There is no simple way to gauge the attitudes and beliefs of the various stakeholders with an interest in opioid therapy (e.g., physicians, regulators, law enforcement officers, patients with CNMP), but initiatives undertaken by legislative bodies and regulators can be viewed as indicators of prevailing attitudes. Because these differ from one community to another, the present discussion focuses on initiatives undertaken in the State of Washington in the United States. The practical reason for this is that we are familiar with these initiatives. There is also evidence that the State of Washington has been a leader in opioid policy. For example, the Centers for Disease Control and Prevention (CDC) opioid guidelines are largely based on the earlier Washington State guidelines.

In the years since 2007, there has been a sea change in these attitudes, and it appears that opioid prescribing by clinicians peaked in 2011 or 2012 and is now declining. With the benefit of hindsight, we can now identify three periods regarding these attitudes.

1. Early history (prior to the 1990s): Before the mid-1990s, Washington State Department of Health regulations prohibited physicians from providing long-term opioid therapy for CNMP patients. This regulation existed in many other states as well and reflected the prevailing view that the risks of such therapy outweighed the benefits.

2. The period of enthusiasm (1990 to 2007): As discussed in Bonica’s Management of Pain, 4th edition, some pain specialists made the case during the late 1980s and early 1990s that opioids were safe and effective in the treatment of CNMP. In 1995, a committee was formed to change the Washington State Department of Health’s regulations regarding opioid therapy. The result, published in 1996, was a regulation that stated, “Under generally accepted standards of medical practice, opioids may be prescribed for the treatment of acute or chronic pain including chronic pain associated with cancer and other non-cancer pain conditions. . . . It is the position of the Department of Health that opioids may be prescribed, dispensed, or administered when there is an indicated medical need without fear of
injudicious discipline.” This regulation reflected an emerging viewpoint that opioid therapy was safe and effective in the treatment of chronic pain. In 1996, the American Pain Society and the American Academy of Pain Medicine issued a joint statement endorsing the use of opioids in care of patients with CNMP. This time frame is also the when long-acting opioids were aggressively marketed by pharmaceutical companies as less prone to abuse and addiction. Marketing of OxyContin was especially conspicuous, but other opioids were also aggressively marketed. As a result of the mentioned influences, there was a dramatic increase in opioid prescribing, both nationally and in Washington State.

3. The period of retrenchment (2007 to present): As indicated in the discussion in Bonica’s Management of Pain, 4th edition, by 2006, some pain specialists had become skeptical that the benefits of opioid therapy for CNMP outweighed the risks. The medical director of the Washington State workers’ compensation system noticed an increase in deaths among injured workers that were concentrated among those receiving high-dose, long-term opioid therapy. He convened a group of academic and community pain specialists who wrote the first Washington State opioid guideline, which was released in 2007. Since then, skepticism about the benefits of long-term opioid therapy has grown enormously. The CDC has declared that we are in the midst of an opioid epidemic that is killing Americans at a higher rate than HIV ever did. In 2014, the National Institutes of Health held a consensus conference that declared that there was no good evidence of the effectiveness of long-term opioid therapy.

As the aforementioned dates suggest, the chapter section on addiction from the perspective of pain medicine in the fourth edition of Bonica’s Management of Pain was written as physicians and regulators were becoming skeptical of opioid therapy for CNMP and were moving into the period of retrenchment. Thus, the discussion reflected ambivalence about opioid therapy for CNMP but did not provide any definite conclusions about the pros and cons of the therapy.

Since that chapter was written, several discoveries have occurred and initiatives have been undertaken that have changed the social environment...
surrounding opioid therapy for CNMP. The most significant are as follows:

1. Changes in the criteria for the diagnosis of “addiction” (formally called substance use disorder) in the DSM-5: These changes were discussed previously. They have dealt to some extent with concerns that we voiced in Bonica’s Management of Pain, 4th edition, about the DSM-IV criteria. However, they do not fully resolve the ambiguities and inconsistencies of usage among investigators for a variety of terms that describe problematic use of prescription opioids—including misuse, abuse, aberrancy, dependence, and addiction. Also, as discussed later in text, the DSM-5 definition does not fully resolve problems that clinicians face in the identification of opioid use disorder in patients with chronic pain.

2. Research on addiction and aberrant behaviors associated with prescription opioids: During the period of enthusiasm for opioid therapy, many pain specialists argued that addiction is uncommon when patients take opioids for their pain. A brief report on an inpatient sample by Porter and Jick was frequently cited to buttress this argument. Recent research has emphatically challenged this assertion. It has been demonstrated that a high proportion of CNMP patients on opioid therapy have abnormal urine drug screens, strongly suggesting aberrant behaviors (Table 91.4). Our best conservative estimate is now that 25% of patients on long-term opioid therapy will misuse their opioids, and 10% will develop opioid use disorder. Also, there is now evidence that a substantial proportion of people using heroin report that they got started on the path to heroin use via consumption of prescription opioids.

3. Research demonstrating adverse effects of opioids: Research has now documented a litany of adverse effects of opioid therapy that were either unknown or not fully appreciated during the period of enthusiasm. These include overdoses requiring emergency room care, myocardial infarctions, low testosterone levels, and injuries in motor vehicle accidents.\textsuperscript{96} Worst of all, there is now convincing evidence of substantial mortality from overdoses of prescription opioids.\textsuperscript{97,98} Thus, although practitioners and researchers have been aware for decades that opioids can cause harm, recent evidence has highlighted the frequency with which adverse effects occur. This emerging evidence has led the CDC and other agencies to use the term opioid epidemic to describe the current situation with respect to prescription opioids for CNMP.\textsuperscript{99}

4. Questionable efficacy: Many RCTs, often sponsored by drug companies, have been performed over the past 25 years. They have generally supported the efficacy of various opioids in the treatment of chronic pain conditions.\textsuperscript{100,101} However, these studies almost uniformly examined the effects of an opioid for a limited period of time—usually 8 to 12 weeks. In fact, one recent review concluded that no well-controlled studies have been done addressing the
efficacy of opioid therapy over a time interval of greater than 1 year. Moreover, research employing large insurance databases to assess longer term outcomes of opioid therapy has presented a bleak picture. For example, multiple investigators have examined the effects of opioid therapy on injured workers by looking at return to work rates (or termination of disability benefits) among workers with common injuries such as back injuries who are prescribed opioids versus who are not prescribed them. These studies have consistently found that workers receiving opioids are less likely to return to work than those not receiving them.

5. Monitoring: Clinicians have been able to monitor patients taking opioids via urine drug screens for many years. However, it is very likely that clinicians are ordering urine drug screens more frequently now than at the time of Bonica’s Management of Pain, 4th edition, because during the past few years, several expert panels have recommended their use. In contrast, PDMPs were virtually nonexistent at the time when the fourth edition of Bonica’s Management of Pain was written. As noted earlier, PDMPs are now available in 49 states. Recent studies have shown that PDMPs reduce opioid use among Medicare beneficiaries and in the general patient population. Another study showed that Florida’s PDMP and pill mill laws were associated with modest decreases in opioid prescribing and use. The decreases were greatest among prescribers and patients with the highest initial opioid prescribing and use.

6. Policy initiatives: As noted earlier, several initiatives have been undertaken in Washington State to rein in opioid prescribing for CNMP. The first of these was a guideline published by the Agency Medical Directors’ Group (AMDG). The AMDG consists of medical directors of the four Washington State–run medical insurance programs—Medicaid, the Department of Labor and Industries (the main Washington State workers’ compensation carrier), the Department of Corrections, and Uniform Medical (the health insurance plan for state employees). In 2006, the AMDG formed a committee to address opioid use for beneficiaries of the mentioned
insurance programs who suffered from CNMP. The resulting guideline, published in 2007, recommended that primary care physicians obtain consultations from pain specialists regarding opioid use for CNMP and expressed the view that opioid doses for CNMP patients should rarely exceed a morphine equivalent dose (MED) of 120 mg per day.\textsuperscript{107} This guideline was the first in a series of initiatives to curb the excesses of the period of enthusiasm. Updated AMDG guidelines were published in 2010\textsuperscript{108} and again in 2015.\textsuperscript{109} These reiterated many of the recommendations given in the 2007 guideline and buttressed them with data about adverse effects of opioid therapy. Other initiatives included legislation that incorporated principles in the AMDG guideline\textsuperscript{110} and the development of a state PDMP. At a national level, the most visible policy initiative was the publication of a guideline by the CDC in 2016.\textsuperscript{104} It incorporated many of the principles articulated in the AMDG guidelines.

7. Changes in opioid prescribing practices: Data from Washington State document that in recent years, clinicians have curtailed opioid prescribing, and there has been a corresponding drop in accidental deaths attributable to opioid use.\textsuperscript{86} We are not aware of recent data on opioid prescribing in other states. We anticipate that reductions comparable to those in Washington State will occur, but there may well be a time lag because the CDC guideline was not published until 2016.

**IMPLICATIONS FOR THE IDENTIFICATION OF OPIOID USE DISORDER**

Given the changes that have occurred during the past 11 years in our understanding of the risks and benefits of opioid therapy for CNMP, it is less likely that patients will be intentionally started on long-term opioids for treatment of CNMP in the future. However, many patients are started on opioids for acute pain and then provided refills indefinitely, which leads to de facto long-term opioid therapy.\textsuperscript{111} Also, there are millions of CNMP patients who are already taking opioids on a long-term basis. Opioid use disorder occurs frequently enough among these patients that clinicians
who prescribe opioids need to be vigilant for its presence. For example, in a large Australian sample of patients prescribed opioids for CNMP, 8.9% met lifetime criteria for opioid dependence using DSM-IV criteria, 8.5% fulfilled International Statistical Classification of Diseases and Related Health Problems, 10th revision (ICD10) criteria, and 9.9% met International Statistical Classification of Diseases and Related Health Problems, 11th revision (ICD11) criteria. Using DSM-5, 8.9% met criteria for moderate or severe opioid use disorder. Another 11.8% met criteria for mild opioid use disorder.112

During the period of widespread use of long-term opioid therapy for CNMP, it is almost certain that many patients who actually had opioid use disorder were not identified. At least two factors contributed to this misidentification. First, if a patient has opioid use disorder but is getting opioids on a regular basis from a physician, drug craving, extreme efforts to get opioids, and other indicators of opioid use disorder are likely not to be present. Second, because there was widespread social support for opioid therapy during the period of enthusiasm, a patient’s demands for opioids could be construed not as an indicator of opioid use disorder but, rather, as reasonable demands for therapy that was widely available. This is the essence of the now discredited “pseudoaddiction” concept that has been popular in the pain management community.113,114 Thus, it is reasonable to anticipate that as opioid therapy is discontinued for patients who previously received opioids, it will become apparent that many of them have opioid use disorder. This expectation is supported by data suggesting that heroin usage has surged in response to the reduced availability of prescription opioids.115

But even if it is true that many patients have hidden opioid use disorder that is being unmasked as their clinicians taper and discontinue opioid therapy, this does not resolve the challenges that the clinicians face when they decide whether or not to diagnose opioid use disorder in individual patients receiving opioids for pain. Clinical experience strongly suggests that when patients who have been receiving opioids plead for continuation of the treatment, they will emphasize the tremendous burden that pain places on them and the respite that they get from continued or increased doses of their opioids. In fact, as described in Bonica’s Management of
Pain, 4th edition, they are likely to say that their pain affects them so powerfully that they are “forced” to take opioids.

**CLINICAL PREVENTION AND MANAGEMENT OF OPIOID USE DISORDER IN PATIENTS RECEIVING OPIOIDS FOR CHRONIC PAIN**

As noted earlier, medication treatment with opioid agonists like buprenorphine or methadone is the best treatment for patients with moderate to severe opioid use disorder. It is not clear how patients with mild opioid use disorder should be treated. Some patients might be tapered gradually to safer low-dose opioid use aligned with the CDC guidelines. Other patients might be tapered off opioids completely. There is evidence that when patients on long-term opioid therapy express motivation to reduce or discontinue their opioids, an opioid taper, combined with motivational interviewing, cognitive-behavioral, and psychopharmacologic support (largely consisting of initiating or adjusting antidepressant medication), can be successful and can be carried out without exacerbation of pain or increase in functional impairment. However, there is a caveat. Of the patients referred to the Sullivan et al. study, 76% were either found to be ineligible to participate or refused to do so. At this point, there is no evidence to guide clinicians as they consider opioid tapers for these patients.

In managing prescription for opioid recipients having problem opioid use, clinicians must first decide if the management should take place in their clinics or the patients should be referred to addiction medicine programs such as the ones described earlier in this chapter. There are no clear-cut criteria for making this decision. Among patients whom pain clinicians continue to treat, the boundary between those who should be tapered off their opioids versus those who should be maintained on methadone or buprenorphine is also not well defined. Experienced clinicians often make an attempt at opioid taper and transition those patients who cannot complete a taper onto buprenorphine-naloxone for long-term maintenance.

**Conclusions: Bridging the Gap between Addiction**
and Pain Medicine

There remain significant barriers to overcome in addressing addiction to prescribed opioids. Since the passage of the Harrison Act in 1914, addiction treatment has been separate from the rest of medical treatment. Treatment facilities are separate, funding is different, and the role of private insurance and public payers is different. Patients with pain typically must accept the label of addiction or opioid use disorder to get treatment in addiction facilities or to get insurance coverage for buprenorphine/naloxone. Many are not willing to do this, and clinicians are often hesitant to force the label on them because of uncertainty about how to construe the patients’ requests for continued opioid therapy. Thus, although patients prescribed opioids for pain might benefit in multiple ways (safety, toxicity, emotional stabilization) from transition to buprenorphine/naloxone or methadone, they are often prevented from making the transition by financial considerations.

Just as addiction facilities are reluctant to treat patients who do not accept the opioid use disorder label, pain facilities are reluctant to welcome addiction services under their roof. Health administrators, clinical staff, and patients in pain facilities are resistant to welcoming those with addiction into their clinics. This results in a great chasm between pain and addiction health services into which many patients with problem or high-risk opioid use fall. These patients are poorly served by the present diagnostic and health services system. We will not be able to reverse the opioid epidemic until this chasm between pain and addiction services has been bridged.

The primary focus of physical therapy is functional restoration via physical reactivation.¹ Therapeutic exercise, movement, and physical reactivation have been demonstrated not only to be central components in restoration of function following injury and disease but are also efficacious elements of managing both acute pain and chronic pain syndromes.¹–⁴ In concert with the functional physical restoration activities, physical therapists may also utilize therapeutic biophysical agents (previously referred to as physical agents or modalities) to complement other treatment elements as part of a comprehensive patient care plan.⁵,⁶ Philosophies and approaches to pain management vary across practitioners and clinical facilities; yet, the use of biophysical agents is widespread.²,⁵ The Centers for Medicare & Medicaid Services reported in 2014 that electrical stimulation and ultrasound therapy ranked among the top 10 procedures receiving Medicare payments to rehabilitation providers.⁵ All physical therapists and physical therapist assistants receive clinical training in the biophysics and safe therapeutic application of biophysical agents as required for licensure and by the Commission on Accreditation in Physical Therapy Education (CAPTE).⁶–⁸

Biophysical agents traditionally involve application of some form of heat, cold, light, electromagnetic, or acoustic energy to the body tissue involved in generating pain.⁶,⁹ In the context of pain management, delivery of energy to tissue may modify the underlying pathophysiologic process generating pain or alter the transmission, central processing, or perception of the pain message.⁶ They may assist in causing temporary analgesia,⁴ resolving inflammation and facilitating tissue repair,⁶,⁹ modifying axonal conduction,⁶ generating a counterirritant,⁶ altering muscle activation, or
increasing extensibility.\textsuperscript{6} Biophysical agents may also curb the development of maladaptive central neuropathic changes that could precipitate secondary chronic pain generators\textsuperscript{10–13} or provide other means of palliative relief via modified pain perception.\textsuperscript{11}

Selection of specific biophysical agents for pain management should be done on a case-by-case basis predicated on clinical impressions regarding the loci and underlying pathophysiologic processes of pain generation.\textsuperscript{5,14} For a particular agent to be therapeutically useful, its effects must either address the pathophysiologic changes occurring at the tissue level or alter neural pain transmission or central processing.\textsuperscript{14} If the origin of nociceptive pain is due to damaged and/or inflamed tissue, then locally operating agents are indicated. However, if pain is being generated by peripheral neuropathic factors or a central neuroplastic remodeling component, then potentially effective agents should be chosen from those capable of influencing neural transmission or central processing.\textsuperscript{15}

Although distal pathophysiology is the primary consideration in the selection of biophysical agents for acute or subacute pain, additional factors must be addressed when considering biophysical agents for use in treating patients with chronic pain. As distal subacute lesions evolve into chronic pain syndromes, the loci of pain generation may migrate.\textsuperscript{14,16–18} Restrictions in activity and mobility in response to initial pain from the inciting lesion may lead to connective tissue changes and alterations in vascular physiology that develop into secondary pain generation sites.\textsuperscript{16,18} Central pain generators may further develop from neuroplastic remodeling of the dorsal horn, thalamus, or cerebral cortex.\textsuperscript{13,17} The application of biophysical agents to the original lesion site may prove ineffective if the sources of the chronic pain are secondary generation sites or neural remodeling that are rostral to the location of perceived pain.\textsuperscript{15}

The use of a passive modality as a sole treatment approach is unlikely to lead to long-term improvement in a patient’s functional status. In treatment planning for pain management, thoughtful use of biophysical agents coordinates their application with physical restoration activities. In 2014, the American Physical Therapy Association established the position that biophysical agents do not effectively represent stand-alone treatments, stating that clinicians should not “employ passive physical agents except
when necessary to facilitate participation in an active treatment program,”
reinforcing their earlier position that “exclusive use of physical agents in
the absence of other skilled therapeutic, or educational intervention, should
not be considered.”

Thoughtful case-by-case consideration should be given to providing
patients experiencing chronic pain an external source of passive palliative
relief. Temporary pain relief via the use of biophysical agents may
create a therapeutic window for the therapist to mobilize tissue or address
movement impairments. For some patients, however, a maladaptive cycle
of pain behavior may develop from psychologic dependence on passive
external palliative agents. Ultimately, this may reduce progress toward
functional restoration by hindering the motivation to actively engage in
therapeutic physical activity. Passive agents may not only provide
disincentives for the patient to approach pain management from an active
or functional perspective but may also reinforce an external locus of
control, whereby the patient attributes pain relief to procedures unrelated
to his or her own actions or pacing. This underscores the importance of
utilizing palliative agents as components of comprehensive treatment
planning rather than as stand-alone interventions for short-lived pain relief.

Biophysical agents currently in use by physical therapists for the
management of pain include superficial heat and cold, light (such as low-
level laser or monochromatic infrared energy [MIRE]), therapeutic
ultrasound, electrical currents (such as transcutaneous electrical nerve
stimulation [TENS] and interferential current [IFC]), materials used to
facilitate multimodal somatosensory desensitization, and new techniques
for influencing central neuroplastic remodeling of pain perception.

Superficial Thermal Agents

THERMOTHERAPY
Superficial heat, or “thermotherapy,” is used to facilitate soft tissue
extensibility, increase circulation, enhance healing, induce relaxation,
reduce muscle spasms, prepare stiff muscles and tight joints for exercise,
and/or control pain. Heat is delivered to superficial tissues via
conduction with clinical applications such as moist hot packs and paraffin
wax dips, or for home therapy with electric heating pads, air-activated wearable heat wraps, microwavable gel packs, or rice-filled cloth bags. Superficial heat can also be applied via convection using agents such as dry heat fluidotherapy or warm whirlpool hydrotherapy.\textsuperscript{20} Thermotherapy is quite commonly utilized by physical therapists across the world, with studies reporting daily use of therapeutic heating agents ranging between 36.5\% and 95\% across diverse practice settings.\textsuperscript{20,21}

As an adjunct to pain management, therapeutic benefits of superficial heat are due to its effects on metabolic, neuromuscular, and hemodynamic processes. Although the physiologic effects of superficial heat primarily influence tissue healing and acute nociceptive pain generation, thoughtfully applied thermotherapy may have utility in the comprehensive management of chronic pain.\textsuperscript{14} The oxygen–hemoglobin dissociation curve shifts to the right with mild increases in tissue temperature, making more oxygen available for tissue repair. Increases in enzymatic activity increase oxygen uptake by the cell, thus enhancing healing.\textsuperscript{6,20} Increased skeletal muscle temperature (to 42° C) has been reported to decrease firing rates of gamma and type II muscle spindle efferents while increasing Golgi tendon organ type Ib fiber firing rates.\textsuperscript{22} This may reflexively lower skeletal muscle tone and spasms. Reduced skeletal muscle activity may assist in breaking the pain–spasm–pain exacerbation cycle.\textsuperscript{6,23} Analgesic benefits of superficial heating of the skin may be centrally mediated, as evidenced by functional magnetic resonance imaging (fMRI) findings that warming of distal tissue increases activity of the thalamus and posterior insula, thus initiating a potentially beneficial psychosomatic effect.\textsuperscript{24,25}

Elevations in nociceptive threshold have been reported due to superficial heat.\textsuperscript{20,26} By increasing activity of afferent thermoreceptive fibers, superficial heat may produce inhibitory modulation of dorsal horn pain gates.\textsuperscript{6} Indirectly, pain may be influenced via local vasomotor effects and increased blood flow. Dorsal horn synapses from first-order thermal receptor afferents inhibit sympathetic vasomotor efferents in the spinal intermediolateral grey area, thus decreasing vasoconstriction neurogenically.\textsuperscript{6} When sympathetic vasomotor outflow is decreased, local vasodilation and increased vascular perfusion may influence pain further by decreasing tissue ischemia,\textsuperscript{27} returning nociceptors to normal firing
thresholds by helping to resolve hyperalgesia, and clearing exacerbating metabolites such as prostaglandins from the region. Blood flow increases of as much as 30 mL per 100 g of tissue have been reported. However, these effects influence primarily superficial blood vessels and the tissues they supply. Less evident is vasodilation in deep muscle vasculature because of the limited ability of superficial agents to increase temperature in deeper structures.

Superficial heat, applied in forms such as hot packs, paraffin, hydrotherapy, and fluidotherapy, has been broadly evaluated for effectiveness in the treatment of both rheumatoid and osteoarthritis. Seven controlled studies have found it a beneficial adjunct, whereas two found it ineffective and possibly harmful by increasing collagenase activity which may have damaged compromised articular cartilage. Comparative studies report beneficial effects of superficial heat for trigger point pain in the neck and back, neck and shoulder pain, and chronic low back pain.

Local tissue temperatures required to achieve therapeutic outcomes are in the range of 40° to 45° C (104° to 113° F). Exceeding this range places tissue at risk for damage because at local temperatures >45° C (113° F) metabolic activity required for repair cannot keep pace with protein denaturation. At therapeutic temperatures, applying heat is contraindicated over hemorrhagic areas; regions of acute injury, acute inflammation, peripheral vascular disease, malignancy, impaired sensation, or thrombophlebitis; the abdomens of pregnant women; tissues that have been devitalized by x-ray therapy; or with patients with existing fever, confusion, sedation, coma, or relevant cognitive impairments. Caution should be used when applying heat over areas of impaired circulation, edema, superficial metal implants, where topical counterirritants have been applied, or over open wounds. Also, exercise proper caution during use with children under 4 years old or older adult patients; patients manifesting poor thermal regulation, cardiac insufficiency, or acute inflammatory disorders; or with hypotensive patients, those manifesting orthostatic hypotension, or anyone prone to syncope when heating large body surface areas.
CRYOTHERAPY

Application of cold, whether via water immersion, ice, gel, or vapor-coolant sprays, is one of the most effective and cost efficient modalities for managing pain and acute injury. Its therapeutic use has been traced as far back as in Egypt around 2500 BCE. Termed cryotherapy, the therapeutic use of cold can be used to control pain, minimize edema, reduce inflammation, enhance movement, and attenuate spasticity.

A primary indication for cryotherapy is to minimize secondary hypoxic injury to adjacent tissue areas immediately following acute trauma. By lowering metabolism of damaged and surrounding cells, they become more resistant to hypoxia resulting from disrupted blood supply to the region, making this the primary reason that cold is the agent of choice for the first 24 to 48 hours after injury. This mechanism of minimizing the extent of tissue damage is dependent on immediate application of cold following trauma and is not a mechanism likely to contribute to the management of chronic pain states. It may also elevate pain thresholds and decrease muscle spasms and tension secondary to myofascial trigger points.

Cryotherapy can be administered using conductive agents such as ice bags, superficial ice massage, bags of frozen corn or peas, cold compression units, cold whirlpool immersion, or via contrast baths, in which alternating heat and cold are used. It can also be administered with convective agents such as vapor-coolant sprays. Different cryotherapeutic modalities can produce a varied range of tissue cooling ability. Following 20-minute exposure over the gastrocnemius muscle, skin surface temperature was reportedly lowered by 19.6°C (35.0°F) using crushed ice, 17.0°C (30.6°F) following ice water immersion, 14.6°C (26.0°F) from contact with a bag of frozen peas, and 13.0°C (23.5°F) using a cold gel pack. Following 15-minute exposure, superficial ice massage decreased intramuscular temperature by 4.3°C (7.7°F) compared to contact with ice bag that lowered temperature by 2.3°C (4.1°F). Depth of intervening adipose tissue layers has a significant influence on the rate of intramuscular cooling and subsequent rewarming. It has been found that 10 minutes are required to produce a decrease in intramuscular temperature of 7.0°C (12.5°F) with a 1-cm layer of intervening adipose
tissue, whereas given adipose thickness of 3 to 4 cm, 60 minutes are required to achieve the same temperature reduction.\textsuperscript{49}

The therapeutic effects of cold result from its actions on metabolic, neuromuscular, and hemodynamic processes.\textsuperscript{6} Decreases in nociceptive input and pain perception via application of cold may occur because of influences in both local and central nervous system mechanisms.\textsuperscript{14} Vasoconstrictive response to cold decreases local release of vasodilating substances and chemical mediators, which in turn decreases nociceptor sensitization.\textsuperscript{6,23} For every 1° C drop in interstitial temperature, nerve conduction velocity of somatosensory afferent fibers drops approximately 2 m/s due to metabolic changes in the axon.\textsuperscript{50} It has been reported that at a skin surface temperature of 10° C (50° F) there is a 33% reduction in nerve conduction velocity\textsuperscript{50} and that local analgesia may be produced by lowering skin surface temperature to 13.6° C (56.5° F).\textsuperscript{51} Aδ nociceptive fibers display the most sensitivity to cold mediated velocity attenuation, whereas blocking conduction of C fibers requires considerably colder temperatures.\textsuperscript{22,43} The effects of application of a cryotherapy agent for 10 to 15 minutes may transcend immediate changes and produce pain reductions for more than an hour.\textsuperscript{6} Prolonged analgesia may be the result of Aδ conduction block and the maintenance of subnormal deep tissue temperature for 1 to 2 hours following cold exposure.\textsuperscript{6,52} Extended cold application has been shown to produce reversible neurapraxia.\textsuperscript{53} Theoretically, by interrupting the pain–spasm–pain cycle, cold application may reduce muscle spasm, thus continuing pain relief after tissue temperature has recovered to precryotherapy levels.\textsuperscript{6} Finally, by applying vapor-coolant sprays over skeletal muscle and combining it with stretch, evaporative cooling may reduce muscle spasm and allow muscle with excess neurogenic tone to be stretched for increased range of motion.\textsuperscript{6,46,54} The vapor-coolant spray has been hypothesized to be effective in this capacity by providing a counterirritation to cutaneous afferents, which in turn leads to a reflex decrease in motor neuron activity and resistance to stretch.\textsuperscript{6}

Existing literature is clear in support of the efficacy of cryotherapy in acute trauma management. It may also play a role in treating some manifestations of chronic pain; however, at the current time, there is little
well-controlled literature supporting its efficacy. Uncontrolled comparative studies and case studies have reported that in the treatment of muscle spasms and myofascial pain, cryotherapy may be a beneficial adjunct. Additional comparative studies have reported it to be a useful clinical tool in managing chronic headache, trigeminal neuralgia, chronic osteoarthritis, and low back pain.

Cryotherapy is contraindicated for patients with Raynaud’s disease or phenomenon; cryoglobulinemia or paroxysmal cold hemoglobinuria; angina pectoris; those prone to cold urticaria, cold intolerance, or hypersensitivity; or over skin areas of impaired somatosensory discrimination, deep open wounds, areas of circulatory compromise or peripheral vascular disease, and regenerating peripheral nerves. Cryotherapy should be used with caution over the main branch of a superficial nerve, on individuals with unstable hypertension, those with significant loss of superficial sensation, poor thermoregulation, aversion or intolerance to cold, poor cognition, or in the very young or very old. Note that with applications to the lower extremity, proprioception and joint stability will be temporarily compromised following treatment, so caution should be exercised with ambulation or return to sports participation quickly after cryotherapy.

Light Therapy

**LASER**

Laser light is in current use for a variety of medical conditions. The U.S. Food and Drug Administration (FDA) has three classifications for medical lasers:

- **Class 4 (IV)—surgical lasers (>500 mW)**
- **Class 3B (IIIb)—nonsurgical lasers (5 to 500 mW)**
- **Class 3R (IIIr)—nonsurgical lasers (<5 mW)**

The Class 3 lasers are not of sufficient intensity to damage cells (with the exception of the retina) and are used to help heal superficial wounds (3A), or provide sufficient penetration to address deeper tissue and joint problems (3B). The first FDA approval for the use of Class 3 lasers for pain management was granted in February 2002 for the treatment of carpal
tunnel syndrome.\textsuperscript{60} Specific low-level laser devices have FDA approval\textsuperscript{60} for treatment of the following pain conditions:

- Muscle and joint pain
- Pain associated with muscle spasm
- Hand and wrist pain associated with carpal tunnel syndrome
- Neck pain
- Lower back pain

Since FDA clearance, physical therapists have utilized laser to treat a range of painful and inflammatory conditions.\textsuperscript{61} Low-level Class 3 laser therapy (LLLT), or “cold laser,” is used in rehabilitation settings to promote healing and manage pain utilizes lasers with power outputs $\leq 500$ mW at a power density of $\leq 50$ mW/cm$^2$.\textsuperscript{9}

Laser therapy utilizes light energy that has the unique properties of monochromaticity, coherence, and collimation.\textsuperscript{6,61} These properties allow laser light to deliver electromagnetic energy to tissue depths slightly below the dermis.\textsuperscript{62} Indirect physiologic effects occur at deeper levels due to the promotion of chemical reactions that mediate processes at greater tissue depths.\textsuperscript{6,61,62}

Lasers most frequently utilized for LLLT are of the semiconductor diode configuration that produces light in the red and near-infrared portions of the electromagnetic spectrum, utilizing wavelengths ranging from 632.8 to 904 nm.\textsuperscript{9} Diode lasers are usually hand held probes that allow for treatment of small, localized areas. Superluminous diodes (SLDs) also produce light in the red and near-infrared portions of the electromagnetic spectrum. They are brighter but less powerful than diode lasers. The advantage of SLDs is to allow hands-free operation and the ability to treat larger surface areas.\textsuperscript{62} Single-laser diodes may be mounted in a wand for treatment of small areas, or in a cluster arrangement, which may contain a mix of diodes, for treating larger areas.\textsuperscript{9} Depth of penetration for therapeutic laser light is determined by both absorption and scattering of the specific light frequency by body tissue. Visible red laser light (wavelength of 632.8 nm) has a depth of tissue penetration $<1$ cm, whereas infrared (wavelengths of 780 to 860 nm and 904 nm) can reach depths $<5$ cm.\textsuperscript{9} Infrared lasers typically combine with a red laser light source to both let the therapist and patient know the laser is on and to help
visually guide the invisible infrared beam.

Although the mechanisms by which low-level lasers may modulate pain are not definitively established, there is consensus in the literature that LLLT can induce photomodulation effects of chromophores within affected tissue. Cellular chromophores (light absorbing molecules) absorb photons from laser light as it penetrates the skin. Via influence over respiratory chain enzymes, chromophores may then undergo photobiomodulation in the form of either photobiostimulation or photobioinhibition. A dose–response interaction effect occurs based on the Arndt-Schultz law of photobiologic activation. Low doses of laser light activate photobiostimulation responses that are potentially efficacious for wound healing, whereas higher doses of laser light initiate a photobioinhibition response that may be beneficial for pain management.

With possible application to temporary pain relief, LLLT has been hypothesized to influence nerve conduction velocity. There are reports in the literature indicating both slight increases and decreases in peripheral nerve conduction velocity due to low-level laser application with resulting changes in distal latencies. Other studies report no effect on nerve conduction velocity following LLLT. The influence of LLLT on clinically significant changes in nerve conduction velocity appears uncertain. Other mechanisms by which LLLT may influence perceived pain remain to be explored.

Numerous studies have addressed the effects of LLLT with respect to treating a wide array of pain-generating conditions. For most disorders, the literature is somewhat divided between studies showing some clinically significant beneficial effects over controls and those that do not. Based on a critical review and preponderance of quality evidence from 157 studies, Belanger concluded that the therapeutic effectiveness of LLLT may be considered substantiated with strong evidence for the following conditions: rheumatoid arthritis, osteoarthritis, herpes/postherpetic neuralgia, myofascial/trigger point pain, and neck and low back pain. Controlled human studies reporting benefits from LLLT have been published that address pain conditions originating from various specific loci. Examples include carpal tunnel syndrome.
temporomandibular disorders,\textsuperscript{83} postsurgical abdominal pain,\textsuperscript{84} trigeminal neuralgia,\textsuperscript{85,86} plantar fasciitis,\textsuperscript{87} chondromalacia,\textsuperscript{88} orofacial pain,\textsuperscript{89} ankle sprains,\textsuperscript{90} and tendinopathies.\textsuperscript{91,92} However, at the present time, there appears to be insufficient evidence supporting the use of LLLT for treating acute muscle soreness.\textsuperscript{9}

Contraindications to LLLT include exposing any of the following to laser light: photosensitive skin areas; hemorrhagic areas; any area within 4 to 6 months after radiation therapy; neoplastic lesions; unclosed fontanelles or epiphyseal growth plates in children; the abdomens of pregnant women; over the heart, vagus nerve, or sympathetic innervation routes to the heart of cardiac patients; or locally to endocrine glands.\textsuperscript{6,9,42,61} Eye exposure is also contraindicated, so both patient and therapist must utilize protective eye wear that must be precisely matched with the frequency of light emitted by the therapeutic laser to afford protection. LLLT should be used with caution over areas with compromised sensation, reproductive organs, infected areas, and with patients displaying fever, epilepsy, or mental confusion.\textsuperscript{6,9,42}

**MONOCHROMATIC INFRARED ENERGY**

Infrared radiation, once widely used as a superficial heating agent, has recently emerged as form of light therapy that may have effects on processes leading to pain relief, tissue repair, and restoration of protective sensation.\textsuperscript{93} Current infrared devices produce MIRE from the near-infrared portion of the electromagnetic spectrum at a wavelength of 890 nm through a series of gallium aluminum arsenide diodes in a flexible pad.\textsuperscript{61} Infrared light may also be presented as pulsed infrared light therapy (PILT).\textsuperscript{93}

The physiologic effects of MIRE on biologic tissues are thought to be due to photochemical reactions in the skin similar to LLLT rather than thermal reactions. Light energy from MIRE devices causes an increase in plasma nitric oxide (NO) from red blood cells, leading to vasodilation and increased circulation. NO is thought to facilitate vascular perfusion, resulting in improved tissue oxygenation, delivery of nutrients, and removal of waste products of metabolism.\textsuperscript{94–96} The vascular effects and increased oxygenation to the tissues may facilitate wound healing and
potentially explain the promotion of nerve growth and resultant improvement in sensation that has been observed in some individuals with mild peripheral neuropathy.\textsuperscript{61,94,97}

The small volume of literature available on MIRE suggests that it has potential for the treatment of pain and spasm associated with temporomandibular joint dysfunction and healing of chronic wounds.\textsuperscript{61} It has also been widely promoted as a treatment for the pain and sensory loss associated with diabetic peripheral neuropathy (DPN).\textsuperscript{93,98} In a systematic review of randomized controlled trials assessing the effectiveness of MIRE or PILT on diabetic neuropathy, four studies assessed self-reported pain symptoms, with three finding no significant improvement.\textsuperscript{93} One study reported improved peripheral sensation and as well as decreased foot pain in an experimental group with less severe peripheral neuropathy but not in a group with more severe peripheral neuropathy.\textsuperscript{95} Infrared therapy was found to improve sensation in three studies\textsuperscript{97,99,100} and three reported no improvement.\textsuperscript{101–103} Infrared therapy was not found to improve nerve conduction, blood flow, tissue temperature, and transcutaneous oxygen pressure\textsuperscript{94,99,102} and was not found to improve most measures of quality of life or self-reported disease severity.\textsuperscript{102} There appears to be a lack of consistent evidence at this time supporting the use of infrared light therapy as a treatment for DPN in a physical therapy setting.\textsuperscript{93}

The precautions and contraindications to MIRE include avoiding placement over the low back or pelvic regions of pregnant women, cancerous lesions, anesthetic skin fields, areas of active hemorrhage, epiphyseal growth plates in children, and anterior neck region over the thyroid.\textsuperscript{61} Goggles are not required during treatment because the diode arrays block the infrared radiation from the eyes. However, the pads should not be placed over the eyes.\textsuperscript{61}

**Therapeutic Ultrasound**

Ultrasound is one of the most commonly employed thermal agents in rehabilitation medicine. It is widely used, and sometimes misused, as an adjunct to the management of pain and inflammation by physical therapists.\textsuperscript{4,104} Recent studies have found that 82.4\% of physical therapists
Ultrasound is the generation of high-frequency mechanical waves via acoustic energy. As acoustic waves pass through body tissue, their kinetic energy may be converted to thermal energy as the waves encounter tissues of varying sonic impedance. Clinically, ultrasound is capable of producing elevations in temperature at tissue depths of up to 5 cm through the conversion of acoustic energy into heat. Therapeutic ultrasound can be used as a thermal agent to increase deep tissue temperature or increase pain threshold, or as a nonthermal agent to address inflammation and facilitate tissue repair. Ultrasound is also utilized to deliver medication, such as steroid or analgesic preparations, into the tissues.

Therapeutic ultrasound utilizes a reverse piezoelectric effect. Acoustic waves are generated by a crystal sound head at frequencies of either 1 MHz or 3 (or 3.3) MHz. Amplitude densities are typically between 0.1 and 3 W/cm$^2$. Frequency and depth of penetration of the therapeutic ultrasound beam are inversely related. That is, 3 MHz ultrasound is capable of producing heat in tissues up to 2.5 cm from the skin surface, whereas ultrasound delivered at 1 MHz can reach depths of up to 6 cm. These parameters are in contrast to the ultrasound sources used for diagnostic imaging whose purpose is not to generate heat. Diagnostic ultrasound beams carry higher frequencies and lower wattage.

