuleaux, a German mechanical engineer as well as author. Reuleaux’s
works in the late 1800s, inclusive of The Kinematics of Machinery, emphasized the relationship among mechanical links or “kinematic pairings.” He theorized that any mechanistic movement could be broken down into these fundamental pairings and that the sequences of movement within and between these pairs produced a resultant “kinematic chain” directly related to constraints placed on them. Therefore, movements at one location directly affected movements at another location in the mechanical link. Although kinematics relate more strictly to description of movement, it can be assumed that kinetics (forces that cause motion) can be used to explain kinematic relationships.

Arthur Steindler, an orthopedic surgeon and professor at the University of Iowa, adapted these theories into the analysis of human movement. Steindler was very involved in analysis of movement and pain associated with a variety of orthopedic diagnoses, including scoliosis, foot deformities, and back pain as well as upper and lower extremity reconstruction. Steindler proposed that the segments in the human body be thought of as rigid, overlapping units in series, where in successively arranged joints create an overlying kinetic chain and ultimately a collection of multisegmental movement patterns. He divided these movements into two categories: open kinetic (where the terminal segment moves freely) and closed kinetic (the terminal segment is restrained from free motion). It is acknowledged, however, that, unlike machines, no motion of the human body is “true” closed chain, as there always exist some component or segment that is unrestricted during movement (whether it be upper or lower body).

Regardless of whether or not a kinetic chain is open or closed, in order to achieve a desired human movement pattern two kinetic chain variables of interest are considered: adequate range of motion (ROM) (kinematic element) and adequate force production (kinetic element). In the assessment of musculoskeletal pain, it should not and cannot be assumed that each joint has adequate freedom and/or strength to achieve the desired movement pattern (neuromuscular control plays a significant role but is to be discussed in a later section in more detail). One may present with inadequate strength and/or inadequate ROM at a particular joint, thereby lending to a compensatory faulty movement pattern (and likely undue
tissue stress) at any given joint involved in the movement.

A prime example of a faulty closed chain movement pattern is that of a flexible foot deformity leading to excessive subtalar joint (STJ) pronation and/or delayed return to supination during gait propulsion. In a weight-bearing position, STJ pronation is correlated with a position of knee flexion, valgus, and medial tibial rotation. If one is unable to adequately control STJ pronation during the initial loading phase or propulsion phase of gait, the knee will be placed in a position of excessive medial tibial rotation, valgus, and flexion. This may lend to excessive stress on supporting structures such as the medial collateral ligament and patellofemoral joint. However, if tissue structures at the knee fail to control motion adequately, the femur may then incur excessive internal rotational forces, and in such cases, the hip or even the sacroiliac (SI) joint may be affected.

In this example, the variable of concern is not a restricted ROM but rather inadequate strength or control to adequately maintain proper positions within a closed kinetic chain movement. This is one isolated example but lends insight into concerns of any multijoint movement (running, walking, bending, throwing, etc.). Although a patient may present with a localized tissue or joint insult, it is paramount that any clinician receiving a patient reporting localized pain acknowledge the role of faulty movement mechanics in the assessment of pain etiology and appropriate management.

**ADVERSE NEURAL TENSION**

When observing an athletic contest or a performance art, one can appreciate movement of the human body. Although the primary function of the nervous system is to conduct impulses, the nervous system must also be able to move along with the rest of the body. However, in addition to movement alone, nervous system function is also dependent on normal physiology. Neurodynamics refers to the interactions between nervous system mechanics and physiology. Adverse neural tension is a subset of neurodynamic theory that specifically deals with abnormal mechanical responses of the nervous system as its tissues are taken through a ROM. Due to commonality of use, we use the term adverse neural tension (ANT)
in this chapter. Literature on “nerve stretching” can be found as far back as the 1880s.\textsuperscript{9,10} Although a full review of the underpinnings of ANT theory is beyond the scope of this book, a bedrock principle for the pain clinician is that abnormalities in nervous system movement or physiology can provoke symptoms.\textsuperscript{7} Failure to engage in the protective adaptations mentioned earlier renders the nervous system vulnerable to edema, ischemia, fibrosis, and hypoxia.\textsuperscript{11,12}

Testing for ANT can be made a part of the clinical evaluation based on the patient’s presentation. The best known test is the straight-leg raise (SLR). However, evaluations for many other peripheral nerves are possible and should be considered when a patient presents with limb pain or paresthesia with movement, or restricted ROM. The nervous system’s sensitivity to movement can be considered as a proxy of its physiology, including blood flow, ion channel activity, and inflammation.\textsuperscript{13} Therefore, the aim of a neural tension evaluation is to test the mechanics and physiology of the nervous system.\textsuperscript{13} Findings of ANT may suggest the need for neural mobilization, which aims to facilitate nerve gliding, reduce nerve adherence, disperse noxious fluids, increase nerve vascularity, and improve axoplasmic flow.\textsuperscript{11}

Shacklock\textsuperscript{7} has elegantly summarized the connection between the musculoskeletal and nervous systems: Very simply, the musculoskeletal system is felt to be the mechanical interface to the nervous system. This interface occurs at both central and peripheral levels. Centrally, the mechanical interface consists of the cranial and spinal canals, which contain the central nervous system, cranial nerves, and spinal nerve roots. Peripherally, the nervous system interfaces with bone, muscle, joints, and other tissues. The critical concept for the clinician to recollect when evaluating pain is that as the body moves, the mechanical interface between the musculoskeletal and nervous systems changes dimensions, placing force and deformation on nerve structures, which may potentially generate pain or other symptoms.\textsuperscript{7}

The nervous system must be able to adapt to mechanical loads and may undergo a variety of adaptations in order to do so, such as nerve elongation, sliding, cross-sectional change, angulation, and compression.\textsuperscript{11}
As an example, the SLR is a commonly used provocation test that has been shown to displace not only the lumbar nerve roots\textsuperscript{14,15} but more proximal structures such as the conus medullaris as well.\textsuperscript{16–18} During elbow flexion, the ulnar nerve will lengthen while the median and radial nerves will shorten.\textsuperscript{12} Additionally, sliding movements are also possible. The median nerve has a mean displacement of 2.09 mm with fist motion of healthy volunteers.\textsuperscript{19} Median nerve displacement is reduced in patients with carpal tunnel syndrome (CTS) when compared to normal volunteers, with smaller amounts of median nerve motion seen when comparing mild to severe CTS.\textsuperscript{20}

Several physical examination maneuvers are available to assist the clinician in determining whether ANT is present and related to the patient’s presenting complaints. Commonly used neural tension tests are detailed in the following text (images courtesy of Michael Schmidt, PT, DPT, and Preston Roundy, PT, DPT).

**Lower Limb**

**Straight-leg raise:** The SLR is among the most commonly performed evaluations of patients with neuropathic leg pain. Performance is straightforward: The patient is positioned supine. The knee of the symptomatic leg is kept extended, and the leg is flexed at the hip (Fig. 89.1).

![FIGURE 89.1 Straight-leg raise.](image)

A positive response will provoke the patient’s typical leg pain, frequently cited as being between 30 and 70 degrees.\textsuperscript{13}
Upper Limb

Neurodynamic testing of the upper limb can be likened to straight-leg raising of the arm. The median, ulnar, and radial nerves can all be evaluated. Although passive positioning of the patient is possible, patients actively positioning themselves is most straightforward. If provocation of symptoms is not achieved with limb positioning alone, additional stress may be incorporated through neck or shoulder positioning.

**Median nerve:** Neurodynamic testing of the median nerve may be considered when upper limb pain is speculated to be neuropathic and possibly localized to the median nerve pathways, provoked with forearm pronation or supination, or nerve conduction testing suggests median nerve injury. The patient can be asked to look at the palm, extend the elbow, and then extend the arm until it comes level to the head. A positive test would provoke the patient’s typical arm symptoms at any step of this test (Figs. 89.2 and 89.3).

**FIGURE 89.2** Median nerve A.

**FIGURE 89.3** Median nerve B.
Radial nerve: Neurodynamic evaluation of the radial nerve may be considered when the patient presents with lateral elbow pain or a diagnosis of lateral epicondyliitis. A very straightforward way to perform this test is for the patient to actively perform it. The patient can be instructed to hold the arm to the side, flex the wrist, internally rotate the arm, and look at the palm over the shoulder. Subsequently, the patient should be asked to depress the shoulder girdle (by “pushing the wrist to the floor”) and to laterally flex the neck (by “looking away”). A positive test would provoke typical lateral arm symptoms (Fig. 89.4).

Ulnar nerve: Neurodynamic testing of the ulnar nerve is best performed with the elbow in flexion. The patients can be asked to look at their hand and hold it up as if they were carrying a tray of food at their shoulder. Additional provocation may be added by asking the patient to look away, add more elbow flexion, or depress the shoulder girdle (Figs. 89.5 and 89.6).
Neuromuscular control is often overlooked in musculoskeletal rehabilitation. A muscle or muscle group may be quite strong, but if it does not fire at the appropriate time (within a synergistic movement pattern), the proper movement pattern is already forfeited. The muscle might as well not fire at all. Neuromuscular control is a combination of sensory feedback from the body part, premotor planning, and motor execution. Impairments in any of these pathways can lead to altered mechanics of movement with a resultant musculoskeletal dysfunction and pain.

This is commonly seen in persistent pain after ankle inversion injuries as well as patellofemoral pain. Normal neuromuscular control can be lost through injury or disuse and but can be regained through appropriate retraining. In addition, the effects of neuromuscular training can be seen in those without pain, in the setting of sports performance enhancement independent of strength gains.
Proprioceptive neuromuscular facilitation uses predictable patterns to facilitate efficient muscle movement. These exercises are often prescribed as balance or proprioceptive in nature. Proper movement patterns require properly timed muscle activation. For example, when lifting an object, a person must first fire the foot and ankle muscles to stabilize the feet on the ground. Then, one must fire the thigh muscles to stabilize the knee. Next, the hip girdle muscles must stabilize the pelvis before the spine extensors can elevate the torso. If the gluteus maximus fails to fire before the erector spinae fires, the pelvis will remain anteriorly tilted and abnormal motion will occur in the lumbar spine.

Corrective technique focuses on the pattern of movement rather than the overall strength gains, which can explain why traditional gym exercises do not necessarily correlate to improvement in pain. This is a key concept in explaining why use of physical and occupational therapy for pain syndromes can be helpful even in the active population.

BIOMECHANICAL CONSIDERATIONS IN THE SETTING OF COMMON PHYSICAL EXAMINATION TECHNIQUES

In the setting of pain, the goal of any proper patient examination is to not only elucidate the painful complaint but also hypothesize causation of pain. In doing so, one must consider the biomechanical nature of musculoskeletal pain syndromes. Basic tenets such as inspection, palpation, and ROM may be highly informative and help achieve a more comprehensive interventional plan.

**Inspection:** Evaluation of the patient begins with visual inspection. Pattern of shoe wear, assistive device usage, brace needs, general posture, and habitus as well as gross movement patterns during standing, walking, and transfers are significant considerations. These observations provide an overall view of how the patient moves about his or her environment and help the clinician to discern what may be gross mechanical abnormalities.

**Palpation:** Palpation provides the clinician with information about generalized tenderness, potential targets for injection, tissue texture, and also pain patterns. Kinetic chain abnormalities will often present with palpable pain patterns. For example, patellofemoral pain has been
associated with iliotibial band, hamstring, and gastrocsoleus restrictions as well as leg length discrepancies, hip muscle dysfunction, overpronation, patellar malalignment, and patellar hypermobility. Given these biomechanical correlations, a patient with patellofemoral pain has the potential to demonstrate tenderness about the ipsilateral SI joint, greater trochanter, iliotibial band, pes anserine, or medial tibial structures as well. The clinician is thus cued to treat distant areas of dysfunction in order to affect pain at the site of concern.

**Range of motion:** Lack of adequate ROM may be the most common biomechanical deficit seen and one of the easiest to address. Deficits in ROM can cause pain directly or may lead to pain elsewhere. The musculoskeletal clinician must have knowledge of normative values, employ adequate examination skills to identify major ROM limitations, decide which of these contribute most significantly to the patient’s symptoms, and implement appropriate therapies to correct the deficits. For example, during gait, an ankle plantar flexion contracture can cause excessive knee extension and resultant increased hip flexion and forward trunk lean. According to kinetic chain theory, one must address ankle mechanics to normalize the dysfunction at the knee, hip, and spine. This may be required to facilitate adequate pain intervention. ROM restrictions can be due to shortening of muscle-tendon units, restrictions in joint capsule distensibility, ANT, or bone-on-bone contact at joint interfaces. The first three conditions are almost always amenable to specific stretching techniques. ROM deficits due to bone-on-bone contact are generally not improved with therapeutic exercise or physical modalities but at times can be addressed by compensatory strategies.

In addition, quality of ROM can be assessed in the setting of functional movements. For example, functional forward bending is a combination of hip, pelvis, and a spinal movement. This is often clinically evaluated by having a patient bend forward and measuring the distance between the patient’s fingertips and the floor. A subject with restricted hamstrings and gluteal muscles will present with increased lumbar and thoracic flexion to reach as low as a subject with highly flexible hamstrings and gluteal muscles. This second subject may exhibit minimal motion through the spine as he or she is able to achieve the required amount of “bend” using
Strength assessment is another part of comprehensive patient examination. Whether it is through manual muscle testing (MMT), or a more formal dynamometric assessment, the goal of strength testing is threefold: (1) determining etiology of strength deficits (i.e., deconditioning, pain inhibition, poor neuromuscular control; these often improve with repeated cueing) or neural deficit, (2) painting a clinical picture of overall strength, and (3) demonstration/determination of kinesiophobia (an important factor in chronic pain). As a general rule, the patient should be examined with regard to muscles surrounding the region that is painful and in the regions immediately proximal and distal to the painful region. For example, in a patient with elbow pain, the clinician should evaluate strength in the shoulder, elbow, and wrist. Given that strength deficits are relative, contralateral strength values should be used as an internal control.

Additionally, because many pain complaints are concerning for an underlying spine etiology (e.g., a radiculopathy), it is often useful to examine the key myotomes in the affected region. Using the same example of elbow pain, the clinician would evaluate muscle strength of the C5–T1 myotomes bilaterally to assess for focal weakness. These have been covered earlier in this book.

Admittedly, MMT is a faster method than more formal strength measurement such as dynamometry or manual sphygmomanometry. However, one must acknowledge that the MMT grading scale of 0 to 5 consists only of ordinal values. These values represent directional relationship only and should not be used as replacement for interval or ratio measures, such as torque, force, or percentage of muscle activity. In fact, Beasley27 noted that a knee extensor strength loss of 50% is needed before clinicians reported a grade change within MMT.

With regard to kinetic chain theory and altered neuromuscular control, the testing of muscles distant to the presenting complaint becomes important during the development of a rehabilitation plan. Just as patients with patellofemoral pain present with distant palpable tender sites, they will often demonstrate weakness as well, typically about the hip abductors, hip extensors, and hip external rotators.28 This evaluation process is a joint
experience, one undertaken by both the clinician and the patient, which may ultimately improve patient compliance in a physiotherapy program.

Two primary factors contribute to relative strength deficits in ambulatory patients without major nerve or muscle injury. The first might be considered a relative disuse weakness. In relative disuse, the body part is not immobilized but is infrequently used in a manner that develops strength. Triceps weakness in sedentary office workers is a good example of this. Although these individuals may be “pushing papers” all day long, they may go for decades without ever performing elbow extensions against enough resistance to prevent gradual weakness from developing.

The second primary factor that contributes to relative strength deficits in ambulatory patients without major nerve or muscle injury is a process sometimes referred to as muscle de-education.29 This is a process in which the individual fails to activate or abnormally activates a given muscle because of pain, fatigue, maladaptive biomechanics, or psychological basis. Over time, the normal neuromuscular engram for the intended movement becomes more difficult to retrieve, and in time, the neuromuscular control system essentially “forgets” the normal motor control pattern for that requested movement. Most often, muscle de-education involves the patient losing the ability to fire a muscle with the correct timing or with enough synchronous motor units for the intended movement. The patient adopts a maladaptive neuromuscular firing pattern and substitutes other muscles to perform the task. Proper motor synergy and contraction/relaxation timing is lost. Ultimately, it is the clinician’s responsibility to identify all strength deficits, determine rationale (neuromuscular or musculoskeletal etiology), decide which are clinically relevant to the patient’s symptoms, and implement an appropriate rehabilitation plan.

ENDURANCE

Endurance refers to the capacity to continue to functionally exert oneself. Although patients with pain complaints may occasionally be limited by cardiovascular endurance, the more common context for assessing endurance in a pain patient is local muscular endurance.

As an individual bears weight during a functional activity, the forces of
his or her activity (e.g., the ground reaction force while walking) have to be borne by the different structures throughout the kinetic chain. These include bone, joints, articular cartilage, ligaments, and muscles. Ideally, muscles bear a substantial amount of these reactive forces, which reduces the forces transmitted across other structures. However, with repetitive iterations, local anaerobic energy systems are stressed and loading muscles will fatigue. Although these muscles may be able to bear reactive forces initially, with each repetition, these same muscles may lose their ability to attenuate force and, hence, allow transmission to other structures.

The phenomenon of muscle fatigue has important implications both diagnostically and therapeutically. Oftentimes, patients will complain of pain presentations that are initially mild but worsen with increased activity. This is seen especially in the case of postural muscles, which must have sustained exertion against gravity and may present with pain by the end of the day or with any prolonged positioning. Strength measurements may initially appear “normal” on physical examination; however, recall that MMT inherently does not test muscle endurance. Therefore, it may be necessary during examination to exercise a patient to fatigue to simulate those circumstances when the patient is having pain. For example, if a patient complains of knee pain that worsens with walking long distances or climbing stairs, a component of the pain complaint may be poor muscular endurance in the quadriceps and hip abductors. When testing knee extension and hip abduction by MMT, the “strength” may appear normal because the patient’s limitation is muscular endurance rather than peak torque production (as tested via MMT). Therefore, the patient may be better assessed by performing repetitive single-leg squats. This can fatigue the quadriceps and hip abductors relatively quickly within the time frame of the examination and allow the clinician to assess whether poor muscular endurance is contributing to the patient’s pain complaint. If the clinician assesses that poor muscular endurance is contributing to a patient’s pain complaint, improving muscular endurance should be a focus in the patient’s physical therapy protocol.

Biomechanical Considerations in Common

4542
Musculoskeletal Pain Syndromes

The first part of this chapter highlights key concepts underlying the biomechanical evaluation of pain. Following are selected common axial musculoskeletal pain syndromes that are often ameliorated by the patient engaging in a focused, active rehabilitation program. This list is not exhaustive but serves as a basis for the application of the concepts discussed earlier. The goal of this section is to enlighten the reader on the clinical utility of a biomechanical evaluation of patients presenting with musculoskeletal pain. It will be noted that these anatomic regions overlap in their presentation and redundancy is a product of the very nature of the interrelatedness of biomechanical evaluation.

CERVICALGIA

Patients presenting with chronic atraumatic neck pain often have a history of constant posterior neck, suboccipital, and/or upper trapezius area pain with qualities of pressure, tightness, and spasm. Often, the symptoms are present upon waking and decrease somewhat with movement and a warm shower but worsen as the day progresses. This may be exacerbated by various sedentary positions such as driving, sitting in class or meetings, computer work, reading, or knitting. The pain is usually temporarily improved with lying down or reclining with the head supported as in a lounge chair but may return or worsen with prolonged inactivity, prompting the subject to get up and move about to reduce the pain. In addition, they may have had a prior diagnosis of cervicogenic headaches. To further evaluate, one must understand the functional role of the neck and common pitfalls in daily living.

The obvious functional role of the neck is to hold the head. On second pass, however, that role becomes more nuanced, as the head’s role is to house a large and heavy brain, position eyes for binocular vision, position ears for hearing in stereo, and place the nose and mouth for their respective roles. In addition, it positions the head to maximize facial expression due to social human nature. As seen earlier, positioning of the lower spine affects head posture; postural muscles that are suboptimally positioned will have to work harder but maintain the same endurance than those kept in more agreeable alignment with gravity. Slouched sitting will cause
excessive thoracic flexion; in this posture, the arms and scapulae slide off
the body and the shoulders round forward. This positions the head more
forward than intended. Compensatory strategies for this forward head
posture include excessive proximal neck extension to raise eye gaze off the
floor and facilitation of the upper trapezius and levator scapulae. Muscle
balance theory states that a strong, tight muscle group will reflexively
inhibit the antagonist group. Thus, as the cervical and thoracic
paraspinals along with the upper trapezius and levator scapulae become
chronically hyperactive, hypertrophied, and facilitated, reflex inhibition of
the middle and lower trapezius, rhomboids, and deep cervical flexors are
seen. This pattern was coined by Dr. Vladimir Janda as “upper crossed
syndrome.” Of note, this neuromusculoskeletal pattern can present
clinically as pain in multiple regions, including cervical, thoracic, and
periscapular regions, as well as in the presentation of rotator cuff
impingement.

There are several clinical patterns in addition to myofascial cervical and
upper trapezius pain common to this posture that can be amenable to an
active physical therapy and biomechanical restoration program which are
highlighted in the following text.

**Occipital neuralgia:** The greater and lesser occipital nerves can
become entrapped as they pierce through suboccipitals that have become
hypertrophied and shortened. Occipital nerve blocks have been used in this
setting; however, providers may find that patients receive temporary relief.
From a positioning standpoint, a forward head posture with
hypertrophied/facilitated posterior cervical musculature will continue to
produce entrapment of the nerves unless the tension is removed from the
suboccipital region. Restoration of the head over the neck (as opposed to
in front of it) will reduce tension in this region. Due to kinetic chain
theory, optimization of this cervical posture requires improvement of the
positioning of the lumbopelvic, thoracic, and periscapular region. This
positional effort is largely patient-driven following adequate instruction
and can help free the patient from cyclical pain relief by external forces
(i.e., injections).

**Cervical facet pain:** In the sagittal plane, the typical cervical vertebrae
(C3–C7) are limited in extension by the zygapophysial (facet) joints. The
forward head posture produces increased lower cervical flexion and upper cervical extension than a neutral to retracted head posture, and efforts at neck extension in the forward head posture lead to decreased extension at the lower cervical segments compared to the neutral head posture.\textsuperscript{32} (It is of note that segmentally, the atlantoaxial joint has paradoxical motion in flexion and extension when compared with the typical vertebral segments.)\textsuperscript{31} Increased efforts at neck extension in the forward head posture will presumably increase the segmental extension seen at all, but the lower cervical segments due to this inhibition and are more likely to affect facet loading. Restoration of the neutral head posture can alleviate some of this excessive upper cervical extension.

**Cervical radiculopathy:** Similarly, the classic neural tension and distraction signs for cervical radiculopathy are Spurling’s test, which is described by placing the neck in extension and rotation with an axial load.\textsuperscript{33} In patients with poor cervical posture, the typical upper cervical vertebrae are already in a relatively extended position, and addition of rotation in this position essentially reproduces the Spurling’s maneuver. Cervical extension has been shown to decrease the cross sectional area of the neuroforamen in particularly C3–C4 and C4–C5.\textsuperscript{34} Additional rotation in this position can further compromise the exiting nerve, and clinically, a patient with poor neck posture may complain of radicular symptoms with daily functional tasks such as turning his or her head with driving as he or she is already in a relatively extended position.

**PERISCAPULAR AND THORACIC PAIN**

In pain management involving the thoracic region (inclusive of the shoulder complex and upper extremity related referral), the attending clinician may have the tendency to direct intervention at a specific location or tissue of concern. Just as with other body regions (discussed within this chapter), this approach is not unwarranted. Musculoskeletal trigger points are an obvious concern, incurring a local pain response associated with the area of hypertonicity. A variety of interventions (not covered in this chapter) exist to manage these trigger points, inclusive of injection, dry needling, manual therapy, and thermomodalities. However, in discussing these abnormal musculoskeletal soft tissue states, one must explore the
etiology from multiple perspectives.

Although the exact mechanism of soft tissue trigger point development is not fully understood, there is general consensus that these myofascially derived trigger points (or “taut bands”) are related to localized muscle overuse syndrome, such as that following a novel, repetitive, or excessive cyclical loading task. This is not surprising, given that a general “training effect” is based on principles, outlined by Hans Selye in the “general adaptation syndrome.” The patient may report performing large amounts of repetitive or intense loading, such as typing, repeated lifting, pulling, or pushing, which would serve to create an “overtraining” condition and negative tissue response. However, if the stimulus activity does not appear to fully justify the patient’s current presentation, the question must be posed: “Is there some force or some movement pattern lending to an inappropriate amount of stress being placed on the problematic structure(s)?” This is where the clinician must consider biomechanics associated with the movement at hand.

**Periscapular pain:** The attending clinician’s consideration of faulty movement pattern is paramount in assessing etiology of the patient’s current localized complaints. This is especially true with regard to the shoulder and thoracic region complex. Although the labrum serves to deepen the glenoid fossa to an extent, the humeral head is roughly 3 to 4 times as large as the admittedly shallow glenoid fossa, lending to the glenohumeral (GH) joint’s significant amount of mobility. The tremendous amount of movement available to the GH joint lends itself to risk of injury. If structures that are designed to stabilize this joint are not performing properly, the region is at risk. One must consider the stability of the GH joint, neuromuscular control, and scapulohumeral rhythm as well as patient posture.

As an example, let us consider a patient with subacromial region pain and upper trapezius region pain. One may be concerned about impingement (primary or secondary) as well as upper trapezius trigger point presentation. First, the anterior-posterior force coupling created by the infraspinatus, teres minor, and subscapularis, when operating symmetrically, serve to compress the humeral head into the glenoid fossa during dynamic activity. This limits aberrant arthrokinematic translation.
that may be associated with impingement. However, research has noted
that overdevelopment of the internal rotators and subscapularis
musculature (especially within a throwing population) typically lend to an
imbalance in this coupling.\textsuperscript{40} It would behoove the clinician to consider
this proper strength and activation coupling with regard to pain.

A second consideration is that of proper scapular dynamic stability. A
generally accepted ratio of humeral to scapular movement is 2 to 1 (in that
for every 2 degrees of humeral movement, the scapula moves 1). This
needs to be maintained and appropriately timed to ensure proper GH joint
position. Researchers has shown that in those with shoulder impingement,
the serratus anterior has decreased levels of activity, the lower and middle
trapezius have delayed activation, and there exists an overtly dominant
activation of the upper trapezius.\textsuperscript{41,42} This thereby lends to faulty scapular
mechanics, altered scapulohumeral rhythm, and hence a potentially
excessive stress to subacromial structures.

Additionally, static and postural concern warrants attention. If a patient,
such as that mentioned earlier, is continuously performing an overhead
reaching task in an excessively kyphotic position, he or she may be
“asking” the shoulder complex to perform a significantly larger amount of
relative overhead flexion than capable of (an amount potentially not
available passively) regardless of proper scapula-humeral rhythm. The
patient may present with a dysfunctional scapular position, such as medial
border dysfunction, where in the scapula is excessively internally rotated
such that the medial border is raised from the rib cage. This posture has
been associated with GH instability.\textsuperscript{43} Such a posture may imply
weakened, inhibited, excessively stretched supportive structures (serratus
anterior musculature, middle and lower trapezius musculature, rhomboid
musculature) or even restricted pectoralis minor musculature, such as that
noted in the commonly termed upper crossed syndrome. Such concern
would then warrant tests to rule in/out neuromuscular concerns in
activation or pure musculoskeletal concerns in length, strength, or
restriction. Patients may complain of thoracic region pain; however, the
treatment requires correction of dysfunctions of the GH and
scapulothoracic regions for long-term improvement: Simply injecting
trigger points will not resolve the offending process.
Furthermore, if an excessively kyphotic resting position were evident, he or she would be required to achieve correlating and likely excessive amount of cervical lordosis in order to maintain gaze forward on the horizon. Such a pathologic resting state may lend toward the muscle overuse scenario as etiology of trigger points (i.e., prolonged levator scapulae, scalene, and/or deep posterior cervical musculature activation) and may even lend to excessive cervical facet joint closure stresses (as discussed in further detail within other sections of this chapter).

**Thoracic pain:** Interestingly, pure thoracic region spinal pain is reported much more rarely than other spinal region complaints regardless of the previously mentioned postural and dynamic concerns. One report noted that out of all spinal pain reports, only 15% of those resided within the thoracic region (vs. 44% in the neck and 56% in the low back).\(^4^4\) Although not common, and typically experienced unilaterally and localized,\(^4^5\) pain related to thoracic spine dysfunction must be mentioned, given that the contractile structures making up the scapulothoracic complex utilize both the ribs and vertebral segments as points of attachment (serratus anterior, trapezius musculature, pectoralis major, and anterior scalenes to name a few), thereby lending to relative scapular or relative rib movement. Clinicians should be versed in, aware of, and able to assess concern for abnormal rib positions and consider postural abnormalities and muscle activation patterns within the kinetic chain when ruling out thoracic positional concerns.

Proper shoulder and thoracic biomechanics must be considered in lieu of localized management of irritable structures. However, this is not to say that local tissue management is to be overlooked or minimized. In fact, literature has shown a correlation between local musculature trigger points and correlating muscle inhibition as well-altered motor activation patterns.\(^3^5\) The cause-and-effect relationship becomes muddied to some extent as one considers this correlation. Local injection is not by any means contraindicated as it is a valuable intervention for pain management with a soft tissue, myofascial component. Rather, it is recognized as valuable only within a comprehensive approach, acknowledging that there may be a complex interplay among causality and perpetuation of complaints involving mechanics of movement.
LUMBAR PAIN

Low back pain is the leading cause of disability in the world and is the sixth leading contributor to global disease burden.\textsuperscript{46,47} The cause of chronic low back pain can be frustratingly difficult to elucidate. Although various studies have documented the primacy of the intervertebral disk,\textsuperscript{48,49} followed by the zygapophysial joints,\textsuperscript{48,50,51} and SI joints,\textsuperscript{48,52} these diagnoses can require invasive techniques, such as provocation discography or image-guided diagnostic injections. Axial low back can occur with or without leg pain. When leg symptoms are present, they may signify radiculopathy, radicular pain, or somatically referred pain. These entities have been defined by the International Association for the Study of Pain\textsuperscript{53} and have been more recently articulated by Bogduk.\textsuperscript{54} Briefly, radiculopathy implies a conduction block along a spinal nerve or its roots and may or may not be painful.\textsuperscript{53} Radicular pain is evoked by ectopic discharges from a dorsal root or its ganglion and does not suggest the presence of an objective neurologic deficit.\textsuperscript{53} Somatically referred pain is not dermatomal and signifies the convergence of nociceptive afferents on second-order neurons in the spinal cord.\textsuperscript{53} The variability of these clinical presentations may lead treating providers to obtain cross-sectional imaging to help localize the source of pain. Yet, the situation is hardly helped by magnetic resonance imaging (MRI), which can commonly show abnormalities, even in asymptomatic individuals.\textsuperscript{55} The confluence of these factors illustrates a common clinical reality: Identifying the pathoanatomic source of low back pain is often difficult, resource-intensive, and may be impossible. In these scenarios, the treating provider may wish to use a biomechanical and active rehabilitation approach for both diagnostic and therapeutic purposes.

Core stability: Perhaps, no single intervention for chronic, axial low back pain has received as much as attention as core stability. The “core” has been defined as a box with the abdominals in the front, paraspinals and gluteals in the back, diaphragm as the roof, and the pelvic floor/hip girdle as the floor.\textsuperscript{56} Clinical instability is defined as a significant decrease in the capacity of the stabilizing system of the spine to maintain the intervertebral neutral zones within the physiologic limits.\textsuperscript{57} Objective changes of core musculature have been demonstrated in patients with
chronic low back pain. The lumbar multifidus muscles are important extensors of the lumbar spine. The lumbar multifidi have been noted to atrophy and become replaced with fatty tissue in patients with chronic low back pain.\textsuperscript{58–60} When noted, a stabilizing program directed at activating the lumbar multifidi is an important part of the rehabilitation of a patient with chronic low back pain. In addition to muscular dysfunction, impaired neural feedback control may also lead to instability. A basic framework may be conceptualized as follows. The central nervous system, upon sensing a lack of intervertebral stiffness, may compensate by increasing trunk muscle activation to maintain stability, and static contractions prolonged over a period of time may lead to pain.\textsuperscript{61} The goal of core stabilization is to achieve muscular contraction to achieve stability.\textsuperscript{62} Although a variety of core stabilizing programs are possible, many seem to incorporate elements from the Saal and Saal’s protocol on conservative treatment of patients with lumbar disk herniations.\textsuperscript{62,63} Per their description, stabilization exercises may be divided into basic and advanced levels. Basic levels of core stabilization involve supine and prone positioning. Patients may be advanced through transitional, kneeling, and standing positions. The goal of this program was to develop isolate and cocontraction muscle patterns to stabilize the lumbar spine in neutral position. Although core stabilization exercise has strong construct validity, further research will be needed to determine its efficacy.\textsuperscript{64}

**Mechanical diagnosis and therapy:** A patient may present with leg pain, which may be radicular or somatically referred. The history and examination, which may include an evaluation for ANT, can assist with this distinction. The mechanical diagnosis and therapy (MDT) is a paradigm that was developed by Robin McKenzie in the 1950s.\textsuperscript{65} The MDT provides a means for treating the patient’s symptoms without necessarily establishing a pathoanatomic source. A key portion of establishing a mechanical diagnosis hinges on patients performing repeated end-range lumbar movements to establish whether leg pain may “centralize.” McKenzie\textsuperscript{66} himself has defined centralization as the phenomenon “whereby the intensity of pain reduces or disappears distally but remains or moves (and in some cases increases) proximally.” The “directional preference” is that direction of testing that elicits a
centralization response. Once the directional preference that achieves centralization is identified, the patients are then empowered to self-manage their problem through the use of directional exercises that match their directional preference.\textsuperscript{67} The value of this approach is that it allows the patients to transition to self-care and affords them the ability to control their symptoms. The prevalence of centralization and directional preference has been reported to be 70\% to 87\% for acute low back pain and 32\% to 52\% for chronic or radicular low back pain.\textsuperscript{67} If a directional preference exists, patients will benefit the most from exercise that matches their directional preference. One protocol had matched patients to exercise that was opposite of their directional preference.\textsuperscript{68} One-third of this group had to withdraw from the study within 2 weeks due to nonimproving or worsening symptoms. Additionally, the presence of centralization and directional preference is a predictor of outcome. In a study of 243 subjects, those who centralized had significantly greater pain reductions and return-to-work rates than those who did not centralize.\textsuperscript{69} In addition to being therapeutic, the presence of centralization and directional preference may be diagnostic as well. The only conclusive test for discogenic pain remains provocation discography which is invasive and of debatable clinical value. However, one study has found the presence of centralization to correlate with positive discography. In this study of 63 patients, 47 expressed a directional preference and 16 did not.\textsuperscript{70} Of the 16 who did not show a directional preference, only 2 had positive discography. Of the 47 who did show a directional preference, 34 showed had positive discography. This study demonstrates the strong correlation between the presence of a directional preference and discogenic pain.

In summary, the cause or treatment of chronic low back pain is often not illuminated through history, exam, or advanced imaging. However, the need to establish a pathoanatomic diagnosis may be eliminated through active biomechanical techniques, which may serve both a diagnostic and therapeutic value.

SACROILIAC AND HIP GIRDLE PAIN
If there is one theme that has emerged through this discussion of pain and biomechanics, it is that one cannot completely isolate a specific joint or
region with regard to etiology of musculoskeletal pain when repetitive movement is involved. The human body, as a functional closed chain system of joints, works synergistically, with the proper amount of joint excursion, proper amount of muscle activation, and in the correct temporal sequence in order to successfully carry out the task at hand. These functional tasks could be as simple as everyday ambulation or as unique as repeated single-leg squatting in an attic, hopping down a step or rapidly sidestepping to in sport. One could argue that during daily activity, the loading of the lower extremity and lumbopelvic complex is more relevant to pain management than any other region. Although it is beyond the scope of this chapter to fully delve into the biomechanics of the lower extremity and lumbopelvic complex, the correlation between faulty loading mechanics, dysfunctional muscle activation, and pain must be acknowledged and discussed.

There is a body of literature drawing kinetic/kinematic connections between the foot, ankle, knee, femoroacetabular joint, and pelvic complex. As cited previously in this chapter, the pronated STJ is associated with a position of medial tibial rotation, knee valgus, femoral medial rotation, and a hip adduction. Loading of the foot is associated with a pronation moment, serving to increase the impulse time and reduce the amount of force placed through the lower extremity during loading. Accordingly, the body is required to oppose all associated moments (at the knee, hip, and pelvis) throughout the loading chain. This entails producing subtalar supination, ankle plantarflexion, lateral tibial rotation, lateral femoral rotation, femoral abduction, and femoral extension (for our purposes, innominate and SI movement are not discussed here). More recent bodies of literature have confirmed these multijoint correlations, noting that lateral tibial rotation assists in raising the medial longitudinal arch of the foot and that proximal (hip) musculature is highly involved in controlling both femoral and tibial rotation. The musculature within the lower extremity must work synergistically and with proper synchronicity to maintain alignment. Just as in the shoulder complex, if one region is restricted, weakened, or activated with an improper timing sequence, the other regions are required to overcompensate or suffer faulty mechanics, either of which may lend to stress of musculoskeletal structures and
potential pain.