Molecules within soft tissue vibrate due to rarefaction and compression as ultrasonic acoustic waves pass through them. Heat is generated, and thus increased tissue temperature, from microfriction caused by this increased vibratory movement of molecules. Sonic impedance variations within body tissue facilitate heat generation in the presence of acoustic waves. In general, tissues with high absorption coefficients (i.e., those with low water content or collagen-rich structures such as tendon, cartilage, and bone) will attenuate more ultrasound energy than tissues with low absorption coefficients such as fat or muscle. The thermal effects of ultrasound, which include acceleration of metabolic rate, increased circulation, reduction of pain and muscle spasm, changes in
nerve conduction velocity, and increases in collagen tissue extensibility, are essentially the same as those of superficial thermal agents except that the structures heated are different.\textsuperscript{104}

Nonthermal effects of ultrasound are theoretically thought to be caused by the processes of cavitation, microstreaming, and acoustic streaming.\textsuperscript{6,104,107} As oscillating acoustic waves pass through soft tissue, microscopic bubbles, or cavities, are formed from the effect of cyclic drops in pressure on normally present minute gas pockets. Ultrasound produces a state of stable cavitation such that the microscopic bubbles formed pulsate without imploding. A flow of fluid is then established around the pulsating microbubbles, which is referred to as microstreaming, along with acoustic streaming which is the circular flow of cellular fluids.\textsuperscript{6,9} These processes have been reported to alter vascular wall permeability and cell membrane activity and facilitate soft tissue healing.\textsuperscript{9,107} In order to produce the beneficial nonthermal effects of ultrasound without causing an appreciable rise in tissue temperature, a pulsed mode with a duty cycle of 20\% or less is used.\textsuperscript{6}

The primary clinical indications for continuous (thermal) ultrasound are soft tissue shortening due to decreased collagen tissue extensibility in structures within 6 cm of the skin surface or pain attenuation. Via alterations in tertiary molecular bonding, heating collagen increases its extensibility. This property allows therapists to utilize ultrasound in treating structural contributors to chronic pain,\textsuperscript{16} such as maladaptive shortening of connective tissue, joint contractures, scar tissue, and tissue adhesions.\textsuperscript{6,9}

Pain is commonly treated with ultrasound due to its potential to influence inflammatory conditions, edema, or lack of connective tissue extensibility.\textsuperscript{104} Increased nociceptive thresholds may occur with exposure to continuous thermal ultrasound, thus giving the agent the potential to reduce perceived pain by influencing peripheral nociceptive activation and transmission.\textsuperscript{6,9,14,22} Hypothesized mechanisms for increased nociceptive threshold include heat activation of large diameter afferent fibers, alteration of nociceptor receptor sensitivity, and counterirritation.\textsuperscript{14}

Nonthermal (pulsed) ultrasound has been demonstrated in vitro and in animal models to influence many cellular parameters of tissue healing,
including increases in blood flow, intracellular calcium levels, skin and cell membrane permeability, rate of protein synthesis by fibroblasts, NO synthesis in endothelial cells, proteoglycan synthesis by chondrocytes, mast cell degranulation, and release of chemotactic factor and histamine. The majority of human trials exploring these effects have been limited to individuals with a variety of chronic wounds that may not, however, respond to the ultrasonic energy in the same way. Due to promising in vitro findings, low-intensity pulsed ultrasound, or “LIPUS” (frequency between 1 and 1.5 MHz, duty cycle ≤20% and intensity ranging from 0.03 to 0.8 W/cm²), has been investigated as a potential means to promote tissue healing in humans for conditions ranging from skeletal fractures to tendinopathies. However, in vivo studies and systematic review have found insufficient evidence that LIPUS is effective in managing inflammation or facilitating soft tissue healing. Its use for these purposes in clinical practice cannot be recommended at this time. There is, however, a preponderance of evidence substantiating the use of LIPUS for facilitating fracture healing.

Noncontact low-frequency ultrasound (NCLFUS) employs low-frequency ultrasound energy to deliver a saline mist to dermal wounds. It is used to débride and cleanse tissue covering a wound; remove fibrin, exudates, and bacteria; and increase cell membrane permeability to accelerate chronic wound healing. Reviews of efficacy studies indicate that the use of NCLFUS for promoting dermal wound healing may be considered substantiated based on current “moderate” evidence, with a notable absence of studies reporting no benefit.

Another application of nonthermal ultrasound is for treating pain and inflammation via phonophoresis to enhance topical agent absorption through the skin. Ultrasound is hypothesized to alter the permeability of the stratum corneum which may facilitate the passage of the medication transdermally into the tissues. Steroid preparations such as dexamethasone and hydrocortisone or analgesics such as salicylates and lidocaine are used between the sound head and the skin surface within a coupling medium. Although the purpose of this mode of medication delivery is to facilitate local tissue effects, drugs administered via phonophoresis do enter general circulation and systemic contraindications.
must be taken into account. Current evidence is quite divided, however, regarding whether delivery of corticosteroids or analgesics via phonophoresis promotes either a decrease in perceived pain or increases skin analgesia, with some studies reporting improvement in pain conditions and others showing little or no effect.

In controlled human studies, ultrasound has been reported to be an effective clinical tool with substantiated benefits in the management of pain associated with arthritic disorders, shoulder pain, adhesive capsulitis, soft tissue lesions, prolapsed intervertebral discs, and back pain. Mixed results have been reported in controlled studies for its effectiveness in the management of carpal tunnel syndrome, elbow epicondylitis, and shoulder calcific tendonitis. Limited evidence suggests positive benefits from ultrasound in treating phantom limb pain, postherpetic neuralgia, and myo-fascial pain. No significant benefit over controls has been reported in studies reviewed assessing the effectiveness of ultrasound for treating subacromial bursitis, shoulder peritendonitis, postextraction dental pain, and perineal postlabor pain. There is a strong consensus of evidence that ultrasound is not effective in the treatment of postexercise muscle soreness, delayed onset muscle soreness, or ankle sprains.

The potential influences that therapeutic ultrasound may have on pain mechanisms primarily occur at the tissue level. It is therefore of little potential value for treating central pain states or chronic pain conditions perpetuated by neuroplastic remodeling. Consideration of utilizing this biophysical agent with patients experiencing long-standing pain should be based on individual evidence that the patient’s pain generation has a nociceptive component due to an active peripheral lesion or inflammation.

Contraindications include the direction of ultrasonic acoustic energy over reproductive organs; pregnant abdomens; eyes; epiphyseal growth plates in skeletally immature patients; fractures; malignant lesions; hemorrhagic, ischemic, thrombotic, insensate, or infected regions; tuberculosis infection; plastic implants or cemented areas of prosthetic joints; areas exposed to radiotherapy within 6 months; central nervous system tissue; spinal cord region postlaminectomy; and electronic implants.
and neurostimulators. Caution should be exercised to use only pulsed low doses over areas of acute inflammatory pathology to avoid increased inflammatory response.

**Electrical Current**

Electroanalgesia is the use of electrical stimulation for pain modulation. The majority of analgesic biophysical agents have their therapeutic effects at the tissue level or site of the lesion, whereas electroanalgesia is thought to primarily operate by interrupting the neural propagation of pain. The most frequently utilized forms of electroanalgesia in clinical settings are TENS, IFC, and the delivery of analgesic medication to subcutaneous tissue via iontophoresis.

**TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION**

TENS is an attractive therapeutic option for pain management. It is nonpharmacologic, noninvasive, easy to use, low cost, and presents no side effects. It can be delivered in different ways to modulate various types of pain. For example, sensory– or motor-level stimulation is used to modulate peripheral nociceptive or neurogenic pain, whereas noxious-level stimulation may be used if pain is centrally mediated.

There are four different modes of TENS currently in clinical use that may produce electroanalgesia: sensory-level stimulation, motor-level stimulation, brief-intense stimulation, and noxious-level stimulation. Sensory-level stimulation is used for immediate temporary relief of acute, chronic, or postoperative pain. This type of stimulation, which is also known as high-frequency or “conventional” TENS, delivers high-frequency (80 to 110 Hz), short-duration (50 to 100 microseconds) pulses at an amplitude just below the motor threshold that causes comfortable paresthesia in the area of the electrodes. Conventional TENS affects primarily large diameter Aβ afferent fibers and is thought to work via the “gate control” theory proposed by Melzack and Wall. As Aβ fibers are stimulated, the patient experiences a reasonably comfortable paresthesia. Constant modulation of the parameters of the electrical
stimulus by the TENS unit is essential to minimize habituation to the analgesic effects. This type of TENS is appropriate for use during exercise, work, or functional activities. It should be noted that for a given patient, determination of an optimally effective TENS electrode placement site requires some time and exploration by an experienced therapist.

Motor-level stimulation is used for the management of chronic pain or in instances where longer duration pain relief is desired. This type of TENS, also known as “acupuncture-like,” delivers a current intensity sufficient to generate visible muscle contractions using low pulse frequencies (typically 1 to 4 pulses per second) and long pulse durations (~200 microseconds). It is proposed to control pain by stimulating the production and release of endogenous opiates such as enkephalins and endorphins as well as activating µ-opioid receptors. Acupuncture-like TENS is usually applied over a trigger point, motor point, or acupuncture point related to the painful region. Another type of stimulus presentation for motor-level TENS is called “burst train.” This approach is something of a hybrid combining conventional and acupuncture-like TENS. It delivers a long-duration (~200 microseconds) series of high-frequency (~100 Hz) pulses, at a low pulse rate (1 to 4 pulses per second), using an amplitude sufficient to cause muscle twitches. Due to its reported ability to produce more comfortable muscle contractions, this presentation is preferred by some patients. Motor-level TENS is not recommended for use during activities of daily living or exercise because of interference from muscle twitching.

Brief-intense TENS combines the stimulus parameters that cause both sensory- and motor-level stimulation, which is then delivered at the highest tolerable intensity. It is most often used during painful procedures such as wound débridement, wound dressing changes, joint mobilization, suture removal, or venipuncture. Brief-intense TENS is high-frequency (100 to 150 Hz), long-duration (150 to 250 microseconds) pulses at an amplitude that will cause strong paresthesia and a motor response under or between the electrodes, applied over a brief period of time (typically <15 minutes).

Noxious-level stimulation, which is sometimes called “hyperstimulation,” is thought to lead to analgesia via activation of the
descending pain suppression system mediated by the release of endogenous opiates. This mode of TENS is usually only attempted if other types of stimulation have not been effective. Noxious-level stimulation requires low- or high-frequency, long-duration (250 microseconds to 1 second) pulses at an amplitude that causes a painful sensation that is maintained for 30 to 60 seconds. It is reported to produce a concurrent depolarization of sensory (Aβ), motor (Aα), and nociceptive (Aδ and C) peripheral nerve fibers. This mode is typically applied over acupuncture, motor, or trigger points. It is generally quite uncomfortable, producing both muscle contractions and brief pain just below level of intolerance. It should only be used with patients who are fully aware of, and agreeable to, the expected discomfort.

The primary indication for TENS is attenuation of acute and subacute pain; yet, it has theoretical utility for chronic pain conditions where peripheral nociception is not the primary mechanism of pain generation. TENS has been suggested as a treatment option used to reduce painful input to the spine as early as possible in order to fight central pain generation via dorsal horn remodeling of N-methyl-D-aspartate receptors. It has also been hypothesized to use early sensory-level TENS over long stretches of time to body regions other than the painful locus, thus providing a competing attentional stimulus to decrease the probability of long-term cortical remodeling. As yet, there is no efficacy data available to assess the viability of these hypothesized approaches.

Prolonged usage of either high- or low-frequency TENS has been demonstrated in both animal and human studies to produce tolerance, thereby decreasing analgesic effectiveness. Cross-tolerance may also occur between TENS and opioid use due to adaptive changes at μ-opioid receptors in the spinal cord. There is evidence that low-frequency TENS operates centrally by triggering descending inhibitory pathways from the ventral lateral periaqueductal gray area which then projects to the ventral horn of the spine and activates μ-opioid receptors in the rostral ventral medial medulla, spine, and periphery. Because opioid drugs that activate μ-opioid receptors are commonly used, the tolerance developed by many people taking opioids may render low-frequency TENS ineffective for them. One early study demonstrated that people who had developed
presurgical tolerance to opioid use experienced no postsurgical analgesic benefit from TENS.\textsuperscript{154}

Significant clinical effectiveness has been reported in controlled human studies for TENS in the management of postoperative abdominal pain,\textsuperscript{155} postoperative thoracic pain,\textsuperscript{156} osteoarthritis,\textsuperscript{157,158} postoperative orthopedic pain,\textsuperscript{159} neck pain,\textsuperscript{160} trigeminal neuralgia,\textsuperscript{161} migraine headache,\textsuperscript{162} postamputation and phantom limb pain,\textsuperscript{163} dysmenorrheal pain,\textsuperscript{164} peripheral neurogenic pain,\textsuperscript{165,166} and shoulder pain secondary to stroke.\textsuperscript{167} There is less consistency in the clinical efficacy literature for the use of TENS to help manage low back pain,\textsuperscript{168–170} labor and postlabor pain,\textsuperscript{171,172} myofascial pain,\textsuperscript{173,174} and pain associated with rheumatoid arthritis.\textsuperscript{175,176}

Over-the-counter FDA-approved TENS units are now available and have become widely popular for independent home use. Costs range from around $25 for self-contained patch units for specific regional analgesia (e.g., shoulder or low back pain) to over $200 for higher quality, feature-loaded devices (e.g., multichannel, electromassage). Although TENS units are generally quite safe, it should be emphasized that proper usage and electrode placement are essential elements of effectiveness. It is highly recommended that potential users of these home electrotherapy devices schedule a session with experienced physical therapist to go over proper use, discuss tolerance issues, and determine hands-on the optimal electrode placement for the individual.

**INTERFERENTIAL CURRENT**

IFC was developed in the 1950s by Hans Nemec\textsuperscript{177} and first appeared in American clinics in the 1980s.\textsuperscript{41,143} It is one of the most commonly used electroanalgesic modalities in rehabilitation clinics.\textsuperscript{146} Its potential clinical advantages over other forms of electroanalgesia is theorized to be its ability to deliver therapeutic electrical stimulation to deeper tissue areas and with greater comfort for patients. To accomplish this, IFC utilizes two intersecting kilohertz-frequency AC carrier currents (~2,000 to 5,000 Hz) typically delivered via a cross-quadripolar placement of four electrodes.\textsuperscript{144} Skin resistance to these middle-frequency currents is much lower than for the range of frequencies utilized in conventional TENS units. Skin
impedance to a 4,000-Hz current has been measured at ~40 Ω, compared to ~3,200 Ω for a 50-Hz current. This decreased skin resistance allows a middle-frequency current to be delivered deeper into the tissue while using significantly reduced required current amplitude at the skin surface and, therefore, keeping the current amplitude at a very comfortable level for the patient.

Fundamental to IFC is that the two intersecting carrier currents differ in frequency by up to 250 Hz. As the currents intersect within the body tissue, there are moments when they are out of phase and cancel each other out (destructive interference) and other moments when they are in phase (constructive interference). This results in a deep wave whose frequency is the difference between frequencies of the two carrier currents, termed the beat frequency (typically 20 to 250 Hz). Given the heterogeneity of body tissue conductance, the precise location of the beat current varies yet is usually strongest beneath the electrodes. Most instrument configurations fix the carrier frequency of one channel and allow a frequency “sweep” of the second channel to both limit habituation effects and allow the beat current to migrate to different locations between the electrodes, thus expanding the field of analgesia.

The precise mechanisms for electroanalgesic effects of IFC are speculative at this time and have not been experimentally confirmed. The most often cited mechanism is large-fiber pain inhibition via the gate theory of pain. Other hypotheses include increased blood flow, physiologic blockade of neural conduction, activation of descending analgesic pathways, and placebo effects. It appears unlikely that IFC produces any physiologic effects that are different from TENS units. However, due to its potential ability to cover larger and deeper fields, IFC may be indicated for deep diffuse pain, whereas TENS may be more appropriate for more superficial, focal areas of pain. It is frequently reported that analgesic effects of IFC are of short duration and are usually limited to when IFC is actually being applied (typically in 10- to 20-minute sessions).

IFC is one of the most commonly used electroanalgesic modalities used in rehabilitation clinics and is utilized clinically for a wide range of disorders. Earlier literature has been inconclusive regarding IFC
efficacy for pain modulation, with studies reporting conflicting findings. However, over the past decade, a number of randomized controlled investigations are beginning to show some consistent effects for a limited number of conditions. Controlled studies assessing the ability of IFC to modulate induced pain in healthy subjects have reported decreased pain sensitivity to muscle pressure \(^{181}\) and increased pain thresholds to mechanical pressure in skeletal muscles following induction of delayed onset muscle soreness.\(^ {182}\) In randomized, placebo-controlled trials investigating the treatment of pain associated with knee osteoarthritis, IFC was found to be effective over controls \(^{183}\) and as effective as TENS and shortwave diathermy \(^{184}\) in studies involving 203 and 30 participants, respectively. IFC was also reported to be effective for knee osteoarthritis over sham IFC for improving stationary pain, pain with movement, perceived disability measures, and walking velocity.\(^ {185}\) Investigating responses from a combined total of 300 participants, similar randomized, controlled findings are in evidence for treating chronic low back pain, with IFC providing a significant level of measured pain relief, over placebo, roughly equal to that of TENS \(^{186}\) and decreased pain medication utilization.\(^ {187}\) In a controlled study of 63 patients with carpal tunnel syndrome, both IFC and TENS improved visual analog pain ratings, electrodiagnostically assessed median nerve distal latencies and sensory nerve conductance velocities compared to splinting therapy, and compared to TENS, IFC showed increases in functional capacity and decreased perceived symptom severity.\(^ {188}\) IFC has been demonstrated in a study of 30 hemiplegic patients to provide decreased pain intensity during movement of the hemiplegic shoulder and increased pain-free range of motion compared to placebo.\(^ {189}\) It should be noted that due to the temporary nature of IFC effects, studies are typically assessing and reporting episodic or short-term attenuation of pain, with one low back pain study finding IFC pain reduction effectiveness occurring only during the first treatment session.\(^ {187}\) Beyond temporary palliative relieve, IFC’s long-term efficacy or ongoing utility for chronic pain syndromes appears to be an open question.

**IONTOPHORESIS**

4677
Electrical currents can also be utilized to resolve inflammation, enhance healing, and facilitate delivery of topical medication transdermally. As early as 1741, Pivati hypothesized that an electromotive force could be used to deliver medications through the skin. The validity of this idea was first demonstrated with animals by Leduc in 1900. Iontophoresis is the utilization of direct current to facilitate transdermal delivery to target tissues of local ionizable anesthetics and anti-inflammatories. It allows local medication delivery without the use of a needle. Ionic medications carrying a positive electrical charge are drawn to cathode electrodes and repelled by anode electrodes, whereas negatively charged medication compounds display the reverse behavior. Iontophoresis was originally thought to drive the ions through the skin and into deeper tissues via electromigration. Recent work suggests that iontophoresis may promote transdermal penetration through electroporation, by increasing the permeability of the stratum corneum, similar to phonophoresis. Although iontophoresis has been demonstrated to effectively deliver select medications to target tissues, the actual depth of penetration of drug delivery is uncertain. Several studies have found diffusion of various drugs at tissue depths ranging from 3 to 20 mm.

For managing pain conditions via iontophoresis, several ionic compounds are in use. Negatively charged medications include dexamethasone (4 mg/mL in aqueous solution) for inflammation and salicylates (2% to 3% sodium salicylate solution or 10% trolamine salicylate ointment) for analgesia, inflammation, and chronic muscle and joint pain. Positively charged medications include hydrocortisone (1% ointment or solution) for inflammation, lidocaine (4% to 5% ointment or solution) for soft tissue pain and inflammation, and magnesium sulfate (2% ointment or solution) for skeletal muscle spasms. Physical therapy clinics are typically equipped to administer medication via iontophoresis. However, the patient must bring the ionic medication preparation prescribed by the referring physician to the clinic.

The most salient precaution regarding the use of iontophoresis is based on the fact that it utilizes direct current. Sustained application of DC iontophoresis will result in a hydrogen ion concentration beneath the anode and hydroxyl ions beneath the cathode. When used to excess, the
accumulated pH changes may result in electrochemical acid or base burns to the skin. These subdermal pH changes also have the potential to affect drug ionization and stability. There exist iontophoresis delivery units that utilize alternating current with a “DC offset” to potentially ameliorate this concern; however, efficacy evidence for this approach is lacking.

A relatively recent advance is the availability of small, wireless battery-operated iontophoresis devices, or “iontophoresors.” These may be worn at home by the patient and reduce the need to be present in the clinic in order to utilize this transdermal form of medication delivery. These compact single-adhesive patch devices deliver DC from a button size 0.1 to 4 mA battery via a microcircuit integrated to anode and cathode electrodes with imbedded ionized medication in a saline suspension. The very low amplitude current can deliver medication for periods up to 24 hours.

Although there are few controlled studies in the literature addressing the use of iontophoresis for managing chronic pain, there are reports of significant clinical effectiveness in treating arthritic disorders with dexamethasone and salicylate. There are individual clinical studies reporting success with dexamethasone delivered using this method in treating postherpetic neuralgia, epicondylitis, plantar fasciitis, carpal tunnel syndrome, and Achilles tendonitis.

Contraindications to the use of electroanalgesia include its use in individuals with a known cardiac arrhythmia; over the anterior cervical region or carotid sinuses; over a gravid uterus; over infected areas or sites of active bleeding; in the presence of an implanted defibrillator, demand-inhibited cardiac pacemaker, or any other implanted electrical device; and for individuals with venous or arterial thrombosis or thrombophlebitis. The use of iontophoresis is contraindicated for patients with sensitivity to ionic medications and over open skin lesions.

Precautions should be exercised when using electrical stimulation in the presence of skin irritation or open wounds, malignancies, osteoporosis (with motor-level TENS), or cardiomyopathies; with transthoracic electrode placement (potential for inducing cardiac arrhythmias); over areas of heavy scarring; over tissues susceptible to hemorrhage or
hematoma; on patients with movement control disorders or impaired cognition; on areas of anesthetic skin; over superficial metal implants; on craniofacial regions for patients with a history of stroke or seizures; and on patients who are driving or operating heavy machinery. Limited duration drops in arterial blood pressure have been reported during stimulation to the pelvic floor. With the use of adhesive electrodes, precautions should be taken to prevent skin damage due to adhesive irritants and pH changes under electrodes when using direct current for iontophoresis or for prolonged applications such as TENS.

**Somatosensory Desensitization**

Somatosensory desensitization, utilized extensively by physical therapists and occupational therapists, is considered a requisite component of standard care in the treatment of complex regional pain syndrome (CRPS) and phantom limb pain. Desensitization therapy involves exposing a patient’s painful skin region to direct physical contact with a progression of materials that have the potential to trigger somatosensory irritation. This intervention belongs to a family of treatment approaches for chronic neuropathic pain that paradoxically involve patient exposure to increases in pain that may be linked to physical restoration and functional activity. Other approaches in this category include “pain exposure physical therapy” (PEPT) and “graded exposure” (GEXP), which are showing promise in pain reduction via functional restoration involving carefully dosed exposure to progressive-loading exercise programs coupled with management of pain-avoidance behavior. These strategies are based on the idea that behavioral avoidance of mobility, tactile contact, and functional activity may in some cases maintain the pain condition. Therapeutically managed graded pain exposure may help “reduce peripheral and central sensitization and may restore the local autonomic regulation and cortical representation.”

The indication for this therapeutic tool is treatment of allodynia associated with chronic pain conditions such as CRPS. Alldynia is a painful response to nonnoxious somatosensory stimulation. One of the hallmarks of CRPS, allodynia is not the same phenomenon as the
normal hyperalgesia that follows tissue damage. Patients experiencing allodynia may avoid the most seemingly innocuous tactile contact, sometimes refraining from wearing even delicate clothing over the affected area. Allodynia treatment via desensitization aims to attenuate this abnormal somatosensory response and help the patient return the affected area (typically a limb) to normal somatosensory exposure and functional usage. Somatosensory desensitization is also used in the treatment and prevention of postamputation phantom limb pain.

Traditional somatosensory desensitization protocols involve having the patient lightly rub the painful skin field with a progressive series of coarse or irritating materials. Early desensitization therapy for CRPS used the chemical irritant capsaicin as the desensitizing agent. In current practice, materials may progress from soft fabrics to items such as small pebbles or dry pasta. Twice daily, the patient rubs the material over the affected area for approximately 3 minutes, then rests for 2 to 3 minutes, and finally rubs again for 3 more minutes. Each week, the patient advances to a coarser or potentially more irritating material. Treatment course may span 2 to 4 months and includes home application and in-clinic checks at least weekly. Somatosensory desensitization is contraindicated over an active lesion that may be harmed by contact with physically irritating materials or mechanical pressure.

Attenuation of allodynia via desensitization may be due to multifaceted mechanisms. These have been hypothesized to involve somatosensory habituation, reintroduction of large fiber diameter afferent pain inhibition, altered central processing of somatosensory input either at the dorsal horn or parietal lobe, prevention of the development of new permanent neuroplastic pain pathways in the neuromatrix, normalization of exposure to the distal environment, and management of pain avoidance behavior. During the course of desensitization, the patient is encouraged to begin reintroduction of the limb or body area into normalized functional usage. With direction from the therapist, this reintroduced usage may facilitate a positive spiral of ascending exogenous analgesia and activity. Normal activities of daily living then become a continuation of the desensitization therapy and its
ongoing effectiveness.\textsuperscript{10,14}

Many patients who have undergone successful desensitization to light touch or who never manifested light touch allodynia may still find nonnoxious levels of pressure, vibration, or thermal variation to be painfully intolerable.\textsuperscript{10,208,213} Desensitization therapy may therefore be specific to a given somatosensory modality.\textsuperscript{214} Therapeutic desensitizing agents must be matched to the type of somatosensory stimulation triggering the allodynia.\textsuperscript{208,213}

Studies have reported success in managing tactile,\textsuperscript{10,215–217} thermal,\textsuperscript{213} vibratory,\textsuperscript{218} and pressure-related allodynia.\textsuperscript{208} A 2016 systematic review investigated the current state of evidence on somatosensory desensitization, representing 10 studies and a combined total of 68 patients.\textsuperscript{200} This review reported that conclusive efficacy evaluation is limited due to small sample sizes, frequent lack of controls, and inconsistency in desensitization protocols across investigations and that many studies combined desensitization therapy with multimodal treatments.\textsuperscript{200} Although currently available research is limited, the consistency of positive results supports the utilization of desensitization in the treatment of people with CRPS while stronger efficacy evidence is sought.\textsuperscript{200}

In addition to attenuating allodynia, case study findings report the total body area of reported pain distribution decreasing, or retreating, as a function of desensitization,\textsuperscript{219} as quantified using a pain distribution scale.\textsuperscript{220} It is also meaningful to note that a study on the effects of pressure desensitization found that increased usage of analgesic medication during the desensitization trial did not appear to diminish the effectiveness of treatment.\textsuperscript{208} Significant reductions in subsequent pain medication usage and pain intensity, combined with improved functional usage, suggested that use of analgesics to tolerate the desensitization therapy may not interfere with the treatment’s effectiveness.\textsuperscript{208}

Desensitization of painful regions may additionally impact somatosensation in proximal limb areas unaffected by pain.\textsuperscript{219} There is emerging evidence that as a result of chronic pain in distal limb segments, proximal limb regions may develop diminished somatosensory thresholds and acuity.\textsuperscript{10,219} This is plausible if remodeling of the somatosensory
cortex has resulted in increased representation of painful regions at the expense of diminished cortical representation of proximal nonpainful areas of the limb.\textsuperscript{212,221} A 2017 study of somatosensation in nonpainful limb regions of CRPS patients found notable improvements (toward normalization) in both somatosensory acuity and perceptual thresholds in proximal limb areas that paralleled distal pain reduction over the course of desensitization treatment.\textsuperscript{219} These findings suggest expanding the scope of what may be considered affected body regions in patients with chronic pain to include not only painful sites but also adjacent nonpainful areas that are manifesting decreased somatosensation as a result of the ongoing focus on the painful areas and likely cortical remodeling. Potential impact may include previously unrecognized proprioceptive attenuation, limb placement impairments, and reduced functional limb usage.

**Emerging Interventions**

**MANUAL LYMPHATIC DRAINAGE**

There is growing clinical interest in the application of lymphedema reduction techniques for the management of both subacute and chronic pain conditions.\textsuperscript{222} Referred to as complete decongestive therapy (CDT), these techniques have been utilized to manage edema and related pain resulting from primary lymphedema conditions such as Milroy disease, Park-Weber syndrome, and Klippel-Trenaunay syndrome, or secondary lymphedema resulting from causes such as surgery, trauma, radiation, obesity, or infection.\textsuperscript{223,224} CDT involves a systematic approach utilizing manual lymphatic drainage (MLD), short stretch compression bandaging, decongestive exercise prescription, compression garments, and patient education.\textsuperscript{223,224}

Early resolution of edema and prevention of fibrosis development can be an important factor in recovery and pain management for subacute conditions.\textsuperscript{16} It may also be a useful element for addressing pathophysiologic deactivation mechanisms integral to the development of chronic pain states such as CRPS.\textsuperscript{16,18} A key feature of this sequela is that disuse of distal skeletal musculature leads to venous stasis, followed by edema, decreased arterial perfusion, the establishment of an anaerobic
environment, local acidosis, and finally fibrotic tissue changes.\textsuperscript{16} It has been hypothesized that introduction of CDT early in this process, to break the cycle of chronic lymphostasis, may be beneficial in treating CRPS, or in some cases perhaps interrupting its development.\textsuperscript{225}

Studies assessing the efficacy of CDT for treating CRPS are limited at this time. An initial prospective, randomized investigation compared 35 outpatients experiencing CRPS type I of less than 6 months standing who received either physical therapy with MLD or physical therapy exercises alone.\textsuperscript{225} The symptoms of patients with high pain levels in the lymphatic drainage group were reported to show improvement.\textsuperscript{225} A randomized trial involving 34 patients with CRPS demonstrated statistically significant short-term reductions in edema after MLD treatment.\textsuperscript{226} The long-term efficacy of this treatment approach for CRPS has not yet been established.

Protocols described in efficacy studies and structured interviews conducted with certified lymphedema therapists experienced with the utilization of CDT for patients with CRPS have yielded implementation recommendations. As a general rule, decongestive therapies for CRPS may be most beneficial in the early stages before fibrosis has developed (<12 months following acute injury). In the presence of allodynia, a course of somatosensory desensitization should precede usage of CDT elements. Compression bandaging and/or garments should be the last treatment element introduced.\textsuperscript{225,226}

General contraindications for lymphedema therapy include history of peripheral vascular disease, chronic venous insufficiency, thrombosis or other venous blockage, ongoing thrombophlebitis, hemorrhage, acute enuresis, malignant tumors, renal insufficiency/failure, and congestive heart failure.\textsuperscript{223,224}

**CUPPING**

Cupping is an ancient technique whose therapeutic application has been traced as far back as the Egyptian “Ebers Papyrus” (circa 1500 BC) and has a history of reported usage in Chinese medicine extending at least 2,000 years.\textsuperscript{227,228} Traditionally, it involved heating small cups of glass, earthenware, or bamboo that were then placed on the skin where the cooling of air within the “cups” created a partial vacuum, thus drawing the
skin deeply into the cups while rupturing small blood vessels and creating a local area of ecchymosis. Current techniques involve either traditional heat or a vacuum apparatus using unheated glass or compressible silicone cups to create the partial vacuum. Western applications frequently refer to cupping as “myofascial decompression.”

Cupping is widely performed by current practitioners of traditional Chinese medicine and across the world, particularly in eastern Asia and the Middle East. Interest in the technique is growing in Western countries and physical therapy clinics, in part highlighted by the number of athletes appearing at the 2016 Summer Olympics in Rio de Janeiro conspicuously displaying numerous circular skin welts derived from the use of cupping purported to aid in muscle recovery following intense training. It has been applied as a treatment modality for a broad spectrum of conditions such as facial paralysis, respiratory disorders, postexercise muscular soreness, herpes zoster, and cervical spondylosis and diverse pain conditions ranging from carpal tunnel syndrome and nonspecific low back pain to fibromyalgia syndrome. One factor in its growing popularity as a potential therapeutic adjunct to pain management may be due to the fact that patient surveys have consistently cited pain as the most common reason for people seeking therapeutic alternatives to conventional medicine.

Fundamentally, cupping is performed using one of two methods, either “dry” or “wet.” Dry cupping simply draws a small skin field into the cup via the partial vacuum. In traditional Chinese medicine, cups are applied over acupuncture points. Cups are left in place for varying amounts of time anywhere from less than 3 to as long as 15 minutes. Other procedural variations may be used depending on the desired therapeutic effect, such as pulsating (or “pneumatic pulsation therapy”), “quick,” “shaking,” and “balanced” cupping. A dry form of “moving cupping” involves sliding the cups along a skin surface that has been lubricated with massage oil. This method has been explored for use in mobilizing subcutaneous connective tissue to break down adhesions or scar tissue and possibly facilitate myofascial release. Theoretically, cupping may be advantageous in this regard because other methods of mobilizing or releasing underlying connective tissue (e.g., deep tissue massage or
Graston Technique) involve compressing tissue, whereas cupping acts to pull and separate tissue. Although there is a recent proliferation of instructional resources on how to use cupping for “myofascial decompression,” to date, there is not adequate published research demonstrating whether cupping can mechanically generate specific force necessary to address adhered tissue below the skin surface or clinical evidence establishing its effectiveness for this purpose.

Wet cupping, which is widely used in eastern Asia and the Middle East,

involves first making skin incisions beneath where the cups will be placed so that the technique may withdraw blood and, in theory, extract “harmful substances.”

There does not appear to be a research foundation at this time establishing specifically what harmful substances are extracted and whether the quantities withdrawn are sufficient to produce therapeutic benefit. Due to its invasive nature, wet cupping is not within the licensure parameters or practice domain of most physical therapists, unless they have additional training and certification.

The mechanisms of action for therapeutic benefits associated with cupping are unclear,

with those currently offered in the literature being primarily untested speculative hypotheses or vague generalizations.

It is often stated that the basis of cupping is to “regulate and promote movement of qi and blood.”

The assertion is that, “by doing so, cupping is able to alleviate pain, caused by blood stasis and qi blockage. Cupping may also accelerate microcirculation and relieve muscular spasm.”

No physiologic evidence has been cited for these mechanisms.

Physiologically, cupping is creating a skin region of negative pressure resulting in rupture of superficial capillaries and a defined area of ecchymosis. Without supporting evidence, this effect has been cited as increasing blood circulation,

modulating lymph flow,

and reducing blood stasis.

It is also thought to provide stretch to nerve and muscle,

thought to remove waste products (e.g., lactate) from the body via wet cupping,

and theorized to release “a chemical transmitter that can block pain, such as serotonin, endorphin, and cortisol.”

Alteration of local metabolism as a result of cupping was assessed in a study of six healthy individuals and six with chronic neck pain, which found slight increases in pain threshold immediately
postcupping and creation of a local anaerobic state evidenced by increased lactate and lactate/pyruvate ratio occurring between 160 and 280 minutes following the procedure, with no signs of a change in pain thresholds during this anaerobic period. Suggested perceptual mechanisms for potential analgesic effects from cupping have included a counterirritant effect to increase pain thresholds and stimulate inhibitory nociceptive pathways, triggering of “diffuse noxious inhibitory control” (DNIC), tactile stimulation from the procedure producing an analgesic effect via the gate theory, and the influence of a powerful placebo effect.

Because of expanding interest in cupping as a therapeutic option for pain management, a thoughtful assessment of research into its potential efficacy and knowledge of verified plausible mechanisms of action are warranted prior to clinical implementation. To date, there have been a notable number of randomized controlled studies (RCTs) and at least six systematic reviews published related to the efficacy of cupping for treating a very wide variety of disorders, including both acute and chronic pain conditions. The majority of research has addressed wet cupping. However, due to generally low methodologic quality of studies, there exists broad consensus among both investigators and reviewers that evidence for cupping is inconclusive at this time.

Cao et al. published a 2012 review of 135 RCTs addressing cupping efficacy (132 appearing in Chinese). “Meta-analysis showed cupping therapy combined with other traditional Chinese medicine treatments was significantly superior to other treatments alone in increasing the number of ‘cured’ patients with herpes zoster, facial paralysis, acne, and cervical spondylosis.” The reviewers discussed a “lack of well-designed investigations.” This was due in part to the finding that according to application of the Cochrane risk of bias tool, none of the 135 trials reviewed were “low risk of bias” and “nearly all” determined to be “high risk of bias.” This review was updated in 2014 with 16 additional studies involving 921 total participants. All trials were assessed via Cochrane criteria as “low risk of bias,” and addressed nonspecific low back pain, chronic neck pain herpes zoster, osteoarthritis, shoulder pain, shoulder–hand syndrome, scapulohumeral periarthritis, carpal tunnel syndrome, acute ankle sprain, and headache. The review concluded that
Cupping therapy may reduce pain intensity in chronic or acute pain.\cite{228} Based on systematic review of 14 RCTs, Al Bedah et al.\cite{230} reported in 2016 that there exists “promising evidence in favor of the use of wet cupping for musculoskeletal pain, specifically neck pain, carpal tunnel syndrome, nonspecific low back pain, and brachialgia.” In an overview of five earlier systematic reviews, Lee et al.\cite{239} concluded that “cupping is only effective as a treatment for pain, and even for this indication doubts remain.” In addition to those cited in systematic reviews, trials suggesting positive responses to cupping therapy impacting measures such as decreased subjective pain intensity ratings, pain-related function, pain medication usage, and improved quality of life have been reported for chronic tension and migraine headaches,\cite{241} carpal tunnel syndrome,\cite{236} osteoarthritis of the knee,\cite{242} chronic neck pain,\cite{234,243} and nonspecific low back pain.\cite{233,235}

Available studies have yielded “suggestive evidence for the effectiveness of cupping in the management of pain conditions.”\cite{231} However, the consistent view in current literature is that the limited quality of studies does not yet provide convincing evidence that the effects of cupping on pain is sufficient to draw firm conclusions.\cite{233,235} Due to methodologic quality, most cupping studies have been published in low-impact journals.\cite{230} The quality of available studies is primarily limited by inadequate placebo controls and resultant lack of blinding.\cite{228,231} For this type of treatment, it is difficult to implement an effective placebo in that participants can readily tell the difference between actual cupping and sham procedures.\cite{236} One of the few attempts to provide a placebo control was in a recent study of patients with fibromyalgia syndrome, where patients were told they would receive either “traditional cupping” or “modern gentle cupping.”\cite{238} The “modern gentle cupping” control utilized silicone cups with small holes that would very quickly release the negative pressure inside the cup. The authors reported “effects of cupping therapy were small and comparable to those of a sham treatment, and as such cupping cannot be recommended for fibromyalgia at the current time.”\cite{238}

The vast majority of published trials, including all of the 135 studies cited in Cao et al.’s\cite{227} 2012 systematic review, report patients experiencing no serious adverse effects from cupping.\cite{227,234–236} Resulting
ecchymosis is considered a natural response to the procedure and is reported to typically resolve in 2 to 5 days or may persist up to 2 weeks.\textsuperscript{228} Potential adverse effects may include burns (with heated cups), mildly increased pain,\textsuperscript{238} skin infections (with wet cupping), or fainting (three cases reported).\textsuperscript{231}

Cupping is contraindicated for patients with congestive heart failure, renal failure, systemic inflammatory conditions (e.g., rheumatoid arthritis), hemophilia or other blood coagulation disorders, or those taking anticoagulant medication; over the eyes; over skin areas with burns, open wounds, active inflammation, infections; or with underlying severe edema, neural tissue sensitivity, large or varicose veins, hernia, or severe edema.

**MIRROR THERAPY AND GRADED MOTOR IMAGERY**

Treatment modalities utilized by physical therapists to address chronic pain conditions have broadened in scope to include interventions that target cortical reorganization.\textsuperscript{5,9,15} It is recognized that in the development of chronic pain, there is a progression from nociception of distal tissue damage to a dominance of maladaptive neuroplastic remodeling\textsuperscript{17,244} of the spine’s dorsal horn and the body representation of both somatosensory\textsuperscript{245} and motor\textsuperscript{246,247} cortical areas. Physical agents that influence pain mechanisms associated with distal tissue damage may be of limited effectiveness, or inappropriate, for treating chronic pain states where the central nervous system is playing the primary role in the generation and/or perpetuation of pain.\textsuperscript{14,15} An emerging treatment approach for cortical remodeling is “mirror therapy,” sometimes used in conjunction with graded motor imagery.\textsuperscript{11,12}

Mirror therapy was first introduced in 1996 by Ramachandran and Rogers-Ramachandran,\textsuperscript{248} who hypothesized that individuals with phantom limb pain had a visual–proprioceptive dissociation in the brain. They found that patients experienced a reduction in symptoms by simply viewing a mirrored reflection of their intact limb.\textsuperscript{248} This approach has since been utilized for patients with cancer, stroke, focal dystonia, and chronic neuropathic pain conditions such as CRPS types I and II.\textsuperscript{12}

The technique of mirror therapy involves positioning a mirror on a midsagittal line in front of a patient so that the painful, or amputated, limb
is blocked from view. In place of the distal painful limb, what the patient sees is a reflection of the intact nonpainful limb. The simple technique creates a vivid visual illusion for the patient, such that somatosensory stimulation or movements and functional activities of the nonpainful limb appear as though they are being conducted with the affected limb. This perceptual slight-of-hand provides a visual and somatosensory message to the neuromatrix that the involved limb can be perceived, is performing movement, and engaged in activity without triggering pain, thereby theoretically contributing to cortical reorganization in opposition to the maladaptive remodeling that is perpetuating the pain experience. Detailed guidelines for the clinical implementation of mirror therapy with phantom limb pain, based on extensive evidence review, have recently been published by Rothgangel et al.