Patellofemoral joint pain is a prime example. In the setting of patellofemoral joint pain, literature emphasizes deficiency in quad activation/strength\textsuperscript{73} and poor hip stability (with emphasis on gluteus maximus deficiency\textsuperscript{74}) as well as poor foot control and excessive pronation\textsuperscript{75} as contributing factors to continued complaints. It would behoove the clinician managing such a patient to attend to these biomechanical concerns. If, in fact, the hip cannot compensate for a weakened gluteus musculature, one may note development of Trendelenburg gait, potential bursal irritation, and/or glut medius overuse pathology. Scenarios such as this must be pursued and considered for proper long-term remediation. However, select populations of patients may have faulty mechanics, poor musculature activation, and/or altered motor control/timing in the lower extremity but without painful presentation in the lower extremity. One must be concerned about manifestation more proximally (i.e., lumbopelvic region). There is a biomechanical correlation between the lower extremity and the lumbopelvic region. As an example, deficits at the hip may manifest proximally rather than distally depending on that patient’s abilities to compensate, and this must be acknowledged, thereby drawing attention to the pelvic ring.

As discussed in earlier sections, the lumbosacral region is a common site of pain management. However, one cannot discount the importance of loading forces placed on the entire pelvic complex during weight bearing. The relationship between the lumbar spine, SI joints, and femoroacetabular joints are inseparable when it comes to movement and determination of pain etiology. Current thinking acknowledges the pelvic girdle as a load-transfer system\textsuperscript{76} and, as such, able to both attenuate and generate forces. The proper function of this system depends on the stability of both hip joints and SI joints. The hip joints have a multitude of muscular support and an obvious congruency associated with the ball and socket–type joint. However, the SI joints, being planar, rely heavily on a system of dense ligamentous structure as well as less direct muscular elements connected via fascia tensioning. These elements are in a delicate balance, serving to tension across the SI joints and create stability.

Literature has reported a multitude of structures highly involved in SI
joint and general pelvic ring stability. It is beyond the scope of this chapter to discuss these in full detail. However, emphasis has been placed on myofascial attachments of the latissimus dorsi and the multifidus as well as the “guy wire system” of dynamic stabilization created by the deep erector spinae, the psoas major, and the quadratus lumborum. Given a general understanding of anatomy, one can understand how integrated the lumbar and pelvic region become given such information. To complicate matters further, the gluteus maximize has been recognized as a dynamic link between the thoracolumbar fascia and the tensor fascia lata, thereby emphasizing the connection to the lower extremity loading during tensioning of the pelvic girdle.

As noted earlier, the SI joint’s planar shape dictates that adequate pelvic girdle function relies very heavily on the concept of dynamic stability. Adequate muscle force generation is required each loading bout, local muscular endurance is needed for repetitive activation, and effective neuromuscular control is required and must ensure proper timing of each muscle activation. If any one attribute is in deficit (i.e., a relevant structure is inflexible, overly flexible, weak, or activated improperly), the system begins to fail, and the patient may become symptomatic due to overstress of any single structure.

Although it is not the purpose of this chapter to explore in detail true medical diagnoses, pain at the SI region cannot be assumed to stem from the SI joint. Referral patterns as mentioned previously (with regard to the lumbar spine) must be considered. Furthermore, pain at the SI joint is not synonymous with true sacroiliitis (as potentially ruled in/out with intra-articular injection). Both the dorsal SI and interosseous ligament have been implicated as an overlooked source of pain in the setting of lumbopelvic dysfunction.

Ultimately, poor dynamic stability, passive restrictions, or altered neuromuscular control within the entire lower closed chain system have the potential to affect the pelvic ring structures and vice versa. It may be thought of as “uncommon” for overpronation to lend to pelvic stress and resultant dysfunction or for weakened gluts to lend to SI region pain. However, such biomechanical-based concerns should be entertained and ruled out. With regard to pain, mechanics, and effective long-term
management, the mindful clinician must acknowledge, assess, and implement intervention to address these concerns.

Conclusion

Thorough evaluation of neuromusculoskeletal pain requires the use of biomechanical evaluation and principles to guide pain treatment and patient expectations. The principles of kinetic chain theory, ANT, and neuromuscular control form the groundwork whereupon pain syndromes can be addressed. The clinician should have raised suspicion for kinetic chain dysfunction in patients with neuromusculoskeletal pain whose symptoms are recalcitrant to focal treatment modalities, that are only temporarily improved with passive treatments, or that are poorly defined by anatomic structures. Treatment begins with educating the patient on the global nature of the body dysfunction and includes the patient actively engaging in improving found deficits. Improvement is sustained through the patient continuing with active management techniques over time, often with a physical or occupational therapist–prescribed home exercise program, and adherence begins with the patient recognizing the clinician’s understanding of the biomechanical interface of the body with its environment.

“Rehabilitation is a continuous process.”
Rehabilitation may be described as a “return to ability . . . the return to the fullest physical, mental, social, vocational, and economic usefulness that is possible for the individual.” The focus is placed more on one’s abilities rather than their disabilities.

Historical Overview: Pain Rehabilitation and Functional Restoration
In 2016, in response to the Institute of Medicine’s (IOM) recommendations to improve the scope and breath of pain management, the National Pain Strategy (NPS), a call to develop a comprehensive population health level strategy to address pain prevention, care, education, and research, was released. Included in the plan is a need to focus on biopsychosocial-based self-management and more formal multidisciplinary team-based models of care. NPS defined “high-impact pain” as pain associated with “substantial restriction of participation in work, social, and self-care activities.” This chapter is a foundation to apply a “rehabilitation model” to address the critical needs facing those patients suffering with the debilitating effects of chronic pain, including high-impact chronic pain. In this approach, “function” and “restoration” of previous activity remains the focus of providers in the rehabilitation team.

HISTORY OF PAIN REHABILITATION
Early evidence of a rehabilitation approach to the injured person or worker dates back to the Egyptians under Ramses II in 1500 BC where organized treatments of injured workers, fees for treatment, and compensation for
The development of more expertise and a more rational treatment and management approach of pain was delayed until the birth of the field of anesthesia in the 1840s and the isolation and synthesis of morphine by Sertturner in 1806 and salicylates from willow bark in the late 1800s. The modern development of a rehabilitation model evolved only after World War I and World War II with the birth of the fields of physical and occupational therapy as a means to “rehabilitate” injured returning soldiers. Pain rehabilitation developed in the context of evolution of the medical specialties of physical medicine and rehabilitation, anesthesia, psychiatry, and occupational medicine during the 20th century. John Bonica championed a more comprehensive “multidisciplinary” approach in the United States in 1947 and later at the University of Washington in 1960. Wilbert Fordyce, a psychologist and collaborator of Bonica, incorporated operant conditioning and other behavioral approaches with more specialized 8-week inpatient programs in the late 1960s. In 1982, John Loeser formalized a more “structured program” at the University of Washington, a 3-week daily program, which has become a model for “interdisciplinary” treatment. A more biopsychosocial approach to pain rehabilitation has also been facilitated by the merging of behavioral and cognitive fields and the subsequent cognitive-behavioral approach to the assessment and treatment of pain in the 1980s and 1990s. A proliferation of pain treatment facilities was seen between 1980 and 1995 and included the advancement of interventional procedures. A more recent conceptualization of pain focuses on behaviors within the pain system, a biopsychomotor model of pain, which incorporates three interdependent behavioral subsystems: (1) communicative, (2) protective, and (3) social response behaviors. This model assumes that a pain system can only be adaptive if the sensory component of the pain system is accompanied by behaviors designed to act on the source or cause of injury or illness. This may help to explain the wide variability observed in pain behaviors seen across different patients despite relatively similar levels of reported pain intensity and objective tissue pathology. The biopsychomotor model of pain can be extended to include behavioral factors such as communicative behavior (grimacing), protective behaviors (i.e., withdrawing a limb from the fire), and behaviors
designed to elicit social responses (i.e., empathy and solicitous behavior from others). This model, like the biopsychosocial one, emphasizes that dysfunction may develop in behavioral systems separate from pain sensation, and subsequent treatments targeting pain behavior would more likely lead to greater clinical outcomes and provide a more pragmatic and inclusive model for the spectrum of pain rehabilitation (Fig. 90.1).

**FIGURE 90.1** Biopsychomotor response to pain. (Redrawn from Sullivan MJ. Toward a biopsychomotor conceptualization of pain. Clin J Pain 2008;24[4]:281–290, with permission.)

**HISTORY OF FUNCTIONAL RESTORATION AND WORK REHABILITATION**

Functional restoration (FR) programs, based on a return-to-work model, evolved along with advancements in occupational medicine beginning in the 1970s. Prior to this, programs of “habit training” focused on restoring workers affected by disease or injury in the 1920s and later by the incorporation of vocational rehabilitation mandated at the federal level in 1923 and the Vocational Rehabilitation Act. In the 1950s, more objective measures were used to track progress and measure outcomes and served as the starting point for more formal work conditioning and work hardening programs championed by Lillian Wegg and Florence Cromwell. In the 1970s, work hardening emerged as a formal industrial management service and adopted a similar multidisciplinary approach used in the management of chronic pain and disability. Standardized work stimulation equipment, assessment, and treatment protocols were incorporated into
standard practice in the 1980s and led to formal accreditation by the Commission on Accreditation of Rehabilitation Facilities (CARF) in the late 1980s and early 1990s.\textsuperscript{17–19}

Gatchel et al.\textsuperscript{20} described eight classic critical elements of an FR approach which serves as the foundation for most multi- and interdisciplinary rehabilitation-based programs. Elements include quantification of physical deficits on an ongoing basis, psychosocial and socioeconomic assessment used to individualize and monitor progress, and an emphasis on reconditioning of the injured area or body part. The team-centered FR approach also includes generic simulation of work or activity, disability management with cognitive-behavioral approaches, psychopharmacologic management focusing on improving analgesia, sleep, and affective distress, many times detoxifying patients from medications (i.e., opioids or benzodiazepines).\textsuperscript{20}

**WHAT IS PAIN REHABILITATION?**

A pain rehabilitation model can be applied to the entire spectrum of pain conditions, from acute musculoskeletal injuries, to subacute and recurrent injuries aggravated by poor ergonomics and/or physical impairments, to more complex chronic pain conditions where interplay of biologic, psychologic, and social influences is more apparent. Pain rehabilitation is based on a structured, individualized approach. The formal assessment identifies specific problems and needs most relevant to the patient and relates the problem to impairments and psychosocial factors, selecting appropriate measures to monitor progress and treatment. The rehabilitation program includes planning and coordinating various interventions with a focus on treating the specific impairments by restoring function and identifying compensatory strategies. Additionally, addressing activity limitations by addressing environmental and personal factors may help in restoring patients to previous levels of functioning and preventing or limiting disability.\textsuperscript{1}

A traditional definition of rehabilitation, based on a biomedical model, places the concept of rehabilitation as a secondary intervention, used to restore patients to their previous level of (residual) physical, psychologic, and social functioning, and, if possible, return them to (modified) work.\textsuperscript{21}
Waddell and Burton\textsuperscript{22} question this assumption in that the biomedical definition assumes that disability is a “matter of permanent impairment,” that sickness and disability imply an incapacity to work, that rehabilitation focuses on “irremediable permanent impairment,” and that rehabilitation is a second-stage process following acute medical management and only is carried out after treatment ceases. Waddell and Burton\textsuperscript{22} have implied this may be inappropriate in that in many chronic pain conditions (i.e., low back pain), objective factors (pathology and impairment) account for a small part of the incapacity. These chronic conditions are characterized more by “symptoms and distress” than tissue abnormality.\textsuperscript{22} A number of biopsychosocial risk factors (i.e., lower level of education, higher preoperative pain, low work satisfaction, longer duration of sick leave, somatic complaints, and passive avoidance coping) have been identified as predictors of poor outcomes after surgical interventions contributing to loss of function, increased disability, and persistent elevated levels of subjective reports of pain.\textsuperscript{23,24} These biopsychosocial risk factors may serve as important potential targets for pain rehabilitation.

**STAKEHOLDERS IN REHABILITATION**

Pain rehabilitation also involves the coordination of a number of important stakeholders involved in the care of the individual patient or worker. Stakeholders may include various health care providers, managed care organizations and insurers, the workers’ compensation carrier, society, the individual patient, and family members. This complex health care process and related list of stakeholders involved may sometimes add, as described by Shultz et al.\textsuperscript{25} and Gatchel et al.,\textsuperscript{20} a political dimension to the individual patient’s assessment and treatment process. Success in treatment may vary depending on stakeholder and may indirectly lead to antagonistic, confrontational, and misinterpreted feelings by the patient suffering with pain. Criteria of success may vary significantly depending on whether it is assessed by the patient or by society in general (Fig. 90.2). Many times, contrary to what is seen in other areas of clinical medicine, the pain rehabilitation clinician may find himself or herself in a potentially conflicting role in the treatment of patients with chronic pain (Table 90.1). The focus of care should remain on providing appropriate clinical services,
serving as a patient advocate or adjudicator, without crossing ethical boundaries resulting in harm to the client.26

This chapter focuses on an overview of assessment and treatment strategies included in a pain rehabilitation–based approach to acute and chronic pain conditions. As part of the clinical continuum, the more comprehensive and integrated treatment approaches commonly referred to as multidisciplinary, interdisciplinary, and/or FR27 will be examined. Important psychological factors related to chronic pain and disability, the continuum of treatment models from more acute to integrative approaches, specific responsibilities of members of a pain rehabilitation team (i.e., physical and occupational therapist, psychologist, relaxation therapist, and vocational specialist), and an overview of more specific work rehabilitation approaches including work conditioning, work hardening, and functional capacity testing will be reviewed.
Models of Rehabilitation

Conceptual models of pain rehabilitation are based on historical advances that initially described pain as a purely sensory phenomenon evolving to include a more mind–body approach to understanding disability and function (Table 90.2). Hippocrates and Galen (c. 150 AD) described an imbalance of bodily “humors” as a means of developing chronic pain and distress as a model for understanding suffering.28 In the 1600s, a dualistic mechanistic model emerged. René Descartes (1596–1650) theorized damage to the body would stimulate specific neural pathways, giving rise to the sensation of pain.28 Through the mid-19th century, medicine focused on the individual’s unique manifestations of the disease process. In the mid-1800s, the expanding understanding of pathologic anatomy shifted the focus to a more biomedical model. In 1965, Melzack and Wall29 proposed the gate control theory of pain which proposed that pain experience was determined by physical, motivational, cognitive, and emotional factors, and transmission of nerve impulses could be modulated by spinal gating mechanisms at the level of the dorsal horn. Melzack30 elaborated on this more dynamic role of pain networks further with the “neuromatrix” model, arguing that the brain and central nervous system play a dominant role in the pain experience.

BIOPSYCHOSOCIAL APPROACH VERSUS BIOMEDICAL MODEL FOR PAIN MANAGEMENT

The biomedical model assumes a causal relationship between a specific physical pathology and the presence or intensity of pain symptoms. It
emphasizes the importance of eliminating pain by restoring normal function in the organ or body part from which pain is thought to emanate. Although the more disease-based biomedical model enabled the medical sciences to flourish and improved our ability to treat infection and other disease processes, its fundamentally limited scope led to less profound success and relative treatment resistance in the treatment of many chronic pain states. A biomedical model may be more advantageous in treating more acute pain states, where interventional procedures, pharmacotherapy, and surgical interventions may lead to recovery of pain or hasten time to recovery. But the biomedical model poorly addresses related mental health issues and frequently relies on dualistic decision pattern, whereby if the patient does not respond to an intervention, then the pain may be not be “real” or just “in their heads.”31 Many more complex pain conditions remain resistant to a purely biomedical approach (i.e., chronic low back pain, neuropathic pain, and fibromyalgia).32 George Engel33 helped to shift the thinking from a purely biomedical model of disease management to a more comprehensive biopsychosocial model of illness. Recently, the World Health Organization34 has embraced a biopsychosocial model of disability (Fig. 90.3), which incorporates a dynamic interaction between the individual health condition and contextual factors.

The pain rehabilitation approach is based on a fundamental understanding of the individual’s unique condition as it relates to (1) impairment, (2) disability, and (3) functional limitation. Impairment is the loss of normality psychologically, physically, or functionally at the level of
the organs and body systems. Examples of physiologic impairments include muscle weakness, loss of range of motion, and pain. Disability is a restriction or lack of ability to perform activities due to related impairments such as inability to function in a specific vocation, as a spouse, student, or parent. Functioning has been described as an umbrella term for body functions, body structures, activities, and participation, denoting a positive interaction between the individual or patient and contextual factors (i.e., background of the individual’s life and current situation). Functional limitation is a deviation from the normal behavior of performing activities of daily living (ADLs) and may include problems with transfers, standing, ambulation, running, and stair climbing. A formal model proposed by the International Classification of Functioning, Disability and Health integrates the individual components into a biopsychosocial-based model where a “health condition” is substituted by “chronic pain” (Fig. 90.4). Chronic pain is affected by body function, activities, and participation as well as influences from the environment and personal factors.

A patient-centered approach is necessary if one is to effectively address these important individual concepts. A team-centered approach focuses on helping patients to achieve individual goals, which enable them to improve physical and psychosocial function, decrease pain, and improve quality of life. By working together, the rehabilitation team is able to help patients achieve better outcomes than could be achieved by an individual.
practitioner or intervention (i.e., surgical procedure, injection, pharmacotherapy). Basic treatment goals of both acute and chronic pain rehabilitation programs focus on functional improvement; improved abilities to perform ADLs, return to leisure, sport, or vocational activities; and improved pharmacologic management of pain and related affective distress (Table 90.3).

**TREATMENT APPROACHES: PAIN REHABILITATION**

A pain rehabilitation approach encompasses a wide range of treatment options including more directed therapies for acute pain conditions to more comprehensive and collaborative multi- and interdisciplinary approaches (Table 90.4).

**TABLE 90.4 Pain Rehabilitation Levels of Care**

| Unimodal (acute) |
| Collaborative |
| Coordinated |
| Multidisciplinary |
| Work conditioning |
| Work hardening |
| Interdisciplinary |
| Integrative |

**Acute Rehabilitation**

An approach to managing acute pain conditions relies on a more focused understanding of causative and aggravating factors, changes to affected tissues and related overload stresses, and includes three important phases: (1) acute, (2) recovery, and (3) functional. Within each phase, specific treatment focuses are applied by the therapist or clinician, and tools or skills are taught by the treating therapist with a goal of ongoing self-management and practice. Acute management may involve relative rest,
passive modalities (ice, heat, ultrasound), interventional procedures (i.e., trigger point injections, epidural, and facet injections), and oral and topical analgesics. Recovery phases focus on more advanced stretching and strengthening, increasing endurance, and assessing and treating postural changes that may be contributing to chronic pain.\textsuperscript{36}

**More Comprehensive Team Models: A Pain Continuum**

Rehabilitation treatment models include a continuum of care based on patient severity and needs with increasing complexity of treatment philosophies, a need for greater communication, and decreasing individual team member autonomy.\textsuperscript{37} Each of these models occupies a position along a continuum of care based on increasing levels of coordination, diversity of philosophies, and decreased hierarchical structure and practitioner autonomy. The left side of the treatment continuum (Fig. 90.5) shows the least collaborative model, parallel practice, where health care providers function quite independently. As one moves to the right, services become more coordinated with decreasing level of autonomy and increasing diversity of philosophies. From a structure standpoint, moving left to right increases the complexity of care, whereas reliance on hierarchy and clearly defined roles decreases. Complexity and diversity of outcomes increases while, from a process perspective, communication, participants, synergy, and importance of consensus building increases. Multi- and interdisciplinary treatment is even more structured, usually involving a number of specialties with less evidence of practitioner autonomy.

![FIGURE 90.5](Continuum of team models. The most common practice model is parallel practice in which each practitioner oversees only the problems within their isolated discipline with little or no interaction with other practitioners caring for the same patient. The most effective models for caring for those with chronic pain involve programs designed to allow for frequent, direct, and repeated interactions among the providers caring for each patient in the form of multidisciplinary and interdisciplinary treatment programs. (Redrawn from Boon H, Verhoef M, O’Hara D, et al. From parallel practice to integrative health care: a conceptual framework. BMC Health Serv Res)
With parallel practice, independent health care practitioners are working within their defined scope of practice such as in an emergency room setting or an acute cardiac unit (i.e., nurse, phlebotomist, physician, radiology technician) where the goal is rapid assessment and treatment in the most efficient manner. Consultation may include a pain physician referring a patient to an addiction specialist or surgeon for recommendations and shared treatment responsibilities. Collaborative practice may include the use of a case manager to help coordinate treatment between the patient and physical therapist. In a collaborative approach, information is shared on an ad hoc basis; practitioners normally practice independently sharing information regarding a particular patient. In coordinated treatment, patient records are shared among clinicians providing treatment for a specific therapy where the case coordinator or case manager is responsible for ensuring information is transferred to all team members. Differentiating between multi- and interdisciplinary treatment will be reviewed in greater detail in the following text. Although commonly used interchangeably, the terms interdisciplinary and multidisciplinary have important distinguishing features.

**Multidisciplinary Treatment**
Focused treatment programs for acute conditions may involve individual physical therapy directed by the pain physician, followed by a coordinated program including ongoing communication with the patient’s case manager and therapist. With chronic pain conditions, more diverse assessment and treatment teams include multi- and interdisciplinary programs. In the multidisciplinary model, patient care is planned and managed by a team leader, usually a pain specialist (anesthesiologist, physiatrist, neurologist, psychiatrist, or primary care provider) or a psychologist and is often hierarchical with one or two individuals directing the services of a range of team members, many with individual goals. Treatment may be delivered at different facilities or centers where individual patient progress is not regularly shared between distinct disciplines. The growth of multidisciplinary pain treatment centers in the
1980s led to the need for development of standards and formal accreditation processes. A committee on standards for Pain Treatment Facilities was established by the American Pain Society in the early 1980s, and a process was subsequently developed to accredit multidisciplinary pain centers (MPCs) by the CARF. Non–CARF-accredited programs also exist. Furthermore, the International Association for the Study of Pain delineated four levels of pain programs: MPCs, multidisciplinary pain clinics, pain clinics, and modality-oriented clinics. Multidisciplinary pain clinics and centers, many of which include an even more integrated comprehensive interdisciplinary approach, include similar basic treatment disciplines; however, the MPCs are usually associated with major health science institutions with an additional focus on pain-related research and outcomes.

**Interdisciplinary Treatment**

Even more collaborative, the interdisciplinary model involves team members working together toward a common goal. Team members are able to communicate and consult with other team members on an ongoing basis, facilitated by regular face-to-face meetings. Incorporation of the cognitive and behavioral psychological approaches along with the development and emergence of the field of health psychology led to the development of more interdisciplinary models under the more general “multidisciplinary” umbrella. Interdisciplinary pain programs may also be referred to as FN programs, which provide outcome-focused, coordinated, goal-oriented services. FR as an approach implies an emphasis on quantification and graded increases in function versus pain reduction, cognitive-behavioral therapy (CBT), occupational therapy, and work conditioning. FR programs were developed in the mid-1980s by Mayer et al. in the United States and have been incorporated with the basic program structure of interdisciplinary programs. The basic treatment model is based on Fordyce’s classic contingency management techniques and graded activity related to operant learning processes. FR aims at decreasing or eliminating learned pain behaviors.

The interdisciplinary model provides practical strategies for assessing and treating pain-related deconditioning, psychosocial distress, and
socioeconomic factors related to disability. An interdisciplinary team model is characterized by team members working together for a common goal, making collective therapeutic decisions, and having face-to-face meetings and patient team conferences to facilitate communication and consultation. Importantly, in this model, team members possess a combination of skills that no single individual demonstrates alone. Interdisciplinary teams may be led by a physician (medical director), psychologist, or nurse and include comprehensive assessment including pain medicine, pain psychology, and vocational rehabilitation. In some institutions, physical and occupational therapy assessments are also included in the formal assessment. Interdisciplinary programs are usually housed in one facility with periodic interdisciplinary team meetings to assess and adjust treatment progress, program coordination, and discharge planning. Programs primarily focus on restoring joint mobility, muscle strength, endurance, and conditioning and cardiovascular fitness. Coordinated vocational and therapeutic recreation services are also important aspects of care and focus on aiding patients in returning to work, improving behavioral factors (i.e., coping, catastrophizing, and problem solving) in the workplace, clarifying return-to-work level of functioning, and many times, individual occupational therapy.

In general, formal interdisciplinary programs vary in intensity and may include 3 to 8 weeks of 4- to 8-hours-per-day programs with tailored group and individual therapies usually provided in an outpatient or, less often, in an inpatient hospital setting. Long-term follow-up studies of interdisciplinary treatment programs have demonstrated improved return-to-work rates, pain reduction, and quality of life.\textsuperscript{40,41} The reader is referred to the chapter on interdisciplinary pain treatment (see Chapter 106).

**Outcomes of Multi- and Interdisciplinary Treatment Programs**
An early prospective trial documented high rates of return-to-work versus control subjects with improved physical capacities, self-reported disability, depression, and pain scores.\textsuperscript{42} Maintained posttreatment improvements in pain, perceived health, and psychological and physical function have been demonstrated in long-term studies (6 months and 5 years).\textsuperscript{43,44} The
interdisciplinary treatment approach is supported by evidence suggesting these programs are more cost-effective and provide at least equal or greater efficacy than other pain treatments (i.e., spinal cord stimulation and implantable devices, conservative care, and surgery). Additional evidence-based studies have demonstrated outcomes and treatment cost-effectiveness data supporting FR treatment which included multidisciplinary and interdisciplinary treatment programs. A recent analysis examined the cost utility of interdisciplinary treatment of chronic spinal pain. Cost utility involved the calculation of cost of the specific treatment relative to desired treatment goal (increased functioning and decreased pain) relative to pharmacologic treatment with or without anesthetic interventions. Interdisciplinary treatment was associated with better cost utility supporting interdisciplinary treatment as both less costly and more effective. Patients undergoing complex lumbar spine surgeries have also demonstrated improvements in pain and function. Although early intervention and referral for pain rehabilitation treatment should intuitively favor greater outcomes as compared to referrals late in the treatment process, studies have demonstrated that patients with long-term disability, many of whom have a greater incidence of pretreatment surgery, may still benefit from comprehensive treatment with similar improved return-to-work rates and decreased lost time rates. Rehabilitation-based multidisciplinary treatment has demonstrated high cost-benefit with regard to decreasing treatment costs and increasing workplace return to work. Sustained improvement in pain, mood, function, and opioid reduction or discontinuation was demonstrated in a large cohort of patients enrolled in a structured FR program. Patients entering treatment on opioids retained similar benefits regardless of opioid dose (i.e., high or low daily morphine equivalent doses).

Team Building and Stakeholder Coordination

CASE MANAGEMENT

Case management involvement is an important resource in the management of work-related injuries. Case management has been conceptualized as a system-based approach based on Bronfenbrenner’s.
systems theory, which incorporates an interaction of microsystems (worker factors), mesosystems (workplace, health care utilization, insurance system factors), and macrosystems (economic, social, and legislative factors).

Case managers are primarily assigned to injured workers’ cases to help facilitate communication between stakeholders and medical providers and coordinate and clarify issues related to return to work and job description, respectively. A practical problem-based approach in rehabilitation management process is the rehabilitation cycle and includes four important interdependent steps: assessment, assignment, intervention, and evaluation (Fig. 90.6). Case management assessment includes identification of patient problems and modification and adjustment of goals. The assignment step involves the assignment to specific health care professionals who understand intervention principles and goals. Intervention more specifically refers to treatment disciplines and interventions with specific goals and milestones. Finally, evaluation refers to the evaluation of goals and level of achievement.

![The rehabilitation cycle.](image)

**FIGURE 90.6** The rehabilitation cycle. (Redrawn from Stucki G. International Classification of Functioning, Disability, and Health (ICF): a promising framework and classification for rehabilitation medicine. Am J Phys Med Rehab 2005;84[10]:733–740, with permission.)

Tate et al. suggested success of any collaborative workplace rehabilitation relationship is contingent on (1) company policy endorsing a commitment to rehabilitation, (2) educational opportunities offered or available for the injured worker by the employer, and (3) identification of key decision-making points involved in the ongoing relationship. Training the nurse case managers in basic fundamentals led to improved work placement as compared to untrained case managers who were more likely to place the injured worker in a sedentary or light duty job position.

Applying a continuum of care model, many times facilitated by strong
case management presence, includes a coordination of disciplines, services, providers, and care levels. A continuum of care model developed in Canada for the treatment of musculoskeletal conditions included medical management, active physical therapy, chiropractic management, and multidisciplinary assessment and rehabilitation. Implementation of the program resulted in more rapid and sustained recovery, greater patient satisfaction, and dramatic cost savings as compared to usual care.59

**APPLYING TEAM VALUES**

Decision making in pain rehabilitation has been found to incorporate common decision values shared by the team members, worker, and stakeholders. Shared “general values,” as described by Loisel et al.,60 are those that stress work is therapeutic, pain is multidimensional, and interventions should be graded. These values should in turn be shared by the team members, the worker, and stakeholders facilitated by reassurance and the delivering of a single message as a way of more successfully returning a patient to work or previous level of function.60 These same values can be applied to the many barriers presented to the individual patient and stakeholder (Table 90.5).

Assessment, Goal Setting, and Progression through Treatment

**PAIN REHABILITATION PRINCIPLES**

Assessment of patients prior to entering a rehabilitation program is based on a comprehensive examination of physical, psychological, and social or relevant vocational factors. Also, the evaluating clinician must work to develop trust and rapport with the patient in order to understand barriers to recovery (i.e., contentious relationships involving family, employer, case manager, and/or the legal system) that may potentially lead to a delay or reduction of clinical improvement. Many times, the success of developing that relationship starts at the initial evaluation. Understandably, patients undergoing a rehabilitation program are often asked to make significant changes in the ways they cope with pain and function. Readiness to make such important changes has been found to be associated with treatment success, and readiness to self-manage pain increases from pre- to post-MPC treatment. Based on the transtheoretical model of behavior change, individuals are seen to progress through a number of stages involving decisions about change and include precontemplation, contemplation, action, maintenance, and acceptance phases. These basic concepts are important for the physician to explore during the evaluation and often become a focus of discussion between other potential treatment disciplines (i.e., pain psychologist, physician, and vocational counselor) when deciding whether the patient is an appropriate candidate for treatment. The pain rehabilitation clinician must be consistent and clear in promoting exercise and activity as essential, safe, and effective for the correction of functional impairments. The clinician must also be aware of various fears,
negative attitudes, financial, and vocational stressors many chronic pain working and nonworking patients are sometimes struggling with and be able to confront the patients on these issues in an open and understanding manner (Table 90.6).

Rehabilitation Specialists: Activities and Conceptual Models

A pain rehabilitation team may include a pain physician (i.e., anesthesiologist, physiatrist, psychiatrist, neurologist, and/or primary care physician), physical and/or occupational therapist, a pain psychologist, relaxation (biofeedback) therapist, vocational and therapeutic recreational...
therapists, social workers, and nurses. Ongoing communication between treating disciplines, including monitoring of progress and adjustment of patient goals, is coordinated by the pain physician. A rehabilitation model is based on a clear, concise, and consistent therapeutic message, which focuses on the patient assuming a more active role in self-management, flare-up management, and exercise progression. Goals of treatment remain somewhat consistent across all disciplines and focus on improving function and decreasing pain. More specialized roles of individual therapists (i.e., physical and occupational therapy, pain psychology, and vocational rehabilitation) and treatment goals are reviewed in the following text based on an FR approach.

THE THERAPIST’S ROLE: BUILDING AN EFFECTIVE THERAPEUTIC RELATIONSHIP

Besides obvious clinical skills and application of therapies by specific disciplines, the relationship between treating therapist (i.e., physical therapist, occupational therapist, psychologist, etc.) and patient is based on an ability to establish a mutually effective relationship based on ongoing respect, collaboration, and exchange of ideas. A successfully established working alliance will only help to improve outcomes. A process model for patient–practitioner collaboration includes a four-component model based on initially developing a therapeutic relationship, followed by mutual inquiry, problem solving, and negotiation. The therapist must also be cognizant of the patient’s beliefs, skills, emotional state, and expectations in effectively developing and adjusting a specific treatment plan and subsequent interventions. A therapeutic relationship involves the establishment of clear and attainable short- and long-term goals, the therapy intervention and training, and discharge planning (i.e., home exercise program). Therapists involved in pain rehabilitation treatment must be adept in their ability to assess initial levels of functional ability and then monitor and progressively increase the individual patient’s level and complexity of therapeutic exercises. Therapists assess secondary impairments in addition to their primary pain-related diagnoses (i.e., general inflexibility, deconditioning, regional myofascial pain and dysfunction, and other related postural abnormalities), which expands the
area of treatment. Physical and occupational therapists apply a more functional cognitive and behaviorally mediated therapeutic approach and help the patient slowly integrate other aspects of the program into his or her home program.

The basic principles of CBT are also introduced and facilitated by the physical and occupational therapy team members and may include goal setting, education, monitoring and documenting exercise and conditioning progress, and ongoing challenging and redirecting of maladaptive thoughts and behaviors. The integration of these approaches may help foster patient optimism, may decrease the fear of reinjury, and may maximize patient compliance. Common cognitive-behavioral objectives may be applied across disciplines as well as by pain psychology professionals in helping the pain rehabilitation patient change maladaptive thoughts and behaviors and include helping patients to combat demoralization, view pain as more manageable, alter or unlearn maladaptive thoughts or behaviors, bolster confidence, and improve problem solving (Table 90.7).

**INCORPORATING BEHAVIORAL APPROACHES IN PAIN REHABILITATION**
Pain rehabilitation approaches rely heavily on incorporating behavioral principles and approaches (i.e., operant, cognitive, and respondent) into active therapies. The cornerstone of operant therapy is graded activity. The basic premise of a graded activity program is based on Fordyce’s combined use of graded activity progression and contingency management techniques. This treatment targets helping patients to increase healthy behaviors with positive reinforcement while, at the same time, decreasing maladaptive pain behaviors and beliefs and increasing tolerance for activity.\textsuperscript{39,71} Often, graded activity programs are also incorporated with exercise therapy and problem-solving training.\textsuperscript{72}

**PHYSICAL THERAPY**

Physical therapists specialize in gait training, locomotion, core strengthening and stability, joint deficiencies, and proper biomechanics. Active treatments include instruction in strengthening, postural reeducation, and related therapeutic exercise (see Chapter 93). Passive treatment modalities (i.e., local application of heat, cold modalities) may be more efficacious for acute injuries; they are used more judiciously with chronic pain conditions. The use of modalities with chronic pain rehabilitation should shift to an emphasis on facilitating increased activity before or after formal treatment sessions or exercise and as a means of managing pain flare-ups more independently.

Manual therapy, the manipulation of soft tissues, continues to occupy a large part of the modern physical therapist’s scope of practice. Not necessarily new to medicine, manual techniques were described by Hippocrates (460 BC) with traction and immobilization as a means of reducing fractures.\textsuperscript{73} Galen later recommended techniques to treat “outwardly dislocated” vertebrae.\textsuperscript{74} Modern physical therapy’s use of manual techniques is based on principles of osteopathic medicine introduced by Andrew T. Still in 1871 and chiropractic treatment pioneered by Daniel Palmer in the late 1800s. Today, many therapists receive special training and certification from a number of “schools” of manual therapy including Maitland, Paris, Kaltenborn, and McKenzie (Table 90.8).\textsuperscript{75–77}
Cortical reorganization is coming in to focus for chronic pain management through physical therapy. Evidence of neuroplasticity in amputees with restructured primary sensory cortex receptive fields has been well established. Techniques include graded motor imagery and mirror therapy. These efforts target a rehabilitation program designed for synaptic exercises through the use of tactile and visual stimuli (i.e., computer, flashcards, mirror) and behavioral relevance (i.e., imagined movements, education) controlling for attention.

**THERAPEUTIC EXERCISE**

Therapeutic exercises targets muscle and joint deficiencies (i.e., weakness, decreased conditioning, and contracture) and serves as the basis for rehabilitation of patients with acute or chronic musculoskeletal, postoperative, and posttraumatic rehabilitation protocols (Table 90.9). The pain clinician must be cognizant of basic principles of physiology and guiding a patient through an individualized active strengthening program.
This section reviews important definitions and concepts related to therapeutic exercise. With rehabilitation of any injury, strength and endurance are important targets for assessment and treatment. Muscular strength is the ability of a muscle to generate force against resistance. Maintenance of strength of one’s muscle, or, more importantly, muscle groups, will help to improve function and prevent new or reinjury. Strength training also incorporates balance and coordination of movement. Muscular endurance is the ability to perform repetitive muscular contractions against some resistance over time. Endurance will tend to increase with strength. Improvements in muscular endurance may be more advantageous with regard to improving daily function.

<table>

<td>Functional improvement in activities of daily living</td>
</tr>
</tbody>
</table>

In general, skeletal muscular contraction can be divided into three types
of contractions: isometric, concentric, and eccentric. Isometric contraction occurs when the muscle contracts without changing length. Isometric or static strength is necessary for performing many ADLs and in functional tasks or sports activities where a stable base of support is necessary for effective and efficient movement of joints. In pain rehabilitation, isometrics may be useful when joint motion is painful, a joint or joints are immobilized, or muscle or muscle groups are weak. In concentric contraction, the muscle shortens in length while tension increases to overcome or move some resistance. With eccentric contraction, resistance is greater than the muscular force being produced, lengthening the muscle while producing tension. This type of muscle activation may be associated with a higher incidence of delayed-onset muscle soreness after exercise. Thus, concentric exercises may be the focus of the program prior to progressing to more eccentric, unloaded ones.