Mirror therapy is frequently implemented by first taking the patient through preparatory laterality recognition training and then graded motor imagery practice prior to utilization of mirrors. It has been suggested that until patients experiencing chronic pain can establish “an accurate cortical representation of their body,” they should not proceed with graded motor imagery or mirror therapy. This is theoretically due to a common “neglect-like” response, whereby the patient cognitively walls off the involved limb to help affectively cope with the pain, resulting in a distorted body image evidenced by an impaired ability to distinguish left from right. Clinical studies report enhanced efficacy findings when mirror exercises are prefaced by laterality training and graded motor imagery practice.

Case reports and small uncontrolled studies have reported reductions in the intensity, or resolution, of phantom limb pain, sometimes after as little as 3 weeks of therapy. Randomized controlled trials investigating the impact of mirror therapy on phantom limb pain have reported significant reductions in phantom pain, attenuation of phantom pain that was not significantly different from the use of TENS, and no significant reduction in phantom pain or phantom sensations, yet increased conscious awareness of the phantom limb. Three single-blind randomized controlled trials using mirror therapy combined with laterality training and graded motor imagery found that at 6 weeks, patients with upper limb
CRPS type I reported significant decreases in pain, swelling, and disability. One of these studies reported significantly decreased pain associated with increased function at 6 weeks and at 6-month follow-up. Perceiving the illusion of two intact limbs has been reported to trigger emotional reactions in some patients. In at least one study, patients experienced significantly increased cognitive focus on the painful limb. Additional reported reactions that reported when viewing the mirror-image limb have included nausea, dizziness, and sweating. Those reactions may be addressed via graded exposure to the treatment.

Either with or without laterality training and graded motor imagery, mirror therapy is a simple, safe, noninvasive, and cost-effective intervention whose efficacy in the long-term management of chronic neuropathic pain has yet to be fully explored.

Conclusion

There is a broad spectrum of therapeutic biophysical agents available to aid in the management of both acute and chronic pain conditions. Determination of the suitability of biophysical agents and selection of the appropriate modality should be made with careful consideration of the mechanism of pain generation for the individual patient and pursued with careful treatment response monitoring. It should be reemphasized that although the use of biophysical agents for treating pain is common in physical therapy settings, their use should be viewed as adjunctive. Effective pain management involves not only the attenuation of pain perception but also restoration of compromised or lost function. Appropriate, comprehensive treatment integrates the application of biophysical agents with other indicated therapeutic activities and patient education to address the mechanisms of pain generation and perception while facilitating functional restoration.

Exercise Therapy for Low Back Pain

ELLEN McGOUGH and JOYCE M. ENGEL

Exercise is a frequently prescribed nonpharmacologic intervention for low back pain (LBP). Exercise for therapeutic purposes is defined as the systematic, planned performance of bodily movements, postures, or physical activities. Regular exercise improves general fitness, results in a sense of well-being, and is associated with lower incidence and severity of comorbid conditions such as depression, fatigue, and insomnia, which are often associated with persistent pain. The purpose of this chapter is (1) to describe clinical evaluation and decision making for the development of exercise interventions for individuals with LBP, (2) to discuss physical and psychosocial elements of exercise interventions that ultimately impact outcomes, and (3) to present available evidence for exercise therapy approaches across stages of LBP.

LBP of musculoskeletal origin is a common problem and a major cause of disability. More than 56% of American adults (125 million) had a musculoskeletal pain complaint in 2012. Eighty percent of the population report LBP at some time during their lives, and LBP is the most common cause of work-related disability in people under 45 years of age. Annual financial costs (direct medical expenses, lost income, lost productivity) of all persistent pain syndromes exceed $500 billion annually. Over and above the financial cost of LBP, the human cost, in terms of suffering and impact upon quality of life, cannot be estimated.

According to the American Chronic Pain Association, “persistent” pain is a more accurate description than “chronic” pain, as the former includes information on how pain can interrupt functioning, well-being, and quality of life. The term persistent pain therefore is used throughout this chapter. LBP is considered a condition, rather than a disease, with multiple
physical and psychosocial factors that impact the prognosis for recovery across the continuum of acute to persistent LBP conditions. LBP not originating from serious spinal pathology or nerve root pain is often classified as “nonspecific LBP” due to our current inability to identify pathologic changes. However, several classification systems have been developed to provide a framework for selecting rehabilitation interventions for the treatment of musculoskeletal LBP, including approaches to exercise. Despite the fact that the majority of patients with isolated LBP cannot be given a precise pathoanatomic diagnosis, exercise interventions hold promise for reduction of pain and disability.

Exercise for musculoskeletal LBP is just one component of a multimodal treatment program which often includes education of anatomy and pathomechanics, postural modification, body mechanics training, manual therapy, functional training, and physical modalities (e.g., thermotherapy, cryotherapy, electrical stimulation). Due to the complex nature of persistent pain, multidisciplinary interventions are often indicated which typically include exercise, relaxation training, cognitive restructuring, vocational counseling, and medication management.

Designing an individualized exercise program is a dynamic process initially based on the patient’s impairments and exercise tolerance and then adapted to address functional goals. Specific exercises are used for the purpose of addressing LBP symptoms and physical impairments. A specific exercise approach is often selected based on a movement-based diagnosis or theory of contributing pathophysiology, for example, disk pathology, lack of segmental motor control, or dysfunction in joint mechanics. Exercise interventions designed to address body region impairments are often based on theories of movement dysfunction and muscle imbalance that contribute to mechanically induced LBP and focuses on the correction of postural alignment, modifications of faulty movement patterns, and improvement of neuromuscular control.

As acute symptoms subside, patients should transition from specific exercises to global exercise that emphasizes fitness and prevention of relapse. Global exercise programs include components of aerobic, flexibility, strengthening, coordination, and agility exercises. A progressive exercise prescription should be incorporated as soon as the
patient demonstrates adequate tolerance and regional movement control, with the ultimate goal of integrating regular exercise into the patient’s daily routine.

The overall goal of rehabilitation programs for individuals with LBP is to restore function, assist patients in returning to activity and social participation, and prevent recurrence. Functional restoration involves not only improving physical performance but also the integration of skills into the individual’s social and physical environments. In addition to physical factors, psychosocial, environmental, and personal factors should be taken into consideration when prescribing exercise.29–31

There is broad agreement that LBP and disability should be managed according to a biopsychosocial model which includes health-related, personal, psychological, and social dimensions and the interactions between them.10,19,31 Although the origin of LBP and disability may be caused by a biologic condition, the development of persistent LBP and incapacity are subject to dominant psychosocial influences.10 The International Classification of Functioning Disability and Health model is a biopsychosocial model designed to measure health and disability at the individual and population levels.32

Disability is an umbrella term for impairments, activity limitations, and participation restrictions.33 Three dimensions related to functioning and disability include (1) body functions and structures, (2) activities at the individual level, and (3) participation in society. Impairments of body functions and structures are defined as problems with physiologic functions and/or anatomic parts, such as loss of joint range of motion or reduced muscle strength. Activity restrictions are problems with executing a task or action and reduced participation includes lessened involvement in lived situations such as work, recreation, or social activities. Contextual factors include aspects of the human-built, social, and attitudinal environments that create the lived experience of functioning and disability as well as personal factors such as sex, age, coping styles, social background, education, and overall behavior patterns that may influence how disablement is experienced by the individual.30 Environmental factors may include physical or social barriers or facilitators to activity and participation.32
Changes in attitudes and beliefs may have as much impact as physiologic changes, resulting from exercise, on the activity and participation of individuals.\textsuperscript{10,34–36} This indicates that physical, psychosocial, environmental, and personal factors should all be considered when designing individualized exercise programs (Fig. 93.1).

**Individualized Exercise Programs**

**MUSCULOSKELETAL EXAMINATION FOR LOW BACK PAIN**

A systematic musculoskeletal examination involves the patient’s history, a systems review, special tests, and measurements.\textsuperscript{37} The goals of the clinical examination include (1) to identify contributing impairments; (2) to screen for serious medical problems and precautions related to physical activity; (3) to implement validated outcome measures; (4) to establish
baseline status and assess their response to intervention; (5) to establish baseline exercise tolerance; (6) to identify barriers to activity and participation; and (7) to understand the patient’s goals, preferences, and resources to successfully follow through with in exercise program.38

In addition to questions regarding pain patterns and the nature of the back problems, the examination should include inquiry related to medical history (including previous musculoskeletal problems and interventions used), psychosocial issues, and environmental barriers to activities and participation. A systems review is also conducted to screen for red flags and to identify potential problem areas. Screening of the neurologic system through testing of key muscles, sensation, and reflexes is an essential component of an LBP evaluation. Current guidelines also emphasize attention to psychosocial factors, at acute through chronic stages of nonspecific LBP, that may impact rehabilitation prognosis and intervention planning.11,39 Learning about the patient’s understanding and beliefs related to their back problem is important. For example, screening for yellow flags, psychosocial factors including fear, unhelpful beliefs in severity of health conditions, catastrophizing, and poor problem solving is helpful in identifying patients at risk for persistent pain and disability.40,41

Anatomical structures that may contribute to pain should be tested with a systematic approach including tests of active and passive movement, tissue palpation, end range testing, repeated movements, and sustained postures.21,37,42 Examination of a patient’s postural alignment, willingness to move, body mechanics, and movement patterns should also be incorporated to gain an understanding of problems related to posture and general mobility.37 Functional performance tests and task analysis provide information related to the ability to perform activities needed to return to activity and participation, including employment.37,42

The results of a comprehensive musculoskeletal examination are used to identify physical impairments and psychosocial factors for which purposeful exercise interventions can be aimed. Key elements of an individualized prescription, including exercise interventions, coping strategies, and education, are based on evaluation (Table 93.1). The patient’s ability to perform specific exercises serves as an additional source of feedback for both the patient and clinician. During the acute
stage of management, specific exercises are selected and modified based on the patient’s responses to body position, direction of movement, and dose (intensity, duration, and frequency).

Individualizing the exercise program by mutual goal setting, to meet both physical and psychosocial needs, is essential in maximizing adherence and achieving patient satisfaction. Supervision and adequate compliance are common aspects of randomized clinical trials that have demonstrated positive outcomes for exercise interventions for persistent LBP.

**DESIGNING INDIVIDUALIZED EXERCISE PROGRAMS**

The purpose of exercise interventions refers to the patient’s and clinician’s goals: (1) specific exercises designed for symptom reduction or addressing physical impairment, for example, impaired muscle performance, joint mobility, flexibility, or kinesthetic awareness and (2) global exercises for improving overall strength, flexibility, and endurance. It is important to
adapt an individualized program for the stage of management and exercise capacity. \(^{38,44}\)

Depending on the stage of management, an exercise program for LBP may comprise specific exercises alone, specific and global exercises, or primarily global exercises. At any stage of management, matching the patient’s baseline exercise and pain tolerance is essential to facilitate program adherence. \(^{43}\)

**EXERCISE RECOMMENDATIONS BASED ON THE CLINICAL COURSE**

**Acute Lower Back Pain**

Acute pain is often defined on the basis of the duration of an episode of LBP as well as the suspicion of inflammation because signs and symptoms including pain, muscle guarding, and tissue irritability are typically present. \(^{11,45}\) The acute episode is generally considered to be within 4 to 6 weeks; however, relapse or recurrence is common. During acute episodes of LBP, advice to stay active is recommended over bed rest because inactivity does not promote recovery and may even be detrimental to recovery. \(^{10,11}\) Moderate-quality evidence exists for small improvements in pain relief and functional status in favor of advice to stay active in patients with acute LBP, but minimal effect has been reported in patients with sciatica. \(^{46}\) In general, advice to continue typical activities and participation including work, when reasonable, is also recommended for the management of acute LBP\(^ {11}\); however, modification to reduce compressive and tensile forces on injured tissues is often needed.

During the acute stage, low-intensity and specific exercises are recommended including direction-specific and submaximal isometric muscle contractions performed in a neutral spine position or within the pain-free ROM. \(^{11,24,38,45,47}\) Moderate- to strong-intensity muscle contractions are poorly tolerated due to pain and inflammation. \(^{11,45}\) Gentle active and/or passive exercises specific for symptom reduction are recommended during the acute stage of LBP. \(^{38,48,49}\) Additional treatments such as manual therapy, electrical stimulation, and cryotherapy may be used for symptom management during the acute stage of management. \(^{38,45}\)
Subacute Lower Back Pain
Subacute pain is defined as LBP persisting 4 to 12 weeks and/or reduced tissue irritability and increased tolerance for movement. As acute pain and muscle guarding subside, impairment may persist in muscle function, motor control, postural awareness, and functional activities. The patient is encouraged to gradually increase activity, performing exercises in the pain-free range to avoid further tissue irritation. Submaximal strengthening and gentle stretching can be incorporated. Progression to postural and kinesthetic awareness and education in body mechanics, ergonomics, and relaxation can also be progressed at this stage of management. In addition, education on relapse prevention and self-management of acute pain episodes is important. Manual therapy, electrical stimulation, and cryotherapy may be used for symptoms management during the subacute stage of management.

RECURRENT LOWER BACK PAIN STAGE OF MANAGEMENT
Relapse of LBP after an acute episode is frequently reported. In an acute exacerbation or recurring LBP exercise interventions of neuromuscular reeducation to promote dynamic (muscular) stability to maintain the involved lumbosacral structures in less symptomatic, midrange position is indicated. Specific exercises to reduce symptoms and promote trunk mobility and coordination, are indicated along with promotion of activity and education to reduce the frequency and intensity of symptoms.

PERSISTENT LOWER BACK PAIN STAGE OF MANAGEMENT
Persistent pain and disability are associated with physical deactivation and deconditioning, influenced by both physical and psychosocial factors. Guidelines for persistent LBP emphasize promotion of activity and participation rather than a focus on protection of structures and pain relief. Supervised exercise, cognitive-behavioral therapy, body mechanics education, and progressive general fitness programs are recommended. Current evidence suggests that exercise is an intervention with few adverse
events that may improve physical function in individuals with persisting pain of musculoskeletal origin.\textsuperscript{54} Progressive moderate- to high-intensity exercise is recommended for patients without generalized pain (due to neural sensitivity), and low- to moderate-intensity exercise for patients with conditions associated with generalized pain.\textsuperscript{38} Behavioral interventions aimed at improving coping strategies and assisting patients in changing beliefs and attitudes about their pain in conjunction with exercise prescription are highly recommended.\textsuperscript{38,39} In general, individualized exercise programs with regular clinician follow-up and a higher exercise dosage are associated with clinically significant improvement in function in patients with persistent LBP.\textsuperscript{1}

During chronic (persistent) stages of LBP, some experts have recommended that exercise programs be guided not by the patient’s pain complaints but instead by a predetermined stepwise system for exercise and activity progression. Fordyce\textsuperscript{55} outlined such an approach when he applied operant conditioning principles to a graded exercise program for persons with persistent pain. An individual’s tolerance to activity is achieved through the use of a quota system.

**Quota Programs for Exercise Dosage**

Persons with persistent pain often disengage from routine activities. A quota system is a practical approach to making baseline exercise recommendations and progressively increasing the patient’s tolerance for activity. Intervention should begin with a series of baseline trials in which the patient is asked to perform a demonstrated exercise to his or her tolerance. Tolerance is defined as the point at which a patient stops exercising due to pain or fatigue. The physical therapist then establishes a quota for each prescribed exercise or activity to be performed daily. Typically, initial quotas are slightly lower than baseline trials (e.g., approximately 75\% of baseline mean) and are increased by predetermined small increments (e.g., about 10\% every few days). The patient is praised for meeting his or her goal. Unlike traditional exercise programs in which the patient exercises to his or her perceived tolerance, the patient instead achieves a quota. The quota system eliminates the linking of pain with function that might result in overdoing on “good days” and avoiding
exercise or activity on “bad days.” Rest breaks are scheduled instead of according to the patient’s perceived need. Resting at the time of the individual’s reported pain onset or exacerbation is avoided as it reinforces pain behaviors. A gradual increase in activity also lessens the likelihood of an exacerbation of pain. Quota programs have been effective in increasing functional performance in persons with LBP. Modalities (heat or cold) may be applied to prepare the patient for therapeutic exercise or to initiate activities.

RELAPSE MANAGEMENT
Frequently, patients with persistent pain experience an acute pain episode or a significant exacerbation of their pain resulting from increased activity. Until the patient has recovered from the acute incident, the intensity of strength, flexibility, and aerobic conditioning exercises should be reduced, but the patient should be encouraged to maintain a tolerable level of exercise to avoid deconditioning from inactivity. The patient may return to specific exercises to manage symptoms and regain mobility. An incremental, gradual increase in conditioning exercises can then be implemented. The individual should be encouraged to increase his or her use of coping and self-management strategies throughout the flare-up.

THE APPLICATION OF COMMON EXERCISE APPROACHES FOR LOWER BACK PAIN
Specific Exercise
Through one-on-one evaluation and specific exercise instruction, the patient will ideally develop an understanding of principles for movement control and activity progression that will lay the foundation for progressing to a global exercise program and facilitate return to activity and participation. Specific exercise such as spinal stabilization or direction-specific exercise may play a mediating role in reactivation through mechanisms involving early symptom management, improved kinesthetic awareness, and spinal region motor control.

Spinal Stabilization Exercise Application
Submaximal training of deep lumbar musculature for the purpose of
segmental muscular stabilization and movement control has also been referred to as motor control exercise for the lumbar region.\textsuperscript{22,25,62,63} Research suggests that local impairments in the muscle system may be a problem of motor control and coordination rather than simply a strength deficit.\textsuperscript{38,62} Spinal stabilization is a specific exercise approach designed to enhance the control of spinal orientation and intervertebral movement via training of deep trunk muscles, specifically the lumbar multifidus and transversus abdominis\textsuperscript{23} and sometimes also the rectus abdominis, quadratus lumborum, internal oblique abdominals, and erector spinae.\textsuperscript{64} The ultimate goal of spinal stabilization exercises is to integrate local motor control into global functional movements, especially to prevent potential mechanical stress or pain.\textsuperscript{64}

Spinal stabilization (or motor control) exercises should be administered with direct one-on-one supervision, sometimes using ultrasound imaging, surface electromyography, or pressure monitoring devices to provide feedback to the clinician and patient about desired muscle recruitment.\textsuperscript{25,65} The exercises are low intensity and designed to be completed frequently throughout the day and integrated into daily activities.\textsuperscript{23} Usually starting in the supine position with the hips and knees flexed, the therapist assists the patient in finding a neutral lumbopelvic position defined by anatomic landmarks and patient comfort. The patient is then asked to perform submaximal muscle contractions of the deep abdominal or multifidi muscles. Exercise progression proceeds from static (isometric) exercise in a supported position (supine or prone) to static exercise in less supported positions (e.g., 4-point, kneeling, or standing). The application of spinal stabilization during functional activities is emphasized across all stages of management, such as transitions from supine to sitting, sitting to standing, and ultimately to activities addressing the patient’s participation goals (e.g., home, work, leisure). To facilitate improved functional mobility, the patient is instructed to perform submaximal muscle contractions during functional activities, especially when anticipating positions of potential mechanical stress.\textsuperscript{64}

Directional Preference Exercise
Another form of specific exercise is the McKenzie approach to LBP.
Exercises based on directional preference (DP) are at the foundation of the McKenzie approach. DP is identified as a posture or repeated end-range movement in a single direction (flexion, extension, or side-glide/rotation) that immediately decreases lumbar midline pain or reduces the extent of referred symptoms to the extremities. Exercises effective for symptom reduction are selected following a systematic examination in which the patient performs a series of repeated and sustained movements. Patients are instructed to perform specific exercises that reduce peripheralization of symptoms and minimize LBP. Peripheralization of symptoms occurs when movements or positions cause symptoms to radiate away from the midline of the back, into the buttock, or into the lower extremity. This applies to axial LBP as well as symptoms associated with sciatica. Centralization of symptoms occurs when symptoms move toward the midline of the spine, away from the periphery. The patient is instructed that if centralization occurs during exercise, they are performing the exercise correctly. Conversely, exercises that cause symptoms to radiate away from the midline of the back, and perhaps into the buttock or low extremity, involve the wrong movement direction and/or incorrect position.

In conjunction with DP exercises, postural correction and body mechanics instruction are a major component of an intervention using the McKenzie approach. For example, a common condition of mechanical LBP presents when pain increases during flexed postures and movements. In this case, the patient would be assisted in an exercise progression that facilitates lumbar extension. Education to maintain posture with a bias toward lumbar extension with the use of lumbar rolls or back supports would be emphasized. Instruction would also be provided to maintain lumbar lordosis during all functional movements.

In summary, specific exercises such as DP and spinal stabilization are typically used for symptom relief, early mobility, and local motor control. Specific exercises are beneficial not only during the acute phase of management but also in addressing specific impairments at any stage of recovery. For example, a patient with persistent pain may benefit from spinal stabilization exercises along with a general strengthening and conditioning for impaired spinal region motor control. Similarly, a
patient with persistent pain may address a local impairment, through symptom reduction and improving mobility, with the use of DP exercise.\textsuperscript{48,49} While maintaining a focus on increasing activity and participation, an individual with persistent LBP may be able to manage local impairments through the use of specific exercises.

**Global Exercise**

With the resolution of acute symptoms, a gradual progression to global exercise is indicated to improve strength and endurance of large muscle groups, optimize general flexibility, and increase aerobic capacity. Emphasis on neutral spine mechanics and motor control is recommended during movement and exercise activities to avoid a relapse of acute symptoms.\textsuperscript{44} During therapy sessions, the clinician is able to provide feedback to assist patients to integrate principles of motor control and body mechanics into the performance of daily functional activities.\textsuperscript{44} The overall goal of a global exercise program is to develop a regular exercise routine that is integrated into one’s daily life and promotes well-being, prevention of injury, and enhanced activity and social participation. Matching the patient’s goals and personal preferences for exercise is essential for maximizing exercise program adherence. In addition, considering physical and psychosocial barriers and facilitators to exercise is critical.\textsuperscript{29}

A minimum of 150 minutes of aerobic exercise at moderate intensity (30 minutes per day, 5 days per week) or 60 minutes of vigorous-intensity exercise (20 minutes per day, 3 days per week) is recommended by the American College of Sports Medicine (ACSM) and the American Heart Association (AHA) to prevent chronic health conditions. Moderate intensity is defined as physical activity that involves exercising with enough intensity to raise one’s heart rate and break a sweat but still be able to carry on a conversation.\textsuperscript{68} Types of aerobic training may include brisk walking, running, cycling, or aquatic exercise. Exercise that allows partial unloading of joints such as aquatic exercises, use of an elliptical trainer, or low-resistance cycling are recommended for patients with difficulty with high-impact weight-bearing exercise (e.g., spinal stenosis, lower extremity osteoarthritis). Postural alignment as well as impact forces should be
considered for all patients with LBP including education about shock-absorbing footwear and exercise surfaces. Walking and other low-impact activity (e.g., aquatic exercise) are feasible for most people, but exercise often needs to be adapted to the individual’s needs. Walking typically results in extension movements of the spine; therefore, patients who have no change in symptoms or reduced symptoms with extension may benefit from walking, if impact force is controlled (footwear, angle of the treadmill platform, quality of the platform used). In contrast, patients demonstrating increased pain with extension movements of the spine may do better with aerobic exercises in which the spine is neutral or slightly flexed (e.g., stationary bike).

A minimal strength training intensity of 8 to 12 repetitions, 2 days per week is recommended by the ACSM and AHA for all adults. Muscle-strengthening activities may include resistance exercises to strengthen major muscle groups; progressive open kinetic chain weight-training exercises (e.g., free weights, pulleys, weight machines); progressive closed kinetic chain exercises (e.g., squats, lunges, push-ups); or methods of controlled movement that target strength, flexibility, and body alignment, including Pilates and yoga.

Recommendations regarding exercise dosage are similar for adults of all age groups, but older adults will need more attention to balance and safety issues for exercise. As patients become more active, their general health improves, but the risk of musculoskeletal injury increases. Therefore, guidance in pacing of activity, self-management of symptoms, and safe body mechanics are critical in facilitating ongoing activity and participation. It is essential that guidelines for exercise performance and progression be provided to each patient (Table 93.2).

Psychological and Educational Approaches

Traditional medical and rehabilitation interventions have failed to reduce persistent pain, primarily because of their focus on impairments and body structures rather than addressing the complexity of the problem. Psychological and educational treatments may be used in conjunction with exercise to alleviate severe pain and associated distress, pain interference with activities, and disability.

Behavioral strategies, a common intervention, assume pain and disability are influenced by psychological and social factors. Treatment emphasizes removing the underlying organic pathology, reducing disability through environmental modifications, and cognitive processes. Three behavioral interventions are used: respondent, operant, and cognitive.

According to Fordyce, pain behavior is classified as respondent if its onset and frequency of occurrence were due to tissue damage. Respondent treatment modifies the physiologic response directly (e.g., reduction of muscle tension). As illustrated, the patient is taught relaxation training and electromyographic biofeedback. Therapeutic exercise, physical agent modalities, splinting, adaptive equipment, and consumer education in proper posture, body mechanics, and energy conservation principles for routine activities of daily living are other respondent interventions.

Operant interventions use positive reinforcement of well (healthy) behaviors (e.g., praise for exercising) and withdrawal of attention toward pain behaviors (e.g., limping), time-contingent versus pain-contingent pain management, and significant other involvement. Outcome measures for

---

LBP, low back pain.
operant treatment programs have emphasized return to work, increased
activity levels and participation, decreased pain-related health care
utilization, reduction of pain behaviors, and increased well behaviors. The previously described quota program is based on operant treatment principles.

Cognitive-behavioral strategies strive to identify and modify patient’s cognitions (thoughts) regarding the pain and associated disability. Imagery, attention diversion, and modification of maladaptive thoughts (e.g., fear of pain), feelings, and beliefs can be used to restructure the negative thoughts. A 2012 Cochrane review concluded that cognitive-behavioral therapy, compared with treatment as usual or wait-list control conditions, had small yet statistically significant effects on pain and disability and moderate effects on mood and catastrophizing posttreatment. By 6- to 12-month follow-up, however, the only significant effect was for mood. In addition, brief educational interventions using an educational booklet have positive effects on patients’ beliefs about LBP and have shown improved physical outcomes.

Evidence to Support Exercise Therapy for Lower Back Pain

There is support for the efficacy of exercise interventions for LBP; however, there is not yet a clear understanding concerning which components of exercise account for its benefits. Several possible reasons exist for the lack of clarity around the efficacy of various exercise interventions, including (1) research study design and methodology problems; (2) unclear definitions for acute, subacute, recurrent, and persistent (or chronic) LBP; (3) the inclusion of heterogeneous study populations in many studies; (4) multimodal treatment interventions in addition to exercise; and (5) the main effect of exercise programs may be a result of factors other than physiologic changes (i.e., psychosocial factors).

EVIDENCE FOR SPECIFIC EXERCISE APPROACHES

Efficacy of Spinal Stabilization Exercises
In a study by Hides et al.,24 fewer recurrences of LBP occurred following spinal stabilization exercises for first-episode LBP patients when compared to no exercise intervention. In patients with persistent LBP, supervised trunk strengthening or stabilization exercise programs incorporating flexibility and body mechanics instruction have been shown to be more effective than a waiting list, transcutaneous electrical nerve stimulation (TENS), advice to take regular walks, or to independently complete a home program.2 The greatest benefits of spinal stabilization occur during the initial phases of the rehabilitation process,67 whether the stage of management is considered acute, subacute, recurrent, or persistent.19

Immediate or short-term benefits of incorporating spinal stabilization exercises have been shown, but there are limited long-term benefits beyond those of a general (global) exercise program. In a randomized controlled trial (RCT) involving patients with LBP, patients who participated in a spinal stabilization exercise program or manipulation treatment reported higher function and global perceived effects at 8 weeks versus patients participating in programs that included aerobic, strengthening, and stretching exercises. In addition, the immediate effect of stabilization did not differ from the effect of manipulation, and there were no between-group differences at 6- and 12 months follow-up.25 A meta-analysis of exercise studies in patients with LBP reported that stabilization exercises were as efficient as manual therapy for reducing pain and disability.78

The groups performing spinal stabilization exercises in addition to global exercises had similar long-term outcomes to those performing group exercises or participating in a conventional physical therapy (PT) program (i.e., exercise, manual therapy, education, modalities).79,80 In addition, general (or global) exercises reduced disability in the short term to a greater extent than a stabilization-enhanced exercise approach in patients with recurrent LBP.79 Another RCT demonstrated no additional benefit, in terms of pain, function, or disability, of adding specific stabilization exercises to conventional PT treatment.81

Proprioceptive neuromuscular facilitation (PNF) exercises applied to the lumbar region could be considered a form of specific exercise for local
neuromuscular retraining. Improved trunk range of motion, muscle endurance, and decreased pain were reported in women with persistent LBP after completing a 4-week program of PNF exercises. Improvement was reported after 4 weeks of training with dynamic resistance exercises, demonstrating better outcomes than static muscle recruitment (isometric).

Efficacy of Directional Preference Exercises
The application of specific exercises based on DP shows potential benefit for patients early in the rehabilitation process during the acute, subacute, and persistent stages of management. Pooled results of four trials comparing passive therapy with McKenzie exercises for acute LBP showed a statistically significant decrease in pain and disability favoring the McKenzie approach at 1-week follow-up. At 4 weeks, however, no difference in disability levels was noted between treatments. At the 12-week follow-up, patients advised to stay active produced superior results over the McKenzie exercises. A study in patients with persistent LBP to evaluate the effect of 8 weeks of the McKenzie exercise approach versus intensive dynamic strengthening showed a greater reduction in pain at 2 weeks in the McKenzie exercise group. At the 8-week and 8-month follow-up, however, there were no significant differences between groups in self-reported disability, global change of back-related quality of life, over-the-counter pain medications, or the number of visits to a general practitioner. A more recent RCT in patients with persistent LBP that compared the McKenzie method to a placebo-controlled group and reported that the McKenzie group had a small but significant reduction in pain intensity (immediately after a 5-week intervention) but no difference in disability or function.

EVIDENCE FOR USING CLASSIFICATION SYSTEMS FOR EXERCISE SELECTION
Matching the Exercise Program to the Patient
Treatment-based classification systems for LBP that match exercise approaches to patient baseline characteristics and impairments have been studied. Patients with acute and subacute LBP who received specific
exercise interventions matched to their baseline impairments (manipulation, spinal stabilization exercises, or DP exercises) showed a significantly greater improvement on a disability scale after 4 weeks of treatment than those randomly assigned to a treatment group. Long et al. reported significantly greater short-term (2 weeks) improvement in pain and function when patients were matched to a specific exercise direction based on symptom relief compared to those matched with the opposite direction or multidirectional exercises. Because 46% of patients were considered to have chronic complaints, it appears that exercises based on DP have the potential to produce at least short-term improvement during all stages of LBP (acute, subacute, recurrent, or persistent stages of management). Fritz et al. reported lower disability scores among patients receiving stabilization exercises who were classified with segmental hypermobility compared to those classified with segmental hypomobility.

Selecting specific exercises, based on subgroups of baseline characteristics, appears to improve outcomes for acute and subacute stages of management, but these subgroups do not hold up for persistent LBP. Instead, persistent pain is more closely associated with psychosocial factors. Elevated baseline scores on the Fear-Avoidance Beliefs Questionnaire (indicating fear of movement) during the acute stage of LBP have been associated with altered movement patterns, activity limitations, and reduced participation at later stages of management. A psychosocial approach to fear-avoidance beliefs involves a reduced emphasis on anatomic findings, encourages the patient to take an active role in his or her rehabilitation, and educates the patient to view back pain as a condition, rather than a serious disease, and that pain does not equal harm. George et al. randomly assigned patients (<8 weeks of symptoms) to receive fear-avoidance–based PT (psychosocial approach + standard care PT) or standard care PT for a 4-week intervention period. Scores on the Oswestry Disability Questionnaire at 4 weeks and 6 months were found to be dependent on an interaction between the type of PT (PT + fear-avoidance approach vs. standard PT) and the initial level on the Fear-Avoidance Beliefs Questionnaire. Therefore, baseline fear-avoidance beliefs remained a significant predictor of disability at 4-week
Fear-avoidance beliefs have been found to be a significant predictor of patients’ disability, even after adjusting for age, sex, and pain intensity.\textsuperscript{36} It follows that patients with elevated levels of fear-avoidance beliefs related to their back pain may be more successful when cognitive restructuring interventions are incorporated into the delivery of exercise programs.

**EVIDENCE FOR GLOBAL EXERCISE APPROACHES**

Aerobic training, muscle strengthening, stretching, and skill training (e.g., work tasks, sport-specific activities) are associated with decreased pain, improved function, and reduced disability in patients with LBP.\textsuperscript{16,17} Twelve weeks, 3 times per week of moderate- to high-intensity aerobic exercise, individualized by activity type (treadmill, walking, stair climbing, cycling) and baseline fitness was more effective in reducing pain, disability, and psychological strain in individuals with chronic LBP compared to those randomized to a 12-week passive modality program (electrophysiologic agents and thermotherapy).\textsuperscript{89} A review of exercise benefits in overweight and obese individuals with persistent LBP reported that resistance, aquatic, and Pilates exercise programs demonstrated the greatest benefits and resistance, aquatic, and walking exercises had relatively high adherence rates and minimal adverse events, suggesting that these modes of exercise may lead to better outcomes.\textsuperscript{90}

Although the quality of evidence examining exercise for persistent LBP is low, there is consistent evidence that global exercise programs have a small to moderate effect on improving pain, physical function, and disability levels, and minimal adverse affects.\textsuperscript{54} Yoga and Pilates programs, designed specifically for individuals with back pain, are more effective than nonexercise interventions but no more effective than other exercise interventions.\textsuperscript{71,91,92} Taken together, this suggests that the selection of an exercise approach is best determined by considering individual preferences and capacity to exercise.

Global exercise programs are generally accepted as an effective intervention for subacute and persistent LBP, particularly when patients have been advised in program progression, self-management of symptoms, and safe body mechanics. Exercise intensity, mode, and individualization
of exercise prescription have been identified as elements that positively impact outcomes in adults with persistent LBP. 

Conclusion

The four core topics of the chapter are summarized in Tables 93.3 through 93.6.

**TABLE 93.3 The Benefits of Exercise for Lower Back Pain**

- Reduce risk for musculoskeletal injury
- Reduce risk of comorbidity
- Improve mood
- Increase sense of well-being
- Improve activity and participation
- Reduce the risk of reoccurrence or relapse of low back pain

**TABLE 93.4 The Purpose of Specific versus Global Exercises**

- Specific exercises are used for the purpose of reducing symptoms, improving mobility, and enhancing motor control. This creates the foundation for the performance of global exercises and functional activities.
- Global exercise programs encompass exercises for general fitness including aerobic, flexibility, strengthening, and endurance exercises for the purpose of promoting well-being, preventing injury, and enhancing activity and social participation. The ultimate goal is to integrate a global exercise program into one’s daily routine.

**TABLE 93.5 Individualized Exercise Programs**

- Individually designed exercise programs with a higher dose (intensity, frequency, duration) and regular follow-up are associated with improved pain, function, and disability in patients with persistent pain.
- Individualizing the exercise program by mutual goal setting to meet both physical and psychosocial needs is essential in maximizing exercise adherence and achieving patient satisfaction.
- Exercise program delivery should be adjusted to meet the patient’s psychosocial needs and goals.
- Adherence and satisfaction are likely to be enhanced by considering the patient’s goals, environmental barriers, interests, and preferences.
- Cognitive-behavioral strategies integrated into an exercise program may improve mood, enhance participation, and reduce disability.

**TABLE 93.6 Efficacy of Exercise Interventions for Low Back Pain (LBP)**

Classification Systems
Developing subgroups or classification systems may aid in specific exercise selection. Physical impairments may be most important when designing exercise programs for patients during the acute and subacute stages of management. Psychosocial factors become more important in the management of chronic or persistent pain, although it should still be considered during acute episodes of LBP. For example, catastrophizing and fear-avoidance beliefs need to be addressed.

### Specific Exercises
- Specific exercises demonstrate efficacy for short-term improvement in pain and function during the acute, subacute, recurrent, and persistent stages of management.
- Spinal stabilization exercises have not demonstrated long-term efficacy beyond that of global or general exercise programs. However, there may be clinical value at all stages of management that is not easily measured.
- Spinal stabilization exercises have demonstrated short-term benefits in all stages of management and in preventing recurrence of LBP.
- Exercises based on directional preference (e.g., McKenzie approach) show potential benefit for symptom reduction during the first few weeks of the acute, subacute, recurrent, or persistent stages of management.

### Global Exercises
- Consistent small to moderate effects of global exercise programs have been reported for improvements in pain, physical function, and disability in patients with LBP, especially persistent LBP.
- Aerobic conditioning, muscle strengthening, stretching, and skill-training exercises are associated with decreased pain, improved function, and reduced disability.
- Attention to program progression, self-management of symptoms, postural alignment, and body mechanics are important for enhancing long-term activity and participation in global exercise programs.

### References

This chapter looks at therapies that historically have been classified as being “unorthodox,” “complementary,” or “alternative” to conventional medical interventions for pain. A contemporary definition of “complementary and integrative health” (IH) will be considered in the context of the complex and clinically challenging field of evidence-based pain medicine. A rationale for studying these unorthodox treatments of pain is presented. The challenges of an evidence-based approach to incorporating these “integrative” therapies into pain management are explored. And finally, a brief survey of several commonly available complementary and IH therapies and the evidence regarding their utility in pain treatment are provided.

What Is Complementary and Integrative Health?

Identifying and defining nonmainstream approaches to health and healing have been problematic for decades. How these various professions, therapies, and approaches to healing have been characterized by the dominant, conventional medical mainstream is emblematic of the history of antagonisms and misunderstandings between the two. How the IH disciplines have come to define themselves is also instructive of both their differences and similarities. Drawing meaningful distinctions between conventional biomedicine and the array of alternative methods may be useful to illuminate how each can contribute to better care for patients in pain.

Integrative medicine practitioners tend to consider their approaches as holistic and in contrast to a reductionistic approach that is ascribed to
modern, specialty-driven biomedicine. Holistic practitioners use

Rather than focusing on illness or specific parts of the body, this ancient approach to health considers the whole person and how he or she interacts with his or her environment. It emphasizes the connection of mind, body, and spirit. The goal is to achieve maximum well-being, where everything is functioning the very best that is possible. With Holistic Health people accept responsibility for their own level of well-being, and everyday choices are used to take charge of one’s own health.1

In contrast, the reductionist approach of conventional medicine (CM) adheres to the theory that every complex phenomenon in medicine can be explained by reducing the complexity of health and disease into simple, basic, physical mechanisms and applying a treatment intended to correct the abnormalities, primarily through the use of drugs and surgery.

The Divide

The emergence of organized medicine early in the last century marginalized a large number of existing healing disciplines at that time. Some of these had enjoyed long and successful traditions treating the public. As Cohen2 points out,

Although American colonies began with pluralistic notions of health care, the poor state of science, paltry qualifications of many would-be physicians, general lack of medical standards, and a cornucopia of charlatans eventually led to state regulation of healers—largely through the mechanism of licensure—and thereby to the triumph of biomedicine over competing communities of healers such as naturopathic and homeopathic physicians. Legally, state statutes made unlawful practice of medicine a crime and defined medicine in broad terms, encompassing any activity that potentially could be construed as diagnosis and treatment.

As a result, Western, scientific, reductionist biomedicine became the “real” medicine in legal terms. The resulting cultural authority of CM discounted traditional healers. The hegemony of this dominant paradigm
was not seriously challenged until the last few decades of the 20th century.