Strength and muscular endurance are dependent on size of muscle or muscle groups, number of muscle fibers, neuromuscular function and efficiency, and biomechanical factors. Neuromuscular training (NT) is a growing area of practice with most work in rehabilitation of musculoskeletal injuries including anterior cruciate ligament reconstruction. NT can include balance exercises, plyometrics, agility training, and joint mobility exercises. Plyometric exercise, initially used to enhance sports performance, may also be used in later stages of an active therapy program as a means of returning the patient to previous levels of sport or work. Plyometric exercise causes a lengthening of the muscle-tendon unit followed immediately by shortening, hence called the stretch-shortening cycle. Plyometrics are used with various demands placed on the musculoskeletal system, usually initiated at lower intensity and progressed to more difficult and physically challenging higher intensity levels. The higher intensity levels may serve to resolve postinjury neuromuscular impairment and prepare the body to respond more effectively and safely to rapid changes in position and movement as well as greater levels of force seen in higher intensity exercise and physically demanding work tasks.

EXERCISE PRESCRIPTION
The goal of an exercise prescription is to maximize the benefit for the patient with pain. Four basic goals include:

1. Changing sedentary behaviors to more active ones
2. Modifying risk factors for disability (e.g., obesity, hypertension, deconditioning)
3. Maintaining or improving exercise capacity as it relates to strength, aerobic capacity, balance, and flexibility
4. Enhance psychosocial function

Exercise prescription and focus may vary depending on the patient’s age, medical comorbidities, and individual pain-related impairments (i.e., muscle strength, joint pain, joint contracture). Clinicians should be able to optimize therapeutic treatment by balancing the focus of therapy while being mindful of potentially harmful activities. Stretching has been known to increase range of motion of joints, enhance muscle coordination, reduce muscle tension, and increase circulation/energy levels. Strengthening enhances the integrity of muscle, tendons, and other connective tissues, which in turn, improve motor performance and decrease injury risk.Endurance exercise may help to reverse the cycle of deconditioning and weakness commonly seen with chronic pain patients and is an important part of the pain rehabilitation program. Circuit exercise programs, popular with the elderly population, have been shown to provide significant improvements in cardiorespiratory fitness, muscular strength, body composition, and serum cholesterol levels. Aquatic-based therapies offer a partial reduction of stress throughout weight-bearing joints by lowering gravitational burden. This can be considered for patients who have limited range of motion, generalized weakness, poor motor coordination, and/or at a fall risk due to impaired postural deficits (i.e., balance issues, spatial/proprioceptive deficits, sensory disorders). Temperature-controlled facilities can be recommended for additional physiologic effects of exercise have been shown to have analgesic effects, enhance mood, and improve self-efficacy.

**OCCUPATIONAL THERAPY**

**Activities of Daily Living**

Occupational therapy focuses primarily on functional mobility and ADLs
as well as activity tolerance and ergonomic retraining. Occupational therapists typically concentrate on educating patients regarding proper posture and ergonomics related to upper limb functional activities such as lifting and computer usage as well as proper standing, sitting, carrying, and lifting postures (Table 90.10).

</tbody>
</table>
In general, occupational therapists address upper extremity–related ADLs including feeding, hygiene, grooming, bathing, and dressing. Occupational therapists spend considerable time with the patient, educating them on the potential for increases in pain with reinitiation of movement early in the treatment process. Focus may later change to lifting training and tolerance building. Coaching on proper body mechanics could include a basic assessment of maladaptive movement patterns, restriction in joint and soft tissue structures, as well as abnormal postures and bending or lifting techniques, which may exacerbate and/or be the cause of ongoing pain and dysfunction. Occupational therapists are also responsible for managing and directing more individualized work conditioning and work hardening programs as well as administering functional capacity evaluations (FCEs), often in coordination with the vocational rehabilitation team and employer.

## Pacing

Another important concept occupational therapists are primarily responsible for is directing and instructing patients on activity, work, and leisure pacing. Pacing may be either an appropriate or a maladaptive behavior. Good pacing may include activity scheduling, taking breaks to complete a pain-inducing activity as compared to overdoing activities, and the “crashing and burning” approach with prolonged periods of rest and “down time” in order to recover from activity related flare-ups (Table 90.11).

<table>
<thead>
<tr>
<th>Useful</th>
<th>Maladaptive</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Gradual increase in activity</td>
<td>Overdo activities</td>

<td>Increase activity until “intolerable” pain</td>
</tr>
<tr>
<td>3. Varies mixed activities and rest</td>
<td>“Crash and burn”: take extended periods of rest or</td>
</tr>
</tbody>
</table>
The therapist is then able to work with the patients in improving their daily routines, incorporating pacing, taking appropriate breaks, and prioritizing activities while incorporating self-management skills learned in other disciplines such as relaxation techniques and stretching into the patient’s daily routine at work, at home, and in leisure activities. Occupational therapists may also provide job site interventions, which include assessing ergonomics and monitoring for job site safety issues. Services may also include job site training where a trained occupational or physical therapist accompanies the injured worker.

**PAIN PSYCHOLOGY**

Psychological interventions as part of a pain rehabilitation program have been shown to enhance recovery, decrease disability, and enhance psychosocial functioning.\(^{87-90}\) Psychological interventions focus on addressing maladaptive cognitions, passive avoidance, depression, anger, and pain-related anxiety. Initial focus of psychological treatment includes challenging patients to change maladaptive thoughts and behaviors. As stated earlier, an individual’s readiness to make important changes has been hypothesized to be an important factor in treatment success and serves as an important initial clinical question posed by the treating psychologist.\(^{61,63,91}\) Over time, patients are also challenged to consider taking a more active role in management and incorporating nonpharmacologic and pharmacologic therapies into their individualized program. Problem-solving training may help to teach patients to choose more effective responses to pain and improve function.\(^{72}\) Incorporating group pain psychology interventions with an active physical therapy program has been shown to enhance posttreatment outcomes as compared to physical therapy alone on measures of functional impairment, employment of active coping strategies, medication use, and self-efficacy beliefs.\(^{92}\)
One of the more critical elements of pain psychology involves CBT. As regarded as first-line psychosocial treatment for individuals with chronic pain, CBT techniques include relaxation training, setting and working toward behavioral goals/activation, problem solving, and cognitive restructuring. Symptom associations of pain-related beliefs and appraisals regarding pain intensity, depression, physical disability, and activities/social role limitations are indicated for CBT. In particular, catastrophizing—magnification and rumination about the source of pain and perceived inability to cope with pain—has consistently been found to be associated with physical and psychosocial dysfunction.

Combining group CBT and relaxation therapy with an individually based multidisciplinary treatment (CBT, physical and occupational therapy, and social work) program demonstrated an additive effect with greater improvement on measures of pain, sleep, activity levels, and medication use.

Chronic pain frequently accompanied by underlying psychiatric/psychological disorders often benefit from mindfulness meditation. It is characterized by paying attention to the present moment with openness, curiosity, and acceptance. The premise behind mindfulness meditation to target the high prevalence and refractory nature of chronic pain in conjunction with negative consequences of maladaptive behavior, which improved self-referential processing, leads to increased interest in treatment plan including adjunct to therapy and alternative interventions. The goal is to refocus the mind on the present, thereby increasing awareness of one’s external surroundings and inner sensations, allowing the individual to step back and reframe experiences. Clinical applications of mindfulness meditation include substance use, stress reduction, tobacco, fixation, and chronic pain.

RELAXATION TRAINING
Furthermore, incorporating relaxation techniques (i.e., deep breathing, progressive muscle relaxation) with therapeutic stretching can help the patient progress in the exercise program and improve activity tolerance. Biofeedback is a treatment that has been shown to be quite effective in the management of pain. The treatment serves to help a patient become
more aware of their physiologic responses to pain or other stressors. In general, relaxation training focuses on helping the patient to acquire self-management tools for reducing tension and decreasing pain. Initial treatment involves basic education explaining how biofeedback-assisted therapies work and helping the patient to understand they are able to control or modulate physiologic functioning of their own bodies by “seeing” or “hearing” their own physiologic function (i.e., breathing, limb temperature, and sweat).

Respiration assessment should always precede heart rate variability (HRV)-related biofeedback due to potential for dysfunctional breathing. Stimulation of the parasympathetic system through biofeedback produces autonomic relaxation, which in turn, directly counteracts stress effects. Clinical application of breathing assessment includes postural or biomechanical deficits such as clavicular or reverse breathing, thoracic versus inappropriate abdominal usage, hyperventilation, or transient apnea.

Representation of reverse breathing. X-axis is time. Y-axis is blood volume pulse heart rate. Notice the discordant inhalation/exhalation and respiratory rate (blue line) patterns in relation to heart rate. (Source: Adapted from Chapter 16 Respiration Assessment. Shaffer F. HRV Biofeedback Tutor 2018. biosourcesoftware.com.)
Skills training include training with basic biofeedback technologies such as respiratory biofeedback, surface electromyography, and/or thermal biofeedback. Techniques include diaphragmatic breathing, progressive muscle relaxation, and autogenic techniques. Patients are encouraged to log their practice sessions in their relaxation practice log. Relaxation training is provided in one-on-one and in group settings usually provided by a health psychologist, biofeedback specialist, or physical or occupational therapist. At the conclusion of formal treatment, patients should be independent with relaxation self-management techniques and be able to incorporate practice and technique integration with normal daily activities and during times of symptom flare-up or elevated levels of distress.

**Work Rehabilitation: Work Conditioning and Work Hardening**

Work conditioning and work hardening are an important core component of work therapy in the field of industrial and pain rehabilitation. This field of modern occupational therapy developed after World War II with a focus of FR in wounded veterans as a means of securing employment in the civilian world after returning from duty. Work therapy also includes acute treatment, job analysis and placement, and FCE. Multidisciplinary
principles were applied to occupational therapy–based work rehabilitation in the 1950s with the development of improved assessment tools and systems and the addition of vocational counseling, medical management, and industrial engineering. In the 1970s, work hardening and conditioning programs were combined with behavioral medicine approaches that focused on reducing abnormal illness behaviors in a more comprehensive treatment of injured workers primarily with low back pain. Eventually, standards were established and subsequently updated by CARF in the late 1980s and early 1990s, respectively. Work rehabilitation usually begins once a patient has reached a treatment plateau in active physical therapy and is unable to return to work due to pain-related impairments (Table 90.12).

Work conditioning is usually concentrated on the physical components of flexibility, strength, coordination, and endurance and involves one discipline of treatment (i.e., physical or occupational therapy). A more multidisciplinary approach is seen with work hardening, which incorporates behavioral and vocational components with a formal focus on return to job-specific tasks or positions. Work conditioning is routinely coordinated with acute medical management as compared to work hardening, which is usually provided later in therapy within the rehabilitation phase of treatment.

Work hardening programs were initially described by Matheson at
Rancho Los Amigos Hospital as a work-oriented program focused on improvement in the client’s productivity versus symptom reduction or increased physical capacity. A “client” can be described as an injured worker with impairments that do not match their job position, a worker with disease-based impairments with diminishing physical capacity, a job applicant who may not have the physical abilities to perform the intended job, or a currently employed worker in transition to a job requiring higher physical function.\(^\text{105}\)

Work hardening is an individualized, work-specific, multi- and interdisciplinary program centered primarily on returning patients (i.e., the injured worker) to their previous level of work or work demands. Work hardening uses real or simulated work tasks and progressively increasing conditioning, flexibility, neuromuscular control, and tolerances (Tables \textit{90.13} and \textit{90.14}). Goals of work hardening include (1) attaining optimal physical tolerances and abilities, (2) maximizing cognitive and psychosocial functioning, (3) developing appropriate worker behaviors, (4) reducing fear and increasing confidence for the resumption of productive work, and (5) identifying problems that may necessitate placement in an alternative job.\(^\text{106,107}\)

\textit{Table 90.13 Components in a Typical Work Hardening Program}
### Table 90.14 Work Hardening Program Standards

1. Improve strength and endurance in relation to return to work goal
2. Simulation of critical work demands, tasks, and environment of the job worker will return to
3. Education: body mechanics, pacing, safety, and injury prevention, promoting worker responsibility and self-management
4. Assess for need for job modifications (i.e., equipment changes or additions, ergonomic modification); availability for on-site job modification assessments
5. Individualized written plan which includes observable and measurable goals
6. Safe work or therapy environment that is appropriate for reaching vocational goals
7. Quality assurance system; outcomes based on program and worker goals
8. Documentation or reporting system that includes initial plan, regularly scheduled team conference notes with monitoring of progress, record of attendance, and compliance
9. Evaluation and modification of work behaviors (i.e., timeliness, attendance, interpersonal relationships)
10. Criteria for admission includes physical recovery sufficient to allow for progressive reactivation and participation for a minimum of 4 h/d for 3 to 5 d/wk along with a defined work goal
11. Criteria for discharge clearly stated (i.e., patient met goal stated in plan, patient did not participate according to program plan, goals not feasible to attain)

An individualized work hardening program incorporates a three-step process which includes an initial formal job analysis to determine specific duties, completion of a baseline work tolerance evaluation, and establishment of the individual work hardening plan. Work hardening standards have been established by a number of groups and may vary depending on the state or the federal governing body.\(^{108}\)

Occupational therapy manages most work conditioning and work hardening treatments as part of the pain rehabilitation program. Assessment of the injured worker is more comprehensive than the assessment done during standard occupational therapist evaluations. Patients are placed in programs of a set number of days, usually 4 to 5 days per week over a 4- to 8-week period. Both programs are highly based on objective measures obtained during the program evaluation which includes tolerances and capacities for lifting, pulling, standing, sitting, reaching, climbing, kneeling, and/or crawling. The treatment program is based on the individual patient’s own job demands and work level (sedentary, light, medium, heavy) and developing improved conditioning.
and tolerances for activities (Table 90.15). Although formal psychological counseling is not a core discipline, these programs are based on helping patients work through and unlearn fear-avoidance beliefs and movement patterns, pain-related fear, catastrophizing, and pain-related anxiety.

**OUTCOMES OF WORK CONDITIONING AND WORK HARDENING PROGRAMS**

Reviews of work conditioning and work hardening programs have found evidence of improved return-to-work rates and fewer work days off in treated patients versus controls.109–111

**Measuring Physical Capacity**

Functional capacity testing provides a means of measuring function by obtaining objective and subjective data with performance-based testing. Testing can be divided into two groups of tests including examining isolated parts of the body or “functional units” (i.e., lumbar spine, shoulder) and the ability of the functional unit to interact with other bodily functional units or activities such as lifting capacity. Lifting capacity many
times involves the interplay of the biomechanical chain of a number of systems. A common example of the biomechanical chain includes transferring forces from a simple lifting task from the ground. Here, forces of the biomechanical chain include transferring forces from the hands through the elbow and shoulder (upper extremity functional unit) to the lumbar spine and hips (lower extremity functional unit) to placing the object and transmitting forces to the floor.

**FUNCTIONAL CAPACITY TESTING**

FCE is a process where the individual’s ability to perform a specific task or physical demands of a job is assessed, bridging the gap between observed physical impairment and work capacity. Matheson describes the FCE as “a systematic method of measuring an individual’s ability to perform meaningful tasks in a safe and dependable basis.” FCEs have three specific purposes: (1) to improve the likelihood that the patient will be safe in a job task, (2) to assist in improving role performance through assessing and identifying functional decrements as a means of providing appropriate treatment or therapy, and (3) to determine presence of disability for bureaucratic or legal entities that may assign a quantifiable level of impairment or apportionment or deny monetary or medical disability benefits.

The FCE is a valuable tool for the physician, vocational counselor, therapist, or employer to establish a specific attainable work goal based on objective data. In theory, by comparing performance demonstrated on the FCE to the required physical job demands of the individual worker, meeting or exceeding all job requirements simulated during testing will help to determine if the patient is safe to return to work. Better performance on an FCE, many times defined by lower number of failed tasks during testing, may be associated with lower risk of recurrence after return to work.

Various types of FCEs can be performed as a means of obtaining specific vocational goals including establishing functional goal setting, disability rating, job and occupation matching, and work capacity evaluation. In general, the FCE can be done before treatment and usually once a patient has reached a treatment plateau or has completed a
formal acute or subacute therapy program. As a means of determining impairment of disability, an FCE may compare measured functional capacity either to the patient’s preinjury baseline abilities or population norms. Accurate measurements of a worker’s preinjury capacities rarely exist, and health care providers are many times inaccurate in estimating the worker’s preinjury functional level or physical capabilities.\textsuperscript{118}

The FCE is used to establish a final level of functioning and includes a statement regarding validity, effort, and pain behaviors. A number of validated FCE tests and programs are available from a number of vendors and are individually designed for specific disorders such as low back pain or upper extremity conditions. These tests can be incorporated into a larger battery of tests used in the formal FCE.

Strength testing may include assessing lifting, carrying, pushing and pulling, work stimulation, and circuit testing (Table 90.16).

</tr>
</tbody>
</table>

Common assessment and job simulation devices include the Purdue Pegboard Test, the Crawford Small Parts Dexterity Test, and the Jebsen Hand Dexterity Test. Testing usually lasts between 2 and 6 hours and may
also be performed over a number of days to observe for fluctuations in performance depending on change in pain or to make sure the patient meets the demands of more continuous work-related physical activity.

Performance reliability is used to determine performance credibility based on the assumption an individual will produce similar outcomes in a series of trials. Additional objective measures may also be assessed including increase in heart rate during and immediately following performance of a strenuous task. Performance credibility can be subjectively determined by assessing for consistency and incongruity between specific tasks and tests. Reports of pain and pain behavior should be specific to the body part and correlate with the level or area of injury. Performances that do not follow normal or expected patterns may also be indicative of less than sincere effort.

Subjective credibility measures may include the individual’s perceived physical strain or effort and may be rated on a number of Ratings of Perceived Exertion scales. In one example, scores range from 6 to 19 (e.g., 6 [“no exertion”], 7 [“very, very light”], 15 [“hard”], to 19 [“very, very hard”]) and increase linearly with exercise intensity. Values of the scale correlate to heart rate (0.8 to 0.9), ranging from 60 to 200 beats per minute.

Grip strength assessment in the FCE serves two important purposes: to assess handgrip strength and to document performance of maximum voluntary efforts. A common test used in many clinics and mentioned in FCE reports is the Jamar hand dynamometer (Sammons Preston Rolyan, Bolingbrook, IL), a calibrated hydraulic hand dynamometer, which measures static grip strength at five grip spans. The therapist is able to produce a graphical representation of the forces produced at five grip positions, revealing a classic “biomechanical curve,” with the lowest force values occurring in positions 1 and 5 and the highest at positions 2, 3, or 4. Inability to produce this bell-shaped curve could cast doubt on the individual’s sincerity of full maximal effort. Force variability of multiple trials can be applied to normative data and can also be used to indicate noncredible performance.
An important and controversial area of FCE results lies in its ability to demonstrate validity, reliability, and accuracy. Lemstra et al. examined the tester’s ability to judge maximal effort in a standard lifting protocol. They found high specificity but low sensitivity (62%), with only a small number of commonly used maximal lifting tests (5 of 17) able to differentiate between maximal and submaximal effort. Results of a functional capacity test can be used in conjunction with a more detailed understanding of the individual’s job description as a means of establishing return-to-work restrictions and formal levels of work (see Table 90.15).

What Does an “Invalid” Test Mean?
In clinical practice, “invalid” test results may be related to the patient demonstrating less than full effort in performance. Although not always consistent with malingering, a number of other causes (i.e., physical ability, disability, pain intensity, and fear of reinjury) have been identified and should be considered when interpreting and making clinical decisions based on an invalid test or test with evidence of less than “full” or “maximal effort” (Table 90.17).

</tbody>
</table>

The result of an FCE can have far-reaching consequences including injured workers having compensation terminated or losing their job or seeing a reduced medicolegal settlement in patients believed to be exhibiting submaximal effort. In order to establish one’s functional capacity, the injured worker must perform at his or her maximal ability or effort. A number of tests have been used as a means of validating effort. Methods used to assess sincerity of effort include Waddell nonorganic signs, pain behavior description, symptom magnification, coefficients of variation, correlations between physical evaluation and function, grip measurements, and temporal relationship between heart rate and increased levels of pain with activity.

**Role of Opioid Management in Pain Rehabilitation**

The role of chronic opioid management in pain rehabilitation remains a controversial topic. Pain rehabilitation programs as early as the 1960s focused primarily in reducing and/or eliminating opioids secondary to fears of tolerance and development of iatrogenic addiction. This approach still characterizes many interdisciplinary programs today. However, the shift to more liberal use of opioids for chronic noncancer pain in the 1990s and the assumption that risk for addiction was minimal led to increased use of opioids in the treatment of chronic pain. The more recent reappraisal of the benefits and potential harms of chronic opioid use has also led to more questions regarding the accuracy of predicting aberrant behavior, and quantifying rates of addiction use has been complicated by an appreciation for not only the potential risk for developing aberrant behaviors, misuse, abuse, and opioid use disorders, including overdose-related deaths. Common adverse effects include cognitive impairment, endocrine dysfunction (sexual dysfunction and opioid induced hypogonadism), mood disorders, and hyperalgesia. In 2016, the Centers for Disease Control and Prevention (CDC) published guideline for opioid management in primary care and recommending nonpharmacologic therapy, including biopsychosocial-based rehabilitation approaches, as preferred first-line treatment to opioid therapy, and if opioid therapy is necessary, their use should be in conjunction with
nonpharmacologic interventions. Unfortunately, patients referred for pain rehabilitation treatment include many opioid treatment “failures” and/or patients additionally managed with other controlled substances (i.e., benzodiazepines and hypnotics). A number of reasons for “failing” should be considered during the evaluation and subsequent treatment planning and include ruling out improper or maladaptive opioid or controlled substance use, poorly designed opioid and/or pharmacologic regimen, poor or limited analgesic response with adverse effects, opioid-induced pain sensitivity, or a combination of these factors (Table 90.18).

</tbody>
</table>

A pain rehabilitation approach may also offer a patient self-management treatment tools with potentially similar or even greater clinical outcomes than those achieved by his or her opioids. Concurrent pharmacologic management may include a structured taper off the currently used opioid, conversion to methadone, or conversion to buprenorphine products. Use of U.S. Food and Drug Administration-approved buprenorphine products for opioid dependence (i.e., buprenorphine and buprenorphine and naloxone) requires specialized licensure by clinicians. Treatment of withdrawal signs and symptoms primarily includes the use of oral or transdermal clonidine, an \( \alpha_2 \)-adrenergic agonist, and adjuvants for withdrawal-related myalgias, insomnia, anxiety, and gastrointestinal distress. The advantage of a structured and relatively controlled environment of most multi- and interdisciplinary treatment programs is that it offers an opportunity for patients with limited or maximized improvement on chronic opioids to reduce or eliminate opioids while at the same time...
learning to apply new nonpharmacologic approaches to management of their pain. This structured environment is ideal for more successfully integrating a more rational polypharmacy approach.

Behavioral medicine treatments can be effectively incorporated into a structured multi- or interdisciplinary rehabilitation-based program. Treatment of the chemically dependent patient can include two types of therapies: (1) psychotherapeutic strategies and (2) mind–body therapies.\(^{149}\)

Psychotherapeutic strategies include supportive-expressive psychotherapy, drug counseling, family therapy, and motivational enhancement therapy. Mind–body therapies, in general, include CBT, group support and education therapy, and relaxation therapy (i.e., deep breathing, imagery, hypnosis, and biofeedback) (Table 90.19).

Patients can be successfully weaned or have their opioid dose decreased during an FR rehabilitation-based approach. Active opioid withdrawal did not adversely impact short-term outcomes following a 3-week outpatient pain program,\(^{150}\) and physical and emotional functioning were favorable in a fibromyalgia cohort that completed an interdisciplinary pain rehabilitation program which included withdrawal of opioids, nonsteroidal anti-inflammatory drugs, benzodiazepines, and muscle relaxants.\(^{151}\)

**Conclusion**

Rehabilitation is a continuous process, relying on a comprehensive,
pragmatic approach that focuses on an individual’s physical impairments and function-related disability. The field of modern pain rehabilitation developed along with the growth of a number of medical specialties (i.e., anesthesia, rehabilitation medicine, psychiatry, neurology, and occupational medicine), physical and occupational therapy, and health psychology. Pain rehabilitation assessment and treatment is based on a biopsychosocial model. A narrower dualistic biomedical model may fail to adequately assess and help patients to manage the complexities of ongoing pain, affective distress, and environmental and social issues. Treatment goals in pain rehabilitation programs include improving psychosocial functioning; decreasing pain; improving aerobic conditioning; and facilitating safe and successful return-to-work status, return to leisure pursuits, and activities at home and in the community.

A pain rehabilitation approach includes planning and coordinating various medical interventions (i.e., pharmacologic and nonpharmacologic), educational activities, and coordinating a patient’s participation with specific rehabilitation-based disciplines (i.e., physical and occupational therapy, pain psychology, relaxation, and other mind–body therapies). Vocational rehabilitation can serve as an additional treatment option and may be coordinated in patient-specific work-based therapies such as work conditioning and work hardening programs. Work conditioning and work hardening may be more specific levels of treatment for the injured worker as a bridge to progress patients after completing acute rehabilitation and more closely simulating work activities, respectively, prior to returning to previous levels of sport, function, or work. Functional capacity testing may be used as a more objective means of establishing a baseline level of function, establish treatment and work goals, or finalize return-to-work level of functioning. Validity measures may also help to identify physical and psychosocial factors that are contributing to the injured worker’s level of functioning and clarify discrepancies in tolerances and effort.

The pain rehabilitation clinician must work with the patient in conjunction with various stakeholders (i.e., case managers, insurance providers and adjustors, legal personnel, and family members). The clinician’s role may include additional responsibilities beyond not only working to help patients decrease pain and increase function but also as an
advocate for the patient with insurers, employers, and rare circumstances as adjudicator, helping the insurer or employer to decrease or identify inconsistent or fraudulent patient behavior. Optimal patient outcomes are facilitated by the clinician and team members establishing a therapeutic environment with the patient characterized by ongoing coordination of care, communication between treatment team members and the patient, providing consistency of message, and collaboration between team members.

This chapter on assessment and treatment of substance use disorders provides guidance, particularly for practitioners interested in pain medicine, on how various forms of substance use disorders are diagnosed and managed clinically. Because detection and management of opioid use disorder poses a major concern for physicians using opioids to treat patients, and because diagnosis of opioid use disorder in this context is often confounded by pain issues, the chapter focuses special attention on this complex clinical conundrum. More specifically, the chapter focuses on patients with chronic nonmalignant pain (CNMP) because issues related to opioid use disorder are more vexing in these patients than in patients with cancer or other life-threatening illnesses.

Various surveys indicate that individuals with chronic pain disorders are more likely to have substance use disorders than are individuals in the general population, and individuals with substance use disorders also have high rates of pain disorders. Therefore, practitioners treating pain disorders are likely to encounter patients with substance use disorders and will need to know how to screen for and recognize these disorders, diagnose these disorders, make appropriate referrals for and/or treat these disorders, monitor for these disorders during ongoing pain treatment, and manage therapy for chronic pain in the context of these disorders.

The first section of the chapter presents the assessment and treatment of all major forms of substance use disorders from the perspective of addiction medicine. The second section focuses on assessment and treatment of opioid use disorder from the perspective of the pain specialist.
The panoply of substance-related disorders includes intoxication, withdrawal, substance use disorder (otherwise known as addiction), and substance induced psychiatric disorders (e.g., psychosis, mood disturbance, or anxiety caused directly by the use of the substance). Substance use disorders occur with a variety of commonly used substances such as alcohol, cannabis, cocaine, opioids, sedative/hypnotics, stimulants like amphetamines and methylphenidate, inhalants, psychedelic agents, and tobacco. A standardized set of criteria characterizing these disorders is provided in the Diagnostic and Statistical Manual of Mental Disorders (5th ed., DSM-5).\(^4\) Intoxication and withdrawal obviously differ by substance and can generally be diagnosed through history and physical examination. The criteria for substance use disorder which will be covered in greater detail in the following text are identical across substances.

What is currently termed a substance use disorder in DSM-5 was known as either substance abuse or dependence in prior versions of the DSM, with abuse being considered a milder form of the disorder. The use of the term dependence generated some confusion and controversy. In contrast to a commonly held conception of “dependence” as notating purely physiologic changes that occur in response to repeated exposure to a substance, in prior versions of the DSM, “dependence” referred to a syndrome of physiologic signs and symptoms combined with an array of behavioral disturbances. Prior to the advent of DSM-5, some suggested that the phrase “substance dependence” referring to the Diagnostic and Statistical Manual of Mental Disorders (4th ed., text rev., DSM-IV-TR) syndrome be replaced with the term addiction to avoid confusion between purely physiologic dependence and the syndrome of substance dependence.\(^5\) Others felt that the term addiction has negative connotations leading to stigmatization. A compromise was settled on with DSM-5 using the term substance use disorder. It is commonly understood that the terms addiction and substance use disorder are essentially synonymous and interchangeable.
SCREENING AND RECOGNITION

Clearly, some initial evidence must arise through screening to suggest that a patient has a substance use disorder to trigger a thorough diagnostic assessment. In many cases, screening and diagnostic evaluation may overlap. The idea of “universal precautions” in pain medicine has been advanced as one way to detect potential substance use problems in all pain patients, so there may be some value in routine use of some or all of these screening procedures. However, it is often too time-consuming and cumbersome to perform them in primary care, and there is no strong evidence that universal precautions or routine screening leads to better outcomes.

History

Generally, a thorough history of substance use obtained through a matter-of-fact, nonjudgmental interviewing style will provide a great deal of information or even a formal diagnosis. Most patients are not aware of guidelines for safe quantities of alcohol consumption and will readily divulge the amount of their drinking. Many patients are more reluctant to discuss use of illicit substances, but some will freely admit to such use if they do not fear sanctions or punishment. Oftentimes, this openness is more likely to occur during initial intake. Patients may be less forthright during the course of treatment if they believe they have something to lose by admitting to use. If time allows, it is worth asking explicitly about frequency and quantity of use for each class of substance along with route of administration. It is also quite important to ask about any history of current and past problematic substance use, as such problematic use is known to increase the risk of recurrence in the context of pain management. It is useful to know what types of substance use disorders treatment, if any, have been helpful for the patient in the past.

Recommended safe quantities of alcohol use consist of no more than four standard drinks per day (or more than 14 total per week) for men and three standard drinks (or more than 7 total per week) for women. The recommended quantities are less for women because women tend to have less total body water and thus a lower volume of distribution for alcohol. Quantities of different forms of alcohol that define a standard drink are
listed in Table 91.1. If patients acknowledge regularly consuming more than the recommended amounts or describe heavy drinking such as five or more drinks on one occasion for men or four or more for women, a more thorough diagnostic evaluation for alcohol use disorder should be pursued.

For illicit substances, any suggestion of more than occasional recreational use of marijuana should prompt a more thorough diagnostic evaluation. It is also important to look for tobacco use disorder, as this disorder has been associated with increased risk of opioid misuse in a number of studies.\(^1\),\(^9\)

**Physical Examination**

Signs of possible substance use problems evident on physical exam include hypertension (common with excessive alcohol use), track marks indicative of recent or past injection drug use, pupillary constriction or dilation, inflamed nasal turbinates from intranasal substance insufflation, wheezes or rhonchi on lung exam from substance smoking, enlarged, tender liver from excessive alcohol use, other substance toxicity or hepatitis, or any stigmata of excessive alcohol use such as flushed facies, spider angiomas, palmar erythema, etc. Any of these findings should trigger further screening and possible thorough diagnostic evaluation.

**Laboratory**

Routine blood work can provide an indication of excessive alcohol use. Suggestive findings include elevations in liver transaminases or
macrocytic, hyperchromic red blood cells related to alcohol’s interference with folate absorption, and subsequent folate deficiency. Positive serologies for past or current hepatitis B or C infection or HIV infection would raise concerns about a substance use–related mode of transmission.

In addition, specific laboratory testing to detect presence of substances in body fluids offers a convenient component of screening. Typically, urine is tested, although tests can also be readily performed in oral fluid or blood. Substances that have been used are likely to remain present in urine for a longer period than they will in other body fluids (Table 91.2). For urine testing, a screening test is typically performed via immunoassay. When needed, confirmatory tests using high-performance liquid chromatography/mass spectrometry or gas chromatography/mass spectrometry can be ordered. It is important to note that the routine urine assay for opioids does not detect oxycodone, methadone, buprenorphine, or fentanyl which each requires a specific screening test. Heroin can only be detected shortly after use if its intermediate metabolite, 6-monoacetylmorphine, is present. Subsequently, 6-monoacetylmorphine is rapidly metabolized to morphine. If morphine appears in a urine toxicology specimen, it could represent either pharmaceutical morphine use or heroin use. It is difficult to detect alcohol in urine, blood, oral fluid, or breath unless the use has been quite recent. However, the alcohol metabolites, ethyl glucuronide or ethyl sulfate, indicating recent alcohol use can be detected in urine, blood, or hair.

**Self-report Questionnaires**

A number of self-report questionnaires have been designed to help in screening for substance use disorders, and these can be utilized prior to, concurrent with, or subsequent to the history, physical, and laboratory evaluation to help determine whether a patient warrants more thorough diagnostic evaluation. Although the instruments described in the following text have definite utility in primary care and general populations as well as selected samples such as psychiatric patients, they have not been tested in pain patients.

In screening for alcohol use disorders, the currently most frequently used instruments are the Alcohol Use Disorders Identification Test (AUDIT)\(^\text{14}\) and the Michigan Alcoholism Screening Test (MAST).\(^\text{15}\) The AUDIT has 10 items related to quantity and frequency of alcohol consumption and to maladaptive behaviors associated with alcohol use and can be completed in about 5 minutes. Each item is scored 0 to 4. A score of 8 or more for men under age 60 years or 4 or more for women or men over age 60 years are considered positive screens indicative of need for further assessment. A shorter version of the AUDIT, the AUDIT-C, which asks only 3 questions related to consumption has also been validated as a screening instrument in primary care settings.\(^\text{16}\) The MAST contains 25 questions and focuses more on problem behaviors associated with alcohol use. Each item counts for 1 point, and a score of 6 or more indicates a positive screen with need for further assessment. There are shorter versions of the MAST which also appear to function as adequate screening...
In the context of managing pain patients where urine toxicology should be readily available, self-report instruments to screen for drug use problems are probably less useful than a positive urine toxicology. However, if use of a self-report screening instrument is desired, a commonly used instrument is the Drug Abuse Screening Test (DAST). The DAST is based on the MAST and has 28 items concerning both intensity and frequency of drug use and problematic behaviors associated with drug use. As with the MAST, each item counts for 1 point, and a score of 6 or more points to the needs for further assessment. Shorter versions of the DAST also exist.

A much briefer option to screen for a possible drug use disorder is the single item question, “How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?” This single item performed as well as the DAST-10 at detecting a substance use disorder.

One recently validated instrument that screens for all major substances is the Tobacco, Alcohol, Prescription Medication, and Other Substance Use (TAPS) tool, which is reasonably brief and can be self-administered.

**PRESCRIPTION DRUG MONITORING PROGRAM**

Most states in the United States provide prescription drug monitoring programs (PDMPs). How they function and what the requirements are to access them vary widely from state to state. They do provide information on most controlled substance prescriptions that individual patients have obtained. Checking the PDMP can be very helpful in verifying the prescription medications that the patient is reporting via history.

**DIAGNOSTIC ASSESSMENT**

As noted earlier, criteria provided in DSM-5 represent the most standard way to make a diagnosis of a substance use disorder. At times, it proves fruitful to interview family members if the patient is not forthcoming.

Table 91.3 contains DSM-5 criteria for opioid use disorder as an example. The criteria for a substance use disorder are identical across all substances. To determine the presence or absence of the diagnosis, the
interviewer should focus one by one in turn on each substance of potential relevance and systematically go over each of the criteria with the patient for each substance.

**TABLE 91.3 Diagnostic and Statistical Manual of Mental Disorders, 5th Edition, Diagnostic Criteria for Opioid Use Disorder**

A problematic pattern of opioid use leading to clinically significant impairment or distress, as manifested by at least two of the following occurring within a 12-mo period:

1. Opioids are often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control opioid use.
3. A great deal of time is spent in activities necessary to obtain the opioid, use the opioid, or recover from its effects.
4. Craving, or a strong desire or urge to use opioids
5. Recurrent opioid use resulting in a failure to fulfill major role obligations at work, school, or home
6. Continued opioid use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of opioids
7. Important social, occupational, or recreational activities are given up or reduced because of opioid use.
8. Recurrent use of opioids in situations in which it is physically hazardous
9. Continued opioid use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance
10. **Tolerance**, as defined by either of the following:
    a. A need for markedly increased amounts of opioids to achieve intoxication or desired effect
    b. A markedly diminished effect with continued use of the same amount of opioid
11. **Withdrawal** as manifested by either of the following:
    a. The characteristic opioid withdrawal syndrome
    b. Opioids (or a closely related substance) are taken to relieve or avoid withdrawal symptoms.

This criterion is not considered to be met for those taking the substance solely under appropriate medical supervision.

Mild = 2–3 symptoms.
Moderate = 4–5 symptoms.
Severe = 6 or more symptoms.