**FRINGE MEDICINE AND QUACKERY**

In the early 1960s, British author Brian Inglis developed a model in his book entitled *Fringe Medicine*. This title consigned nonstandard approaches to healing to the periphery of science and the health care system. Inglis considered such professions as homeopathy, bone setting, herbalists, and psychotherapy as fringe medicine. Being on the fringe implied that healers of this stripe were so far removed from the mainstream as to pose no threat to the public or to the dominance of biomedicine.

In the succeeding 30 years, many of these fringe approaches to healing persisted and grew despite persistent opposition from the dominant medical establishment. For example, in the 1950s, the American Medical Association (AMA) developed ethics policies that forbade physicians from interacting with “unscientific, cult practitioners” such as chiropractors. The AMA Committee on Quackery was formed in 1963 targeting vitamins, homeopathy, chiropractic, naturopathy, all alternative cancer treatments, and other practices which compete with the drug sales of pharmaceutical companies. The chiropractic profession fought back in the courts. In the case of *Wilk v. American Medical Association*, the AMA was found to have engaged in an unlawful restraint of trade under the Sherman Antitrust Act. And although the AMA’s Committee on Quackery was disbanded, other groups have taken up the charge to criticize and marginalize these therapies (see [http://www.quackwatch.com](http://www.quackwatch.com)).

**“UNORTHODOX” MEDICINE**

This unhappy stand-off persisted until Eisenberg et al.’s seminal study in 1993 revealed the depth and breadth to which these fringe practices had penetrated health care delivery. This paper reported a survey of respondents’ use of a variety of what Eisenberg termed “unorthodox medical practice.” These were defined by Eisenberg in exclusionary terms, that is, in terms of what these therapies are not. Unorthodox medicine in Eisenberg’s view is not taught in medical schools, not available in hospitals, and not generally considered real medicine.
Today, neither of these perspectives, fringe or unorthodox, provide meaningful distinctions between mainstream conventional biomedicine and those forms of healing that are different. Neither perspective bears up to careful scrutiny of the current state of complementary and alternative medicine. Eisenberg et al.\textsuperscript{5} amply demonstrated that the volume of visits for health care delivered outside of the orthodox mainstream exceeds that of conventional care provided in physician offices—hardly an image of a fringe factor in the overall picture of the health care delivery system.

The popularity of complementary medicine with the public has not gone unnoticed by conventional medical institutions either. Health insurance plans, hospitals, and academic medical centers have integrated, to one extent or another, nontraditional health care providers and therapies into their programs. A 2001 survey of regional health plans in the northeast United States found nearly universal coverage for chiropractic, with just under half of insurers covering acupuncture (usually for chronic pain) and massage therapy (MT).\textsuperscript{6} A 2005 American Hospital Association survey revealed that 370 of 1,394 respondent institutions (26.5%) offer some form of complementary health care.\textsuperscript{7} A similar survey in 2010 found 42% of responding hospitals offered at least one integrative medicine service.\textsuperscript{8}

Integrative medicine topics are being introduced into the curricula of up to 64% of US medical schools.\textsuperscript{9} The American Medical Student Association has developed the Educational Development for Complementary and Alternative Medicine program to promote medical school education on alternative medicine topics. The Academic Consortium for Integrative Medicine and Health is composed of 69 academic medical centers and health plans including Harvard, Duke, Stanford, Thomas Jefferson, and Yale medical schools as well as health plans including Cleveland Clinic, Mayo Clinic, Memorial Sloan Kettering, and Veterans Health Administration. The stated mission of the consortium is to “advance integrative medicine and health through academic institutions and health systems.” With a vision of “a transformed healthcare system promoting integrative medicine and health for all.”\textsuperscript{10}

These developments indicate the trend of increasing integration of conventional and integrative medicine. Contemporary integrative medicine has moved well beyond the “unorthodox” label offered by Eisenberg.
COMPLEMENTARY AND ALTERNATIVE MEDICINE

The fringe and unorthodox labels are a carryover from more contentious times. Over time, other labels have included “nontraditional” medicine in supposed contrast to traditional conventional medical care. However, considering that some of these nontraditional therapies predate conventional interventions, for example in the case of acupuncture by 3,000 years, traditional versus nontraditional seems irrational. “Integrative” and “integrated” medicines have had some currency as well. The term alternative medicine suggests that the therapies are used in place of CM. Integrative medicine often refers to alternative medicine therapies delivered by CM practitioners or at least in conventional medical settings. Integrated medicine implies the thoughtful collaboration of conventional and alternative medicine providers in the treatment of patients. The notion of complementary medicine is supported by evidence showing that most patients use both conventional and complementary interventions, seeking to integrate their own care. The favored terminology until 2015 by the National Institutes of Health (NIH) has been complementary and alternative medicine (CAM) with the National Center for Complementary and Alternative Medicine (NCCAM) (Table 94.1).

| **Integrative health** | stress and anxiety management that often affects patients coping with complex and chronic disease.  
| | A collaborative approach to health care delivery that is characterized by a high level of communication between patients and their health care providers as well as between their conventional and integrative health providers. |

**COMPLEMENTARY AND INTEGRATIVE HEALTH**

Recognition of the growing volume of integrative medicine use, the accumulating research evidence, and how patients actually use the medicine ultimately led to a name change for NCCAM. The December 2014 Congressional omnibus budget measure renamed the Center the National Center for Complementary and Integrative Health (NCCIH). As the Center’s Web site notes,

> The change was made to more accurately reflect the Center’s research commitment to studying promising health approaches that are already in use by the American public. Since the Center’s inception, complementary approaches have grown in use to the point that Americans no longer consider them an alternative to medical care. For example, more than half of Americans report using a dietary supplement, and Americans spend nearly four billion dollars annually on spinal manipulation therapy. The name change is in keeping with the Center’s existing Congressional mandate and is aligned with the strategic plan currently guiding the Center’s research priorities and public education activities.\(^{11}\)

**BRIDGING THE DIVIDE: ONE KIND OF MEDICINE**

The work of NCCIH is reflective of increasing the quality of research-focused complementary and IH interventions. The current trend toward evidence-based medicine (EBM) may eventually point the way to a reconception and resolution of the distinction between CM and IH. IH is frequently dismissed by critics as being unscientific and without evidence of its safety, efficacy, and effectiveness. However, over the last decade, the emergence of complementary medicine on the national research agenda through the NCCIH and other institutions has furthered the development of academic and intellectual infrastructure of IH that can explore the
scientific evidence which demonstrates the utility of complementary therapies.

Originally formed as the Office of Complementary Medicine, the federal budget for NCCIH grew from $2 million in fiscal year 1992 to $121.4 million in fiscal year 2007. The body of research is growing. There are currently thousands of clinical trials of IH interventions. A 2000 survey of over 5,000 controlled trials found “The overall quality of evidence for IH RCTs is poor but improving slowly over time, about the same as that of biomedicine [emphasis added].” Systematic reviews of the IH literature are prevalent. There are hundreds of Cochrane Collaboration reviews of alternative therapies (see http://www.cochranelibrary.com/topic/Complementary%20%26%20alternative%20medicine/)

Angell and Kassirer noted several years ago in The New England Journal of Medicine editorial that in the future, medicine will be divided into those approaches to health and healing that are backed by scientific evidence and those that are not. They conclude that “there cannot be two kinds of medicine—conventional and alternative. There is only medicine that has been adequately tested and medicine that has not, medicine that works and medicine that may or may not work. Once a treatment has been tested rigorously, it no longer matters whether it was considered alternative at the outset.”

A 2005 Institute of Medicine report on complementary medicine emphasizes, “The committee recommends that the same principles and standards of evidence of treatment effectiveness apply to all treatments, whether currently labeled as conventional medicine or CAM.” This evidence-based perspective will continue to erode the barriers between health care that is provided in the tradition of Western scientific medicine and the healing disciplines that, in some instances, predate modern medicine by millennia. This perspective may well put to rest the arbitrary and, at times, antagonistic differentiation between IH and CM.

WHAT IS DIFFERENT ABOUT COMPLEMENTARY AND ALTERNATIVE MEDICINE?

There clearly are differences between health care available in conventional medical physician offices, clinics, and hospitals and that provided by IH
practitioners. There are three features of IH that tend to distinguish it from CM. In general, IH therapies are individualized to each patient rather than using a standardized clinical protocol. IH almost universally incorporates a philosophy of health that emphasizes and leverages the innate capacity for healing in every individual. And finally, IH tends to acknowledge the existence of properties of living systems that are resistant to understanding by contemporary reductionist scientific methods of inquiry.

These distinguishing features present significant challenges to research methods and thus to assembling meaningful evidence. They also create opportunities to develop more effective, efficient, and humanizing care for a very difficult population of patients—especially those with pain. Some have recognized the limitation of CM. For example, an editorial observation by Cicerone\textsuperscript{15} on evidence-based practice and the limits of rational rehabilitation points out that “we need to acknowledge the subjective meanings of illness and disability to the patients we serve. Any efforts to build our practice based on the best available systematic evidence are unlikely to succeed unless we include patients’ values and beliefs and incorporate this perspective into our rehabilitation research. This aspect of evidence-based rehabilitation raises important questions about our fundamental roles and how we will choose to practice and define our field in the future.”

Individualized treatment is a hallmark of most IH therapies. For example, an acupuncture practitioner may evaluate two patients, both with the same CM diagnosis, but develop two radically different treatment plans based on the oriental medicine (OM) examination findings and assessment. This approach seems to work well for patients as revealed by observational studies. Studies of patients who obtain care from IH practitioners reveal high levels of satisfaction with the practitioners and the outcome of the therapies. IH providers spend time with their patients, and they are successful in explaining to patients the nature of their health problems. Treatment planning tends to be collaboration between therapist and patient. Interventions are developed that are consistent with each patient’s own needs and preferences.

Philosophy of care is not something that most CM practitioners ponder extensively. However, philosophical discourse underlies many IH
therapies. Chiropractic, for example, contains an extensive literature that can only be described as philosophy. Beginning with the founder, D. D. Palmer, chiropractic thinkers have historically focused on not so much the rational scientific underpinnings of this healing art but on the art itself. Innate intelligence is posited by Palmer and his successors as a fundamental life force that when fully expressed without interference, maximized expression of health occurs, naturally and without need of intrusion from outside agents like drugs and surgery. In this chiropractic philosophical worldview, the aim of the chiropractor is to locate and correct interferences with this natural expression of the life force. Other IH disciplines have identified this life force known as “qi” in acupuncture and oriental medicine (AOM), “prana” in yoga, “doshas” in Ayurvedic medicine, and “vix medica naturae” in naturopathic medicine, each discipline has elaborated some measure of a conceptual life force that guides and propels healing and health.

CM, with its intellectual traditions anchored in Western scientific thought, is understandably skeptical of notions of innate intelligence, qi, or other conceptualization of a putative life force. Finding no testable hypotheses to investigate a possible life force, CM has largely dismissed such philosophical musing. Oschman\textsuperscript{16} provides a comprehensive review of this seeming impenetrable intellectual barrier between the IH and CM worldviews.

WHO USES COMPLEMENTARY AND INTEGRATIVE HEALTH?

The research on IH utilization is often confusing and contradictory. Research is complicated by a number of factors, including a lack of consensus on what therapies, interventions, and practitioner types constitute IH. Varying methodologies for collecting data, the variety of populations, and settings in which data are gathered provide sometimes contradictory conclusions. Further challenges to IH research is when it is studied in different countries where the availability of IH may vary considerably due to tradition, licensure, and cultural acceptance.

However, despite the inconsistent nature of research efforts, it is certain that IH use is widespread across populations, clinical conditions, settings,
and sociodemographic groups. In 1993, Eisenberg and colleagues’ paper alerted the CM community to the magnitude of IH utilization. This discovery revealed an ongoing phenomenon in the general population that has been verified and replicated in many subpopulations. A search of PubMed for “IH utilization” returned over 1,500 citations. These include abstracts referring to various clinical populations (cancer, inflammatory bowel disease, autoimmune deficiency syndrome, diabetes, hypertension, allergies, rheumatic conditions, chronic fatigue, fibromyalgia, emergency department patients) and sociodemographic groups (veterans, racial and ethnic groups, geriatrics, women, children, athletes). In short, no matter what population is examined, IH use is prevalent.

IH use is particularly widespread among patients with chronic pain conditions. Nayak et al. reported on a small sample of spinal cord injury patients with chronic pain. About 40% of respondents had used some form of IH during the preceding year. Forty-four percent of chronic pain patients being treated with opioids reported concomitant IH use. Twenty-seven percent of veterans with cancer or chronic pain reported IH use. More veterans would have used IH had it been covered by insurance. Tsao et al. found that, given a choice of several IH interventions, over 60% of pediatric patients (and their parents) opted to try at least one IH approach in addition to CM treatments. A survey of 43 pediatric anesthesia fellowship training programs showed 38 (86%) offered one or more IH therapies.

CATEGORIZING COMPLEMENTARY AND INTEGRATIVE HEALTH THERAPIES

There is considerable diversity in IH practices and deciding which discipline to include under the rubric IH and which to exclude can be problematic and markedly affects the study results of IH utilization. In 1993, Eisenberg et al. limited his survey inquiries to 16 commonly used interventions but included “relaxation therapy . . . lifestyle diets, spiritual or religious healing by others.” Eisenberg et al. do note a categorical difference, however, between IH therapies that are delivered by a professional, such as massage and acupuncture, and those that are largely self-administered without the involvement of a trained and licensed
provider, such as lifestyle diets and intercessory prayer. Hospitals reporting the integration of IH most frequently identify massage, body movement therapies (qigong, yoga, tai chi), relaxation, acupuncture, guided imagery, and therapeutic touch (TT) as the IH modalities of choice. Conspicuous by their absence from the hospitals are some of the most frequently encountered IH modalities, such as chiropractic, nutraceutical, and herbal therapies.

NCCIH has categorized IH in two domains: natural products such as nutritional supplements, probiotics, and herbs and mind–body interventions such as massage, yoga, manipulation, acupuncture, and movement therapies. The array of CAM therapies can be further categorized by their intellectual and philosophical nature as being either essentially biologically based or energy-based. Biologically based therapies are explained and practiced fundamentally in ways that are familiar to practitioners trained in the CM model of Western scientific inquiry. Clinical conditions are mostly described in terms of disturbed anatomy and physiology. Treatment interventions are categorized by their physiologic effects. Outcomes are measured in objective clinical terms. These disciplines, such as chiropractic and natural medicine, often view themselves as being within the context of orthodox scientific thought. Many chiropractors, for example, have rejected the theories of Palmer. Some of these therapies have been rigorously scrutinized through the lens of conventional medical scientific investigation. Many of these disciplines are developing intellectual, administrative, and physical infrastructure to conduct research in the mold of CM as part of a commitment to evidence-based practices.

In contrast, energy-based therapies are most often founded on putative notions of natural systems of “invisible energetic relations and connections that govern living form and function.” Although some of these energy-based therapies have undergone scientific inquiry, most notably acupuncture, the fundamental worldview of energy-based healers has not been altered to conform to the understandings offered by rational reductionist methods. For example, science has attempted to understand the physiologic basis of acupuncture in terms of its neuroendocrine effects. However, few acupuncture practitioners endorse or, more importantly,
practice within this intellectual context. Most acupuncture practitioners prefer instead to explain what they do in the language of AOM, such as the flow of chi throughout the meridians of the body.

For purposes of the discussion in this chapter, consideration of IH therapies is limited to those commonly accessible in the community to chronic pain patients and, for the most part, administered under the guidance of licensed health care professionals. Although this approach may exclude some valuable and frequently used therapies, it does encompass IH therapies that are in regular use by chronic pain patients, have been evaluated by research, are at least somewhat institutionalized, have been used or referred to by CM providers, and are capable of being integrated clinically and administratively into the CM care of chronic pain patients.

Why Consider Complementary and Integrative Health Therapies in Pain Management?

There is a compelling case for why CM physicians, especially in the challenging field of pain medicine, should better understand IH therapies. Based on the study results of IH utilization, it is quite likely that any given pain patient is using at least one IH therapy concurrently with CM treatments. Clinical inquiry into IH use is important because patients often fail to reveal their use of IH therapies to their CM providers. There are potential complications that arise with the combination of IH and CM therapies, and awareness of these enhances safety and quality of care. Understanding the rationale for and evidence that supports IH use in pain conditions places the clinician in a helpful role of providing objective information to pain patients. And, perhaps most significantly, integration of IH therapies can be effective and improve the quality of care for chronic pain patients.

Some 50 million Americans suffer from chronic or severe pain.\(^{24}\) It is estimated that 40% of them fail to achieve adequate relief.\(^{25}\) Surveys of IH users note a high prevalence of chronic conditions, including chronic pain. Observers of IH note that “consumers will continue to use IH, particularly in chronic conditions, in which patients struggle to find any treatment that
may cure their condition or improve their quality of life.”

Most IH interventions are “low-tech, high-touch” in nature. They are often perceived as inherently safe and natural by patients and practitioners. However, there is a growing body of evidence that illuminates adverse reactions to commonly used IH therapies either by themselves or when combined with CM. Drug–herb interactions, for example, present potential challenges to patient safety and compromises of therapeutic intent. In 1993, Eisenberg noted that patients use IH and CM concurrently for the same condition upward of 83% of the time however IH users failed to disclose IH use to CM physicians. Subsequent investigation by Eisenberg et al. indicates that this failure to disclose has not improved over time. Better understanding by both CM and IH practitioners of risks can modify the potential for adverse outcomes.

Avoiding adverse CM–IH interactions can obviously improve patient care. Asking patients about their use of IH, especially from an objective and evidence-based perspective, can enhance patient communication. The cultural competency of being able to provide nonjudgmental acknowledgment of IH use, particularly when it can be supported by objective evidence of safety and effectiveness, can reinforce a productive therapeutic relationship between patients and their CM physician.

It is well recognized that effective physician–patient communication is a critical element in predicting better patient satisfaction and compliance with chronic pain treatment. Moreover, as reliable evidence of IH effectiveness emerges, CM physicians may be in a position to better integrate evidence-based IH approaches in an active manner rather than passively accepting what chronic pain patients may already be attempting to integrate on their own.

CHALLENGES OF EVIDENCE-BASED COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPIES

Developing the evidence about IH therapies for chronic pain is problematic from a number of perspectives. IH therapies are often inherently resistant to analysis by commonly used clinical research methods. For example, in the hierarchy of evidence, the randomized
controlled trial (RCT) is considered to be the criterion standard. Yet, many argue that this methodology, although well suited to the study of drugs, may not be the best research design to study complex, individualized treatments routinely offered by CAM practitioners.29,30

For instance, trials of manipulative therapy have been plagued by the difficulty in developing a “sham” manipulation and concurrently controlling for the nonspecific effects of the hands-on practitioner–patient interaction with the theoretically inert sham treatment. Similarly, acupuncture research using sham acupuncture points irritates acupuncture practitioners who note that any needling at any point on the body affects the flow of chi and therefore cannot be considered an inert intervention in the same way that a placebo pill is used in a clinical trial of drug therapy. Functional magnetic resonance imaging and positron emission tomography imaging studies have demonstrated brain changes with sham acupuncture procedures compared to “true” acupuncture.31

Furthermore, evidence about treatment interventions for chronic pain is confounded by the complex nature of the condition itself. Patient selection is often a significant challenge to study validity. For example, aggregating patients with mechanical low back pain (LBP) into a conceptually uniform study group may satisfy a study methodology, but it ignores the wide variety of disorders that produce this pain population. Given this clinical heterogeneity, it is no wonder that trials with this fundamental design flaw frequently come up with equivocal results and fail to reveal significant differences in effectiveness between treatments. A conventional medical analog would be treating undifferentiated chest pain as gastroesophageal reflux disease (GERD).

The challenges of applying evidence of this nature to the practical realities of treating patients have been increasingly recognized.32 Fortunately, researchers in the IH fields are actively developing research methodologies that are more appropriate both for the individualized nature of CAM interventions and the complex, multifactorial nature of chronic pain. Pragmatic controlled trials, for example, evaluate interventions in real-world settings that involve the specific effects of the intervention as well as the nonspecific effects of the therapeutic relationship, expectations, values, and beliefs that combine to affect the clinical outcomes of interest.
Publication and indexing biases also are obstacles to assembling high-quality evidence about IH therapies. As is the case with CM, studies with positive results are more likely to be submitted for publication. Many studies of IH are in foreign language journals, thus limiting their exposure to English-speaking audiences. A subtler bias also is observed in CM-published research on IH. As one IH researcher put it, “A negative study of acupuncture concludes that ‘acupuncture doesn’t work.’ The analogue would be a negative drug trial that concluded ‘pharmaceuticals do not work’” (R. Hammerschlag, personal communication, February 20, 2005).

Despite these challenges in developing an evidence-based approach to the use of IH therapies in chronic pain conditions, clinical evidence is accumulating. Many formerly unproven and unscientific therapies have, in fact, been shown to be safe and effective. Achieving the goal of Angell and Kassirer’s “one kind of medicine” is becoming a reality in health care and in the treatment of chronic pain.

The Complementary and Integrative Health Therapies: The Evidence

The following is a brief overview of commonly available IH therapies and the evidence that supports them. Evidence from systematic reviews, especially from the Cochrane Collaboration (http://www.cochrane.org), and from clinical practice guidelines is noted. These therapies are categorized as biologically based and energy-based.

BIOLOGICALLY BASED THERAPIES

These therapies are based mainly on concepts of biology and physiology commonly accepted in conventional biomedicine. These therapies rely on clinical theories, therapeutic approaches, and rationales that are couched in terms consistent with current scientific understanding of biology and physiology familiar to CM.

Manipulation

Manipulation is the most frequently used IH therapy. It is widely practiced by a variety of specialties including doctors of chiropractic (DC),
osteopathic physicians (DO), medical doctors (MD), physical therapists, and some lay practitioners. It is estimated that DCs deliver over 90% of all manipulative therapy. According to the 2007 National Health Interview Survey (NHIS), patients spent an estimated $3.9 billion on visits to practitioners for chiropractic or osteopathic manipulation. Chiropractic training in manipulative techniques is arguably the most extensive among manipulation practitioners.

Manipulation is thought to improve pain by locating and treating disturbed joint and muscle function described as dysfunction, subluxation, fixation, and other terminology that may vary by discipline, training, and technique. Manipulation practitioners primarily treat spine pain and dysfunction, but these techniques are also applied to the rest of the musculoskeletal system.

Historically, manipulation has also been applied to nonmusculoskeletal disorders. It is hypothesized that somatoautonomic reflexes activated by manipulation can modulate visceral function. This linkage has not been elucidated nor confirmed in the paucity of current research. Despite the lack of a comprehensive neurobiologic rationale, there have been some studies that suggest weak but favorable evidence for positive effects of manipulation for a number of conditions including asthma, hypertension, infantile colic, otitis media, cervicogenic vertigo, and others.

Of the CAM therapies, manipulation has been studied the most extensively. NCCIH has identified over 500 clinical trials of manipulative and other body work therapies such as massage. Although the results are often and predictably inconclusive, there is clear evidence that manipulation is superior to sham treatment and equivalent to other conservative interventions for acute spinal pain. Systematic reviews of acute and chronic LBP conclude that the evidence supporting manipulation is on par with other interventions typically employed in conventional medical practice. Other systematic reviews show long-term benefit for neck pain, headaches, and chronic mechanical spine pain.

A 2007 clinical practice guideline from the American Pain Society (APS) and the American College of Physicians (ACP) recommends manipulation, among other IH treatments, for both acute and chronic LBP. An updated 2017 ACP systematic review and clinical practice
guideline reinforced the recommendations for nonpharmacologic interventions for acute and chronic LBP including manipulation as well as yoga, tai chi, acupuncture, and MT. The ACP systematic review concluded, “. . . several non-pharmacologic therapies for low back pain were associated with small to moderate, primarily short-term effects on pain.” In contrast, the ACP review of drug therapy concluded, “Several systemic medications for low back pain are associated with small to moderate, primarily short-term effects on pain.” Of interest as well is a 2016 Cochrane review that “. . . found high quality evidence that paracetamol [acetaminophen] is no better than placebo for relieving acute low back pain . . .” and despite practice guidelines and recommendations that include acetaminophen as a first-line treatment.

**Therapeutic Massage**

MT encompasses more than 150 named body work systems and perhaps thousands of variations and individual techniques. Therapeutic, clinical, or medical massage is engaged to treat specific clinical conditions. The physiologic effects of massage are well documented, including muscular relaxation, improved blood and lymph circulation, and neuro-hormonal-immunologic effects.

There are numerous clinical trials of massage for pain. However, clinical trials of MT are difficult methodologically because of the impossibility of blinding subjects or therapists, a lack of an effective placebo and often small numbers of subjects in the trials. Physical Medicine and Rehabilitation Clinics of North America reviewed therapeutic massage in 1999. A 2007 review concluded that there is robust evidence in favor of MT for chronic LBP and more modest support for massage in the treatment of chronic headache, shoulder pain, mixed pain conditions, fibromyalgia, and carpal tunnel syndrome.46

A recent Cochrane Review of massage for LBP concluded that although the evidence was of generally low quality, MT did provide short-term improvement in pain for acute, subacute, and chronic LBP. Short-term improvement in function was also observed.47 An “evidence map” developed by the Veterans Affairs identified some high-quality systematic reviews that noted “potential benefits” for pain related to labor, shoulder,
neck, back, cancer, fibromyalgia, and temporomandibular joint.\textsuperscript{48} Reported methods often do not qualify the type of MT provided. A recent review of complementary health approaches to pain management in the September 2016 Mayo Clinic Proceedings concluded that the preponderance of positive versus negative trials of MT showed at least short-term benefit for neck pain. Lower quality trials showed benefit for LBP as well.\textsuperscript{49}

**Natural Medicine Therapies**

A number of IH interventions use nutritional supplements and herbs (known collectively as nutraceuticals) in the treatment of chronic pain. Although these natural medicine approaches are most commonly identified with naturopathic physicians (ND), herbs and supplements are frequently used by acupuncture/OM and chiropractic providers as well. Many nutraceutical interventions are thought to modify disturbed metabolism that underlie chronic pain conditions such as fibromyalgia. Although much nutraceutical information on the Internet is proprietary and commercial in nature, there are evidence-based sources of information for a number of painful conditions.\textsuperscript{50} Natural medicine can be used directly for analgesia (white willow bark, for example), anti-inflammatories (omega-3 fatty acids), and antispasmodics (valerian and passiflora are examples). Nutritional and herbal interventions are most commonly applied to modify perceived underlying physiologic disturbances such as fibromyalgia, depression, osteoarthritis, and rheumatoid arthritis.\textsuperscript{50} Of commonly used nutritional approaches, glucosamine and chondroitin sulfate have been most extensively studied. Glucosamine has been shown to slow cartilage deterioration and relieve pain in knee osteoarthritis.\textsuperscript{51,52} A 2014 Cochrane review concluded that some herbal preparations (cayenne, devils claw, white willow bark) reduced LBP more than placebo and in one (white willow bark) about the same as rofecoxib.

**Body Awareness Therapy**

A number of approaches to chronic pain treatment involve the idea of improving postural coordination by using conscious processes to alter
automatic postural coordination and ongoing muscular activity. These body awareness therapies (BAT) may be practiced by physical and occupational therapists, massage therapists, as well as nonlicensed body work professionals. Two common BAT have been described: Alexander technique (AT) and Feldenkrais method (FM).

AT is described as “a method that works to change (movement) habits in our everyday activities. It is a simple and practical method for improving ease and freedom of movement, balance, support, and coordination. The technique teaches the use of the appropriate amount of effort for a particular activity, giving you more energy for all your activities. It is not a series of treatments or exercises, but rather a reeducation of the mind and body.”

A 2003 systematic review of AT revealed few high-quality RCTs but noted promising results with Parkinson disease and back pain. A 2008 RCT published in BMJ conducted a cost-effectiveness analysis of a number of body work interventions and concluded that AT followed by exercise was the most clinically effective and cost-effective intervention. A more recent systematic review found “strong evidence” supporting the effectiveness of AT for chronic LBP.

FM is a technique said to improve function by “expanding the self-image through movement sequences that bring attention to the parts of the self that are out of awareness and uninvolved in functional actions. Better function is evoked by establishing an improved dynamic relationship between the individual, gravity, and society.” In 2004, Jain and colleagues provided a “critical overview” of the method, its use and the relevant research, and research gaps concerning this BAT. A 2014 systematic review found “further promising evidence” for the effectiveness of FM in improving balance in the elderly as well as in reducing pain.

**Breath Pattern Retraining**

In 1975, Lum introduced the concept of disordered breathing patterns as the underlying cause of “a collection of bizarre and unrelated symptoms” including cardiovascular, neurologic, respiratory, gastrointestinal, musculoskeletal, psychologic, and other syndromes. More recently, Chaitow has emphasized disturbed breathing patterns as the cause of
chronic pain. Proposed mechanisms are summarized as “respiratory alkalosis, leading to reduced oxygenation of tissues (including the brain), smooth muscle constriction, heightened pain perception, speeding up of spinal reflexes, increased excitability of the corticospinal system, hyperirritability of motor and sensory axons, changes in serum calcium and magnesium levels, and encouragement of myofascial trigger points.” Breath pattern retraining therapists note that the respiratory mechanism is the only physiologic function that is under both autonomic and voluntary control.

A 2005 RCT involving chronic LBP patients revealed equivalent improvement from 12 sessions of breath therapy as measured on a visual analogue scale (VAS), Roland-Morris Scale, and 36-Item Short Form Survey (SF-36) when compared to high-quality, extended physical therapy. Breath therapy was found to be safe.61

Prolotherapy
The use of proliferation therapy (prolotherapy) has waxed and waned in popularity for nearly a century. Often provided by CM practitioners, prolotherapy is also frequently in the therapeutic armamentarium of naturopathic medicine (ND). The underlying theory is that following an injury, failure of adequate tendon or ligament healing results in instability, connective tissue insufficiency, or lack of tensile strength. Normal use of these compromised structures causes pain. Prolotherapy consists of injections of an array of substances intended to trigger growth factors in local connective tissue and restart the repair sequence that results in more normal and functional tissue.

A 2005 critical review of prolotherapy retrieved over 30 studies of prolotherapy for spinal pain.62 These reflected wide variation in treatment protocols and concluded that “clinical studies published to date indicate that it may be effective at reducing spinal pain.” Case reports, case series, and nonrandomized trials suggest that prolotherapy is helpful for a variety of musculoskeletal disorders. RCT evidence, however, is conflicting.63,64 A Cochrane review concluded that “if used alone, prolotherapy injections do not have a role in the treatment of chronic low-back pain. When combined with other treatments, they may give prolonged partial relief of
The Tensegrity Model

Tensegrity (or biotensegrity) is not a therapy in itself but rather a concept of how biologic systems function from the ultrastructure of the cell to the organism. The concept is attributed to sculptor Kenneth Snelson, and the term was coined by Buckminster Fuller to represent “tensional integrity.” Snelson noted, “Tensegrity describes a closed structural system composed of a set of three or more elongate compression struts within a network of tension tendons, the combined parts mutually supportive in such a way that the struts do not touch one another, but press outwardly against nodal points in the tension network to form a firm, triangulated, pre-stressed, tension and compression unit.” Donald E. Ingber of Harvard Medical School and Stephen M. Levin, an orthopedic surgeon, have applied tensegrity concepts to biology and medicine. Ingber has postulated that cell function is regulated mechanically via tensegrity. Levin contends that the integrity of the musculoskeletal system “is a function of continuous tension, discontinuous compression, so that the skeleton, rather than being a frame of support to which the muscles and ligaments and tendons attach, has to be considered as compression components suspended within a continuous tension network.” Many body work practitioners including physical therapists, chiropractors, massage therapists, martial artists, and others have incorporated the tensegrity model into evaluation and treatment approaches.

The Fascia Model

The tensegrity “model” in some respects is similar to other concepts founded perhaps initially by Andrew Taylor Still, the founder of osteopathy. Other generations of “body workers” have proposed similar models of the human locomotor system including D. D. Palmer’s formulation of chiropractic being founded on “tone.” More contemporary practitioners have elaborated further models such as Ida Rolf’s concepts of “structural integration.” Ultimately, these various fields of clinical study and practice came to suggest fascia as an underlying anatomical and physiologic structures and processes that help explain the often-remarkable pain and disability.”
success of various manual techniques from massage, soft tissue and joint
manipulations, to acupuncture and physical therapy.

Fascia is something of a stepchild in anatomy. Students of human
dissection are well aware of the prevalence of the layers of fascia that
invest the organs and tissues. However, fascia has historically been
 disregarded and considered merely an impediment to dissection. Research
over the past few decades has begun to illuminate the role of the fascia as a
continuous connective tissue system throughout the body. It is postulated
that far from being passive, inert structures, the continuum of fascia allows
it to serve as a body-wide mechanosensitive signaling system.  

Stecco and colleagues provide a summary of contemporary research on the
characteristics of the human fascial system. Knowledge of this body-wide
connective tissue system “may contribute to clinicians’ understanding of
the myofascial system and the role which the deep fasciae may play in
musculoskeletal dysfunctions.”

Beginning in 2007, the Fascia Research Society has sponsored a series of Fascia Research Congress meetings
dedicated to the emerging field of fascia studies.

**Trigger Point Manipulation**

Travell and Simons offered an early treatise on myofascial trigger points
(TrPs) which were defined originally as “a hyperirritable spot in skeletal
muscle that is associated with a hypersensitive palpable nodule in a taut
band. The spot is tender when pressed and can give rise to characteristic
referred pain, motor dysfunction, and autonomic phenomena.”

Although the existence of this clinical finding is well recognized, the
understanding of the etiology of TrPs is evolving. McPartland offered
“molecular and osteopathic perspectives” on the TrP phenomenon in 2004.
They postulated that “TrPs are evoked by the abnormal depolarization of
motor end plates . . . presynaptic, synaptic, and postsynaptic mechanisms
of abnormal depolarization (i.e., excessive release of acetylcholine [ACh],
defects of acetylcholinesterase, and upregulation of nicotinic ACh-receptor
activity, respectively).” More recent work by Shah and colleagues at the
NIH Rehabilitation Medicine Department have developed microdialysis
techniques that have confirmed “that biochemistrys associated with pain,
inflammation, and intercellular signaling are elevated in the vicinity of
active MTrPs.”

In sharp contrast, in a “critical evaluation of the trigger point phenomenon,” the authors claim to have debunked these perspectives as well as other putative explanations of TrPs. They concluded that the TrP phenomenon “has no scientific basis. . . .” More recent work has begun to suggest the relationship of central sensitization to the creation and maintenance of TrPs.

No objective diagnostic tests for TrPs are available. TrPs are diagnosed by manual palpation to identify a tender nodule, often at characteristic locations in muscle that, when stimulated, produce characteristic radiating pain as reported by the patient. Despite this low-tech diagnostic method, TrP detection has good test–retest reliability. Various approaches to treating TrPs have been elaborated including manual compression, “spray and stretch,” injection, dry needling, and modalities (ultrasound, electric stimulation, low-level laser). TrP treatment is often rendered by certain CM physical medicine practitioners, but most frequently by chiropractors, acupuncturists, massage practitioners, and other IH providers.

**ENERGY-BASED THERAPIES**

In contrast to the biologically based therapies, a number of “energy-based” interventions are common among IH practitioners as well as some CM clinicians. Energy medicine is a domain in health care that deals with putative energy fields of two types: veritable, which can be measured, and putative, which have yet to be measured.

The veritable energies include mechanical vibrations (such as sound) and electromagnetic forces, including visible light, magnetism, monochromatic radiation (such as laser beams), and rays from other parts of the electromagnetic spectrum. These veritable energy-based therapies involve the use of specific, measurable wavelengths and frequencies to treat patients.

In contrast, putative energy fields are based on the concept that human beings are infused with a subtle form of energy. This vital energy or life force is known under different names in different cultures and traditions, such as “qi” in traditional Chinese medicine (TCM), “ki” in the Japanese Kampo system, “doshas” in Ayurvedic medicine, and elsewhere as
“prana,” “etheric energy,” “fohat,” “orgone,” “odic force,” “mana,” and “homeopathic resonance.” Vital energy is believed to flow throughout the material human body, but it has not been unequivocally measured by means of conventional instrumentation. Nonetheless, therapists claim that they can work with this subtle energy, see it with their own eyes, feel it, and otherwise sense its presence and quality and then use it to effect changes in another’s physical body to influence health.

**Veritable Energy Therapies**

**Magnetic Therapy**

Magnetic therapy has a long and controversial history in medicine. It has recently regained popularity in the marketplace. Application is by way of various devices such as electromagnetic coil and static magnets worn in garments or jewelry or held in place with adhesive patches. Magnetic therapy is typically applied to the skin overlying the affected area. The popular press indicates the use of magnets for treating a wide variety of chronic pain problems such as migraine, osteoarthritis, and injury to muscles, ligaments, and tendons. Contraindications are few but do include pregnancy, pediatric age, and presence of implantable electronic devices.

Contemporary clinical trials of magnet therapy have produced conflicting results. A study of carpal tunnel syndrome in 2002 found no statistically significant difference between magnets and placebo. But the authors did note, “Although this study did not show magnets to be more effective than the placebo, the reduction in pain with this simple intervention was remarkable.” In a double blind, placebo-controlled trial, static magnets produced statistically significant (P < .05) short-term pain relief in osteoarthritis of the knee. Systematic reviews of magnet therapy are scarce, and EBM reviews for magnet therapy for pain are lacking.

Transcranial magnetic stimulation is a recent development in CM for the therapeutic use of magnetic energy. Cochrane reviews of this intervention have looked at applications for tinnitus, schizophrenia, depression, poststroke, epilepsy, and others. These reviews have been unable to either support or refute magnetic energy therapies.

**Microcurrent Stimulation**
Microcurrent stimulation generally involves apparatus that can supply electrical current usually below 1 mA in various frequency ranges. Microcurrent has been used in CM for the treatment of nonunion fracture and delayed bone healing. The exact mechanism of action is unknown but may involve intracellular regulation of calcium. A narrative review of microcurrent in physical therapy found good support for its use in bone and skin lesion healing. Other applications have only scant evidence.

Microcurrent has found application in the treatment of soft tissue disorders as well. McMakin has published three studies of this modality, which is termed frequency-specific microcurrent (FSM), in chronic pain patients. The studies are case series reports involving head, neck, and facial pain; chronic LBP; and fibromyalgia associated with cervical spine trauma. In this study, McMakin and colleagues also began to explore the mechanisms of FSM. Their subjects revealed reductions in inflammatory cytokines, increases in β-endorphins, as well as subjective reports of pain relief in fibromyalgia with FSM.

Low-Level Laser Therapy

Low-level laser therapy (LLLT) is a form of phototherapy that involves the application of low-power laser light to areas of the body in order to stimulate healing and relieve pain. It is also known as cold laser, soft laser, or low-intensity laser. It is hypothesized that photons are absorbed in the mitochondria. The light energy is converted to chemical energy within the cell affecting the permeability of the cell membrane, which in turn produces various physiologic effects. These physiologic changes affect a variety of cell types including macrophages, fibroblasts, endothelial cells, and mast cells.

Although the underlying physiologic mechanisms are incompletely understood, LLLT is widely used in physical therapy, chiropractic, and other physical medicine disciplines. Although reportedly safe, the modality is relatively new and is still controversial with respect to its effectiveness. A 2005 Cochrane review of LLLT used in rheumatoid arthritis suggested that LLLT “could be considered for relief of pain and morning stiffness for RA patients, particularly since it has few side-effects.” A 2009 systematic review and meta-analysis of 16 RCTs in The Lancet showed
“that LLLT reduces pain immediately after treatment in acute neck pain and up to 22 weeks after completion of treatment in patients with chronic neck pain.”\textsuperscript{84} A 2017 systematic review of LLLT for musculoskeletal pain concluded that despite heterogeneous study methodology, LLLT “appears to be an effective treatment modality to achieve pain relief in adult patients with musculoskeletal disorders.”\textsuperscript{85}

Putative Energy Therapies
Acupuncture and Oriental Medicine
Among the putative energy therapies, none has received more notice and scrutiny than acupuncture. Acupuncture, the use of fine wire needles inserted into various points along meridians, is but one therapy within broader field of OM. The practice of OM includes a range of systems, interventions, schools of thought, and techniques. One such system, TCM, is widely taught and practiced in the United States. TCM encompasses herbs, massage, qigong, and acupuncture.

In the TCM view, the body is a delicate balance of two opposing and inseparable forces: yin and yang. Yin represents the cold, slow, or passive principle, whereas yang represents the hot, excited, or active principle. Among the major assumptions in TCM are that health is achieved by maintaining the body in a “balanced state” and that disease is due to an internal imbalance of yin and yang. This imbalance leads to blockage in the flow of qi (or vital energy) and of blood along pathways known as meridians. TCM practitioners typically use herbs, acupuncture, and massage to help unblock qi and blood in patients in an attempt to bring the body back into harmony and wellness.\textsuperscript{86} These therapies are intended to balance the flow of qi rather than to produce a specific physiologic effect.

Although not synonymous with TCM, needle acupuncture has received the most attention in the research and clinical communities. It is the most common OM therapy received by patients. Acupuncture describes a family of procedures involving stimulation of anatomic locations on the skin by a variety of techniques. There are a number of approaches to diagnosis and treatment in American acupuncture that incorporate medical traditions from China, Japan, Korea, and other countries. The most studied mechanism of stimulation of acupuncture points employs penetration of
the skin by thin, solid, metallic needles, which are manipulated manually or by electrical stimulation.\textsuperscript{87}

The body of research literature on acupuncture is robust. A search on PubMed for “acupuncture” returned more than 25,000 citations. Limiting the search terms to “acupuncture and chronic pain” returned more than 1,500 citations. The Cochrane Collaboration lists over 200 reviews for “acupuncture” and 18 EBM reviews specifically for “acupuncture and chronic pain.” A comprehensive review of this literature base is well beyond the scope of this chapter, but it is apparent that there is conclusive evidence of the effectiveness and safety of this therapy for pain and other clinical conditions.

It is clear that acupuncture is widely used by chronic pain patients. A telephone survey from a decade ago by Breivik et al.\textsuperscript{88} found 13% of chronic pain patients in Europe were using acupuncture. Research methodology challenges in the investigation of acupuncture stubbornly persist. Meta-analyses frequently conclude that although acupuncture can be shown to be effective for pain relief, the therapy itself has not been shown to be superior to other therapies.

Craniosacral Therapy

Craniosacral therapy (CST) developed from the work of an American osteopath, William Sutherland, in the early 1900s. It is founded on the notion of the primary respiratory mechanism that involves intrinsic motions of the cranial bones, the dura, and the flow of cerebrospinal fluid. Rhythmic motions are said to be measurable with instruments, but in clinical practice, it is by palpation that a CST practitioner identifies disturbed cranial rhythms and applies corrective gentle manipulations. Restricted motion of the cranial bones at the sutures is thought to impede cerebrospinal fluid flow and lead to disordered function and disease.

CST is known in the osteopathic profession preferentially as cranial osteopathy. The chiropractic profession has a technique that encompasses much of CST and others as well, known as sacro-occipital technique. CST is also practiced by a variety of other hands-on practitioners including physical therapists, massage therapists, dentists, and lay practitioners.

CST is included under the putative energy category in that the motions
of the primary respiratory mechanism have not been irrefutably demonstrated. Skeptics and critics have challenged the existence of these subtle rhythms. Reliability studies of the manual diagnosis of disturbed cranial rhythms have been disappointing. CST has been studied in clinical trials addressing fibromyalgia, asthma, urinary tract signs in multiple sclerosis, and others. The Cochrane Collaboration contains no EBM reviews of CST. A 2012 systematic review of CST identified only three RCTs and four observational studies that met criteria of the Downs and Black checklist. The review concluded that CST “has the potential of providing valuable outcomes. . . . However, due to the current moderate methodological quality of the included studies, further research is needed.”

Homeopathy

Homeopathy is a system of diagnosis and treatment founded by Samuel C. Hahnemann in Germany in the late 18th century. Homeopathy is currently practiced widely in Europe and Great Britain and by many practitioner types in the United States including MD, DO, DC, ND, and lay providers. Clinical evaluations include detailed history interviews that lead to individualized treatment regimens depending on a host of physical, emotional, and psychological factors. The therapies include the use of homeopathic remedies which are derived from plant, mineral, and other extracts that have been serially diluted, often to the point where, statistically at least, no physical molecules of the original substance remain.

This fact challenges fundamentally the notions of science and the physical universe that underlie CM. Most CM practitioners simply cannot accept the idea that a substance that has nothing physically “there” can have any real effect beyond that attributable to placebo. Nonetheless, a number of studies in reliable scientific journals report the apparent effectiveness of the medicine.

There is an extensive literature on homeopathy. A search of the National Library of Medicine for “homeopathy” returned over 6,000 citations. A strictly nonscientific sampling of these abstracts indicates that pain and chronic pain conditions have not typically been studied. A search of the
Homeopathy: The Journal of the Faculty of Homeopathy for “pain management” retrieved only 197 results.\(^95\) The challenge of submitting homeopathy to rigorous research designs revolves around the highly individualized treatments encountered in practice. As with other natural medicine approaches to pain treatment, a homeopathic practitioner is more likely to be evaluating and treating underlying causes of pain rather than treating pain itself.

Ayurvedic Medicine

Ayurveda, which literally means “the science of life,” is a natural healing system developed in India. Ayurvedic texts claim that the sages who developed India’s original systems of meditation and yoga developed the foundations of this medical system. It is a comprehensive system of medicine that places equal emphasis on the body, mind, and spirit and strives to restore the innate harmony of the individual. Some of the primary Ayurvedic treatments include diet, exercise, meditation, herbs, massage, exposure to sunlight, and controlled breathing. In India, Ayurvedic treatments have been developed for various diseases (e.g., diabetes, cardiovascular conditions, and neurologic disorders). However, a survey of the Indian medical literature indicates that the quality of the published clinical trials generally falls short of contemporary methodologic standards with regard to criteria for randomization, sample size, and adequate controls.\(^96\)

In the prebiblical Ayurvedic origins, every creation, inclusive of a human being, is a model of the universe. In this model, the basic matter and the dynamic forces (dosha) of nature determine health and disease, and the medicinal value of any substance (plant and mineral). The Ayurvedic practices (chiefly that of diet, life style, and the Panchakarma) aim to maintain the dosha equilibrium. Despite a holistic approach aimed to cure disease, therapy is customized to the individual’s constitution (Prakruti). Numerous Ayurvedic medicines (plant-derived in particular) have been tested for their biologic (especially immunomodulation) and clinical potential using modern ethno-validation, and thereby setting an interface with modern medicine.\(^96\)

A PubMed search for “Ayurvedic medicine” returned over 2,800 results.
A 2005 systematic review of Ayurvedic medicine for treatment of rheumatoid arthritis concluded that “there is a paucity of RCTs of Ayurvedic medicines for rheumatoid arthritis. The existing RCTs fail to show convincingly that such treatments are effective therapeutic options for rheumatoid arthritis.” In contrast, a 2011 pilot RCT comparing Ayurvedic medicine with CM (methotrexate) or their combination found “all 3 treatments were approximately equivalent in efficacy.”

However, as with many other CAM therapies, especially the energy-based modalities, the issues raised by double-blind methodologies and placebo effects have not been thoroughly accounted for. For example, the spiritual strength of the Ayurvedic healer and the utility of the placebo effect are both acknowledged and considered significant in many non-Western healing traditions.

**Biofield Therapies**

Biofield therapies encompass modalities such as TT, Reiki, and healing touch (HT). They are based on the idea that humans exhibit nonphysical energy that can be sensed and modulated by a practitioner to affect health. These vital energy concepts are expressed as prana in yoga, chi in OM, qi in Japanese acupuncture, and as spirit in Western traditions. Survey research estimates about 3.7 U.S. adults have used biofield therapies at some point in their life.

The significant challenges to valid clinical research on biofield therapies are similar to found in many other IH fields of study. Primary among them is a lack of biologic plausibility for the existence of biofields in terms that conventional Western medical thought can grasp. Further challenges emerge when considering the issues of patient and therapist blinding, identifying a suitable placebo, differentiating placebo from therapeutic effects, and lack of standardized treatment protocols.

**Therapeutic Touch**

Touch is a fundamental human sense. The skin is arguably the largest sensory organ of the body. The power of human touch has been recognized throughout the history of medicine. TT and its derivatives are energy-based therapies that have become common in some hospitals and other
clinical settings.

From the TT Web site:

Therapeutic Touch is based on the idea that human beings are energy in the form of a field. When you are healthy, that energy is freely flowing and balanced. In contrast, disease is a condition of energy imbalance or disorder. The human energy field extends beyond the level of the skin, and the Therapeutic Touch practitioner attunes him or herself to that energy using the hands as sensors.

Exact methods vary between practitioners, but generally, they will pass their hands over your body from head to toe, front and back, holding them between 2-6 inches from the skin. This is done to assess the condition of the human energy field. They may use rhythmical, sweeping motions with the hands, as if they are smoothing out wrinkles in your energy field. The practitioner may or may not touch you physically.101

The evidence supporting TT is inconclusive. Two Cochrane reviews found insufficient evidence that TT is effective in the management of anxiety disorder or dementia.102,103 However, a pilot trial of TT in a cognitive-behavioral therapy (CBT) program found chronic pain patients who received TT in addition to relaxation and CBT fared better in terms of enhanced self-efficacy and unitary power, as well as having lower attrition rates than patients who only received relaxation training and CBT.104

A study at the University of Wisconsin-Eau Claire studied another touch therapy (Tellington touch) in patients about to undergo venipuncture.105 The intervention is described as “gentle physical touch and consisting of four components: a mental attitude of openness, use of the hands and fingers, breath awareness, and moderate finger/hand pressure.” Analysis of qualitative descriptions by patients and the phlebotomist-nurse demonstrated that this massage-like, caring touch promoted relaxation and produced a helpful distraction in patients about to undergo a potentially painful procedure. Although further study is warranted, the implications for physicians and others who have hands-on contact with patients of any sort, and chronic pain patients in particular seem obvious. Human-to-human contact can have powerful effects in relieving anxiety and pain.
The development of these skills by physicians and other caregivers may be of significant benefit to patients.

Reiki and Energy Healing Therapies
Reiki (pronounced RAY-kee) is Japanese for universal life energy. It is derived from rei, meaning “free passage” or “transcendental spirit,” and ki, meaning “vital life force energy” or “universal life energy.” Reiki is based on the belief that when spiritual energy is channeled through a Reiki practitioner, the patient’s spirit is healed, which in turn heals the physical body. Reiki practice usually involves no direct physical contact between practitioner and recipient. By the practitioner holding his or her hands over the patient’s body, the recipient is said to draw energy from the universal life force through the practitioner.

In the late 1800s, Mikao Usui developed modern Reiki from ancient Asian healing traditions said to be thousands of years old. Introduced to the West in the 1970s, Reiki has become a popular IH therapy in the United States. Reiki and other energy healing (EH) therapies have also attracted the attention of CM practitioners and researchers.

Reiki is practiced by a variety of licensed health care practitioners including CM and CAM physicians, allied health care providers, psychotherapists, massage practitioners, as well as nonlicensed Reiki masters. Although Reiki and other EH therapies are not without their critics, these high-touch, low-tech interventions are being adopted by hospitals, clinics, and physician offices as useful adjuncts to patient care. Higher patient satisfaction, improved clinical outcomes, and lower costs are ascribed to implementing Reiki and other EH therapies.

Healing Touch
HT was developed by Janet Mentgen, an “energetically sensitive” nurse. A certificate program through the Healing Touch Program sponsored by the American Holistic Nurses Association. Mentgen advocated for an evidence-based approach to HT. A 2009 best evidence synthesis concluded that although biofield therapies (Reiki, TT, and HT) are widely used, review of 66 clinical studies showed strong evidence for reducing pain and less convincing evidence for improvement in anxiety, fatigue and quality of life.
Conclusion

Far from being on the fringes of modern health care, many IH therapies have been in regular and frequent use especially by many chronic pain patients. Patients may seek out these therapies on their own from IH practitioners, but they are increasingly provided in conventional health care settings as well.

Many of these unconventional therapies are being subjected to the same rigorous investigation that is expected of all contemporary evidence-based medical practices. Arguably, many IH therapies hold up very well to this scrutiny and do so certainly as well as many commonly prescribed CM treatments (Table 94.2).

CLBP, chronic low back pain; LBP, low back pain.

The fact that IH therapies are in common use by chronic pain patients suggests the need to better understand them. The emerging evidence that they are safe, clinically effective, and cost-effective when appropriately rendered further recommends them. That IH therapies explicitly incorporate the power of intention, awareness, and healing in the human interaction of the therapeutic encounter may well be the key to achieving a more individualized, sensitive, and humanized approach to the treatment of a most difficult and challenging patient population—those with chronic

Electrical stimulation of the peripheral nervous system for medically intractable pain dates from ancient times. Scribonius Largus reported that pain could be relieved by standing on an electric fish. In the 16th through the 18th century, many scientists, including Benjamin Franklin, advocated using various electrostatic devices for headache and other pains. Development of modern stimulation began with transcutaneous electrical nerve stimulation (TENS), which is generally credited to C. Norman Shealy. This battery-powered, pain-relieving device delivers a small electrical current via electrical leads that can be attached to the skin overlying the painful area. In 1965, Melzack and Wall introduced the concept of “gate-control theory,” which hypothesized that stimulating peripheral nerves would block the transmission of pain in the dorsal horn of the spinal cord. Based on this theory, the first peripheral nerve stimulation (PNS) for pain relief in humans was reported by Wall and Sweet, and the first implantable leads were placed by Sweet and Wepsic in 1968. In the 1970s, the applications for PNS expanded with the work of Long, Nashold, Picaza, and others and included mononeuropathy, often posttraumatic or postsurgical, sciatica, reflex sympathetic dystrophy, causalgia, and amputation stump pain. Weiner and Reed were the first to report transcutaneous implantation techniques for treatment of occipital neuralgia in 1999. Recently, several groups have combined percutaneous approaches with real-time image guidance to achieve accurate lead placement from a minimally invasive approach. (For a detailed history, see Slavin.)
Whereas PNS directs stimulation of a peripheral nerve, peripheral field stimulation (PFS) targets terminal nerve branches and pain receptors in the subcutaneous tissue. Goroszeniuk et al.\textsuperscript{14} introduced this concept in a case series in 2006, although the success of peripheral stimulation reported by others was likely mediated through subcutaneous stimulation.\textsuperscript{15} This method has proven to relieve pain effectively and is especially useful in cases where the painful area lies outside clearly demarcated dermatomes or peripheral nerve distributions. Patients undergoing PFS are estimated to have a 50% average reduction of pain.\textsuperscript{16}

The final modality of peripheral stimulation is dorsal root ganglion stimulation (DRGS) that has been used since the mid-2000s.\textsuperscript{17,18} The dorsal root ganglion had previously been a target of resection and ablative techniques to control pain,\textsuperscript{19} but neuromodulation of the dorsal root ganglion became possible and easy to access with percutaneous leads. In 2016, the U.S. Food and Drug Administration (FDA) approved the use of DRGS for complex regional pain syndrome (CRPS) of the groin and lower extremities, which can be difficult to treat with other forms of neuromodulation such as spinal cord stimulation (SCS).

Figure 95.1 graphically depicts all the modalities of neuromodulation of the peripheral nervous system.

![Figure 95.1](image)

**FIGURE 95.1** Peripheral stimulation modalities. The graphic illustrates the nervous system from the spinal cord to peripheral nerve. A, spinal cord stimulation is not a form of peripheral stimulation but shown in the graphic for completeness; B, dorsal root ganglion stimulation; C, brachial plexus stimulation; D, peripheral nerve stimulation; E, peripheral field stimulation.
**Pathophysiology and Mechanisms of Analgesia**

Afferent pain pathways begin in the peripheral nervous system and are carried by myelinated Aδ and unmyelinated C fibers into the spinal cord, where they synapse in the posterior horn of the spinal cord. Second-order neurons cross to the contralateral spinal cord and ascend to synapse primarily in the ventroposterior lateral (VPL) nucleus of the thalamus via the lateral spinothalamic tract. From the VPL nucleus, third-order neurons project to the somatosensory cortex, cingulate gyrus, and insula. In addition to this pathway, sharp pain can also be carried by Aδ fibers to the spinal cord to ascend up the dorsal column–medial lemniscus pathway, where synapses are made in the cuneate and gracile nucleus of the medulla and VPL nucleus of the thalamus on way to the somatosensory cortex.

The mechanism of TENS is thought to be primarily mediated through neurotransmitters and not by modulating electrical activity. Both high- and low-frequency TENS likely mediate their effects through opioid and muscarinic receptors. High-frequency stimulation has been shown to involve γ-aminobutyric acid (GABA), and low-frequency stimulation involves serotonin.

The mechanism of PNS is very different from that of analgesic pain medications and TENS units. The gate-control theory proposes that neuromodulation occurs in the dorsal horn of the spinal cord. Electrical activation of Aβ fibers has been shown to block transmission of pain via Aδ and C fibers at the substantia gelatinosa in the dorsal horn of the spinal cord—closing the “gate.” Furthermore, in contrast to SCS, which modulates only the dorsal column pathway, peripheral stimulation may modulate both the spinothalamic tract and the dorsal column pathway because peripheral stimulation blocks both Aδ and C fibers that travel to the spinothalamic pathway.

There is evidence for both short- and long-term modulation of dorsal horn activity. Short-term effects may be mediated by modulating electrical activity and further support the gate-control theory. Long-term depression of dorsal horn activity may be mediated through gene expression, and it has been demonstrated by both low- and high-frequency (1 to 100 Hz) stimulation.
In addition to the dorsal horn, nerve fibers might also be affected by stimulation. Stimulation of Aδ and C fibers has been shown to reduce excitability.\textsuperscript{29} This may potentially be mediated by decreased conduction velocities, decreased amplitude (especially Aδ fibers), and increased the threshold needed to trigger an action potential.\textsuperscript{30,31} Peripheral stimulation has also been shown to reduce nociceptive and neuropathic pain.\textsuperscript{32} Nociceptive inhibition may result from blocking Aδ afferents consistent with gate-control theory or from decreased excitability of Aδ fibers.\textsuperscript{30,32}

The mechanism of PFS is largely unknown. Some believe the mechanism to follow that of the gate-control theory.\textsuperscript{33} However, others suggest the subcutaneous stimulation blocks depolarization of sensory afferents, inhibits axonal conduction, or modulates the effect of endogenous endorphins.\textsuperscript{34} In their study of visceral abdominal pain, Paicius et al.\textsuperscript{34} suggest that subcutaneous stimulation affects the response of visceral fibers that merge with the subcutaneous fibers in the same dermatome. Like in PNS, PFS is presumed to affect both neuropathic and nociceptive pain pathways.\textsuperscript{35}

As with other methods of peripheral stimulation, the exact mechanism for how DRGS alleviates pain is not well understood. Stimulation of dorsal roots has been shown to affect multiple spinal levels.\textsuperscript{36} Many believe that the dorsal root ganglion neurons are hyperexcitable in pain syndromes and lead to excess activity in the dorsal horn of the spinal cord and, in turn, to increased pain.\textsuperscript{17,37,38} The hyperexcitability is thought to be at least partially mediated by alterations in ion channels.\textsuperscript{39} Some preliminary work has shown that direct stimulation of the dorsal root ganglion stabilizes the excitable neurons.\textsuperscript{40} Detailed mechanistic reviews are available.\textsuperscript{38}

**Stimulation Technologies**

The initial lead implantation techniques for PNS skeletonized the nerve and placed a lead in contact with the nerve. Many of these techniques also included direct stimulation of the nerve to determine the sensory fascicles supplying the painful area.\textsuperscript{8} A variety of electrodes have been used, including “plate” electrodes,\textsuperscript{41} “button” electrodes,\textsuperscript{8} and electrodes that can be wrapped around the nerve.\textsuperscript{5} In addition to their various shapes, the
electrodes can be monopolar, bipolar, quadripolar, or octapolar. The nerves can be anchored in proximity by directly suturing the electrode to the nerve,\textsuperscript{8} wrapping the nerve in mesh and then fastening to the electrode,\textsuperscript{42} or suturing to the surrounding subcutaneous tissue often with a fascial flap between the electrode and nerve.\textsuperscript{41}

Traditionally, the leads are connected to an implantable pulse generator (IPG) that is placed in a subcutaneous pocket. The leads are tunneled to the implantation site, typically located in the infraclavicular area, abdominal wall, or superior gluteal region, among other locations.\textsuperscript{43,44} New wireless systems have been recently introduced to eliminate challenges and complications related to tunneled leads.\textsuperscript{45,46}

Less invasive techniques of percutaneous implantation methods were first introduced by Weiner and Reed.\textsuperscript{11} Since then, percutaneous techniques have been reported for a variety of peripheral nerves and can include insertion of electrodes through a cannulated needle or insertion of a thin electrode toward the nerve after blunt surgical dissection.\textsuperscript{11,47–60}

Placing the electrode in proximity to the nerve is a challenge with percutaneous techniques where the nerve is not visualized. Often, electrodes are placed perpendicular to the trajectory of the nerve, making it more likely that at least some electrodes will be in proximity to the nerve,\textsuperscript{43} and many percutaneous techniques rely heavily on anatomic landmarks and fluoroscopic guidance.\textsuperscript{11,55} Nerve stimulation inducing appropriate distribution of paresthesia verifies percutaneous placement. Even with these techniques, the separation between electrode and nerve is difficult to control, particularly with high rates of lead migration.\textsuperscript{61}

Real-time imaging with ultrasound has improved the accuracy of subcutaneous electrode placement, and many groups now rely on this imaging modality.\textsuperscript{12} Several studies have shown that ultrasound-guided percutaneous placement can successfully place leads in proximity to target nerves.\textsuperscript{56,62–64} Rauck et al.\textsuperscript{56} have shown that leads can be placed within 2 mm of the target nerve and also suggest that leads at least 5 mm away from the target nerve may increase selectivity to desired fibers. Others have successfully utilized ultrasound guidance to place electrodes next to deep targets such as the brachial plexus.\textsuperscript{56,65} Combining ultrasound guidance with percutaneous placement allows accuracy close to that
achieved with open procedures without the tissue damage and risk required in skeletonizing the nerve.

As previously mentioned, PFS allows treatment of painful areas not well covered with PNS and targets subcutaneous afferents and receptors rather than the nerve itself.\textsuperscript{14,15} A major procedural difference in PFS is that the painful region is mapped out and subcutaneous electrodes are placed to maximally cover this area. As in PNS, a trial is performed where the area is stimulated with temporary probes or electrodes. Temporary electrodes are then placed for the outpatient portion of the trial. If pain is improved with stimulation, permanent electrodes are typically implanted. A cannulated needle, such as a Tuohy needle, is used to place cylindrical-type leads that are connected to the IPG.

Placement of the subcutaneous leads at the correct depth is of fundamental importance in PFS. Too superficial can lead to burning or lack of efficacy, and too deep can lead to muscle contractions.\textsuperscript{66} Abejón et al.\textsuperscript{66} uses a radiofrequency probe to determine the appropriate depth and passes the electrode to the tip of the probe. Ultrasound-guided placement of leads is another option to place leads at a prespecified depth—especially useful in patients with high body mass index.\textsuperscript{67}

Largely due to the lack of efficacy of SCS and PNS for some indications (e.g., CRPS) and ease of lead implantation, DRGS was introduced. The implantation of leads in DRGS is typically performed percutaneously and under fluoroscopic guidance, and cylindrical leads as shown in Figure 95.2 are typically used. Some groups insert the leads and pulse generator through a single incision.\textsuperscript{68}
FIGURE 95.2 Hardware photos. The pictures illustrate the types of implantable devices. **A:** Implantable pulse generator associated with a dorsal root ganglion lead. **B:** Patient programmer. **C:** Dorsal root ganglion lead.

Early approaches to implanted percutaneous leads used both anterograde (inserting leads from caudally and advancing cranially) and retrograde (advancing from cranial to caudal). Anterograde insertion aimed to place cylindrical leads in the lateral recess to span multiple spinal levels, whereas retrograde techniques aim for the lead to exit the foramen of a single targeted spinal root. Current techniques and at our institution usually advance leads in an anterograde fashion toward a target dorsal root ganglion as will be explained in detail in the following discussion.

FDA approval of PNS devices is primarily limited to radio frequency coupled devices where pulse generator and battery pack communicate to the stimulating leads through the skin. However, no fully implantable PNS or PFS devices are FDA-approved for the United States, although these full-implantable devices have been approved for use in Europe in the early 2010s. As previously mentioned, the FDA approved DRGS for treatment of CRPS of the lower extremities in 2016.

**Implantation Techniques**

There are numerous target nerves and techniques for placing stimulating electrodes, and techniques vary from institution to institution. In this
chapter, we provide our experience with electrode implantation for a few sample procedures in the following discussion. For additional information on techniques, comprehensive surgical references are available.\textsuperscript{43,44}

**OPEN SURGICAL PLACEMENT**

In the first stage of the procedure, and as shown in Figure 95.3A, the target nerve is exposed and skeletonized, with the length of exposure depending on the size of the electrode. After exposure, the electrode can be placed underneath the traversing nerve, and often, an interleaving plane of fascia is placed between the nerve and electrode.\textsuperscript{43,44} To reduce the likelihood of lead migration, the electrode is secured to the surrounding tissue, and a tension relieving loop is created.

In the second stage of the procedure, the electrode leads are connected to an IPG in a subcutaneous pocket. The lead is tunneled to the IPG implantation location, which depends on surgeon preference and the target nerve. Typical locations include, but are not limited to, the infraclavicular area, abdominal wall, and superior gluteal region.\textsuperscript{43,44}
FIGURE 95.3 Illustrations of procedures. A: Traditional paddle electrodes applied to peripheral nerves. The dissection is carried down to the peripheral nerve (in yellow) to be stimulated. A paddle electrode is placed underneath the nerve. Often, fascial tissue is laid between the nerve and electrode to help secure the electrode. B: Percutaneous placement of cylindrical leads for occipital nerve stimulation. As seen in the depiction, the occipital nerve exits the trapezius and travels above the muscular fascia that becomes the galea/aponeurosis. The occipital leads are placed in the subcutaneous tissue superficial to the exiting greater and lesser occipital nerve. Although the lead in this cartoon entered laterally, others choose to insert the leads in the midline and point the leads.
laterally toward the painful side. C: Use of ultrasound to visualize the sartorius and tensor fasciae latae (TFL). The lateral femoral cutaneous nerve (LFCN), in yellow, travels between these two muscles and can be targeted with a percutaneous lead as seen here. D: Insertion of dorsal root ganglion leads. First, a hollow bore needle is passed through the interlaminar space (left). Once the ligamentum flavum is entered and before entering the dura, the needle is stopped, and an electrode is passed laterally toward the neural foramen to be in proximity to the dorsal root ganglion (right). The dorsal root, dorsal root ganglion, and spinal cord (all enclosed in dura) are in yellow.

PERCUTANEOUS PLACEMENT WITH FLUOROSCOPIC GUIDANCE

For occipital nerve stimulation, the patient is placed with the head turned laterally in Mayfield pins under general anesthesia. A lateral incision immediately inferior to the mastoid notch and in line with the atlas is planned with the assistance of fluoroscopy. A Tuohy needle or peel-away sheath introducer is passed through the subcutaneous tissue superior to the underlying fascia perpendicular to the trajectory of the occipital nerves toward the contralateral side, as shown in Figures 95.3B and 95.4C. Given the reliability of the anatomic landmarks, we forgo intraoperative stimulation of the occipital nerves. A small subcutaneous pocket on top of the fascia is created, and a tension-relieving loop is secured to the fascia. The leads are then tunneled to an infraclavicular pocket where the IPG is implanted.
FIGURE 95.4 Images of peripheral stimulation. A: This fluoroscopic image depicts supraorbital leads. B: The ultrasound image shows tensor fasciae latae and sartorius muscles. The lateral femoral cutaneous nerve (LFCN) traverses between these two muscles which serve as a landmark to target the LFCN. C: The fluoroscopic image shows a cylindrical lead being advanced into the neural foramen. D: This image shows a percutaneously implanted occipital nerve stimulator (note the tension-relieving loops near the entry site). E: This shows implanted saphenous nerve stimulator.

PERCUTANEOUS PLACEMENT WITH ULTRASOUND GUIDANCE
At our institution, patients undergoing PNS typically undergo an ultrasound-guided trial of stimulation to evaluate efficacy. The most successful location for stimulation is captured with ultrasound imaging. Permanent implantation begins with visualization of the lateral femoral cutaneous nerve (LFCN) between sartorius and tensor fasciae latae, as shown in Figure 95.4B. A small incision only big enough to allow the entry of a needle is made in the skin. A hollow bore needle with stylet is passed toward the nerve, as shown in Figure 95.3C. The stylet is removed, and a cylindrical lead is advanced through the needle toward the LFCN. The cylindrical lead is shown in Figure 95.2. The distal portion of the lead is ideally placed in close proximity to the nerve (within a few millimeters), and the proximal portion is several millimeters deep to the incision. The hollow bore needle is removed, and the skin is closed with dressing. The external stimulator is applied with one end overlying the distal electrodes and one end overlying the proximal leads.

**PLACEMENT AT THE NERVE ROOT/DORSAL ROOT GANGLION**

For a patient to undergo L1 DRGS, the needle with stylet is placed in the skin at the level below (L2 to L3) on the opposite side of pain; this means that if a patient needs stimulation of left-sided L1 DRG, the needle is inserted from the right side at L2/3. The needle targets the L1 to L2 interlaminar space under fluoroscopic guidance. As the needle is passed through the ligamentum flavum, less resistance is encountered, which indirectly identifies the epidural space. A J-catheter is passed through the needle and is positioned to pass the tip outside the neural foramen. The foramen is entered and requires an interval increase force to “pop” through the foramen. The electrode is then passed through the J-catheter with the radiopaque leads positioned immediately inferior to the pedicle (see Figs. 95.3D and 95.4C). On lateral fluoroscopy, the lead should be in the foramen; it should not cross the disk/vertebral body because this is more likely to induce motor spasms due to stimulation of ventral root. An “S”-shaped tension-relieving loop is then created in the epidural space by twisting the J-catheter. The catheter and the needle are then removed, leaving only the lead. The leads are then tunneled to the IPG, and the
incision is closed.

**Patient Selection and Preoperative Workup**

A typical workup should include detailed history, psychological evaluation, and thorough physical exam. Routine lab work is helpful to screen for systemic disorders or clotting diatheses. As is the case for many pain conditions, a psychological evaluation is necessary to evaluate whether psychiatric condition may be clouding the clinical picture, and if psychiatric condition is found, successful treatment may also reduce the pain experienced.

Radiographs and computed tomography (CT) scans may demonstrate compressive osseous structures or bony entrapments. Magnetic resonance (MR) neurography may show mass lesions or intrinsic lesions that result in pain. Ultrasound is also useful for diagnosing entrapments, compressive mass lesions, and traumatic injuries. Electromyography (EMG) can aid in localizing the nerve, especially to avoid missing a case of entrapment. However, this test can be painful especially for those experiencing neuropathic pain in the area being studied.

PNS is almost never a first-line treatment for pain conditions but follows exhaustive conservative measures, including physical therapy, analgesic/antiepileptic medications, and anesthetic blocks/injections. Injections provide not only a therapeutic effect but also can aid diagnosis (diagnostic blocks) by providing evidence for the target lesion causing pain. Surgical intervention is usually offered prior to neuromodulation to correct the underlying condition if possible.

Many factors influence the efficacy of peripheral stimulation. Prior to permanent implantation of peripheral nerve stimulators, trial stimulators are used to evaluate whether the painful areas are responsive to electrical stimulation. Only if the area is responsive to temporary stimulation does one consider permanent implantation. Poor response to nerve block is also widely considered a poor prognostic sign.\(^{71}\) Other negative prognostic factors include sensory loss, allodynia, and pain exacerbation with TENS; positive prognostic factors include successful diagnostic nerve block.\(^{16}\)

Generally speaking, insertions of peripheral stimulators are relatively
straightforward procedures that do not require general anesthesia. Thus, clinical judgment should be employed to determine whether the patient is an acceptable surgical candidate. Specific to implantation of peripheral stimulators, the need for frequent MR imaging scans and a remote infection would be relative contraindications.

Clinical Indications and Outcomes

Commonly reported indications for peripheral stimulation are discussed in the following text and include neuropathy (nerve entrapment, postoperative/posttraumatic injuries, or amputation), head/face pain (occipital neuralgia, chronic migraines, cluster headaches, trigeminal neuropathy), back pain, pelvic pain, CRPS, and brachial plexus injury. Peripheral stimulation, however, has also been reported in a number of other pain conditions such as fibromyalgia, \(^{72}\) phantom limb pain, \(^{56}\) poststroke pain, \(^{73}\) postherpetic pain, \(^{74,75}\) cardiac/visceral pain, \(^{76,77}\) hemicrania continua, \(^{57}\) and posttraumatic headaches. \(^{57}\) Major clinical indications are outlined in Table 95.1.

EXTREMITY PAIN
Extremity pain can be treated with a wide variety of stimulation modalities that are detailed below.

Peripheral Nerve Stimulation
Large peripheral nerves provide excellent targets for peripheral stimulation. Sensory nerves in particular are especially suitable targets because they avoid unwanted motor recruitment, although mixed motor and sensory nerves can be stimulated at the risk of motor recruitment at stimulation amplitudes. Indications include nerve injuries causing neuropathic pain (entrapment, posttraumatic, iatrogenic), electrical burns, amputational pain, and CRPS. Target nerves include axillary, median, ulnar, and radial nerves in the upper extremities and sciatic, femoral, posterior tibial, peroneal, and LFCNs in the lower extremities.

Many case reports and case series describe promising results for PNS in medically refractory extremity pain. However, no long-term, prospective, randomized studies have been completed. In general, it could be challenging to evaluate stimulation in large, randomized studies because patients typically can sense therapeutic stimulation. In most studies, a majority of patients report 50% to 80% improvement in pain, although there are reports of full pain relief with follow-up ranging from weeks to two decades. In a 1998 meta-analysis, Long found that 82.5% reported a “good” response.

Some studies have suggested that stimulation of nerves of the lower extremity, specifically the sciatic and posterior tibial nerves, are more likely to fail. Nashold et al. suggested stimulation might be more difficult for the sciatic nerve because sensory fascicles are deep in the sciatic trunk, and that failures could also be due to nerve length, tethering of the nerve, or compression in the tarsal tunnel. Regardless, other studies have achieved acceptable results for lower extremity PNS, and Eisenberg
et al.\textsuperscript{71} reported that 8 of 10 patients had ≥50\% improvement in pain.

**Brachial and Lumbar Plexus Stimulation**

Stimulation of the brachial plexus has been attempted for posttraumatic injury (including traction)\textsuperscript{26,81} and CRPS,\textsuperscript{65} and stimulation of the lumbar plexus has been reported for traumatic/amputation neuropathy.\textsuperscript{82} Traditional treatments for posttraumatic injury include medical management, anesthetic blocks, and implantation of pain catheters.\textsuperscript{26} Implantation at the brachial plexus offers several advantages over stimulation of distal nerves such as broad area of coverage, possibility for a single incision for lead and pulse generator, and protection from migration provided by deep location.\textsuperscript{81} Compared to SCS, implantation of the PNS lead is less invasive. Both posterior and supraclavicular approaches are reported.\textsuperscript{26,83}

In posttraumatic neuropathy, Law et al.\textsuperscript{81} published a series of 22 patients implanted with brachial plexus stimulators at the cords and trunks. Thirteen patients achieved pain control at 25 months. Goroszeniuk et al.\textsuperscript{26} reported percutaneous cylindrical leads at the brachial plexus for a patient with traction injury. The patient stopped all pain medications and at 21-month follow-up noticed improvement in sensory and motor loss from the original accident.

Bouche et al.\textsuperscript{65} reported that 10 of 17 patients implanted for CRPS type 2 had ≥50\% reduction of pain at 1 to 2 years. The study noted no cases of lead migration. Only one patient required surgical correction for an adverse event, a surgical site infection; the stimulator was removed and then reimplanted after the infection cleared.

**Dorsal Root Ganglion Stimulation**

DRGS is especially helpful for neuropathic pain of the trunk and extremities. It is FDA-approved for CRPS of the lower extremities and groin.\textsuperscript{17} Other reported indications include amputational pain,\textsuperscript{84,85} neuropathy of the lower extremities,\textsuperscript{68,86} postherpetic pain,\textsuperscript{87} and postthoracotomy syndrome.\textsuperscript{17}

CRPS is a pain condition commonly treated with neuromodulation—traditionally SCS. However, pain in the lower extremities is difficult to
cover with SCS, and DRGS is often successful in cases refractory to SCS. In one of the few prospective studies, 152 patients with CRPS of the lower extremities were randomized to either DRGS or SCS, and efficacy was defined as a 50% drop in visual analog scale (VAS) pain scores at 3 months. The DRG group had a statistically significant superior result, with an 81.2% response rate compared to a 55.7% response rate for SCS. The efficacy of DRGS was also found to be less dependent on lead position than SCS. Successful DRGS has been demonstrated in several case reports and case series.

Similar to CRPS, many physicians have turned to DRGS for amputation stump pain when other forms of neuromodulation, like SCS, are unsuccessful. Several small series have shown early success. As mentioned previously, PNS can also be used for amputation stump pain.

Our institution uses DRGS for several pain conditions previously treated with other forms of neuromodulation. We favor L5 DRGS over SCS for CRPS of the foot because we have found it more efficacious and less invasive. For improved efficacy, we use L3 DRGS for neuropathic pain in the distribution of the LFCN and L2 to L4 DRGS for femoral neuralgia.

**TRUNCAL PAIN**

**Axial Back Pain**

Historically, low back pain from failed back surgery is an excellent indication for SCS. Typically, the radicular component of the pain is more responsive than the axial component, and stimulating the dorsal columns does not easily provide coverage in the low back, chest wall, or abdominal wall. Obviously, direct stimulation of peripheral nerves is not effective, given that axial back pain is not isolated to the distribution of one nerve or spinal root. However, PFS and DRGS effectively cover the painful area of the back.

Several case reports and case series describe successful control of back pain with PFS. Paicius et al. reported improvement of intractable, axial low back pain in six patients, and in one patient, Krutsch et al. reported improvement of pain severity to 1 on a 10-point VAS without oral pain medications. Two large series and one small series of patients with
variable painful conditions that included low back pain found significant improvement in pain with PFS with up to 1-year follow-up.

In the only prospective, blinded, randomized study, McRoberts et al. placed trial stimulators in 32 patients with chronic, intractable low back pain and divided patients into groups with minimal stimulation, subtherapeutic stimulation, low-frequency stimulation, and standard stimulation. At short-term follow-up, there was a statistically significant decrease in VAS between groups with effective stimulation and those without stimulation. Subsequently, the 23 responders underwent permanent implantation, with 69.5% of patients reporting “excellent” to “good” pain control at 1 year.

Recently, DRGS has been applied to intractable back pain, radiculopathy, or failed back syndrome. Deer et al. implanted trial DRG stimulators in five patients with primarily back pain who experienced, on average, an 84% improvement in VAS pain scores at 3 to 7 days. The average decrease in pain was 80% in the leg and 70% in the foot. Liem et al. permanently implanted 32 patients with DRG stimulators for back and lower extremity pain attributable to CRPS, failed back surgery syndrome, chronic postsurgical pain, disk pain, radicular pain, and lumbar stenosis. The patients were followed prospectively, and at 12 months, VAS scores for the back, leg, and foot had decreased by 42%, 62%, and 80%, respectively. Our current practice is to use PFS for axial low back pain without radicular pain and multicolumn SCS or high-frequency SCS for back pain with radicular pain.

**Pelvic and Groin Pain**

Pelvic pain is another common pain syndrome, as roughly 10% of gynecology visits are related to chronic pelvic pain. Previously, SCS was employed mainly to control the visceral component of pelvic pain. Tamimi et al. demonstrated the successful use of PFS in two patients with chronic pelvic pain and one with laparoscopically diagnosed endometriosis. The subcutaneous leads were placed in the distribution of the L1 root and ilioinguinal nerve.