There are 2 physiologic criteria, tolerance and withdrawal, and 9 behavioral criteria. Two or more of the 11 criteria must be present at any one time over a 12-month period to make the diagnosis. If 2 to 3 criteria are present, the disorder is classified as mild; if 4 to 5 are present, as moderate; and if 6 or more, as severe. The physiologic criteria are not
considered to be met for individuals taking the substance under medical supervision. For example, a pain patient treated chronically with opioids who is taking them precisely as prescribed might display tolerance to the effects of opioids and withdrawal signs and symptoms if the medication is stopped, but in this situation, these two criteria would not be applied to the diagnosis of opioid use disorder. Similarly, this scenario could occur with an attention-deficit/hyperactivity disorder patient treated chronically with stimulants, or with an anxiety disorder patient treated chronically with benzodiazepines. Conversely, an individual might not have either tolerance or withdrawal but could have the DSM-5 defined substance use if he or she meets at least two of the behavioral criteria, although this scenario occurs rarely in clinical practice. Inspection of the criteria reveals that questions about each criterion are unlikely to be interpreted by patients as critical or threatening and unlikely to engender resistance or deception, particularly if posed in a matter-of-fact, nonjudgmental fashion. Although this procedure sounds time-consuming, it frequently can be accomplished in a matter of minutes for each substance of concern. As mentioned at the outset, the diagnosis of opioid use disorder in a patient with CNMP being treated with opioids may not be as straightforward as simple application of the DSM-5 criteria and is discussed in detail in the following text.

Diagnosis of a substance use disorder certainly should not preclude appropriate interventions for a pain problem and in rare instances, with appropriate monitoring and safeguards, may not categorically preclude opioid treatment of chronic pain.

Co-occurring Psychiatric Disorders
Mental health disorders frequently co-occur with substance use disorders.\textsuperscript{21,22} It is likely that chronic pain patients who have substance use disorders will have another non–substance-related co-occurring mental health disorder.\textsuperscript{23} Oftentimes, co-occurring mental health and substance use disorders interact with negative synergy so that exacerbation of one disorder in turn exacerbates the other.\textsuperscript{24} Thus, if a pain patient does have a substance use disorder, it is imperative to evaluate that patient for other co-occurring mental health disorders and provide appropriate clinical intervention (including pharmacotherapy and/or psychotherapy) for any
that are diagnosed.

MONITORING DURING ONGOING PAIN TREATMENT

Even if a patient does not manifest a substance use disorder at the onset of chronic pain treatment, a disorder can certainly arise during the course of treatment. Maintaining vigilance for the development of a disorder involves both observation of the patient for behavioral evidence and routine monitoring techniques. Behaviors that may increase the index of suspicion include missing appointments, having medication shortages, failure to pay bills, or a markedly changed affect during appointments.

Depending on the setting and resources available, it may prove worthwhile to establish routine, monitoring procedures for all pain patients even in the absence of concern. This approach normalizes these procedures, allows patients to expect them, and creates structure that may actually help the patient to feel supported while removing any sense of stigma or accusation that may supervene if the procedures are applied only for cause. The procedures that will be utilized should be specified at the outset of treatment in a written treatment agreement. One obvious routine monitoring procedure to consider is urine toxicology testing as described earlier.

Another potential procedure is unscheduled medication call backs. For this procedure, patients are telephoned and asked to return to the office within 24 hours with all their outstanding medication. When the patients come in, pill counts are performed to ensure that all expected outstanding medication is accounted for. It is also possible to obtain a urine toxicology specimen at that time.

TREATMENT AND/OR REFERRAL

Some general comments about treatment and referral will be made, and then specific interventions for use disorders involving each particular class of substances will be outlined. Most physicians get virtually no training or experience in treatment of substance use disorders and, therefore, often feel helpless or hopeless in the face of these disorders. Although many patients with these disorders who do get treatment get it in specialized settings that operate in parallel to and oftentimes outside of mainstream
medicine, many patients will refuse a referral to such settings, and a growing body of literature supports the efficacy of physician intervention as a reasonable first attempt at treating these disorders.

**Brief Interventions**

Brief office interventions conducted by physicians have demonstrated efficacy in reducing alcohol consumption for patients with problematic alcohol use that does not rise to the level of an alcohol use disorder but very limited if any benefit for alcohol use disorder.\textsuperscript{26,27} Motivational interventions (see following text) which can be incorporated into brief office interventions have demonstrated modest efficacy in nonalcohol substance use disorders.\textsuperscript{28}

Brief interventions should be delivered in a manner that is matter-of-fact, nonjudgmental, supportive, and empathic and definitely not in a manner that is confrontational. The first step consists of stating concern about the patient’s level of alcohol use (or any level of illicit drug use). It is helpful to give the patient direct examples from his or her medical record including bothersome symptoms, physical findings, specific diseases, or lab abnormalities. The next step involves giving direct advice to cut down (or quit) the substance use along with an offer to help. If the patient is not receptive to this advice, and the situation is not emergent, the physician can encourage him or her to consider it carefully and reflect on why he or she considers ongoing use to be a reasonable course of action. A follow-up can be arranged for further discussion.

If the patient appears receptive to advice to cut down or quit, the physician helps the patient to establish a specific goal to cut down or abstain (for a use disorder). Also, the physician provides explicit behavioral suggestions such as avoiding acquaintances who use, avoiding places where use has previously occurred, or seeking social support for quitting, including attending mutual-help groups such as Alcoholics Anonymous or Narcotics Anonymous. A follow-up appointment should be scheduled to monitor progress.

If the patient has alcohol use disorder and is willing to try for abstinence, the brief intervention could be combined with prescription of an appropriate alcohol treatment medication as described in the following
text. If the patient has developed opioid use disorder, the brief intervention could be combined with a recommendation to try buprenorphine also described in the following text. If the pain physician treating the patient has a federal waiver to prescribe buprenorphine, arrangements could be made to stop any opioid analgesic the patient may currently be taking and make a switch to buprenorphine.

**Specialty Substance Use Disorders Treatment**

If a referral to a specialized substance use disorders treatment provider is needed, the referral could be made to an individual practitioner, another physician, psychologist, social worker, or chemical dependency counselor who specializes in substance use disorders treatment and could work with the patient in a private office setting using one or more of the psychotherapeutic or behavioral interventions detailed in the following text. Frequently, the referral will be made to an addiction treatment or substance use disorders program or agency. The American Society of Addiction Medicine publishes Patient Placement Criteria that can aid in determining what level of addiction treatment is appropriate for a given patient. These criteria have not, however, been fully scientifically validated and are based largely on expert opinion.29,30

**Medically Supervised Withdrawal**

Some patients, who manifest withdrawal when stopping their substance use, may need medically supervised withdrawal (also known as detoxification) to stop the substance safely and engage in treatment. The most common substances which require supervised withdrawal are alcohol, sedative-hypnotics, and opioids, although patients may have very unpleasant withdrawal symptoms from marijuana, cocaine, or amphetamines and need some support and monitoring. Medically supervised withdrawal can be accomplished on an outpatient or inpatient basis depending on the severity of the withdrawal. Clearly, alcohol or sedative-hypnotic withdrawal can be life-threatening. Usually, benzodiazepines are prescribed over several days in tapering doses.31 Supervised opioid withdrawal for physiologic dependence on opioids can be accomplished using methadone in a licensed treatment program32 (see
the following text) or with buprenorphine\textsuperscript{33} by appropriately qualified physicians. Alternatively, the $\alpha_2$-adrenergic agonist, clonidine, can be prescribed to attenuate opioid withdrawal signs and symptoms and tapered over several days.\textsuperscript{34} Some paradigms, known as ultrarapid opioid withdrawal, have been developed whereby opioid withdrawal is precipitated with an opioid antagonist such as naloxone or naltrexone under sedation or general anesthesia to complete the withdrawal in a brief period of time. These rapid procedures have no better outcomes than more gradual withdrawal but do have more adverse events such as pulmonary problems and psychiatric instability so they are not recommended.\textsuperscript{35} It is very important to understand that medically supervised withdrawal (detoxification) alone does not constitute treatment. If medically supervised withdrawal is not immediately followed by more definitive substance use disorders treatment, relapse is almost universal.

**Opioid Maintenance Treatment**

Many patients with primary opioid use disorder do not want to undergo withdrawal or have tried it previously with subsequent relapse. These patients might be referred to a federally licensed opioid treatment program.\textsuperscript{36} These programs provide opioid maintenance therapy with either methadone or buprenorphine. Because these medications have long half-lives, they can prevent the emergence of opioid withdrawal when taken on a once a day basis. (More detail on the clinical use of these medications for the treatment of opioid use disorder is provided in the following text.) The structure of the program is largely dictated by federal and state regulations. Patients must have a minimum of a 1-year history of opioid use disorder. In the early stages of treatment, patients must come to the clinic daily for observed doses of medication with take home doses of medication for weekend days when the clinic is closed. The maximum allowed first dose of methadone is 30 mg with subsequent gradual dose escalation to an optimally therapeutic dosage. A physical examination and basic laboratory tests are required as is periodic urine toxicology testing. Regular counseling visits are delivered as needed. As patients stabilize in treatment, as evidenced by regular attendance at dosing visits and other appointments, remaining on a stable dose of medication, and ceasing illicit
substance use as demonstrated by drug-free toxicology specimens, take home doses of medication become available so that patients do not have to attend clinic every day. After 2 years of continuous treatment, stable patients on methadone may receive up to a maximum of 1 month’s take home doses. Patients treated with buprenorphine in these settings can gain access to take home doses whenever they meet criteria for stability without regard to time in treatment. Opioid maintenance treatment has exceptionally good outcomes not only in terms of reducing illicit opioid use but also in terms of reducing other substance use, reducing mortality and morbidity, reducing criminal justice involvement, and improving employment.\textsuperscript{37,38} It is considered to be as cost-effective as other potential life saving treatments such as coronary bypass surgery or renal dialysis.\textsuperscript{39} All physicians are permitted to prescribe methadone for pain management, but only specially licensed facilities can order and dispense methadone specifically for opioid use disorder. Prescription of methadone for pain in patients with signs of opioid use disorder has obvious inherent risks and should be undertaken with careful monitoring precautions in place.

**Intensive Outpatient Treatment**

For patients who do not have opioid use disorder or who have opioid use disorder but decline maintenance therapy and have completed withdrawal, intensive outpatient treatment is often employed. This type of treatment is generally abstinence-based in that it emphasizes the goal of total abstinence from alcohol and all illicit substances. Some programs would accept pain patients on prescribed opioid therapy if the patient has a goal of abstinence from other substance use. Intensive outpatient treatment involves behavioral interventions usually via a group format with several meetings per week over a 4- to 12-week period so that patients receive up to 72 or more hours of total treatment.\textsuperscript{40} Frequent urine toxicology testing is also typically performed. The therapeutic content of the group sessions varies but often includes one or more of the types of behavioral interventions described in the following text. Attendance at mutual help groups such as Alcoholics Anonymous is strongly encouraged. Not surprisingly, patients who complete these programs have better outcomes than those who drop out. Depending on the setting and patient...
characteristics, the dropout rate can be substantial.

**Inpatient Treatment**
For patients who fail outpatient treatment and who can obtain funding for it, inpatient treatment is an option. Inpatient treatment could be as brief as a few days \(^41\) but frequently lasts 28 days and can be extended for many months in a model known as a therapeutic community \(^42\) for patients who have severe, intractable substance use disorders that do not respond to any other interventions. Ongoing outpatient treatment subsequent to completion of inpatient treatment is recommended. Inpatient treatment, like intensive outpatient treatment, is almost always abstinence-based. Many short-term inpatient programs would accept pain patients on opioid therapy if the patients committed to abstinence from other substances. Most therapeutic communities would not accept patients receiving opioid therapy even for pain. The content of the care in inpatient treatment does not differ substantially from the content delivered in intensive outpatient treatment, but the inpatient setting provides a controlled environment that minimizes the risk of relapse and can compress more hours of actual treatment into a shorter overall time frame. \(^43\) In the aggregate, it appears that the quantity or “dose” of behavioral treatment received rather than the setting in which it occurs serves as the key mediator of outcome.

**Specific Behavioral Treatments**
Numerous types of behavioral interventions are used to treat substance use disorders, and many have been empirically validated. Mastery of specific techniques often requires considerable training and practice. Most studies comparing various behavioral intervention techniques find, as with setting, that the specific technique is less important than the total amount of behavioral intervention received. Many practitioners do not deliver the specific interventions in their pure form. In addition to the amount of intervention received, other important mediators of success are the skill of the specific therapist and the therapeutic alliance achieved between the therapist and patient regardless of what technique is used. \(^44\) To impart at least passing knowledge of the names and basic philosophies of the more common techniques, brief descriptions are provided.
Motivational Interviewing
Motivational interviewing is a directive, patient-centered counseling style for eliciting behavior change by helping patients explore and resolve ambivalence. Compared with nondirective counseling, it is more focused and goal-directed. The examination and resolution of ambivalence is its central purpose, and the counselor is intentionally directive in pursuing this goal using the following techniques.\(^45\)

- Seeking to understand the person’s frame of reference, particularly via reflective listening
- Expressing acceptance and affirmation
- Eliciting and selectively reinforcing the client’s own self motivational statements expressions of problem recognition, concern, desire and intention to change, and ability to change
- Monitoring the client’s degree of readiness to change and ensuring that resistance is not generated by jumping ahead of the client
- Affirming the client’s freedom of choice and self-direction

Relapse Prevention Therapy
Relapse prevention is a cognitive-behavioral intervention based on the notion that learning processes play an important role in the development of maladaptive behavior patterns. As applied to substance use disorders, relapse prevention explores the positive and negative consequences of continued substance use, encourages self-monitoring to recognize substance cravings early on, identifies high-risk situations for use, and develops strategies for coping with and avoiding high-risk situations and the desire to use.\(^46\) A central element of this treatment is anticipating the problems that patients are likely to meet and helping them develop effective coping strategies. The skills that patients learn through relapse prevention therapy remain after the completion of treatment, and many maintain the gains they made in treatment throughout the year following treatment.

Drug Counseling
Drug counseling focuses directly on reducing or stopping the patient’s substance use. It also addresses related areas of impaired functioning such as employment status, illegal activity, and family/social relationships as
well as the content and structure of the patient’s recovery program. Through its emphasis on short-term behavioral goals, drug counseling helps the patient develop coping strategies and tools for abstaining from substance use and then maintaining abstinence. The addiction counselor encourages 12-step participation and makes referrals for needed supplemental medical, psychiatric, employment, and other services. Individuals are encouraged to attend sessions one or two times per week.47

12-Step Facilitation Therapy
Twelve-step facilitation consists of a structured and manual-driven approach to facilitating early recovery from substance use disorders. It is intended to be implemented on an individual basis in 12 to 15 sessions and is based in behavioral, spiritual, and cognitive principles that form the core of 12-step fellowships such as Alcoholics Anonymous and Narcotics Anonymous. Twelve-step facilitation seeks to achieve two general goals in patients with substance use disorders: acceptance of the need for abstinence from substances and surrender, or the willingness to participate actively in 12-step fellowships as a means of sustaining sobriety. These goals are in turn broken down into a series of cognitive, emotional, relationship, behavioral, social, and spiritual objectives.48 Twelve-step facilitation has shown excellent results for patients with alcohol use disorder but shows less promise for patients with drug use disorders.49

Contingency Management
Contingency management treatments are based on operant conditioning principles as elucidated by B.F. Skinner: If a behavior is reinforced or rewarded, it is more likely to occur in the future.50 In many contingency management treatments, patients leave urine specimens multiple times each week and receive explicit rewards for each specimen that tests negative for drugs. These rewards often consist of vouchers that have a monetary value and can be exchanged for retail goods. However, contingencies that lack monetary value can also be used. For example, in opioid treatment programs or office-based buprenorphine treatment, the frequency of attendance can be contingent on drug-free urine specimens. Patients who provide drug-negative urine specimens get more take home medication or larger prescriptions, and those who provide drug-positive
specimens have their take home privileges reduced or have to pick up a prescription more frequently. Contingency management has been demonstrated to reduce substance use significantly in numerous studies, but its implementation in clinical practice has lagged, although it has now been implemented widely and successfully throughout the Veterans Affairs health care system.

**Pharmacotherapies**
Currently, there are three U.S. Food and Drug Administration (FDA)-approved medications for the treatment of alcohol use disorder (disulfiram, acamprosate, and naltrexone) and three available FDA-approved medications for the treatment of opioid use disorder (methadone, buprenorphine, and naltrexone). All of the alcohol treatment medications can be used by all physicians, including pain specialists if desired, within the scope of their own practice. Although methadone can be ordered and dispensed for the treatment of opioid use disorder only within licensed clinics, buprenorphine can be prescribed by appropriately qualified physicians (as described in the following text) outside of licensed clinics. Naltrexone for either alcohol or opioid use disorders is not likely to have much utility in pain patients because of its antagonism of μ-opioid receptors and its tendency either to precipitate opioid withdrawal in patients on opioids or to block the effects of opioid analgesics. Nevertheless, it may rarely have potential benefit in selected pain patients not currently on opioids. There are currently no FDA-approved pharmacotherapies for use disorders involving other substances such as cocaine, methamphetamine, sedative-hypnotics, or cannabis, so these disorders must be treated with behavioral interventions alone.

Disulfiram
By inhibiting aldehyde dehydrogenase, a key enzyme in the major metabolic pathway for ethanol, disulfiram causes accumulation of acetaldehyde after alcohol ingestion. The buildup of acetaldehyde usually causes an “alcohol–disulfiram reaction” that typically ensues within minutes of alcohol ingestion. Different individuals exhibit varying degrees of the reaction which may last for several hours. Signs and
symptoms of the alcohol–disulfiram reaction include diaphoresis, flushing, tachycardia, hypotension, nausea, vomiting, and headache. The concept behind the idea of disulfiram is that patients taking disulfiram will fear getting an uncomfortable reaction and thus will be deterred from drinking alcohol. To some extent, change occurs during the informed consent discussion between physician and patient at the time the patient agrees to take disulfiram. During that discussion, the patient may, by agreeing to try disulfiram, be arriving at a decisive interest in achieving abstinence from alcohol.

Obviously, patients must have achieved some time of abstinence before starting disulfiram to avoid provoking the alcohol–disulfiram reaction. Typically, 48 hours of abstinence proves sufficient. The usual starting dose of disulfiram is 250 mg per day. Genetic variability may determine sensitivity to the medication, and patients with high levels of aldehyde dehydrogenase may be less sensitive to the effects of disulfiram and require higher doses of medication, up to 500 mg per day. Some patients may not tolerate 250 mg per day and should have the dose reduced to 125 mg per day.

Disulfiram is associated with a number of mild side effects such as headache, metallic aftertaste, erectile dysfunction, mild fatigue or sedation, and rash. Such side effects frequently dissipate spontaneously or with a dosage decrease. Much more serious adverse events such as optic neuritis, peripheral neuropathy, hepatic injury, or psychotic symptoms or delirium, although rare, necessitate immediate disulfiram discontinuation. Disulfiram-induced hepatic injury can occur idiosyncratically at an estimated rate of 1/25,000 to 1/30,000 patient treatment years. Disulfiram-induced hepatic injury can rapidly proceed to total liver failure. It most usually occurs within the first 6 months of treatment. Symptoms include extreme fatigue, malaise, anorexia, fever, jaundice, scleral icterus, nausea, vomiting, and bilirubinuria. Baseline liver function tests should be obtained prior to initiation of disulfiram treatment and then at 1- to 2-month intervals during the first 6 months of treatment. With the decreased risk of disulfiram-induced hepatic injury after the first 6 months of treatment, liver monitoring can subsequently be done every 3 to 6 months if treatment continues. Many patients who might be considered for
disulfiram therapy present with moderately elevated transaminases related to alcohol use (particularly in the context of hepatitis C). These modest transaminase elevations do not represent a total contraindication to disulfiram therapy. Very rapid rises in bilirubin and transaminases occur in disulfiram-induced hepatic injury and indicate the need to stop disulfiram at once. If the medication is discontinued promptly, the signs and symptoms of liver injury typically fully resolve. If the medication is not stopped, total hepatic failure and death can supervene unless a liver transplant is performed.