Stinson et al. reported the implantation of subcutaneous leads in three patients, not with deep visceral pain but chronic groin pain associated with
open herniorrhaphy. The incidence of intractable, postherniorrhaphy inguinal pain was estimated in 2001 to be 6,800 to 13,600 new cases annually in the United States. Although not referred to as PFS, the method of implantation is similar to PFS because the leads are implanted into the subcutaneous tissue of the painful area and not directly to the nerve proximal to the area of pain. All three patients had 75% to 100% pain relief at 3, 10, and 12 months. Rauchwerger et al. reported successful pain relief in three patients with medically refractory postsurgical ilioinguinal neuralgia who were implanted with subcutaneous leads at 6 to 12 months.

Recently, many have used DRGS to treat groin neuralgia. Although there are no randomized comparisons between DRGS and other modalities of neuromodulation, several series and reviews report success. Regarding postoperative etiologies, Zuidema et al. reported 90% to 100% improvement in postherniorrhaphy at 2 to 3 months and also reported 80% pain reduction in intractable groin pain after resection of Bartholin’s cyst. Rowland et al. successfully used a DRG stimulator at L1 and L2 for chronic and intractable pelvic girdle pain after pregnancy.

We favor DRGS over PFS for most groin neuralgias. We feel the implantation is easier, and efficacy is the same or better. Specifically, L1 DRG is used for ilioinguinal neuralgia and L1 and L2 DRG for genitofemoral neuralgia. However, for neuropathic pain in the pudendal distribution, we use epidural stimulation within the sacral spinal canal of the sacral roots for ease of implementation.

**Other Truncal Pain Syndromes**

In addition to back and pelvic pain, case reports and small series have successfully demonstrated PFS in chronic neck pain, postthoracotomy pain, and chronic abdominal pain. Given the high incidence of postthoracotomy pain (up to 50%), neuromodulation techniques such as SCS and PFS have become useful techniques for these difficult-to-control pain syndromes. Finally, in our experience, DRGS has been helpful for postherpetic pain at the level above the painful dermatome.

**HEADACHE AND FACIAL PAIN**
A major application for PNS is relief of headache, facial pain, and head pain. The target nerves in this region are the occipital nerve and branches of the trigeminal nerves, including the supraorbital, infraorbital, and supratrochlear nerves.

Occipital nerve stimulation is a major target of PNS and one of the first targets of percutaneous nerve stimulation.\textsuperscript{9,11,12,49,51,53,59,61,107} Since its original use, the occipital nerve has been the target for not only occipital neuralgia but also triggered migraine headaches,\textsuperscript{48,54,57,108–113} cluster headaches,\textsuperscript{47,54,55,114,115} hemicrania continua,\textsuperscript{57} and posttraumatic headaches.\textsuperscript{57}

It is not well understood why stimulating the occipital nerve relieves pain outside of its sensory distribution such as migraine headaches. As explained by Goroszeniuk and Pang,\textsuperscript{116} convergence of common pathways (cervico-trigeminal relay) in the brainstem may allow the occipital nerve to act as an access point to modulate various brainstem afferents. This theory is further evidenced by preliminary studies such as Busch et al.,\textsuperscript{117} which shows that the trigeminal-mediated blink reflex is impeded by occipital block. In response to occipital nerve stimulation, preliminary positron emission tomography (PET) studies suggest central changes, including regional blood flow variations to the anterior cingulate, cuneus, rostral-dorsal midbrain, and pulvinar nucleus.\textsuperscript{109} Magis et al.\textsuperscript{115} showed on 18-fluorodeoxyglucose-PET that occipital nerve stimulation normalized elevated metabolism of the midbrain and lower pons but did not decrease elevations of hypothalamus. Additionally, elevations in the metabolism of the anterior cingulate cortex correlated with better response to stimulation. Finally, further proof of a shared occipital nerve and central pathway lies in a study by Aló and Holsheimer\textsuperscript{118} that showed that cervicogenic headaches in the C1 to C3 distribution can transform into chronic migraines.

Other major targets of PNS in the face are the branches of the trigeminal nerve. The supraorbital nerve is a branch of the ophthalmic nerve (V1). The nerve has been stimulated for pain syndromes, including neuropathic facial pain in the trigeminal distribution that is postherpetic or secondary to surgical/traumatic injury,\textsuperscript{60,74,119–121} chronic cluster headache,\textsuperscript{122} and frontal headaches.\textsuperscript{123}
**Occipital Neuralgia**

Much of the early work on occipital nerve stimulation for pain was reported for large series in which the occipital nerve was just one of several nerves stimulated, and the approach was an open procedure that identified the nerve and placed an electrode in proximity to the nerve.\(^9,^{107}\) In 1999, Weiner and Reed\(^{11}\) placed leads at the occipital nerve via a percutaneous approach for patients with occipital neuralgia. Recent studies have demonstrated success in the majority of patients, with follow-up times between 3 months and 6 years. These studies primarily include series from a single institution and usually report success as $\geq$50% decrease in VAS scores.\(^{49,51,59,61,107,124}\) A detailed review of occipital nerve stimulation for occipital neuralgia can be found in Liu et al.\(^{53}\) The occipital nerve is not the only target for occipital neuralgia, as Chivukula et al.\(^{125}\) stimulated the spinal roots and spinal cord for relief of occipital neuralgia.

**Migraine Headache**

Stimulation of the occipital nerve for patients with migraine headaches is an option for patients with migraines refractory to conservative medical treatments. Silberstein et al.\(^{112}\) performed one of the first prospective, multicenter, blinded studies, which involved 157 patients. At 12 weeks, stimulated patients had decreased headache severity and decreased number of headache days compared to controls, although the primary outcome, defined as a 50% decrease in VAS scores, shows no significant difference between treated patients and controls. At 12 months, all patients were moved to the stimulation group, and roughly half had either decreased headache severity, decreased frequency of headache, or both. A downside of the study was the large number of adverse events—41% required surgical management of an adverse event.\(^{48}\)

In the occipital nerve stimulation for the treatment of intractable chronic migraine headache (ONSTIM) trial, the multicenter, randomized study of 66 patients by Saper et al.,\(^{111}\) patients with occipital nerve stimulation had a 39% response rate compared to medically treated controls with a 0% response rate. Response rate was defined as either a $>50\%$ reduction in headache days or a 3-point drop in headache intensity (VAS). Patients who responded to occipital nerve block were randomly assigned to stimulation
and control groups. The stimulation group consisted of patients with an occipital nerve stimulator who adjusted the intensity of the stimulation to minimize pain. The control groups included both medically managed patients and those with occipital nerve stimulation that was turned on for only 1 minute per day and were told that stimulation intensity was at a preset level. Although the number of patients responding to stimulation was significant, the stimulation and control groups did not differ significantly when the number of headache days and overall intensity were averaged over the respective groups.111

In another randomized study, Slotty et al.113 showed that a small group of eight patients treated for chronic migraines had a statistically significant drop in VAS score when compared to controls. The stimulation group was divided into a suprathreshold group and subthreshold group; threshold was set at the level of the patient’s perception of stimulation. VAS score decreased from 8.2 ± 1.22 preoperatively to 1.98 ± 1.56 in suprathreshold stimulation and 5.65 ± 2.11 in subthreshold stimulation. Only patients with a stable response to occipital nerve stimulation were selected for this study,113 in which intensity of stimulation correlated with reduction in pain.

The aforementioned results contrast with those of Lipton et al.108 in the PRecision Implantable Stimulator for Migraine (PRISM) study of 132 patients with medication refractory chronic migraines. Compared to patients with sham stimulation, those with occipital nerve stimulation (active arm) had no statistically significant decrease in number of headache days. In the active arm, 5 to 10 days of percutaneous trial stimulation prior to implantation was moderately predictive of stimulation success at 12 weeks.108 Unlike Silberstein et al.,112 Lipton et al.108 did not use trial stimulation to screen patients for permanent implantation, which is a major difference in study design.

In addition to these larger studies, several case series demonstrate relief of pain from chronic migraines. Popeney and Alo110 implanted 25 patients with occipital nerve stimulators, with an average improvement in Migraine Disability Assessment score of 89% at mean follow-up of 18 months. Oh et al.124 implanted 10 patients with chronic migraines, with near complete resolution of pain at 6 months.
Cluster Headache
Neuromodulation for cluster headaches has been previously reported by Franzini et al., who used deep brain stimulation of the posterior hypothalamus. However, occipital nerve stimulation for cluster headaches has also demonstrated success and is less invasive. Several series show promising results. In these studies, the majority of 41 patients responded well to stimulation at varying follow-up times (3 to 47 months). Additional prospective, randomized trials are needed to further validate this application of neurostimulation technology.

Other targets of neuromodulation to relieve pain from cluster headaches have been studied. Narouze and Kapural employed supraorbital stimulation for both early abortion of cluster headaches and prevention of recurrent attacks up to 14 months later. Schoenen et al. targeted the sphenopalatine ganglion for transorally placed electrical stimulators.

Trigeminal Neuralgia and Facial Pain
Facial pain syndromes have long been a source of chronic suffering for patients, and recently, neuromodulation has been applied toward their relief. Johnson and Burchiel found ≥50% pain relief in 7 of 10 patients with primarily posttraumatic or postherpetic neuropathic pain in the V1 and V2 branches. Eight of these patients had implantation of leads at the supraorbital foramen and two at the infraorbital foramen. Slavin et al. implanted 22 patients with peripheral nerve stimulators for postsurgical, posttraumatic, or unknown nerve injury, targeting the occipital, supraorbital, or infraorbital nerve. Fifteen of the 22 had ≥50% reduction in pain. The results are not subcategorized by nerve, but 4 patients had supraorbital stimulators, and 1 had a combination of occipital and supraorbital nerve stimulators. In a separate report, Slavin et al. implanted supraorbital/infraorbital stimulators in 8 patients with facial pain, and 7 of the 8 experienced ≥50% improvement in pain. Amin et al. was the first study of supraorbital stimulation for frontal headaches. Ten patients underwent implantation, and VAS scores decreased from 7.5 ± 1.2 to 3.5 ± 1.2 at 30 weeks. Additional small case reports and series include studies of supraorbital neuralgia and postherpetic neuralgia.

Other targets for facial pain include the trigeminal ganglion itself.
Studies have demonstrated stimulation of the ganglion for facial pain from peripheral neuropathy, stroke, or postherpetic neuralgia.\textsuperscript{129,130} A thorough review of this topic was presented by Holsheimer,\textsuperscript{131} who found $\geq 50\%$ improvement in VAS scores in 48\% of patients with atypical trigeminal neuralgia; the response rate for those with postherpetic neuropathy was $< 10\%$.

**Complications**

The anticipated complications for any implantable stimulator include infection, lead migration, hardware failure, and lead/wire fracture. Specific complications are reviewed in the following text for each modality of stimulation.

**PERIPHERAL NERVE STIMULATION**

Complication rates vary widely for large studies that implanted electrodes via open techniques. Nashold et al.\textsuperscript{8} implanted sutured button electrodes directly to the fascicles to be stimulated in 35 patients and reported an 8.6\% complication rate, but no patients required surgical revision. Eisenberg et al.\textsuperscript{71} also directly sutured leads to the nerve, with 5 of 46 patients (11\%) having a complication leading to additional surgery. Mobbs et al.,\textsuperscript{42} who wrapped the nerve in mesh in PNS for chronic pain, had an 18\% rate of complication requiring surgery. In Hassenbusch et al.,\textsuperscript{78} the electrode “with a layer of free fascia covering its surface was placed in apposition” to the nerve, and the rate of complication was 27\%.

Historically, open procedures use paddle electrodes placed in proximity to the nerve. These paddle electrodes can be complicated by compression neuropathy\textsuperscript{44} and perineural fibrosis. However, this outcome is much less likely with newer cylindrical electrodes and percutaneous placement.\textsuperscript{43} Some have suggested that percutaneous placement of cylindrical leads may be more prone to migration than open techniques with paddle electrodes, although no studies directly compare open versus percutaneous techniques.\textsuperscript{61,124} The migration of cylindrical leads can be reduced by looping the electrode in the subcutaneous pocket.\textsuperscript{44} In the ONSTIM trial using percutaneous leads in 51 patients, the migration rate was 26\%.\textsuperscript{111}
Dodick et al.\textsuperscript{48} reported that 71\% of 157 patients experienced an adverse event, including 29 lead migration events, in their study of occipital nerve stimulation for chronic migraines. Eighty-five (41\%) of the adverse events required additional procedures. On the other hand, in Mueller et al.’s\textsuperscript{54} study of occipital nerve stimulation, only 1 of 27 patients had lead migration. More data and better strategies are needed to reduce the number of adverse events from lead migration.

**PERIPHERAL FIELD STIMULATION**
Complications of PFS are similar to those of PNS and include infection, lead migration or fracture, lead erosion, hardware failure, and postoperative pain. Several large series have noted adverse events, including lead migration rates of 4\%,\textsuperscript{96} 13\%,\textsuperscript{95} and 22\%.\textsuperscript{33} Reoperation rates are not widely reported, but McRoberts et al.\textsuperscript{33} reported a high rate of 13 of 23 patients (56\%). Seventy-four percent of 111 patients in the retrospective study of Sator-Katzenschlager et al.\textsuperscript{95} had no complications, but the rate of reoperation was not given. Further studies will help to better understand the side-effect profile of PFS.

**DORSAL ROOT GANGLION STIMULATION**
Although generic risks for DRGS include those previously mentioned (infection, lead migration/fracture, device failure, and postoperative pain), cerebrospinal fluid (CSF) leak is a unique risk for this procedure given the proximity of the dorsal root ganglion to the thecal sac. Although the rate of serious adverse events (life-threatening risks, disability, or need for invasive procedure) have been shown to be comparable to SCS,\textsuperscript{89} the total number of adverse events is likely higher. Deer et al.\textsuperscript{89} reported a 10.5\% rate of serious adverse events in 76 patients without any deaths, although the rate of total adverse events was higher in DRGS (46\%) than SCS (26\%). Postoperative incisional pain was the most common procedure-related event, and pain at the IPG was the most common device-related event. Likewise, Liem et al.\textsuperscript{97} recorded 86 events in 29 of 51 patients, with 14.6\% experiencing temporary motor recruitment, 8.5\% CSF leak, and 8.5\% infection. Clearly, more studies are needed as this technique improves and evolves.
Conclusion and Future Directions

Painful conditions are a source of tremendous patient suffering and high health care costs. Patients in pain often turn to addictive narcotic medications that do not relieve pain long term due to medication tolerance and that also have unwanted side effects. Electrical stimulation has been used for many years and provides effective pain relief for those with refractory pain conditions, without the side effects of narcotic medications. PNS has been used for many decades, and in recent years, implantation has become less invasive. PFS has been proposed to treat conditions such as axial back pain that are not effectively covered by a single peripheral nerve. Likewise, DRGS has shown tremendous efficacy in conditions with pain distributed across multiple peripheral nerve roots.

Finally, just as the field has experienced exponential growth recently, new technologies and strategies using peripheral stimulation continue to emerge. Recently, some have combined the use of peripheral stimulation with other forms of electrical stimulation, such as SCS. Furthermore, implantation techniques are becoming less invasive, and many investigators have proposed either small or wireless IPG devices that are easier to implant.

CHAPTER 96

Spinal Cord Stimulation

RICHARD B. NORTH and BENGT LINDEROTH

History

In antiquity, some healers successfully treated pain by placing electrogenic fish on or near the painful area of the patient’s body.\(^1\) This crude form of electrotherapy enjoyed a measure of success but was limited in scope by the geographic and ecologic constraints associated with keeping the fish alive and available. Thus, electrotherapy was not widespread until creation of the Leyden jar in 1745 made it possible for physicians not only to deliver electrotherapy at will but also to exert a modicum of control over how much electrical current the patient received. This was an exciting medical advance, and by the 19th century, physicians were considered well equipped only if they had a portable generator and could provide electrotherapy for a wide range of indications. The advent of empirical medicine in the 20th century, however, caused most physicians to abandon the application of electrical shocks to treat pain. In the mid-1960s, however, neurosurgeon C. Norman Shealy et al.\(^2\) recognized that Melzack and Wall’s newly published Gate Control Theory of Pain\(^3\) provided a theoretical basis for a new form of electrotherapy that could be delivered with implanted electrodes. Shealy et al.\(^2\) called the innovation “dorsal column stimulation”; today, we know it as spinal cord stimulation (SCS).

Melzack and Wall’s\(^3\) Gate Control Theory proposed that the balance of activity between large and small nerve fibers in the peripheral nervous system determines whether or not pain signals are transmitted centrally. According to the theory, when small fiber input is dominant, a pain “gate” opens in the dorsal horn (DH) of the entrance segment of the spinal cord; this gate closes when large fiber activity is dominant. Because electrical stimulation depolarizes large fibers before it affects small fibers, the theory suggests that it should be possible for stimulation to close the pain gate.
This hypothesis inspired Shealy et al.\textsuperscript{2} to deliver current directly to a terminal cancer patient’s spinal cord with an implanted electrode and external pulse generator in a successful bid to relieve the patient’s otherwise intractable pain.

Although the electrical stimulation therapies inspired by the Gate Control Theory have succeeded, the theory itself remains controversial. It predicts that all types of pain will be inhibited, but clinical experience has shown that SCS is more effective for neuropathic pain than for acute or nociceptive pain.\textsuperscript{4,5} Furthermore, large fiber activity can itself signal pain (e.g., the pain of sunburn).\textsuperscript{6}

Despite the fact that the Gate Control Theory does not adequately explain all aspects of the therapies it inspired, it provides a useful description of the general concept of the transmission of pain signals and has stood the test of time to a remarkable degree.\textsuperscript{7}

Within a few years of the introduction of SCS, it was reported that coverage of each patient’s areas of pain by stimulation-evoked paresthesia was necessary for pain relief.\textsuperscript{8,9} For many years thereafter, technical advances in SCS were directed at optimizing this, scaling amplitude to the range from perception of paresthesia to discomfort from the paresthesia.\textsuperscript{10} More recently, automated methods have been developed to maintain amplitude below discomfort threshold based on either postural sensing or evoked potentials.\textsuperscript{11,12}

As shown in Figure 96.1, since 2010, frequencies as high as 10 kHz as well as “burst” (to be distinguished from conventional monotonic) waveforms have been introduced. The therapeutic range for these new waveforms can begin below perceptual threshold, and this is fortuitous, as some patients prefer paresthesia-free stimulation, and as perceptual threshold can coincide with discomfort threshold for frequencies >800 Hz.\textsuperscript{13} It also is now appreciated that even with conventional (monotonic, <1,500 per second) waveforms relief can be achieved at amplitudes below perceptual threshold.\textsuperscript{14} Relevant basic science and clinical experiences will be detailed in the following discussion.
Today, SCS is a minimally invasive, reversible therapy implemented with sophisticated techniques and implanted equipment, including a variety of electrodes and multiple-output pulse generators. Unlike most surgical procedures undertaken to relieve pain, SCS does not ablate pain pathways or result in anatomic change. SCS also offers its candidates the advantage of undergoing a screening trial with a temporary SCS system before proceeding (or not) to implantation.

Pain and its relief by SCS vary by condition and from patient to patient. When SCS is delivered to the right patient by the right (experienced) clinician in the right setting using the right equipment, pain relief is optimized and can be sustained for decades. It is important to remember, however, that SCS is expected to reduce, not eliminate, pain, particularly pathologic (neuropathic) pain which itself is a disease. SCS is not expected or intended to relieve nociceptive or biologically useful pain.

Investigators are continually improving SCS patient care by refining techniques and equipment, and as we learn more about the mechanisms of action of SCS, we will be able to optimize its application.
Stimulation

INTRODUCTION
The work of several investigative teams in the five decades since Shealy et al.\textsuperscript{2} implanted the first “dorsal column stimulation” electrode has helped us identify promising avenues of research, refine experimental techniques, and develop evidence in support of hypotheses that explain aspects of the mechanisms of action of SCS. The challenge in experimental studies is to mimic the human painful condition and deliver stimulation, for example in rats, with parameters that would be clinically relevant in humans. Even in a homogeneous population of laboratory animals, however, the yield of neuropathic pain models is uncertain, and clinical studies must grapple with even greater variability among human subjects and painful pathologies. Furthermore, as already mentioned earlier, the clinical application of SCS elicits a discernible tingling, known as paresthesia, which confounds experimental blinding. An additional challenge is the fact that the universally agreed on measurement of the effectiveness of SCS (reduction in pain) is subjective and depends to an uncomfortable degree on a patient’s ability to remember the intensity of past pain in order to make a valid comparison with current pain. Pain assessment also relies on rather crude measurements, such as verbal rating scales and the Visual Analogue Scale. Thus, patient assessment has to be assisted by measures of medication use, physical activity, well-being, general perception of change, etc.

Despite these obstacles, researchers have learned enough to propose distinct mechanisms of action for the therapeutic effects of SCS in the treatment of neuropathic, ischemic, and visceral pain.

NEUROPHYSIOLOGY AND NEUROCHEMISTRY
SCS affects both spinal and supraspinal circuits\textsuperscript{15–21} and thus does not rely solely on antidromic activation of the dorsal columns.\textsuperscript{17,22} Some SCS effects actually survive disruption of supraspinal circuits by transection of the dorsal columns, the dorsolateral funiculi, and even the entire spinal cord rostral to a lumbar electrode.\textsuperscript{23–25}

SCS modulates DH and/or supraspinal neurotransmitters; thus, the
beneficial effects of SCS often outlast the period of active stimulation (see following discussion).

Most studies indicate that endogenous opioids are not involved in the pain-relieving effects of conventional SCS; for example, the effects of SCS are not reversed by the opioid antagonist naloxone,\textsuperscript{26} and the neuropathic pain of SCS patients is usually resistant to opioid therapy. SCS might\textsuperscript{27} or might not\textsuperscript{28} cause release of spinal opioids. There is some experimental evidence that only stimulation with very low frequencies (e.g., 4 Hz) might involve the release of endogenous opioids.\textsuperscript{29}

Additionally, in patients with angina, SCS during atrial pacing and at rest has been demonstrated to release the opioid peptide β-endorphin into cardiac circulation, indicating that SCS affects “local myocardial turnover of the opioid peptides leu-enkephalin, β-endorphin, and calcitonin gene-related peptide (CGRP), a powerful vasodilator.”\textsuperscript{30}

Nerve or nervous system injury can lead to neuropathic pain, which is often radiating, generally described as “burning,” and in some cases involves hyperalgesia (an extreme sensitivity to pain) and allodynia (pain from normally nonpainful stimuli). In contrast, dull, aching nociceptive pain, which is mediated by receptors in skin, muscle, bone, viscera, etc., is responsive to opioids. Because SCS, in most cases, is not thought to cause the release of endogenous opioids,\textsuperscript{28} the clinical expectation is that SCS will be more effective as a treatment of neuropathic, ischemic, and visceral pain than of nociceptive pain. The fact that SCS is effective in treating ischemic pain, which is considered a form of nociceptive pain, does not necessarily mean that SCS directly affects this type of pain. Instead, SCS seems to exert a beneficial effect on the underlying ischemic condition and pain relief in considered as secondary to that (see following discussion).

Among the things rats and humans have in common are that nerve injury alone sometimes causes allodynia (in neuropathic pain cases merely around 20% report allodynia\textsuperscript{31}) and that SCS is not universally therapeutic. Only in single clinical studies have the SCS effects on allodynia been monitored, but in selected material presented by Harke et al.,\textsuperscript{32} the therapeutic effect on allodynia was similar to that on continuous pain.

Investigators also used models of painful neuropathy to explore the impact of SCS on the pain threshold in rats and found that during and after
SCS, the threshold of withdrawal from innocuous mechanical stimuli increases and that SCS affects only the component of the flexor reflex mediated by A fibers (not the late component mediated by C fibers).\textsuperscript{33} Thus, current thinking holds that, to a large extent, SCS acts at a segmental spinal level,\textsuperscript{34} although additional inhibitory influences might be transmitted by descending serotonergic and noradrenergic pathways. A related study used the partial sciatic nerve ligation model to examine how SCS affects the response to innocuous stimuli in postligation rats with and without allodynia and in controls. Only in the allodynic rats did SCS significantly depress abnormal responses and spontaneous discharge of wide dynamic range (WDR) neurons.\textsuperscript{35} The same research group introduced acetylcholine (ACH) into the list of transmitters possibly involved in the beneficial effects of SCS after a microdialysis study demonstrated that ACH is released in the DHs of rats whose pain-related symptoms after nerve injury decreased in response to stimulation.\textsuperscript{36} These effects seem to be caused by activation of muscarinic M4 and M2 receptors in the DH.\textsuperscript{36,37} This finding might lead to new ways to enhance an otherwise inadequate effect of SCS in certain patients. Allodynia occurs when the activation of nerve fibers in the periphery causes hyperactivity of WDR neurons in the superficial laminae of corresponding DHs.\textsuperscript{38} SCS relieves allodynia by suppressing this hyperactivity.\textsuperscript{35} Treatment with γ-aminobutyric acid (GABA) agonists also has this effect, and SCS induces GABA release in the DH of rats\textsuperscript{18} and activates the GABA-B receptor.\textsuperscript{39,40} SCS also decreases DH release of the excitatory amino acids glutamate and aspartate in rats.\textsuperscript{40} One probable mechanism would be that release of GABA binding to presynaptic GABA-B receptors could inhibit the release of excitatory amino acids (e.g., glutamate).

Investigators have also proposed that SCS might relieve pain by blocking conduction of primary afferents at the branch points of dorsal column fibers and collaterals.\textsuperscript{6} This explanation is insufficient, however, because the effect of SCS extends beyond the dorsal columns and electrical stimulation does not inhibit every type of pain.\textsuperscript{21} Dorsal column activation, however, is more successful than ventral stimulation,\textsuperscript{41} which might exert effects on the spinothalamic tract fibers that transmit nociception.
SCS inhibition of the pathologic response (increased firing frequency of WDR neurons, afterdischarge in response to pressure, etc.) of DH neurons in rats exhibiting symptoms of allodynia after peripheral nerve injury continues for more than 10 minutes, consistent with SCS-induced release of DH and cerebral neurotransmitters, and changes the concentration of neurotransmitters and their metabolites in cerebrospinal fluid.

Through the use of microdialysis and immunohistochemical techniques, investigators have examined the effects of SCS on the cerebral neurotransmitter serotonin. In decerebrate cats, SCS applied with clinical parameters evokes a DH release of serotonin. It was recently demonstrated in neurophysiologic studies with microelectrode recordings from different brainstem regions that both the “serotonergic cells” and the OFF-cells in the rostroventromedial medulla (RVM) are selectively activated by lumbar SCS in neuropathic rats, and this happens only in animals responding to the stimulation in previous behavioral studies. In SCS-responding animals, the tissue concentration of 5 hydroxytryptamine (5-HT) is increased in lumbar DHs following stimulation. The behavioral effects of the 5-HT release in the DHs seem to be mediated by 5-HT2A, 5-HT3, and the 5-HT4 receptors.

Similarly, a massive activation of neurons induced by SCS occurs in the locus coeruleus, another brainstem center, where many noradrenergic cell bodies are gathered. In contrast to the RVM where 5-HT release could be observed at the spinal level, there was no sign of direct projection of noradrenergic neurons activated by SCS to the DHs (as demonstrated by several methods).

Based on the finding that spinal extracellular GABA levels are lower in allodynic rats than in controls but increase in allodynic rats that respond to SCS, investigators have attempted to potentiate the therapeutic effect of SCS in nonresponding rats with concurrent intrathecal administration of normally subtherapeutic levels of GABA or the GABA-B agonist baclofen. This strategy caused a marked increase in the rats’ threshold for paw withdrawal from innocuous mechanical stimulation. Intrathecal administration of the selective \( \alpha_1 \)-adrenosine receptor agonist R-phenyl isopropyl adenosine produced similar results. Administration of subtherapeutic doses of these agents as adjunct therapy with SCS causes
nonresponding rats to respond to SCS.\textsuperscript{51}

In the first clinical study based on this response, however, the addition of intrathecal baclofen and/or adenosine in small doses was effective, but the latter potentiated SCS in only 2 of 5 patients.\textsuperscript{52}

This result caused investigators to try instead other drugs administered orally in man for neuropathic pain. In rodents, the drugs were given intrathecally and intravenously instead: gabapentin and pregabalin in per se ineffective doses in non-SCS-responding rats with partial sciatic nerve lesion. In these rats, the drugs together with SCS reduced tactile allodynia in a dose-dependent manner and enhanced suppression of hyperexcitability of WDR neurons.\textsuperscript{53}

Accordingly, investigators conducted a pilot study that offered intrathecal baclofen (and, in a few cases, intrathecal adenosine) to 48 patients who did not successfully respond to technically adequate SCS.\textsuperscript{54} Although 20 patients achieved satisfactory pain relief with baclofen plus SCS or baclofen alone, only 11 continued treatment: 7 with a combination SCS system and intrathecal baclofen pump and 4 with only a baclofen pump. At mean 67 months postimplant, 2 SCS/intrathecal patients had their pumps removed and the remaining 9 in the group (5 SCS/intrathecal, 4 intrathecal) reported continued pain relief. The baclofen dose was increased 160\% from baseline, but 5 patients reduced their use of other analgesics.

A similar dose-dependent effect occurred in rodents with intrathecal administration of an otherwise subtherapeutic dose of clonidine, which partially exerts its effects via release of ACH in the DH.\textsuperscript{36,55} A small randomized, double-blind prospective clinical study reportedly indicated that clonidine could be equally useful as low-dose baclofen to enhance the effect of SCS.\textsuperscript{56}

We have yet to identify all of the neurotransmitters and neuromodulators affected by SCS, let alone to decipher their doubtless complicated interactions.\textsuperscript{40,42,57} The mechanisms and neurotransmitters known or hypothesized (so far) to be involved in the effects of conventional SCS in neuropathic pain are illustrated in Figure 96.2.
Basic Science of New Spinal Cord Stimulation

Waveforms

HIGH-FREQUENCY SPINAL CORD STIMULATION

In principle, high-frequency (HF) sinusoidal stimulation applied to a nerve or an axon provides a local conduction block (e.g., Kilgore and Bhadra\(^58,59\)). In contrast to HF current application to a peripheral nerve, HF SCS applied to the dorsal spinal cord of lightly anesthetized rats with the pulse width (PW) and the low amplitudes used clinically induced no block of transmission in the dorsal columns (DCs) nor any activation.\(^60\)

Clinical HF SCS is applied via bipolar stimulation at a pulse repetition rate of 10 kHz and a short PW of about 30 microseconds at an amplitude that is below perceptual threshold (see Fig. 96.1).

The “working hypotheses” for HF SCS so far have been (1) a transmission block or (2) activation of some pathways in the spinal cord. However, a recent computer simulation study\(^61\) has demonstrated that both these hypotheses require high stimulation amplitudes that are at the upper...
A third hypothesis was based on observations from studies of the auditory system in cats and on some few patients with cochlear implants. HF stimulation seemed to be able to induce a desynchronization of neural signals from groups of neurons firing in synchrony. This interesting hypothesis has, to the best of our knowledge, never been studied in nociception (review Linderoth and Foreman).

Furthermore, a study by Song et al. has shown that transmission in the DCs is not affected because there is neither fiber recruitment nor block with HF SCS. Another recent study where recordings from rats with nerve injury were performed with tungsten electrodes on single DC fibers provided data supporting the view that no blockade of the DCs is obtained with HF SCS at clinically relevant amplitudes.

It seems that there is a therapeutic effect of HF SCS, but so far, it has not been found superior to that of traditional SCS in our own animal model using monophasic pulses. Because the DCs are neither activated nor blocked by the HF SCS, the mechanisms hypothesized may be segmental. In a rat study with biphasic stimulation, Shechter et al. compared 20%, 40%, and 80% of motor threshold (MT) as stimulation amplitudes. They used 50 Hz, 1 kHz, and 10 kHz applied for 30 minutes on 3 consecutive days. The only amplitude producing relevant data was 40% of the MT. For this amplitude, some effects of SCS emerged over the 3 days, and actually, the frequency 1 kHz proved slightly better—or at least equally effective as the 10 kHz SCS.

It must be remembered that clinical experiences demonstrate that HF SCS (>800 Hz) might result in uncomfortable sensory experiences as soon as the amplitude is beyond the sensory (paresthetic) threshold.

Very recent preclinical studies (unpublished data) using HF SCS (2 to 10 kHz) where DC activation was also studied have yielded interesting results. Application of 10-kHz SCS in the rat through conductive agar from needle electrodes directly over the L5 segment demonstrated no evidence of a DC fiber conduction block nor activation. Stimulation for several hours did not induce asynchronous firing in myelinated primary sensory neurons. In an inflammatory pain model producing more long-lasting pain, SCS using 20% MT for up to 135 minutes, which was
verified to be subthreshold for activation of Aβ projection neurons, occurred after 45 to 90 minutes when compared to control.

The present view of HF SCS mechanisms may be summarized as follows: HF SCS must be applied with low amplitude—below paresthesia threshold; otherwise, it can be very uncomfortable. There seems to be neither activation nor block of the dorsal columns with HF SCS. Although PW is short and amplitude low, HF delivers more energy, and thus, rechargeable or wireless devices have to be used.

The dorsal columns do not seem to be involved in the effect, thus clearly distinguishing HF SCS from conventional SCS. As yet unpublished data indicate that HF SCS might induce a slowly building up, inhibitory effect directly onto superficial neurons in the DH.

BURST SPINAL CORD STIMULATION

The use of irregular stimulation patterns including “burst stimulation” originates from De Ridder’s work with cortical stimulation, but “modulated stimulation” has been used earlier in the clinic. In the 1970s, burst transcutaneous electrical stimulation (TENS) was launched as a variant to steady frequency TENS with very low “electro-acupuncture-like” frequency (1 to 5 Hz) as compared to normal TENS at about 100 Hz. At this time, hypotheses about different mechanisms for burst and HF TENS were discussed, and the burst TENS was applied more for nociceptive pain types, and some data pointed to a possible mediation by release of endogenous opioids. As already mentioned, recent animal studies further indicate that the antinociceptive effect of low-frequency SCS may depend on opioid mechanisms. One manufacturer marketed for a period during the 1980s an external stimulator that could give variable stimulation patterns (“modulated SCS”), but it never became popular, and the apparatus disappeared from the market.

Burst SCS was presented as a stimulation mode, which would also be effective for the midline or axial low back pain component of failed back surgery syndrome (FBSS). De Ridder argues that bursts or irregular firing are similar to normal nerve activity and exert more prominent effects on supraspinal relays (e.g., the thalamus, as “a wake-up call to the brain” to activate neurons). De Ridder et al. have, on the basis of “source
localized electroencephalogram (EEG)” investigations of patients with burst SCS, advanced the idea that burst SCS could activate cortical areas involved in the modulation of pain perception (Fig. 96.3). In a very recent study, De Ridder and Vanneste \(^{72}\) presented data from five patients undergoing tonic, burst, and sham stimulation. In a source-localized EEG subtraction and conjunction analysis, they showed that burst and tonic stimulation share activation of some cortical areas such as the pregenual anterior cingulate cortex, whereas only burst SCS reduced the connectivity between the dorsal anterior cingulate and the parahippocampal cortices.

**FIGURE 96.3** Present hypotheses for mechanisms behind effects of burst stimulation of the spinal cord. Burst spinal cord stimulation (SCS) is hypothesized to especially modulate the activation of the medial (affective/attentional) pathway (right). Conventional SCS more acts on the lateral spinothalamic tract which conveys information of nociception (strength; site). (Adapted from De Ridder D, Vanneste S. Burst and tonic spinal cord stimulation: different and common brain mechanisms. Neuromodulation 2016;19[1]:47–59. Copyright © 2015 International Neuromodulation Society. Reprinted by permission of John Wiley & Sons, Inc.)

The originators of the burst paradigm\(^{72}\) claim that the burst type of SCS preferentially modulates the medial spinothalamic pathway leading to activity changes in subcortical centers involved in emotions, whereas conventional SCS acts more on the lateral tract leading to the lateral thalamic nuclei and eventually to the sensory cortex. They hypothesize that burst stimulation modulates the medial pain pathway by actions of C fibers synapsing onto lamina I neurons with projections to the dorsomedial nucleus of the thalamus and from there to the dorsal anterior cingulum. An earlier functional magnetic resonance imaging (fMRI) study\(^{73}\)
demonstrated that conventional SCS predominantly modulated the lateral pain pathways as judged by changes in blood oxygen levels in the somatosensory cortices.

Burst SCS, at least in rat models, does not seem to involve the DC system\textsuperscript{74}—another difference to conventional paresthetic SCS. More recent data indicate that the effects of burst SCS do not rely on activation of GABA-B receptors\textsuperscript{75} as has been claimed for conventional SCS (e.g., Cui et al.,\textsuperscript{39} Cui et al.,\textsuperscript{40} Meyerson et al.,\textsuperscript{44} Cui et al.,\textsuperscript{76} Ultenius et al.\textsuperscript{77}).

Burst SCS is commonly administered at amplitudes that do not produce paresthesia. In spite of this, as the average frequency is higher, the energy consumption is larger than that of conventional SCS. A recent finding is that the efficacy of burst SCS seems to relate to the electric charge per burst, at least as found in a rat model of neuropathic pain.\textsuperscript{78}

In conclusion, burst SCS as now most often used clinically (5 pulses at 500 Hz repeated with 40-Hz rate at subparesthetic amplitude) cannot be completely explained on the basis of physiologic mechanisms activated or inhibited by stimulation of the dorsal aspect of the spinal cord. Preclinical and clinical studies are underway to shed more light on mechanisms of these novel algorithms.

**MODERATE CHANGES OF CONVENTIONAL SPINAL CORD STIMULATION PARAMETERS**

At present, almost all manufacturers produce stimulators that can generate stimulation frequencies up to and above 1 kHz and PWs up to 1 µsec. Higher frequencies than those typically used for SCS have been available for many years\textsuperscript{79} but have been used and reported for pain only anecdotally. A few centers during the 80s applied high cervical SCS (around 1,000 Hz) for torticollis.\textsuperscript{80}

Because the higher frequencies and longer PWs were available already in the existing stimulators, many centers tried to adapt the stimulation parameters especially in cases with therapy failure after some time with conventional SCS but eventually also in new cases during trials.

It must be kept in mind that frequencies above 800 Hz with stimulation-induced paresthesias can be perceived as very unpleasant,\textsuperscript{13} and so these parameters usually were used at subparesthetic amplitude. In this way,
higher amounts of electric charge could be transmitted from the electrode poles to the neural tissue without discomfort or damage to the nervous system.\(^{81}\)

Recent experiments in the rat have demonstrated that subsensory SCS can exert clear effects on symptoms of neuropathic pain.\(^{60,64,67}\) These studies also show that moderately increased frequencies of 1,000 Hz can be as effective at the subsensory level as 10-kHz SCS. Such changes in SCS parameters to increase transfer of electric charge have been tried clinically in recent years referring to the fact that pulse density (i.e., the percentage active stimulation during a pulse cycle) can be increased from just 1% to 2% up to 20% to 25% for the maximal available settings at a subsensory mode.

The few clinical reports on this type of stimulation now available\(^{14,82–84}\) will be discussed below. Furthermore, some recent studies also illustrate that for each patient, the SCS therapy could be optimized by the use of “individualized” settings and that some patients actually like to keep their paresthetic SCS as part of their stimulation program.\(^{14,84}\) In conclusion to this section, it must be admitted that we are just at the beginning of exploration of the efficacy of slightly changed SCS parameters, and only short-term results are available so far. The mechanisms behind an increased effect has not been studied (besides using higher frequencies; e.g., 500 and 1,000 Hz), and the neurophysiologic/neurochemical correlates are not known.

**COMPUTER MODELING STUDIES**

Finite element computer models of SCS electrical fields in the spinal cord\(^{85–87}\) have confirmed the current and voltage distribution measurements previously obtained in cadavers and primates.\(^{88}\) Application of these models has also led to the prediction that (1) an electrode’s longitudinal position governs its segmental effect; (2) bipolar stimulation with contacts separated by 6 to 8 mm optimizes selection of midline, longitudinally oriented fibers (a longer distance reduces therapeutic effect by favoring dorsal root stimulation); and (3) the electrical field between two cathodes placed on either side of the physiologic midline does not sum constructively in the midline. Clinical experience confirms that the correct
position and spacing of SCS electrodes is essential for therapeutic success and that, instead of expanding the area of paresthesia, positioning electrodes cephalad to the involved spinal levels commonly elicits unwanted, excessive, local segmental effects.\textsuperscript{10}

The first computerized models developed to study the spinal canal represented the meninges, cerebrospinal fluid, fiber tracts, and gray matter with geometric shapes.\textsuperscript{89,90} The equally simplistic, two-dimensional initial computer models of dorsal epidural stimulation\textsuperscript{91–93} were soon replaced by a three-dimensional model that took into account fiber tracts, their branch points, and dorsal roots.\textsuperscript{85,94}

In 1991, Holsheimer and Struijk\textsuperscript{95} developed a new model that merged this three-dimensional construct with a McNeal-type\textsuperscript{96} cable model of the electrical behavior of myelinated nerve fibers and data derived from mammalian myelinated fibers.\textsuperscript{97} The resulting “University of Twente SCS Computer Model” allowed investigators to determine the impact of the location and configuration (anode/cathode, on/off) of SCS electrodes (e.g., to maximize recruitment of deep, midline, longitudinal axons rather than of the lateral, or dorsal root, fibers that can cause discomfort and motor responses) and to suggest ways to optimize SCS equipment design.

The University of Twente model was further refined when the investigators were able to apply data from human sensory fibers.\textsuperscript{98} This improved the accuracy of predictions about the impact of various SCS threshold voltages.\textsuperscript{99} An additional improvement streamlined the mathematical techniques used to predict stimulation effects when computing the three-dimensional action potential field.\textsuperscript{100} Model predictions for “transverse tripole” electrode performance have been validated in part by clinical studies.\textsuperscript{101}

Lempka et al.\textsuperscript{61} recently applied a similar model to kilohertz frequency SCS and reported that at intensities used clinically, stimulation probably does not cause the direct activation or conduction block of dorsal column or dorsal root fibers.\textsuperscript{61} Arle et al.,\textsuperscript{102} on the other hand, inferred from a similar model that because of an interaction between ion gate dynamics and the anodal current distribution over axons, larger fibers that cause paresthesia in low-frequency simulation are blocked at higher frequencies, whereas medium and smaller fibers are recruited, leading to pain relief by
inhibiting centrally projecting WDR cells in the DH.

**CONVENTIONAL SPINAL CORD STIMULATION MECHANISMS IN ISCHEMIC PAIN**

SCS is thought to induce vasodilatation and improve microperfusion in patients with ischemic pain, which is sharp, aching, heavy, and tiring and a signal of local ischemia. Thus, SCS has a beneficial effect on the cause, not merely the symptoms, of ischemic pain. This might explain why ischemic pain is one of the few types of nociceptive pain known to respond to SCS and why the mechanisms seem to be fundamentally distinct from those that provide relief of neuropathic pain.

**PERIPHERAL VASCULAR DISEASE**

To investigate the mechanism of SCS in the treatment of peripheral vascular disease (PVD), better renamed “peripheral arterial occlusive disease” (PAOD) (especially because if the vascular problem affects the venous side, standard SCS produces little or no effect), investigators developed a new animal model that involves applying mechanical pressure to an artery in the groin of rats. Using this model, SCS delivered with clinically relevant stimulation parameters recovered normal microcirculation in 100% of treated rats versus 28% of controls. In addition, administering SCS preemptively reduced the amplitude of the invoked spasm and significantly shortened the time to recovery of microcirculation. In skin flaps with severely compromised arterial blood supply, application of SCS could significantly increase the flap survival as judged 1 week after the provocation. If a CGRP receptor antagonist was given before the SCS treatment, the survival rate decreased considerably, implicating this vasodilatory compound in the effect.

SCS also suppresses efferent sympathetic activity (maintained by nicotinic ganglionic receptors and $\alpha_1$-adrenoreceptors) and might activate antidromic mechanisms at intensities far below the MT, thus causing peripheral vasodilation by stimulating release of CGRP from the terminals of sensory fibers that contain transient receptor potential vanilloid-1 (TRPV1) receptors and the release of nitric oxide from endothelial cells.
The balance between these two mechanisms seems to depend on the activity level of the sympathetic nervous system, the intensity of SCS, and individual patient factors (genetic differences, diet, etc.).

In fact, antidromic activation dominated at low autonomic baseline activity, whereas the sympatholytic effects of SCS were clear with high baseline activity. Later studies have indicated that even small-diameter fibers are involved at SCS intensities much below the MT and have pointed toward additional mechanisms.

The observation that SCS has a powerfully beneficial effect on vasospastic conditions, such as Raynaud’s syndrome, is consistent with theories that the cause of this syndrome is a combination of heightened sensitivity or increased density of α-adrenergic receptors and CGRP-system dysfunction. A stimulation-induced “normalization” of function in each system could underlie the efficacy of SCS in treating this condition.

Up to the present, most animal studies have utilized SCS frequencies that are routinely applied in the clinic (i.e., 40 to 80 Hz), but in a more recent study, higher SCS frequencies up to 500 Hz were tried at intensities 30% to 90% of MT. This study showed that although the MTs for SCS at all frequencies were similar, SCS at 500 Hz induced a significantly larger blood flow elevation in the hind paw than did SCS at 50 Hz. The effects of these frequencies and intensities seem to depend on activation of TRPV1-containing fibers and the release of CGRP. Thus, further trials with new stimulation parameters should be undertaken to increase benefits of SCS.

A review of the mechanisms involved in SCS-induced vasodilation is included in a report by Wu et al. and by Foreman and Linderoth. The mechanisms and neurotransmitters known or hypothesized to be involved in the effects of SCS in ischemic pain are depicted in Figure 96.4.
FIGURE 96.4  Schematic illustration of mechanisms and neurotransmitters possibly involved in effects of spinal cord stimulation (SCS) in ischemic pain. SCS probably indirectly exerts inhibition onto medullary neurons, thus perpetuating sympathetic efferent vasoconstriction via nicotinic ganglionic receptors, mainly $\alpha_1$ ($\alpha_1$ Adrenorec. = adrenoreceptors) peripheral receptors. In parallel, SCS activates an antidromic loop inducing peripheral release of calcitonin gene-related peptide (CGRP), probably also involving small-diameter fibers. An inhibition of nociceptive transmission has also been indicated in experimental studies but is clinically unlikely. c, small diameter unmyelinated “c-fibers”; DC, dorsal columns; NO, nitric oxide.

SPINAL CORD STIMULATION FOR ANGINA PECTORIS AND CARDIAC DISEASE

Investigators studying the mechanism of action of SCS in patients with otherwise refractory angina agree that SCS reduces ischemia\textsuperscript{119} but disagree about how this occurs. Positron emission tomography has indicated that SCS causes a redistribution of coronary blood flow in patients with refractory angina\textsuperscript{120,121} (even though other experimental studies have failed to demonstrate this effect).\textsuperscript{122} On the other hand, the decrease in the depression extending from the end of the S wave to the beginning of the T wave (ST-segment depression) that appears on electrocardiograms (ECGs) during SCS treatment and the observed SCS-induced reversal of lactate production to extraction might indicate an accompanying decrease in cardiac myocyte oxygen demand.\textsuperscript{123}

The SCS-induced protective changes that increase myocardial resistance to critical ischemia\textsuperscript{124} are manifest by the improved tolerance of patients to a deliberately paced increase in heart rate\textsuperscript{119} and by increased time-to-angina in exercise tests.\textsuperscript{119,123} This effect might signal an SCS-induced inhibition of the excitatory effect of ischemia on the intrinsic cardiac nervous system (such an excitatory effect might lead to dysrhythmia and
increased ischemia). The possibility that SCS modulates cardiac neurons is supported by the finding that transcutaneous electrical nerve stimulation increases blood flow in intact human hearts but not in transplanted, denervated hearts.

There is no proper animal model of angina pectoris mimicking the syndrome in humans. The animal studies discussed in the following text are instead focused onto various deleterious effects of experimentally induced chronic and/or acute coronary ischemia.

Because SCS reduces total body, but not cardiac-specific, norepinephrine spillover during pacing to moderate angina, part of the anti-ischemic effect of SCS might owe its potency to an overall reduction in sympathetic activity. An experimental study using induced cardiac infarcts in a rabbit model, however, indicates that the decrease in infarct size with SCS therapy shares some mechanisms with “ischemic preconditioning” but, notably, does not cause cardiac ischemia.

In order to mimic the development of chronic ischemic heart disease in an animal model of myocardial ischemia, progressive occlusion of the arterial blood supply by a device or creation of cardiac infarction of moderate size could be used, after which a period of acute ischemia provocation with or without SCS could be programmed.

In one early canine study, a slowly expanding material lining the inside of a metal constrictor ring was implanted around the proximal left circumflex coronary artery of a group of dogs. This technique progressively reduces blood flow through the artery and facilitates the development of collaterals creating a collateral-dependent myocardial ischemia substrate. In subsequent acute experiments, the exposed heart was paced at a basal rate of 150 beats per minute. An ECG plaque was used to record from multiple sites on the left ventricle supplied by the left coronary artery occluded by the constrictor. In order to stress the heart, either angiotensin II, administered via the local arterial supply to the right atrial ganglionated plexus, was used, or rapid ventricular pacing applied via a standard pacemaker. Both these maneuvers produced an elevation of the ST segments that was markedly attenuated during SCS. In a similar way, ST-segment responses were largely unchanged when rapid ventricular pacing (240 beats per minute during 60 seconds) was induced
These experiments indicate that SCS may attenuate the deleterious effects that stressors, especially chemical activation of the intrinsic cardiac nervous system, exert on a myocardium with reduced reserve capacity. This observation led to the conclusion that SCS produces anti-ischemic effects that contribute to improved cardiac function.

Further evidence to support the anti-ischemic effects of SCS on the heart is the observation that preemptive SCS appears to have a protective effect on the myocardium, which makes it more resistant to critical ischemia as demonstrated by rabbit experiments with left anterior descending (LAD) artery occlusion lasting 30 minutes. In these studies, the infarct size was markedly reduced by preemptive SCS. However, the protective effects of SCS therapy were lost if SCS was begun after ischemia induction.\textsuperscript{129} Patients with SCS therapy for chronic therapy-resistant angina are recommended to use their stimulators at low amplitude most of the day or at least for 6 to 8 hours and to increase the amplitude when needed during an angina attack or when physical stress is expected to produce angina. Thus, the validity of this clinical recommendation is substantiated by experimental data.

In experimental cardiology, there is a well-known phenomenon that a short ischemic episode preceding a longer occlusion of a coronary vessel induces complicated protective processes in the myocardium that diminishes the resulting infarct size. This phenomenon is called ischemic preconditioning, and the details are still not completely known (e.g., Foreman\textsuperscript{130}). Recent studies indicate that SCS-induced local release of catecholamines in the myocardium may trigger protective changes related to mechanisms behind such ischemic preconditioning but without producing any signs of ischemic changes in the heart. There are also other signs indicating that SCS may induce a state similar to that following a short ischemic period, for example, by activating protein kinase C, a substance which is pivotal in ischemic preconditioning.\textsuperscript{129}

An important part of the “general common pathways” in the communication between the CNS and the heart is the intrinsic cardiac nervous system (ICNS). The ICNS is located in the cardiac ganglionated plexuses covered by epicardial fat pads situated on the myocardium.\textsuperscript{131} The ICNS plexuses are composed of mixed somatosensory, sympathetic,
and parasympathetic fibers. The ICNS plays a critical role in coordinating regional cardiac function and providing rapid reflex coordination of autonomic neuronal inflow to the heart. In critical ischemia, the ICNS is vigorously activated. The ICNS responds to ischemic stress by marked activity increase even if the ischemic region is situated far away from the neuron population. If the increased activity persists, it may result in spreading dysrhythmias that may lead to more generalized ischemia and/or to ventricular fibrillation. Several experimental studies have clearly shown that SCS may potently inhibit and stabilize the activity of the ICNS especially during a critical ischemic challenge.

In patients with angina, SCS can relieve the symptoms and signs of ischemia for long periods after the stimulation is terminated which may relate to prolonged effects of SCS on ICNS activity observed at least up to 45 to 60 minutes after SCS stimulation off in dogs. Modulation of the ICNS may be one mechanism that protects the heart from more severe ischemic threats due to generalized arrhythmias. Others have confirmed the observation that experimental animals display less arrhythmia during ischemic provocation when being subjected to SCS. Experiments by Lopshire et al. demonstrated that SCS might improve cardiac function in canine heart failure following an experimental myocardial infarction and continued stress by HF pacing over 8 weeks. In addition, acute experiments with experimental occlusion of the LAD carried out with or without SCS on landrace pigs showed that the stimulation provided positive effects as displayed in the vectorized ECG.

In several of the studies mentioned earlier, the ischemic challenge induced arrhythmias, but in virtually all studies, these were less severe during SCS treatment. This observation was recently supported by a new study.

The use of SCS for angina reached a peak in the 1990s and early 2000s (when it was the best indication for SCS with outcomes >80% of patients clearly helped by the therapy), but thereafter, the use of this technique has diminished considerably also in Europe due largely to increased use of stenting.

It also should be noted that angina pectoris is presently not a U.S. Food
and Drug Administration (FDA)-approved indication for SCS in the United States.

Some of the pathways and mechanisms behind beneficial effects of SCS on cardiac function discussed earlier are schematically summarized in Figure 96.5, which illustrates the mechanisms and neurotransmitters known or hypothesized to be involved in the effects of SCS in angina.

**FIGURE 96.5** Schematic illustration of some mechanisms possibly involved in the effects of spinal cord stimulation (SCS) on coronary ischemic pain. SCS might exert indirect inhibitory effects on nociceptive transmission to higher centers and on the level of sympathetic activity; SCS might also have antidromically transmitted effects. Intrinsic cardiac nervous system (ICNS) are deeply involved in monitoring ischemic events in the heart, and this function is drastically influenced by SCS. The interplay between somatosensory and autonomic influences and the effects of SCS is presently largely unknown but is the subject of intense investigation. DC, dorsal columns; STT, spinothalamic tract.

**MECHANISMS OF SPINAL CORD STIMULATION IN VISCERAL ABDOMINAL PAIN**

The treatment of visceral pain is a relatively new application for SCS, and investigators have proposed that SCS might exert its positive effect on visceral pain (and dysfunction) by moderating the so-called “brain–gut” axis (the neural circuitry thought to control the interface among visceral afferent sensation, intestinal motor function, and the brain).130,135–137
In fact, moving an active SCS electrode along the neuraxis demonstrates that electric activation occurs at various levels; thus, in addition to its beneficial effects on pain and ischemia, SCS inhibits the viscerosomatic reflexes involved with the particular spinal segmental level being stimulated (Fig. 96.6).

![FIGURE 96.6 Spinal cord stimulation (SCS) applied at different levels of the neuraxis might, in addition to affecting pain and peripheral blood flow, induce changes in different target organs mediated via stimulation induced changes in local autonomic activity, dorsal root reflexes, or viscerosomatic eflexes. Some of these changes in target organ function might be beneficial. ICNS, intrinsic cardiac nervous system. (Redrawn after Linderoth B, Foreman RD. Mechanisms of spinal cord stimulation in painful syndromes: role of animal models. Pain Med 2006;7[suppl 1]:S14–S26. Reproduced by permission of American Academy of Pain Medicine.)](image)

Some rodent studies in experimental colonic pain\textsuperscript{137,138} demonstrated that SCS applied with conventional clinical stimulation parameters
significantly decreased the painful symptoms (measured by monitoring of abdominal contractions as response to balloon inflation in the distal colon). Based on these observations, first a case of irritable bowel symptom was successfully treated by SCS, and thereafter, a prospective randomized clinical study in a small series confirmed the beneficial findings in a pilot study.

In fact, as shown in Figure 96.6, SCS might have many as yet unexplored positive effects on visceral problems.

Indications

NEUROPATHIC PAIN

In the United States, the major indication for SCS is the treatment of FBSS, particularly with a component of neuropathic pain. Two randomized controlled trials (RCTs) have demonstrated the superiority of treating FBSS with SCS versus reoperation or optimized conventional medical management. Of course, an FBSS patient with gross instability or a neurologic deficit caused by neural compression that is evident on an imaging study would undergo a corrective surgical procedure before or instead of SCS.

It is easier to achieve pain relief in the limbs than in the low back because low back pain is more likely than leg pain to have a nociceptive component, which is not expected to respond to SCS with conventional waveforms; also, pain/paresthesia overlap in the low back is generally more difficult to achieve, even with complex electrode arrays and detailed psychophysical tests. At one time, achieving low back pain relief with SCS was considered rare; however, Law’s research on techniques to guide paresthesia coverage kept the low back available as an SCS therapeutic target, and clinicians have built on his work to define the best electrodes and contact combinations for achieving pain relief in the low back.

Over the past 5 years, 10-kHz stimulation has been reported to be highly effective for FBSS and in one head-to-head RCT comparison to be superior to conventional SCS. The most recent such comparisons, however, have shown conventional and high frequencies to be equally effective. “Burst” SCS also has been reported to be highly effective.
for FBSS,\textsuperscript{69,70,150} and most recently, an RCT comparing burst with conventional waveforms showed burst to be superior, but in crossover comparisons, a substantial fraction (20\%) of patients preferred the conventional waveform, showing the clinical importance of a device which delivers multiple waveforms.\textsuperscript{151}

The use of SCS to treat pain in the limbs arising from complex regional pain syndrome type I (CRPS I) (reflex sympathetic dystrophy) is also supported by data from an RCT.\textsuperscript{152,153} In that study, 5 years posttreatment, the 20 patients remaining in the group that actually received SCS reported better pain relief and superior global perceived effect than did those patients remaining in the alternate group who did not receive SCS.\textsuperscript{154} More recently, HF and burst SCS also have been reported to be effective for CRPS, with individual patients showing preferences for one or the other, or for conventional waveforms.\textsuperscript{84}

Other neuropathic pain indications for SCS include phantom limb/postamputation syndrome, postherpetic neuralgia, root injury pain, and pain/spasm arising from spinal cord injury or lesion.

**ISCHEMIC PAIN**

In Europe, clinicians have gathered evidence on the efficacy of SCS in the treatment of ischemic pain caused by refractory angina (including syndrome X),\textsuperscript{155--158} PVD,\textsuperscript{159,160} Raynaud’s syndrome, and diabetic neuropathy. As noted earlier, in patients with ischemia, SCS not only treats the pain but also has a positive effect on the underlying ischemia. Thus, the outcome criteria used to document the impact of SCS on critical limb ischemia arising from PVD include survival, limb salvage, and measures of microcirculation\textsuperscript{161} as well as pain relief.

In Raynaud’s syndrome, the few published studies (all of which involve small numbers of patients) demonstrate the positive effect of SCS therapy.\textsuperscript{162--166} This is not surprising because, compared with PVD patients, patients with vasospastic conditions are relatively young, present with relatively few obliterative vessel wall processes, and have symptoms that are often temporarily relieved by destroying or blocking the corresponding sympathetic ganglia.

Some clinicians are using cervical SCS in exploratory trials to improve
cerebral blood flow in patients recovering from stroke, coma, or brain tumors.

**VIScerAL PAIN AND DYSFUNCTION**

SCS and other forms of neurostimulation are also being used to treat visceral dysfunction and pain associated with such diseases as interstitial cystitis, pancreatitis, motility disorders, urinary urgency and frequency, pelvic pain, vulvodynia, and pelvic floor dysfunction.

**Potential Beneficial Outcomes**

**TECHNICAL GOAL**

The technical goal of conventional SCS is to cover a patient’s pain with a comfortable level of paresthesia; this has been a necessary but not sufficient condition for therapeutic success. Recent paresthesia free waveforms and settings have continued to use paresthesia mapping data, whether historical or individualized, to optimize electrode placement. If an electrode migrates or if pain changes location, appropriate paresthesia coverage can be lost. Thus, contemporary SCS systems are designed to allow adjustment of stimulation parameters postimplant to steer paresthesia to a new location or to recapture coverage. Only occasionally does readjustment for these purposes require a surgical intervention.

It is possible for paresthesia to cover the painful area without providing an analgesic effect. Such clinical failure can become evident during the screening trial or can arise after a period of success. On rare occasions, a patient who experiences technical success and pain relief dislikes the sensation of paresthesia and decides not to continue the therapy. New waveforms offer additional options for these patients.

**CLINICAL GOALS**

A commonly used definition of “success” in treatment for pain is a minimum of 50% pain relief, but this and other measures all have limitations. Additional reported benefits of SCS include (1) reduced consumption of medication and other health care resources; (2) improved
ability to engage in the activities of daily living, quality of life, neurologic function, and symptoms of emotional depression; and (3) return to work when uncontrolled chronic pain was the only impediment (and generally when the patient has been out of work for less than 2 years).\textsuperscript{177,178}

In patients suffering from ischemic pain, SCS can improve microcirculation and tissue oxygenation. This, in turn, can promote the healing of ischemic ulcers and increase the possibility of limb salvage.

**Prognostic Factors**

Demographics are of little help in choosing the ideal SCS candidate. Age is only a factor in children, where the safety and effectiveness of SCS is not established, and in the elderly, who might have difficulty dealing with the patient interface (or recharging a battery), but, as for example with driving cars, the effect of advanced age must be assessed on an individual basis.

Researchers have reported some outcome differences between men and women, but these have been minor and of little if any practical value. Thus, the only sex-related caveat is that the safety of SCS during pregnancy is not established (although pregnant women have continued to use SCS rather than suffer known and suspected adverse effects of alternative pain treatments). Even a very short life expectancy does not rule out SCS, which can be cost-effective for short-term use if an external stimulator is used.

Also, we cannot reliably predict SCS outcome based on worker’s compensation or litigation status, but some clinicians consider the unresolved possibility of secondary gain a relative contraindication to allowing a patient to undergo a screening trial in clinical practice and an exclusionary factor for clinical trials.

For FBSS patients, it seems that the chance of success with SCS decreases as the number of prior surgical procedures and the time since the last surgical procedure increases. The type of surgical procedure the patient has experienced is also important; some ablative procedures, such as rhizotomy, dorsal root ganglionectomy, or dorsal root entry zone lesioning, might obliterate the neural substrate on which SCS is thought to
depend.\textsuperscript{179}

For patients with PVD, investigators have reported that 1-year limb salvage is more likely to occur if the baseline supine transcutaneously measured oxygen tension (TcPO\(_2\)) is >10 mm Hg, the baseline sitting-supine score is >17 mm Hg, and the treatment difference is >4 mm Hg.\textsuperscript{180} Some investigators believe that a 50\% improved TcPO\(_2\) score during a 2-week screening period predicts limb salvage\textsuperscript{181} regardless of baseline score or disease stage.\textsuperscript{182} In the case of diabetic neuropathy, however, these investigators found the stage of neuropathy to be inversely related to SCS treatment success,\textsuperscript{183} independent of the stage of the disease.\textsuperscript{184}

**Patient Selection**

One of the first things we learned about SCS was that achieving a successful outcome required the right patient. In any diagnostic group, the presence of seemingly identical pain syndromes was not enough to predict identical (or even any) SCS success in each individual. A major advantage of SCS, however, is that it is possible to perform a screening trial, which involves temporary (typically 7 to 10 days) placement of an electrode to determine the extent of pain/paresthesia overlap and the resulting therapeutic effect. In some European countries, a trial period of several weeks is required for reimbursement.

The screening trial offers the most meaningful prognostic sign of the outcome of SCS, but, of course, not all potential SCS patients proceed to a screening trial. Information to determine a patient’s suitability for a screening trial is gathered from the patient’s history and from the results of a physical examination and imaging studies.

Among the important aspects of the patient’s history are the location, intensity, duration, and characteristics of the pain and the patient’s psychological status. Radiating pain that has an objective basis, is distributed in a manner consistent with information gleaned from a physical examination and imaging studies, and can be labeled with a specific diagnosis is the most straightforward to treat. Imaging studies that are useful for diagnostic purposes can also provide anatomic information, namely, as to spinal canal diameter, that can be helpful or even vital during
SCS implantation.

In the United States, Medicare and many health insurance companies require SCS candidates to undergo a routine psychological evaluation. Although no psychological test reliably predicts the result of SCS treatment (and physicians routinely expect new patients to meet reasonable psychological/behavioral standards), patients who have been living with chronic pain often benefit from psychological screening with the attendant possibility of therapy. Any major psychiatric comorbidity should be addressed before a patient undergoes an SCS screening trial.

Relative contraindications include the following:

- Unresolved major psychiatric comorbidity
- Unresolved possibility of secondary gain
- Inappropriate dependency on pharmaceuticals
- Inconsistency among the history, pain ratings and description, physical examination, and diagnostic studies
- Abnormal pain ratings
- A predominance of nonorganic signs (e.g., Waddell’s signs)
- Alternative therapies with a risk–benefit ratio comparable to that of SCS remain to be tried

Pregnancy

Occupational risk (e.g., of falling)

Local or systemic infection

Presence of a demand pacemaker or cardioverter defibrillator

Foreseeable need for MRI particularly if high field strength will be required and/or the implant will be in or near the area to be imaged.

Some contemporary implants allow MRI on a limited basis.

Presence of a major comorbid chronic pain syndrome

Anticoagulant or antiplatelet therapy

Absolute contraindications include the following:

- Inability to control the device
- Gross spinal instability at risk for progression, or nerve compression causing a potentially disabling neurologic deficit, amenable to corrective surgery
- Coagulopathy, immunosuppression, or other condition associated with an unacceptable surgical risk
Need for therapeutic diathermy

Technique
A discussion of techniques used for the various types of SCS screening trials and for SCS implantations is beyond the scope of this chapter. Instead, we refer the reader to previous publications.¹⁸⁵–¹⁸⁷

Screening Trial
Before the introduction of percutaneous catheter electrodes in the 1970s, physicians used a variety of methods to screen potential SCS candidates, including TENS, which were found to lack prognostic value. The percutaneous electrodes developed to facilitate a screening trial were immediately adopted for chronic use as well. Today, SCS systems in the United States are generally only implanted in patients who pass a screening trial. In Europe, the screening trial is commonly bypassed in patients with typical angina pectoris, a shortcut that reflects the fact that more than 80% of these patients enjoy significant pain relief with SCS.

Beyond indicating that SCS therapy might be successful, the benefits of a screening trial include allowing a patient to experience the sensation of paresthesia before undergoing implantation of the expensive pulse generator. The trial also provides important information that will dictate the choice of a permanent electrode and pulse generator and the optimum stimulating configuration. A successful screening trial commonly is defined by at least 50% patient-reported pain relief despite appropriate (provocative) physical activity and stable or reduced analgesic consumption. Patient satisfaction is another vital outcome. Medicare and many third-party payers require a successful screening trial before implantation.

SCREENING ELECTRODE CHOICE
A percutaneous catheter electrode placed under fluoroscopy provides easy access to multiple target spinal levels and facilitates mapping of pain/paresthesia overlap to determine the optimal longitudinal level for the electrode.
An insulated surgical plate/paddle electrode inserted by laminectomy limits access to spinal levels and mapping but is required if a percutaneous catheter electrode does not access the epidural space satisfactorily. Screening with a surgical plate/paddle electrode is also necessary in some patients to eliminate uncomfortable extraneous stimulation or provide sufficient pain/paresthesia overlap.

**ELECTRODE POSITIONING**

Ideally, patients remain conscious during trial electrode placement under local anesthesia in order to describe paresthesia coverage and have the opportunity to react to changes in stimulation parameters or unanticipated intraoperative events. Evoked potential techniques may be used when general anesthesia is required, as for example in some cases of paddle electrode implantation. 188

**PARAMETER ADJUSTMENT**

Trained professionals work with patients to adjust simulation parameters during the screening trial and after implantation to find the settings that maximize comfortable pain/paresthesia overlap, reduce or eliminate extraneous stimulation, and minimize power requirements. Even when paresthesia-free stimulation settings will ultimately be used, this may be presumed to be the best method for selection of the electrode contacts. Patients are instructed at each stage so as to operate the device appropriately.

**PROCEDURAL RISK REDUCTION**

Implanting an electrode for a screening trial or chronic stimulation is associated with certain risks, including spinal cord or nerve injury, dural puncture, epidural hematoma, and infection. Risk can be reduced by ordering a preimplant MRI of the target spinal levels, performing the procedure under fluoroscopy with the patient conscious, maintaining a meticulously sterile environment, administering prophylactic antibiotics, and observing the patient for a reasonable length of time postprocedure (e.g., overnight). Discharge instructions must indicate when and how patients should contact their physicians, the device manufacturer, and
emergency care providers.

**TRIAL DURATION**
A typical screening trial with a temporary percutaneous electrode lasts a week. In some circumstances, a shorter trial will be adequate, whereas in others, a longer trial might be beneficial. The role of a screening trial is subject to change with recent technical developments: As more and more waveforms become available, and as some patients need to try multiple settings to achieve a satisfactory result, trial duration can increase to an extent causing undue risk of infection. Externally powered implants which can be inserted in their entirety through a needle might mitigate this problem.\(^\text{189}\)

**REMOVAL OF TRIAL ELECTRODE**
Using the same percutaneous catheter electrode for screening and permanent stimulation would reduce the cost of the hardware, but this savings would be offset by the increased cost of anchoring the electrode, which must take place in an operating room. Anchoring a trial electrode for potential permanent stimulation also increases incisional pain, which might confound interpretation of the trial; anchoring also requires use of a percutaneous extension cable, which increases the risk of infection. On the other hand, a percutaneous catheter electrode designed solely for screening is relatively inexpensive, can be inserted under sterile conditions with fluoroscopy, and can be removed easily.

Using the same electrode for the screening trial and permanent stimulation might eliminate the possibility that the replacement electrode will not reproduce the pain/paresthesia overlap, but this strategy also eliminates the opportunity to improve on the results of the screening trial—which can inform the patient as well as the physician.

**Device Options**
In alphabetical order, the major manufacturers of SCS equipment are Abbott (previously St. Jude’s Medical, previously Advanced Neuromodulation Systems, Plano, TX), Boston Scientific (previously
Advanced Bionics Inc, Natick, MA), Medtronic Inc (Minneapolis, MN), Nevro Corp (Redwood City, CA), Nuvectra Corp (Plano, TX), and Stimwave (Pompano Beach, FL).

CHOICE OF ELECTRODE

Percutaneous catheter electrodes are available with up to 16 contacts and can be implanted singly, creating a one-dimensional array or multiply, creating a two-dimensional array. Multiple percutaneous electrodes can be introduced one by one through a Tuohy needle to rest side by side. Use of three or more such electrodes in parallel permits programming of lateral anodes “guarding” a central cathode, which might mitigate dorsal root recruitment causing uncomfortable side effects; however, it can be difficult to achieve and maintain appropriate spacing between electrodes. Figure 96.7 illustrates a selection of available electrodes.
FIGURE 96.7 Percutaneous catheter electrodes (top left) have as many as 16 cylindrical contacts designed for introduction through a needle. Laminectomy electrodes (bottom) have evolved (left to right) from a single column of contacts to as many as seven columns or centerlines, with as many as 32 contacts.

An important role remains for plate/paddle electrodes, which cannot be introduced through a needle and thus require surgical exposure via laminectomy. These electrodes have as many as 32 contacts in multi-column configurations and are insulated to prevent excess stimulation of dorsal structures. The spacing of the columns is fixed, precluding adjustment as well as postoperative migration of one column with respect to another.

Factors that dictate choice of electrode include the location of the pain,
the amount of extraneous stimulation that must be managed, and the
physician’s qualifications and experience (anesthesiologists, e.g., might be
expected to use only percutaneous electrodes).

**CHOICE OF PULSE GENERATOR**

Pulse generators are distinguished by their power sources and output
configurations. The earliest systems incorporated a small radiofrequency
receiver with no implanted battery, powered by an external transmitter and
antenna worn by the patient. The development of lithium primary cells
made the internally powered generator (IPG) feasible in the 1980s; it was
marketed as “totally implanted,” although it still required an external
remote control device. Early IPGs required surgical replacement when the
battery was exhausted, but newer generators, introduced in 2004, have
rechargeable batteries. Most recently, advances in microwave power and
microcircuit technology have led to development of a wireless implant
which can be inserted through a needle and which, as it is passive, need
not be modified to accommodate new waveforms delivered by the external
transmitter.

Since the 1980s, all generators have allowed noninvasive postoperative
reassignment of each electrode contact (to anode, cathode, or off), and
generators now support up to 32 independent contacts. The newest
“multichannel” generators are capable of simultaneously or sequentially
delivering pulses with different amplitudes and widths to different
combinations of contacts, which of course consumes more energy
compared with the simpler generators and thus motivates use of the
rechargeable devices.

Factors that dictate the choice of stimulator/power generator include the
patient’s ability to control the device, the amount of power required, and
patient convenience.

**PROGRAMMING A SPINAL CORD STIMULATION SYSTEM**

The number of contact combinations possible with either a surgical
plate/paddle or percutaneous catheter electrode has grown markedly as the
number of contacts has increased. In fact, more programming options exist
than can be tested (e.g., whereas a four-contact electrode offers 50 functional bipolar combinations of anodes and cathodes, an eight-contact electrode increases the choices to 6050). Thus, all three SCS manufacturers employ computerized equipment to find the best options for an individual patient and save these settings for subsequent use. Not only is initial programming important, skillful reprogramming can compensate for changes in impedance (e.g., due to postural changes or fibrosis), electrode migration, and changes in pain location or intensity.

Although each manufacturer’s adjustment system is unique, each asks the patient to describe the area of pain and paresthesia and (for conventional SCS) to rate pain overlap and intensity at various settings. Figure 96.8 shows a prototype developed in the 1990s to automate this process and interact directly with patients.

![Prototype of a computerized patient-interactive system](image)

**FIGURE 96.8** This computerized patient-interactive system allows the patient to (1) adjust amplitude to a specified level, (2) draw the area of paresthesia to be compared with a pain drawing, and (3) rate pain/paresthesia overlap.

**Patient Management**

The patient should have a postoperative surgical check and SCS adjustment and on postoperative day 7 to 14 return for suture or staple removal and any needed additional adjustment. From that point on, monthly visits should gradually taper to yearly visits.

Patients should understand that SCS is expected to reduce, not eliminate, pain. It is, therefore, important for clinicians to remember that other pain treatments remain available, especially those designed to treat nociceptive pain, for which SCS might not be so effective.

On/off time has a direct effect on battery longevity, but there are no studies of the impact of an imposed duty cycle on pain relief. In some patients, pain relief persists for a week or more after the device is turned
off; others must operate the stimulator continuously. It is possible but rare for an SCS patient to achieve complete resolution of pain and request removal of the system.

Stimulation can induce subtle loss of normal sensation in SCS patients, but this loss is not sufficient to cause undesirable side effects, such as Charcot joints. A change in paresthesia intensity corresponding to a change in posture is a normal, generally benign, side effect of SCS related to normal movement of the spinal cord with respect to the electrode(s). Automated methods have been developed to mitigate this.

These side effects might, however, make certain activities hazardous; thus, we instruct patients to turn off SCS before driving a car or climbing a ladder, etc. The incidence of SCS side effects increases as stimulation amplitude and recruitment increase.

As is standard practice, except in emergency cases that require immediate attention, a physician has the discretion to accept or reject any new patient who was implanted elsewhere. The device manufacturers provide all SCS patients with identification cards with the necessary contact information to facilitate appropriate emergency treatment.

**SPINAL CORD STIMULATION PATIENT PRECAUTIONS**

SCS systems might affect or be affected by electromagnetic fields, and this necessitates certain precautions. When MRI was first introduced, it was generally contraindicated in SCS patients; some systems are now “MRI contingent.” Manufacturers generally recommend that implants be disabled before a patient enters an electromagnetic field produced by antitheft devices, a metal detector, or any other security scanning device. A patient with an IPG must also refrain from scuba diving more than (typically) 10 m deep or entering hyperbaric chambers with an absolute pressure above (typically) 2.0 atmospheres. Everyday precautions include avoiding placing excessive mechanical stress on the system.

Special steps must be taken before an SCS patient undergoes certain routine medical tests (such as cardiac monitoring) or radiation therapy with the pulse generator in the active field. Radiofrequency ablation, electrocautery, and lithotripsy also require caution. Ultrasound over the
device and diathermy in any location are contraindicated in SCS patients.

Spinal Cord Stimulation Treatment Challenges

**CLINICAL FAILURE**
The loss of pain relief despite pain/paresthesia overlap in a functioning system occurs in a minority of patients. This clinical failure might have a neurochemical basis, and it might respond to adjuvant medical therapy with baclofen or gabapentin. Clinical failure can also occur if the patient develops (1) pain in a new location that cannot be covered by paresthesia unless the equipment is revised surgically, (2) troublesome postural changes in paresthesia coverage, or (3) excessive pain/irritation at the implant site that is not caused by infection and cannot be treated locally.

**BIOLOGIC FAILURE**
Infection, the most common biologic failure, is almost always treated successfully (treatment, however, is expensive because it generally requires removal and replacement of the SCS system). The risk of infection is small, however, and is reduced by maintaining sterility and administering prophylactic intravenous antibiotics. Should an infection occur, specimen culture will guide antibiotic therapy. Unless the infection is limited to the skin over the implant, the entire SCS system should be removed until the infection resolves, when a new system can be implanted. Clinicians have reported patients with an “allergic reaction” to the implant, but this is rare and might be undiagnosed infection. A second biologic failure, the development of fibrosis around implanted electrodes, can impede treatment, but this problem generally can be overcome through reprogramming.

**PSYCHOLOGICAL FAILURE**
Psychological problems, such as conversion disorder, can require system removal.

**TECHNICAL FAILURE**
Technical failure, the inability to achieve or loss of clinically useful
pain/paresthesia overlap, can result from suboptimal electrode choice or placement, from electrode migration, or from equipment malfunction. Technical failure can be mitigated by increasing clinician skill and experience, which includes adoption of the best implantation techniques; for example, the risk of percutaneous electrode migration can be nearly eliminated by applying an adhesive to the anchor/strain relief during implantation,187,194 and the risk of fatigue fracture can be lessened by implanting the pulse generator in the lateral abdomen instead of the buttock and by creating strain relief coils in appropriate places.

In patients with suspected spinal stenosis or another anatomic anomaly that increases the risk of spinal cord or nerve injury, it is prudent to obtain an MRI of the target spinal areas before implantation of a surgical plate/paddle electrode. With the SCS system in place, computed tomography myelography is an alternative.

The risk of dural puncture is reduced by using an anesthetic technique that permits patient feedback during implantation of an electrode and avoiding placement in scarred areas, and the risk of epidural hematoma is reduced by preoperative review of the patient’s coagulation history, medications, and blood chemistry and by monitoring the patient for a reasonable amount of time. Uncomfortable extraneous paresthesia or motor responses can be avoided by careful electrode implantation and postoperative adjustment or by use of an insulated surgical plate/paddle electrode.

**EQUIPMENT FAILURE**

Every part of an SCS system can fail. The electrode/lead/extension conductors can develop an open circuit through fatigue, fracture, or corrosion; insulation might fail; the generator battery can be depleted prematurely; or the generator itself can fail (e.g., by supplying excessive or unacceptable stimulation).195,196

**Cost-effectiveness**

Although the initial expense of implanted SCS equipment creates a potential barrier to patient access, investigators have established that SCS
is cost-effective in the treatment of FBSS, CRPS, PVD, and angina. Cost recovery occurs in approximately 3 years in patients with FBSS or CRPS, after 1 year in patients with angina who are not candidates for coronary artery bypass surgery, and immediately in patients with angina who would otherwise receive coronary artery bypass surgery only for symptom relief.

The cost-effectiveness of SCS will be improved by the development of new equipment and techniques and can be enhanced by minimizing the incidence of complications (especially those, such as infection, that require surgical intervention and system replacement) and by careful patient selection.

The incidence of complications can be reduced if the specialist is meticulous, technically proficient, and knowledgeable (e.g., a simple technique nearly eliminates percutaneous electrode migration). One improvement that has had a direct impact on cost-effectiveness is the development of equipment designed to facilitate noninvasive reprogramming to optimize pain/paresthesia overlap. Another improvement, the introduction of rechargeable batteries, is intended to extend the life of expensive implanted pulse generators.