Patients with preexisting cirrhosis or other serious liver disease generally are not good candidates for disulfiram. Other contraindications include pregnancy or lactation, history of prior hypersensitivity to disulfiram, or significant coronary artery disease. The latter group could experience myocardial ischemia during a severe alcohol–disulfiram reaction.

Disulfiram has greater benefit with monitoring of medication administration. Although the largest study to date demonstrated that disulfiram dosed at 250 mg per day over 1-year did not lead to increased abstinence rates or longer time to first drink compared to placebo, it did lead to significantly fewer drinking days over the study year.54

Acamprosate

Acamprosate, which has seen widespread use in Europe for many years, received FDA approval for the treatment of alcohol use disorder in 2004. Acamprosate is believed to modulate both the major excitatory system in the brain, the glutamate system, as well as the major inhibitory system, the \( \gamma \)-aminobutyric acid (GABA) system. Alcohol interacts with these systems as well, but when alcohol is stopped after chronic exposure, glutamatergic hyperactivity and GABA hypoactivity contribute substantially to the alcohol withdrawal syndrome. Acamprosate theoretically acts to counteract these imbalances and so may attenuate symptoms associated with subsyndromal, prolonged alcohol withdrawal such as insomnia, anxiety, and restlessness which could provoke alcohol cravings and relapse.55,56 Acamprosate also may diminish reinforcement derived from alcohol ingestion55 and the amount of alcohol consumed by patients in
treatment who do experience relapse.\textsuperscript{57} Numerous controlled studies of acamprosate demonstrated higher total abstinence rates and longer time to relapse for acamprosate compared to placebo.\textsuperscript{58} For reasons that remain incompletely understood, acamprosate failed to show efficacy in two large clinical trials conducted in the United States.\textsuperscript{59,60} It has been proposed that subjects in the US studies may not have experienced sufficient prolonged subsyndromal withdrawal to benefit from acamprosate.\textsuperscript{61}

Acamprosate has very limited oral bioavailability. It achieves steady state after 5 days and is not metabolized by the liver but excreted unchanged in the urine. The usual dose is 666 mg (two 333-mg tablets) three times daily. The labeling indicates that acamprosate should be started after a modicum of abstinence has been achieved, but there are no safety issues if acamprosate is taken concomitantly with alcohol and abstinence is not essential. In fact, acamprosate should be continued in the patient who relapses to alcohol use.

It is recommended that a serum creatinine level to evaluate kidney function be obtained prior to initiation of therapy because the dose should be lowered in patients with impaired kidney function. Acamprosate is FDA category C, so women of childbearing age must use an effective method of birth control when on acamprosate. All patients should be monitored for suicidal thoughts because such thoughts occurred more frequently among acamprosate treated patients than among placebo-treated patients in clinical trials. Diarrhea is the only common side effect noted with acamprosate.

It is recommended that acamprosate treatment be continued for 12 months, and follow-up studies show increased abstinence rates that persist 1 year after cessation of treatment.\textsuperscript{62} Advantages of acamprosate include its lack of drug–drug interactions and the fact that it is not contraindicated in patients with serious liver disease.

Naltrexone
The \(\mu\)-opioid antagonist, naltrexone, originally developed to treat opioid use disorder (see the following text) was subsequently approved to treat alcohol use disorder in 1994 and is now available in an oral generic formulation. An involvement of the endogenous opioid systems in the
reinforcing effects of alcohol seems likely based on the fact that opioid antagonists block the alcohol-induced release of dopamine into the nucleus accumbens. The ability of alcohol to promote the release of endogenous opioids or to affect opioid receptor binding may account for dopamine release engendered by alcohol and for the blockade of this event by opioid antagonists. Naltrexone changes the subjective experience of alcohol consumption in humans rendering it less reinforcing and more sedating. Naltrexone has demonstrated efficacy in delaying and preventing relapse to heavy drinking and reducing the percentage of drinking days but not in promoting total abstinence in numerous (but not all) clinical trials.

Naltrexone is rapidly and almost fully absorbed after oral administration, achieves its peak effect after 1 hour, and has a half-life of approximately 4 hours (metabolite half-life = 12 hours). The usual dose is 50 mg per day which is sufficient to occupy the majority of µ-opioid receptors. Many clinicians begin naltrexone at 25 mg per day for a few days to minimize side effects and then titrate up to 50 mg per day. Although data are sparse, some clinicians will also increase naltrexone to 100 mg per day if a suboptimal response occurs at 50 mg per day, and the 100 mg per day dose demonstrated modest efficacy in the COMBINE Study.

Common side effects of naltrexone include nausea, headache, dizziness, fatigue, sedation, and anxiety and typically resolve with continued treatment. Oral naltrexone does have a boxed warning for acute hepatitis, although most of these events occurred at doses of 300 mg per day in clinical trials for obesity, and there is little evidence of hepatotoxicity at currently recommended doses for alcohol use disorder. Nevertheless, given the boxed warning, it is judicious to obtain liver function tests prior to initiation and then at months 1, 3, 6, and 12 during therapy.

Because naltrexone blocks µ-opioid receptors, opioid medications will be much less effective in the situation in which an injury or serious medical condition calls for acute pain control. If given in adequate doses (usually higher than would otherwise be required), opioids can generally overcome the blockade, but close monitoring of the patient in an inpatient setting to observe for and manage respiratory depression is advised. Also,
naltrexone is quite obviously contraindicated in patients taking opioids for chronic pain.

Long-Acting Injectable Naltrexone
Although oral naltrexone generally appears efficacious compared to placebo in reducing relapse to heavy drinking, it has not performed well in some studies. However, when patients found to be nonadherent for oral naltrexone are factored out in several other studies, naltrexone demonstrates efficacy for treatment of alcohol use disorder compared to placebo. Consequently, long-acting intramuscular naltrexone, FDA-approved in 2006 for treatment of alcohol use disorder, may eliminate concerns about adherence and has been shown to be effective compared to placebo in reducing heavy drinking. Additional advantages of long-acting intramuscular naltrexone include lower rates of first-pass hepatic metabolism, exposing the liver to significantly lower peak dosages than daily oral dosing. The injectable formulation does not have a boxed warning for hepatic injury. The reduced first-pass metabolism of intramuscular naltrexone leads to lower levels of the active metabolite 6β-naltrexone, which has been correlated with side effects such as nausea. Lower levels of this metabolite may lead to better tolerability of naltrexone’s intramuscular form. Long-acting injectable naltrexone is indicated for patients who have achieved some period of abstinence which could be as brief as several hours. The dosage is one 380-mg gluteal injection every 4 weeks. Patients can be started directly on the injection without a trial on oral medication. In addition to typical side effects seen with oral naltrexone, injection site reactions can occur with the injectable formulation.

Naltrexone for Opioid Use Disorder
For patients with opioid use disorder who have withdrawn from opioids and who do not wish to continue opioid therapy, naltrexone offers, from a theoretical standpoint, an ideal pharmacotherapy. Once a state of full withdrawal is achieved as verified by a naloxone challenge test, naltrexone can be started. With naltrexone on board, the effect of exogenously administered opioids will be blocked so that no euphoria is experienced and physiologic dependence cannot be reestablished. Unfortunately, very
few patients with opioid use disorder remain on oral naltrexone for an extended period so that it performs only slightly better than placebo.\textsuperscript{73} Some populations such as individuals with legal mandates or impaired professionals may do better on oral naltrexone. Obviously, as noted in the preceding text, naltrexone represents a poor choice of pharmacotherapy for some pain patients because it prevents the use of opioid analgesics. If the oral formulation is prescribed, the typical dose is 50 mg per day.

The injectable formulation was approved for opioid use disorder in 2010. A double-blind randomized, controlled trial conducted in Russia showed that active naltrexone injection compared to placebo produced significantly fewer days of using illicit opioids and better retention in treatment.\textsuperscript{74} The only sizable randomized trial conducted in the United States was open label among criminal justice involved patients with opioid use disorder and did show benefit of the injectable formulation compared to treatment as usual, which typically did not include medication.\textsuperscript{75}

### Methadone

As noted earlier, methadone can only be ordered and dispensed for the treatment of opioid use disorder through federally licensed and regulated clinics. Thus, in most cases, patients with chronic pain who need methadone treatment must be referred to one of these clinics. Such clinics are not available in many geographic regions and at times also have waiting lists.

Methadone is ordered and dispensed quite differently when used to treat opioid use disorder than when prescribed for pain. Typically, for treatment of opioid use disorder, a single daily dose is provided in liquid form. The maximum initial dose is 30 mg. The lowest effective dose of methadone for treatment of opioid use disorder is approximately 50 mg per day, with an optimum average dose for most patients of approximately 80 mg per day (±20 mg), although some patients require a dose higher than this range. The daily dose should be sufficient to prevent emergence of withdrawal symptoms at least through the 24-hour dosing period. The dose should be sufficient to greatly diminish or eliminate opioid cravings and opioid use (as determined by both self-report and urine toxicology testing). The dose should create sufficient tolerance such that illicit opioid use does
not cause euphoria. The dose should not be so high that side effects such as sedation, constipation, or loss of libido occur.\textsuperscript{36} Patients who do not stabilize within a few weeks should be evaluated both at the end of the 24-hour dosing cycle just prior to the next scheduled dose to assess the presence of withdrawal signs and symptoms and at 4 hours postdose to observe the patient for any evidence of intoxication or excessive opioid effect at the time of peak plasma levels.\textsuperscript{36} If the patient does have withdrawal signs prior to the dose and no intoxication postdose, an upward adjustment in dose is probably warranted. When patients fail to stabilize after successive dose increases, consideration could be given to obtaining a trough (predose) serum methadone level. Levels below 100 ng/mL are associated with withdrawal symptoms and inadequate dosage.\textsuperscript{76} There are rare ultrarapid metabolizers of methadone who will not become stable on a single daily dose and will exhibit low trough serum levels of methadone. For this small group of patients, splitting the dose by giving them half of the dose observed and the other half as a take-home for the evening generally promotes stabilization.

For patients on methadone maintenance, their daily dose of methadone will rarely be fully, if at all, efficacious in managing acute or chronic pain. These patients may often benefit from additional analgesics, either methadone tablets or another opioid of choice, given throughout the day in appropriately divided doses given in addition to the daily dose of methadone. For acute pain, these additional opioids can be discontinued when the pain subsides. For chronic pain, the additional opioids will need to be ongoing in most cases. Alternatively, or additionally, nonopioid pharmacotherapies and/or behavioral interventions for pain can be applied.

\textbf{Buprenorphine}

Although buprenorphine can be ordered and dispensed through licensed clinics, its pharmacologic characteristics make it a very attractive medication for office-based therapy. Its partial agonist action means that it has a ceiling effect for central nervous system and respiratory depressive effects, making it is far safer in overdose than methadone and other full \(\mu\)-opioid agonists.\textsuperscript{77} This partial agonist property also makes it easier to withdraw from this medication than from methadone. Withdrawing from
methadone can take months or years and be difficult for patients. In addition, buprenorphine has slow onset when administered sublingually (1.5 to 3 hours to peak plasma levels), a long half-life, and high affinity plus slow dissociation from the receptor.\textsuperscript{78,79} Thus, it prevents the emergence of withdrawal symptoms for 24 hours or longer, and by occupying the majority of receptors, it makes very few receptors available for binding of full agonists. Buprenorphine’s long half-life allows for once-daily or even thrice-weekly dosing. Buprenorphine is poorly absorbed by the oral route and undergoes extensive first-pass hepatic metabolism, so for treatment of opioid dependence, it is administered sublingually, buccally, or via a subdermal implant.

Buprenorphine prescription in the office setting was made possible in the United States by the Drug Addiction Treatment Act of 2000 (DATA). DATA allows for office-based opioid maintenance therapy for opioid use disorder using Schedule III, IV, or V medications approved for this use by the FDA. In 2002, the FDA approved buprenorphine and buprenorphine/naloxone for this purpose, and they are the only medications at this time with this indication. In order to prescribe buprenorphine, physicians must obtain a waiver from the DEA, which requires specialty training in addictions or completion of approximately 8 hours of training in management of opioid use disorder, and physicians must be able to refer patients to appropriate counseling and ancillary services. The waiver allows physicians to prescribe buprenorphine to up to 100 patients at a given time with the potential to increase the patient limit to 275 as of 2016.

Buprenorphine is available for sublingual or buccal administration as a single agent or as a combination buprenorphine–naloxone preparation with a ratio of 4 mg buprenorphine to 1 mg of naloxone. (There are also buccal and transdermal formulations available with a pain indication, but the doses are approximately an order of magnitude lower than the doses used to treat opioid use disorder.) The advantage of the combination buprenorphine–naloxone preparation is the prevention of misuse. Buprenorphine has adequate bioavailability sublingually, whereas naloxone is minimally bioavailable sublingually, so the naloxone has no effect on patients when administered as intended. If the combination
medication is dissolved in an attempt to inject buprenorphine, however, naloxone, which also has a high affinity for the µ receptor, will exert its antagonist properties resulting in withdrawal instead of euphoria. The single agent should be reserved for use only in situations where there is no concern for potential misuse, such as in an inpatient setting or for pregnant women to avoid any potential exposure of the developing fetus to even trace amounts of naloxone. Due to the partial agonist properties of buprenorphine, patients need to be clearly educated that they should not take this medication soon after taking other opioid drugs because buprenorphine in that situation may precipitate withdrawal.

An important component of the clinical skill in using buprenorphine involves the induction procedures. Patients who have been taking full agonist opioids must abstain from their full agonist opioids long enough to evidence signs of mild opioid withdrawal. If patients take the first dose of buprenorphine when not in active opioid withdrawal, there is a risk that buprenorphine as a partial agonist will precipitate more severe opioid withdrawal. Patients often require a fair amount of empathic emotional support to assure them that they can handle a period of several hours without opioids and can tolerate a brief episode of mild withdrawal prior to starting buprenorphine. Usually, it is not the mild withdrawal symptoms themselves that are troublesome, so much as the anxiety about more severe withdrawal. If patients are in mild to moderate withdrawal at the time of starting buprenorphine, the first dose usually alleviates much of the withdrawal within 30 to 60 minutes.

Induction of buprenorphine should thus begin approximately 12 to 24 hours after last use of a short-acting opioid drug or 24 to 48 hours after last use of a long-acting opioid drug, and patients should be showing objective signs of withdrawal at the time of initiation of therapy. On the first day of induction, the maximum dose should usually not exceed 8 to 12 mg. Because the transition from methadone to buprenorphine is more difficult than the transition from short-acting opioids, patients who are receiving methadone for pain and wish to transition can be first switched from methadone to a short-acting opioid and then inducted onto buprenorphine. For patients receiving methadone in a licensed clinic for the treatment of opioid use, this switch to a short-acting opioid is not legally permissible,
and such patients must be inducted directly from methadone to buprenorphine.

If, after beginning buprenorphine, patients still have withdrawal symptoms after receiving the maximum first day dose, they should be treated symptomatically with adjunctive agents such as clonidine, antiemetics, antidiarrheals, and benzodiazepines for specific withdrawal symptoms. Over the course of the next 2 to 6 days, patients should be assessed for signs and symptoms of withdrawal with increases in buprenorphine given for persistent symptoms up to a total of 16 mg on the second day and a maximum of 32 mg per day by the end of the first week. Withdrawal symptoms beyond this time typically indicate persisting illicit opioid use.

Following induction, patients will stabilize on a dose over the following weeks, and the dose should be adjusted to the lowest effective dose to prevent withdrawal symptoms, prevent craving of opioids, and suppress illicit opioid abuse. Once this dose is established, patients can be maintained on this medication indefinitely or may choose to taper off.80 Numerous studies have found buprenorphine to be effective in retaining patients in treatment and reducing illicit opioid abuse. A systematic review of studies, which compared 31 studies involving 5,430 subjects in trials of buprenorphine versus either placebo or methadone, found buprenorphine to be effective as a maintenance therapy for opioid use disorder when compared to placebo.81 Compared with methadone, however, especially at higher doses of methadone, buprenorphine may not be quite as effective at maintaining patients in treatment, although this difference is less pronounced at higher buprenorphine doses. Nevertheless, because buprenorphine is a safer medication than methadone, it often makes clinical sense to use buprenorphine as a first-line agent. If a patient fails buprenorphine treatment, the patient can be transitioned to methadone maintenance in a licensed clinic.82 Transition from methadone to buprenorphine is clinically more difficult than transition from buprenorphine to methadone.

As a partial agonist, buprenorphine has analgesic properties, but its analgesic effects may not always be as powerful as those of a full agonist. However, recent evidence suggests that buprenorphine produces less
hyperalgesia than full agonist opioids and so may have some benefit for pain control in patients not responding well to full agonists. Also, although buprenorphine has a ceiling on its respiratory depressant action, it does not appear to have a ceiling on its analgesic activity so higher doses should continue to elicit greater analgesia. Thus, buprenorphine has tremendous potential for management of patients who have combined chronic pain and opioid use disorder. It allows the physician treating such a patient to continue to manage the patient in his or her own office for both disorders along with referral for ancillary counseling if needed rather than terminating such a patient or sending the patient to an addiction treatment provider or facility with the risk of a failure to follow through. As noted, some clinical skill is required to support the patient in abstaining from full agonist opioids long enough to evidence signs of opioid withdrawal such that buprenorphine induction can take place. Patients being treated with buprenorphine for combined pain and opioid use disorder may get better analgesia by taking the buprenorphine in divided doses throughout the day rather than as a single daily dose. Although more data on the treatment of combined pain and opioid use disorder are needed, preliminary reports indicate a positive response for many patients.

Conceptions of Opioid Use Disorder—The Pain Medicine Perspective

The pain management perspective on opioid use disorder provides observations on the historical changes in the attitudes toward and practice of using opioids for chronic pain and on integration of perceptions from pain medicine with those from addiction medicine.

HISTORY OF OPIOID USE FOR CHRONIC PAIN AS IT RELATES TO IDENTIFYING OPIOID USE DISORDER

Ambiguities related to the definition of opioid addiction in CNMP patients and the practical problems associated with identifying this disorder as of 2006 were detailed in the chapter on addiction in the fourth edition of Bonica’s Management of Pain. In the present chapter, we focus on changes that have occurred during the past decade in our understanding of
addiction in these patients and in attitudes toward the use of opioids in the treatment of CNMP.