**Spinal Cord Stimulation Challenges**

In common with most medical therapies, we can improve patient outcomes with SCS by improving patient selection criteria, equipment design, implantation techniques, and clinician training. Continued investigation of the mechanisms of action of SCS will allow us to potentiate the benefits of the therapy, and developing refined outcome measures and appropriate research techniques will help us to optimize clinical application.

The increasing presence of magnetic fields in our environment and in the use of higher field strengths in MRI investigations motivates the development of electrodes and pulse generators that will tolerate the magnetic fields.

SCS remains an underused therapy that should be considered early in the treatment continuum for a large group of patients.

Deep brain stimulation (DBS) and motor cortex stimulation (MCS) have both been used as invasive neuromodulatory therapies in the treatment of medication-refractory pain. Although each has its own specific mechanism of action, both types of therapy have been employed in the treatment of a wide variety of neuropathic pain diagnoses. In addition, DBS has demonstrated additional effects in the pain “neuromatrix” and has also been used to treat nociceptive pain and to modulate the affective components of pain. Despite being used for similar diagnoses, MCS targets primary motor cortex, whereas DBS may involve different targets singly or in combination, including the sensory or ventral posterior (VP) thalamus, the periaqueductal or periventricular gray matter (PAG/PVG), and the anterior cingulate cortex (ACC). Although many published studies have demonstrated the effectiveness of both DBS and MCS, many of these have been in the form of case series rather than randomized, well-controlled, blinded trials.

Both MCS and DBS have been used worldwide as neurosurgical techniques in the management of pain, although studies utilizing DBS tend to be seen from European or Canadian centers. The reason for fewer published studies from the United States is likely secondary to DBS for pain having an “off-label” status due to initial trials that suggested its lack of efficacy. However, recent studies and ongoing research have demonstrated that both MCS and DBS may be effective in the treatment of pain, although further work in the form of large, randomized, blinded, and well-controlled trials are still needed. Ultimately, the demonstration of efficacy will hopefully lead to guidelines that will provide patients with
additional options in the treatment of medication-refractory pain. At the same time, concomitant research in noninvasive therapies such as repetitive transcranial magnetic stimulation (rTMS) may offer another option for therapy and act as a screening tool for surgical candidates.

**Deep Brain Stimulation**

**BASIC CONSIDERATIONS**

DBS has been used in a number of targets for pain, although recent literature suggests a focus on the sensory thalamus or VP thalamus, the PAG/PVG, and the ACC. DBS has been used to treat a number of pain diagnoses, including phantom limb pain, brachial plexus injury, stroke, cephalalgias, multiple sclerosis, spine injury, failed low back surgery syndrome, and chronic cluster headaches, as reviewed in several studies.¹⁻⁶

The use of PAG/PVG targets began from animal research that demonstrated analgesia from stimulation of these areas, with subsequent translation to patients.⁷⁻¹¹ Initial studies suggested that DBS in this region acted via opioidergic mechanisms, supported by a reported effect reversal with naloxone, but later studies challenged these conclusions.¹,¹² Current models suggest that the ventral PAG works via influencing coping behavior, whereas the dorsal PAG has sympathomimetic effects, which may also have opioidergic effects.¹²,¹³ Overall, the PAG target has been primarily used for nociceptive pain.²,¹⁴

DBS for sensory thalamic targets, the ventral posterior lateral and medial (VPL/VPM) nuclei, arose from initial work that demonstrated symptomatic relief from ablative procedures.¹²,¹⁵⁻¹⁷ In these patients, pain is thought to result in increased thalamic firing,¹⁷ and DBS to this region likely affects thalamo-corticofugal descending pathways.⁵ Recordings at these sites have demonstrated increased spike density as well as possible neural hyperactivity when these regions are stimulated.¹⁸ Overall, this target has been favored for neuropathic pain.²,¹⁴

DBS to both VP and PAG/PVG targets is also thought to exert effects by either disrupting synchronous pathologic high frequencies or by enhancing low frequencies.¹,¹² Studies have demonstrated that at both VP
and PAG targets, reduction in pain results from lower frequencies ≤50 Hz, whereas increased sensitivity to pain results from higher frequencies >70 Hz.\textsuperscript{4,12} One group, which has published extensively on DBS for pain, suggests that only demonstrable efficacy should guide the decision for implanting an electrode at the PAG, VP, or both sites,\textsuperscript{1,17} although their own practice is to target the PAG site initially, except in cases of head and facial pain.\textsuperscript{19} Importantly, some patients may have components of both neuropathic and nociceptive pain and may therefore derive benefit from DBS therapy to both PAG and VP sites.\textsuperscript{2}

The ACC has also been reported as a successful DBS target for pain based on the effectiveness of cingulotomy.\textsuperscript{20–24} The ACC is thought to modulate pain processing and is involved in the affective component of pain. As a result, DBS therapy to this target likely affects emotional components to pain rather than nociceptive perception, thereby reducing the “unpleasantness” of pain rather than the pain itself.\textsuperscript{1,4,6,25}

Other targets that have additionally been reported in the literature include the internal capsule,\textsuperscript{26,27} ventral striatum and internal capsule,\textsuperscript{28,29} centromedian parafascicular complex and the intra-laminar zone,\textsuperscript{30} and posterior hypothalamus.\textsuperscript{31,32}

**EFFICACY OF DEEP BRAIN STIMULATION**

Initial studies of DBS for pain in the United States were based on two multicenter trials from 1989 to 1995, which were not randomized or case controlled.\textsuperscript{1,33} Neither trial met criteria for efficacy, with the first trial defining effective therapy as ≥50% of patients with ≥50% pain relief at 1-year follow-up and the second trial defining efficacy as ≥50% of patients with ≥30% pain relief and decrease in the usage of analgesia medication.\textsuperscript{33} Multiple reviews have subsequently commented on the limitations of these trials, which include patient heterogeneity, lack of blinded assessment, and lack of standardization among centers.\textsuperscript{1,17} Nevertheless, as a result of these studies, DBS for pain in the United States has been used with an off-label status.\textsuperscript{33}

Subsequent studies, reviews, and meta-analyses have provided a mixed picture regarding the efficacy of DBS for pain. Many published studies have limited numbers of patients, with few centers reporting larger
numbers. Ultimately, long-term efficacy has been reported in ~83% of patients,\(^1\) with one large case series by a well-published center suggesting an overall long-term efficacy of 67% at their center, with no significant differences in efficacy based on stimulation site.\(^{19}\)

Several meta-analyses have suggested efficacy of DBS for pain. A 2010 meta-analysis examined 13 studies and estimated that 50% of patients had long-term relief with DBS, with a 61% success rate for nociceptive pain diagnoses and 42% success rate with neuropathic pain diagnoses.\(^2\) A 2005 meta-analysis of 6 older studies (from 1977 to 1997) had also demonstrated 55% to 70% pain relief at >1-year follow-up.\(^{13}\) This meta-analysis suggested good to excellent results with PAG stimulation, with further increases in success when combined with thalamic or internal capsule stimulation, a strategy that has been seen in other studies.\(^{34}\)

However, there have been limitations to in-depth analysis of both individual studies and meta-analyses due to factors such as heterogeneity in patient diagnoses and selection criteria, DBS sites, stimulation parameters, and use of unblinded assessments. These limitations have been reflected in recent recommendations from the European Academy of Neurology (EAN) in 2016 and the European Federation of Neurological Societies (EFNS) in 2007.\(^{5,35}\) The EAN’s meta-analysis of studies from 2006 to 2014 that used DBS for a variety of pain diagnoses determined that there was very low quality of evidence.\(^{35}\) Overall, the EAN gave a recommendation of “inconclusive,” highlighting the further need for additional prospective, randomized, controlled trials. Nevertheless, they noted that the overall pain intensity reduction was close to 50% in their included studies.\(^{35}\) This was an update to the EFNS 2007 study, which had calculated an overall 46% long-term success rate of DBS for pain.\(^5\) Further investigations will be required to determine whether specific DBS targets are best suited for particular diagnoses, as there has been lack of consensus.\(^{5,35,36}\)

Few studies have also utilized randomized or placebo-controlled experimental designs. Marchand et al.\(^{37}\) studied thalamic stimulation and examined the effects of placebo stimulation, ultimately demonstrating a significant placebo effect from thalamic DBS. Rasche et al.\(^{34}\) included placebo testing during the trial stimulation phase; ultimately, 57% of
patients passed this phase with demonstrated analgesic effects and were implanted with a pulse generator. Fontaine et al.\textsuperscript{38} reported a randomized, placebo-controlled, double-blind trial to study the effects of hypothalamic DBS in cluster headache and found that although there was lack of efficacy during the randomized phase of the trial, patients derived a reduction in their attacks during the open phase. Finally, Lempka et al.\textsuperscript{28} targeted the ventral striatum/anterior limb of the internal capsule in a prospective, double-blind, randomized, placebo-controlled, crossover study and did not meet its primary endpoint of $\geq 50\%$ improvement in $\geq 50\%$ of patients with active DBS compared to placebo. However, there were improvements in other measures such as depression, anxiety, and quality of life. These studies have suggested legitimate effects from DBS, although its effects may not be adequately measured purely by pain intensity ratings.

Overall, there have been persistent limitations to comparing published studies, which have included diverse patient selection criteria and diagnoses, heterogeneous methodology, and diversity of intracranial targets. In addition, certain effects may not have been fully studied or reported. For example, DBS for pain may result in substantial insertional effects.\textsuperscript{39} As increasingly examined by recent published studies, future investigations may also benefit from assessing patient improvements in areas other than pain, such as mood, anxiety, and quality of life, which may improve to a significant degree.\textsuperscript{40} Although a number of studies have suggested that DBS may be more effective for particular diagnoses, or identified particular targets as being more effective for specific diagnoses, there does not yet appear to be general consensus.\textsuperscript{13,17,36}

Some studies have demonstrated loss of efficacy over time, with some series noting that up to a half of patients who have success during the trial stimulation period do not have sustained benefit at $\geq 1$ year follow-up, which may be attributed to factors such as scarring around electrode targets, brain plasticity, and inconsistent patient reporting.\textsuperscript{17,25} To mitigate these effects, groups have resorted to intensive reprogramming, with authors noting that stimulation parameters may increase with time.\textsuperscript{1,41} Strategies for reprogramming include changing pulse width or frequency or allowing for cycled stimulation or “off” periods.\textsuperscript{17}
SURGICAL TECHNIQUE

Optimal patient selection has been important in ensuring that those who undergo DBS benefit from therapy. A multidisciplinary approach is used to screen potential patients who may benefit from DBS, and neuropsychological testing is a key component, with patients who have psychological etiologies excluded. Patients are also typically medication refractory \(\geq 2\) years, but there are no restrictions on whether patients have undergone other surgical procedures.\(^1\, ^{17}\) Some groups examine patients’ responses to analgesics prior to DBS.\(^{18}\) Quantitative and qualitative assessment of pain is required, as well as quality of life assessments, which may allow clinicians and patients to best see changes that occur after DBS. Contraindications include medical conditions that would make surgery unsafe or anatomic factors such as ventriculomegaly that would prevent placement of an electrode into the surgical target.

DBS electrodes are implanted stereotactically, using either a frame or frameless approach (Fig. 97.1).\(^2\) As a result, high-resolution magnetic resonance imaging (MRI) is required to allow for accurate targeting. Surgery is performed with sedation and local anesthesia; however, some targets, such as the ACC, can be performed under general anesthesia. Targets in the thalamus and midbrain are contralateral to the symptomatic side, whereas the ACC target requires bilateral electrode implantation.\(^1\)

![FIGURE 97.1](image)

**FIGURE 97.1** A: T1-weighted magnetic resonance imaging (MRI) showing planned trajectory and target for placement of a periaqueductal or periventricular gray matter (PAG/PVG) in the axial, frontal, and sagittal planes. B: Postoperative MRI showing ventral posterior lateral (VPL) electrode (lateral) and the wire to the PVG electrode (medial and inferior). (Reprinted with permission from Owen SL, Green AL, Stein JF, et al. Deep brain stimulation for the alleviation of post-stroke neuropathic pain. Pain 2006; 120[1–2]:202–206.)
For targeting coordinates, the PAG is typically found 2 to 3 mm lateral to the third ventricle at the level of the posterior commissure and 10 mm posterior to the midcommissural point and 0 mm vertical; the VP target is typically found 10 to 13 mm posterior to the midcommissural point, 14 to 18 mm lateral, and from 5 mm below to 2 mm above the midcommissural line (Fig. 97.2).\textsuperscript{1,4} To isolate a particular limb, studies have suggested that the arm representation of the VPL is 2 to 3 mm medial to the internal capsule, whereas the leg representation is 1 to 2 mm medial to the internal capsule.\textsuperscript{4} The ACC target is typically 20 to 25 mm posterior to the anterior horns of the lateral ventricles, with the electrode tip near the corpus callosum and the electrode in the cingulum bundle.\textsuperscript{4,25}

Intraoperative physiologic stimulation is used to refine the final target, with microelectrode recording, microstimulation, and macrostimulation. This step is considered critical in order to obtain adequate coverage of the symptomatic region. For instance, patients undergoing VP stimulation should experience paresthesias in previously painful areas, whereas those undergoing PAG stimulation should note a sensation of warmth or analgesia.\textsuperscript{4,13} Once targets are identified, the electrodes are introduced, and the leads are externalized for trial stimulation. Patients undergo postoperative imaging, typically via computed tomography (CT), to look for possible complications.
A trial assessment period typically lasts from 5 to 9 days, during which physicians may test different combinations of stimulation parameters to optimize patient effects. Different approaches have been taken for assessing effectiveness, with some authors using an “N-of-1 trial” approach, in which a patient undergoes randomized pairs of treatments to elucidate the effects of DBS and placebo. Overall, a large percentage of patients typically pass the trial stimulation period. Some authors have noted that DBS to the ACC may take an extended period to demonstrate effectiveness. Stimulation parameters have varied across the literature, with some groups reporting bipolar stimulation parameters in the range of 5 to 50 Hz with pulse widths from 100 to 450 µs and amplitudes from 0.1 to 3 V, although ACC stimulation may require higher settings. Afterward, the most effective electrodes are internalized and connected to either an infraclavicular or abdominal pulse generator.

Overall, DBS is considered to be a generally safe procedure, with adverse events occurring in 8% to 9% of cases. One of the more serious complications is hemorrhage, which has been reported in 1.9% to 4.1% of cases. Device malfunction may also occur. There is a risk of infection, which has been reported in 1.9% to 13.3% of cases. Other minor risks include diplopia and visual gaze effects, headache, and nausea. The risk of permanent neurologic deficit has ranged from 2% to 3.4%, and mortality is rare, ranging from 0% to 1.6%.

Motor Cortex Stimulation

BASIC CONSIDERATIONS
The use of MCS was initiated after a study by Tsubokawa et al. in 1991, with the demonstration that chronic stimulation of the motor cortex with epidural electrodes inhibited thalamic hyperactivity and ultimately led to symptom control. Following this study, neuromodulation of the motor cortex was examined as an option for the treatment of medically intractable central and peripheral neuropathic pain. Based on these initial studies, MCS has been subsequently made an option for patients who have failed pharmacologic therapy or other stimulation techniques like spinal cord stimulation.
Interestingly, MCS is able to achieve pain reduction at voltages below the threshold for muscle contraction, and, at these voltages, it can induce paresthesias. Numerous studies have sought to determine the mechanism of action of MCS, with several proposed explanations. Its effects have been attributed to modulation of connections among somatosensory cortex, thalamus, spinothalamic tract, and motor cortex. MCS results in both direct and indirect waves, with anodal stimulation resulting in direct stimulation and cathodal stimulation resulting in depolarization of horizontal interneurons that trigger indirect waves of stimulation. Ultimately, the indirect waves are thought to result in analgesia via top-down inhibition. Thalamic hypersensitivity is reduced by antidromic modulation, endogenous opioids in the periaqueductal gray and cingulate are released, and regions that modulate pain, such as the orbitofrontal cortex, are activated.

A common inclusion criterion for MCS includes a diagnosis of neuropathic pain with the identification of a lesion within the central nervous system. A consensus meeting suggested that central and peripheral causes are both treatable and can be of a variety of etiologies including trauma or injury from procedures as well as vascular, inflammatory, degenerative, and oncologic causes. Notably, candidates for MCS should have psychological or psychiatric diagnoses and morbidities evaluated, and patients generally have a pain Visual Analog Scale (VAS) of at least 5.

Specifically, centers have used MCS for indications including poststroke pain (including facial, upper and lower extremity, and dystonias), plexus avulsion pain, atypical facial pain, post-irradiation pain for treatment of arteriovenous malformations, phantom limb pain, lumbar plexus pain, chronic regional pain syndrome, root lesions of the upper extremity, multiple sclerosis, syringomyelia, postherpetic pain, trigeminal neuropathic pain and anesthesia dolorosa, sciatic pain, and spinal cord injury, as reviewed in a recent study. Atypical facial pain is felt to be heterogeneous and therefore may have limited treatment success. Despite heterogeneity, most published studies have demonstrated positive responses to MCS, although this may be due to publication bias.
In addition, centers have also varied in terms of their definition of a “good” result, which may or may not depend on the VAS and therefore make comparisons across studies challenging.  

Predictive factors have been inconsistently identified. One study found that the only predictive factor was the patient’s response in the first month after the procedure. Other studies have suggested that motor weakness in the region of pain may be tied to reduction in efficacy, although this did not play a significant role in other studies.

There is increasing evidence that rTMS may be used as a tool to determine which patients may benefit from MCS, although consensus groups have felt that it was less useful for excluding patients from MCS. rTMS provides high positive predictive value for response to MCS but has a high rate of false negatives and lower negative predictive value, although the predictive value of rTMS may be better at examining long-term effects.

**Efficacy of Motor Cortex Stimulation**

Success rates of MCS for pain have been analyzed through case reviews and meta-analyses. Examination of case series that used MCS for chronic neuropathic pain published from 1991 to 2006 demonstrated that ≥40% improvement in pain relief from MCS was seen in 56.7% of patients, with long-term benefit in 45% of patients at ≥1 year. Another meta-analysis of 22 studies from 1960 to 2007 found that 64% of patients undergoing MCS responded to therapy. Finally, a review that specifically examined MCS for facial chronic neuropathic pain indications found that 84% of patients who had implantation of the system had good pain control at the end of the study with long-term follow-up of 30.7 months.

The effects of MCS have also been examined in specific diagnoses, in case it may be applied more effectively for specific indications, although the results have been inconsistent. For instance, some authors believe that MCS for poststroke pain leads to good relief in approximately two-thirds of patients, whereas therapy for trigeminal neuropathic pain leads to good relief in >75% of patients. Some studies have suggested that the use of MCS for diagnoses related to spinal cord injury or brachial plexus pain may be more challenging.
Study of long-term outcomes has been necessary, as many investigations have shown that MCS can lose efficacy at extended time points as patients develop “tolerance.”\textsuperscript{47,48,51,74} Reasons for this gradual loss of efficacy have included brain remodeling and plasticity or scar build up at the surgical site.\textsuperscript{76} Further intensive stimulator reprogramming may lead to return of analgesic effects.\textsuperscript{48,76} However, even with longer follow-up periods, one study found that on the order of 1 to 6 years of follow-up, >50\% of patients still had benefit from MCS, with patients with thalamic central pain felt to have the best result.\textsuperscript{47}

Several trials have been conducted with MCS, although there have been inconsistent results. One crossover trial that examined MCS for refractory peripheral pain in 16 patients demonstrated a mean rate of pain relief, as assessed by VAS scores, of 48\%, with 60\% having a satisfactory or good result with MCS therapy (>40\% VAS score reduction) after prolonged stimulation after a crossover phase.\textsuperscript{70} However, during the crossover period which allowed comparison between “on” versus “off” conditions, there were no significant differences, which were attributed to carry-over effects.\textsuperscript{70} A second crossover trial that tested “on” versus “off” stimulation in patients found that patients had significant benefit from MCS only in the “on” setting, with 60\% of patients ultimately experiencing >40\% pain reduction at follow-up.\textsuperscript{77} A third crossover trial that also studied “on” versus “off” stimulation settings found that patients had pain reduction only in the “on” setting, with return of pain in the “off” setting.\textsuperscript{78} Improvement at 1 year was >40\% for all tested patients.\textsuperscript{78} However, in contrast to these studies, a recent randomized study that examined conditions of low stimulation (subtherapeutic levels) versus high stimulation (therapeutic levels) was stopped due to lack of efficacy.\textsuperscript{64} No differences were seen between the two groups, and a possible nocebo effect was also discovered; however, the diagnoses of the patients involved in the study were limited.\textsuperscript{64} Some authors have noted the importance of a double-blind testing phase during MCS trial stimulation. For example, one study of MCS for trigeminal neuropathic pain in 36 patients included a double-blind testing phase.\textsuperscript{79} Seventeen percent of patients were found to be false-positive responders and did not have permanent implantation of the device, and ultimately, 57.6\% of patients had >30\% pain reduction.\textsuperscript{79}
Reasons for poor response to MCS have included the need for more intensive programming or the need for an extended testing period prior to permanent implantation. One study that did not use a trial period in all patients noted that this may be required in order to increase the rate of successful therapy in patients with permanent implantations; one author noted that typically only about 50% of patients who undergo trial stimulation go on to have the device permanently implanted. In addition, many authors have noted that MCS can have significant placebo effects, with up to 35% of patients experiencing a placebo effect. Nevertheless, one study queried patients as to whether they would proceed with surgery again, and 70% stated that they would.

SURGICAL TECHNIQUE
Preoperative evaluation includes assessment of pain intensity as well as psychological evaluation in order to assess for risk factors that may affect surgical outcome. TMS, as discussed previously, is used at some centers to help predict which patients may have better response to MCS.

Preoperative studies aim to improve target selection and include high-resolution MRI for identification of anatomic landmarks and functional MRI to ensure optimal placement of electrodes over motor cortex. For instance, cases of phantom limb pain and thalamic pain may result in plasticity-related changes that may complicate optimal electrode placement over the motor strip. Neuronavigation is typically employed to accurately determine the surgical site and to allow for anatomic localization.

The procedure can be performed under either local or general anesthesia. A craniotomy or burr hole allows access to the epidural space. From here, mapping is performed to identify the N20-P20 phase reversal that characterizes the location of the central sulcus, which is considered the gold standard for identifying the motor cortex. Additional intraoperative electrophysiology with somatosensory evoked potentials (SSEPs) or motor evoked potentials can further verify the optimal location of the electrode (Figs. 97.3 and 97.4).
At some centers, the dura is opened under certain circumstances. For instance, the dura may need to be opened to access the interhemispheric fissure for providing therapy to the lower extremities or if there is a significant distance between the dura and cortex. Many different types of electrodes have been used, including 4 and 8 contact electrodes, as well as grids, and both parallel and perpendicular orientations have been used. Electrode location can be subsequently confirmed by
stimulating through the contacts, and motor threshold testing can be carried out in the operating room. Some centers choose to coagulate the dura underneath the electrode in order to avoid possible headache that can arise from dural nerve stimulation.

Once the leads are secured in place, they can be either passed to an infraclavicular chest or abdominal pocket to a pulse generator or they can be tunneled out from the skin for postoperative testing (Fig. 97.5). Trial periods for MCS vary, with some centers not performing any trial period, and others typically trialing stimulation for 3 to 7 days, with longer periods having a possible increased infection risk. Patients who have a response have the electrodes permanently implanted, although improvement thresholds that would allow for permanent implantation can range at different centers. As mentioned earlier, patients may develop tolerance to the MCS and require ongoing adjustments or stimulation holiday periods.

Stimulation regimens vary widely, as reviewed recently.\textsuperscript{48,55} Voltage can range from 2 V to ≥8 V, and typically a cyclic mode is used. Generally, the best orientation arises from cathodal stimulation of the precentral gyrus and anodal stimulation of the anterior border of the central sulcus.\textsuperscript{48} Frequencies vary, from 20 to 80 Hz, with pulse duration from 90 to 450 µs.\textsuperscript{48,55} Subsequent programming after pulse generator implantation can take an extended period of time, lasting >3 months at some centers.

Complications of MCS include seizures, wound infection, hardware malfunction, hematomas, and paresthesias.\textsuperscript{47,55,60,61,63,64} Seizures have typically occurred in the setting of increased voltages.\textsuperscript{60,61,64} A large number of studies have reported no adverse events,\textsuperscript{75} and the complication rate overall is considered to be about 5%, with the most common complications being seizure and wound infection.\textsuperscript{55,56} One large examination of case series published from 1991 to 2006 found that infection occurred in about 5.7% of cases and hardware-related issues were found in 5.1%, with seizures occurring in 12% of patients in the early postoperative period.\textsuperscript{74} There may be higher risk of complications with subdural placement of electrodes.\textsuperscript{55}

**Transcranial Magnetic Stimulation**

**BASIC CONSIDERATIONS**

rTMS has been applied to a variety of diagnoses and has been identified as a possible therapy for neuropathic chronic pain. The procedure involves placing a stimulating coil adjacent to the scalp, with the changing magnetic fields subsequently inducing electric currents in local neurons and resulting in depolarization (Fig 97.6).\textsuperscript{81,82}
The rationale for rTMS has been derived from MCS, in which stimulation of the motor cortex corresponding to the region of pain results in pain relief, and the two therapies may share basic mechanisms, although their different stimulation parameters may recruit different substrates. Specific rTMS settings can trigger varying effects; for instance, rTMS at ≥5 Hz can increase excitability and potentiate transmission, but rTMS at ≤1 Hz can decrease it, thereby leading to either long-term potentiation or depression. Other factors such as pulse waveform and coil orientation can also lead to differing effects.

rTMS has been investigated as a therapy for several etiologies, including central pain, facial neuropathic pain, postherpetic neuralgia, fibromyalgia, brachial plexus and peripheral nerve related pain, spinal cord lesions, and phantom limb pain. A majority of rTMS studies have targeted primary motor cortex. For pain, ≥5 Hz frequency has been the most common. Intensity of the pulses is typically tailored to individual motor thresholds; the number of pulses can vary, as can the orientation of the coil. Notably, the effects of rTMS may be temporary, and maintenance protocols will need to be developed.

**EFFICACY OF REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION FOR PAIN**

Recent large-scale reviews of rTMS have demonstrated heterogeneous results. A notable 2014 Cochrane review suggested that although high-
frequency stimulation of the motor cortex can result in short-term effects in single doses, multiple dose studies have not shown a significant effect. In addition, the review failed to demonstrate meaningful clinical effect of rTMS, although it was limited by significant variation among studies and conflicting results.\textsuperscript{82}

Another large review similarly found that low-frequency rTMS was ineffective, but high-frequency rTMS likely results in significant analgesic effects.\textsuperscript{86} This review also suggested that comparison among studies may be affected by variation in therapy time course and posttherapy evaluation, as the effects from rTMS may be most significant after a few days. In addition, there is some debate over whether rTMS is best for particular diagnoses. An earlier meta-analysis had suggested that rTMS for pain that originates from central, rather than peripheral, sources may be more effective.\textsuperscript{93} Notably, however, it has been difficult to perform double-blind studies of rTMS because there are auditory, visual, and sensation changes that occur during the course of therapy which may be difficult to replicate.\textsuperscript{81}

There are typically few complications from rTMS.\textsuperscript{94} The most important adverse events can arise from damage to or heating of implants that are nearby; otherwise, the only significant risk is seizure, which has a very small risk, $<1\%$.\textsuperscript{81} In order to avoid this, high-frequency therapy is typically used in trains of pulses.\textsuperscript{81} Other adverse events may include headache, pain at the stimulation site, muscle pain, dizziness, nausea, and tiredness, although these may be experienced in both therapeutic and sham settings.\textsuperscript{95}

**Conclusion**

Challenges with treating chronic neuropathic pain have prompted a call for the development of additional therapies that go beyond medical management. Although definitive evidence supporting the use of neuromodulation for pain will require ongoing research, data collection, and additional trials, DBS and MCS offer nonablative options that have demonstrated a degree of efficacy in existing literature. However, it has been difficult to optimize these invasive neuromodulatory procedures due
to limitations in reported studies, as described earlier. In addition, similar to the limitations of the majority of studies that have been published regarding DBS and MCS, comparisons among neuromodulatory techniques (such as comparisons among DBS, MCS, and spinal cord stimulation) have been affected by aspects such as heterogeneous patient populations and diagnoses, which have made it challenging to effectively compare these different procedures. Ultimately, ongoing research and well-designed trials are needed to provide more definitive recommendations and guidelines for both practitioners and patients.

References

Local anesthetic blocks are procedures in which a local anesthetic agent is deliberately injected onto a peripheral nerve in order to temporarily stop conduction of action potentials. Local anesthetic agents block conduction of action potentials by acting on the sodium channels of the nerve cell membranes. Their effect is temporary because their pharmacologic action is reversible.

Nerve blocks are an attractive tool in pain medicine because they are the only means by which to stop pain completely. Analgesics may reduce pain, but only local anesthetics stop it.

Virtually any nerve in the body can be blocked in order to relieve pain. All that is required is an access to the nerve and the agent with which to anesthetize it. Many textbooks and manuals have been published that describe the techniques used to do so, and it is not the intention or purpose of this chapter to duplicate these publications. Many of the available procedures have an application in anesthesia for surgical procedures, but they are not germane to the practice of pain medicine. Some procedures have a role in securing relief of pain postoperatively of after a trauma; for those, the distinction between the discipline of pain medicine and the practice of anesthesia is uncertain. These procedures will not be the focus of this chapter.

The short duration of action of local anesthetic agents limits the utility of local anesthetic blocks in pain medicine. For acute pain, their premier utility lies in providing protection from incident pain. For chronic pain, their most straightforward use is as a diagnostic test. Otherwise, they have putative roles as prognostic tests and as therapeutic interventions.
This chapter focuses on the principles of local anesthetic blocks used in pain medicine. It illustrates the more commonly used and useful procedures and reviews the evidence concerning their validity and utility.

**Common Principles**

Irrespective of the purpose for which local anesthetic blocks are used, certain principles apply. These pertain to the physician, the patient, the preparation for the procedure, its contraindication, the procedure itself, and its complications.

**Physician**

Any physician who performs nerve blocks should be suitably trained and experienced. He or she needs to understand the pain problem being addressed and how the proposed procedure relates to the patient’s management. He or she needs to be familiar with the patient, the patient’s complaints, and how the patient expresses him- or herself. The physician should be able to explain to the patient the nature and significance of the procedure to be undertaken and, together with the patient, be able to assess and interpret the response. These requirements require training in more than the execution of the procedure.

The physician needs a detailed knowledge of the anatomic basis of the procedure not only to execute it accurately but also to avoid complications. Similarly, he or she needs to be able to deal with the possible side effects and complications of local anesthetic agents. For procedures performed under image guidance, the physician needs to be able to obtain the correct views and to interpret them accurately.

More difficult to define and to achieve is technical excellence to perform the procedure expeditiously yet accurately with the minimum of stress to the patient. This includes avoiding painful structures during the insertion of the needle and keeping the number of adjustments during its course to a minimum. Acquisition of these skills requires good mentoring and forethought on the part of the practitioner and takes years of training.

**Patient**

The patient should understand the purpose of the procedure to be
undertaken. This requires distinguishing between diagnostic and therapeutic procedures. Unless they are properly informed, patients may mistake a diagnostic block as a treatment and be disappointed when it appears not to have worked when the effect wears off. They should understand the limitations of prognostic and therapeutic blocks as outlined in the corresponding sections of this chapter. In this regard, there is a difference between a patient consenting to a procedure and being fully informed about it.

The patient should be aware of the potential side effects and complications of the procedures, what actions are to be taken to avoid them, and what will be done in the event that they occur.

Both for diagnostic blocks and therapeutic blocks, the patient will be required to assess and report their response. Therefore, before the procedure, the patient should be instructed in how to use instruments such as pain-rating scales and measurements of function. Patients who have pain in multiple sites but who undergo blocks for only one site need to understand which pain is being tested and must be able to report the effects of the block on that particular site of pain. Relief of pain will need to be corroborated by testing activities that usually are limited by pain. For this purpose, the patient must be able to specify a set of suitable activities before the block and be able to test for their restoration after the block.

**PREPARATION**

The preparation of the patient differs according to the nature of procedure to be undertaken and the region in which the target nerve lies. Orders for “nil by mouth” are indicated only for procedures in which loss of consciousness and aspiration of gastric contents are possible complications. Examples include cervical transforaminal blocks and procedures that involve high doses of local anesthetic. In the opinion and experience of the authors, the majority of nerve blocks can be performed safely with the patient having had a light meal even before the procedure. Indeed, fasting may compromise the procedure if the patient is uncomfortable or distressed for not having eaten.

For most local anesthetic blocks, establishing an intravenous line is not indicated, nor is continuous monitoring of respiratory and cardiovascular
function required. The doses of local anesthetic typically administered do not pose hazards that require these preparations. However, appropriate precautions are indicated for procedures that are performed close to vital structures, such as the spinal cord or the vertebral artery, or when large doses of a local anesthetic agent are to be administered. In such cases, an intravenous line should be placed before the procedure in order to ensure access for the rapid administration of fluids and resuscitation drugs, should these be necessary. Vital functions should be monitored (i.e., electrocardiogram, pulse oximetry, and blood pressure). A means of ventilating the patient with 100% oxygen with a bag and mask or via endotracheal tube and suction should be available, along with drugs and equipment to manage a cardiac arrest.

Local anesthetic blocks do not require routine sedation. Proper explanation, continuous communication, and good technique will provide patient comfort without the need for systemic medication. In the case of diagnostic and prognostic blocks, using sedation may confound the validity of response by increasing the rate of false-positive blocks, for which reason it is best avoided.

Only occasional patients will require sedation: those who are markedly apprehensive or who have a manifest anxiety over needles or invasive procedures. In such cases, sedation can be secured by oral agents (benzodiazepines) or intravenous administration of modest doses of sedatives (midazolam, propofol). If needed, analgesia can be provided by short-acting opioids (fentanyl, alfentanil, remifentanil), provided that the procedure is not diagnostic or prognostic. The dose should be titrated to provide sufficient sedation only for the duration of the procedure; the patient should be fully awake or be readily awakened during the procedure in order to be able to report its effects. If intravenous sedation or analgesia is used, it should be complemented with monitoring of respiratory and cardiovascular function. Supplemental oxygen may be required.

**CONTRAINDICATIONS**

Blocks are contraindicated in patients who are unwilling to undergo the procedure or who have attributes that compromise the safe execution of the procedure. The latter include inability to lie still despite sedation,
allergy to the drugs to be used, infection at the site of injection, and anatomic abnormalities, among others.

A coagulation disorder or anticoagulation therapy is a relative contraindication. Blocks of superficial nerves in easily accessible parts of the body may be safely undertaken. Reservations apply for blocks of deep nerves in sites where hemorrhage could compromise vital structures. Guidelines on the management of patients under antithrombotic therapy have been published. Patients with compromised cardiovascular function are more susceptible to either the toxic effects of local anesthetic or the effects of blockade of sympathetic nerves. Appropriate precautions should be taken with such patients if large volumes of a local anesthetic agent are to be used.

COMPLICATIONS

The potential complications of local anesthetic blocks can be categorized as systemic effects of the drugs injected, physiologic effects of the procedure, inadvertent damage to structures other than nerves, and damage to nerves.

Systemic Effects

Allergy to local anesthetic agents is rare. The physiologic consequences and treatment are as for any anaphylactic reaction.

Local anesthetics have direct toxic effects on the central nervous system (CNS) and cardiovascular system (CVS). These effects become increasingly pronounced as blood levels of the offending agent rise. High or rapidly rising blood levels can occur because of inadvertent intravascular injection of the local anesthetic, unusually rapid absorption from a highly vascular region, or the administration of an excessive dose of agent.

Several precautions can be taken to reduce the risk of intravascular injection. For procedures performed under fluoroscopic guidance, a test dose of contrast medium can be administered before injecting the local anesthetic agent. This will likely show vascular uptake. For procedures where the uptake may be to a small but vital vessel, such as a radicular artery, digital subtraction angiography serves to demonstrate the vessel
more clearly. For procedures performed under ultrasound guidance, lack of fluid visualization may be a sign of intravascular injection. In this case, injection should be stopped immediately and the needle should be repositioned.

The needle should be aspirated before injection and after each 2 to 5 mL of injectate, if such volumes are used, in order to ensure no bloody return. For blocks using large volumes, 3 to 4 mL of a mixture of local anesthetic plus 1:200,000 epinephrine may be injected as an initial test dose. If injected intravascularly, such a mixture will cause, with a high degree of probability, a brief and transient (2 to 3 minutes) rise in the heart rate of 20 to 25 beats per minute and a rise in systolic blood pressure of 20 to 30 points because of the β and α effects of the epinephrine. This precaution was originally developed to detect inadvertent intravascular injection during epidural anesthesia, but it applies equally well for other regional techniques.

A rising, or high, blood level of local anesthetic is typically manifest by the onset of CNS features such as anxiety, agitation, tinnitus, muscle twitching, perioral numbness or tingling, and dizziness. As plasma levels rise, tonic-clonic seizures can occur. At even higher plasma levels, neuronal inhibition occurs, leading to respiratory arrest, coma, and cardiovascular collapse. Although most anesthetics produce signs of CNS toxicity prior to either seizure or CVS toxicity, this is not always the case. With highly lipophilic, highly protein bound agents (e.g., bupivacaine), CVS collapse may even precede CNS symptoms.

If a patient manifests features of toxicity during the course of an injection, the injection should be stopped immediately and assistance should be enlisted or summoned. Oxygen (100%), via a bag and mask, should be commenced immediately. If the patient’s oxygen saturation, as judged from pulse oximetry, falls below 90%, positive pressure ventilation should be instituted. A small, anticonvulsant dose of propofol (50 to 100 mg) should be administered. Cardiovascular parameters should be monitored and adverse effects treated: hypotension with fluids and vasopressors (ephedrine 5 to 10 mg), hypertension with vasodilators (labetalol 5 to 10 mg), and tachycardia with β-blockers (esmolol 5 mg, metoprolol 2.5 to 5 mg).
These measures will often abort progressive local anesthetic toxicity. However, if the toxicity appears to be proceeding toward convulsions (agitation, limb jerking, loss of consciousness), further measures are necessary. Positive pressure ventilation with oxygen should be commenced in order to ensure oxygen saturation greater than 90%. If ventilation is difficult, or if the patient convulses, muscle paralysis with 50 to 100 mg succinylcholine should be administered to ensure adequate ventilation. Cardiovascular monitoring and treatment of adverse CVS effects should continue. Intravenous lipid emulsion therapy should be used if these measures fail.⁵

**Physiologic Effects**
Although undertaken to relieve pain, nerve blocks will, or may, block other sensory functions, motor function, balance, and sympathetic function. When these are to be expected but pose no immediate hazard, the patient should be warned to expect them and to not be alarmed by their onset. Appropriate precautions should be taken to compensate against loss of function and to avoid injury. Examples of side effects pertinent to blocks used in pain medicine are numbness or weakness in the limb following spinal nerve blocks, ataxia following third occipital nerve blocks, and hypotension or Horner syndrome following sympathetic nerve blocks.

Blocks targeting particular nerves may spill over to adjacent nerves and produce unwanted effects (e.g., paravertebral nerve blocks may produce inadvertent epidural blockade). Patients undergoing such blocks should be closely monitored for adverse effects and treated early and vigorously in the event that they do occur.

**Damage to Nonneural Structures**
The needles used for local anesthetic blocks have the potential to pierce and damage structures along the course of the insertion or near the target point. Examples include pneumothorax following intercostal nerve block or thoracic spinal nerve block, piercing the esophagus during stellate ganglion blocks, piercing pelvic viscera during sacral spinal nerve blocks, and penetrating the aorta or inferior vena cava during celiac plexus blocks.
Piercing a blood vessel has the potential to produce bleeding or hematoma. In patients with normal clotting mechanisms, it is rare for such bleeding or hematoma to produce significant sequelae. In patients with abnormal coagulation, bleeding may produce hypovolemia, and hematoma may exert pressure effects on adjacent structures. For these reasons, coagulopathy is a relative contraindication for local anesthetic blocks.

**Damage to Nerves**
Targeting a nerve with an injection carries the risk of nerve damage. The resultant symptoms range from minor paresthesia to severe pain. The damage may be caused by piercing the nerve with the needle or by what is injected. Components of the injectate, such as preservative, may be neurotoxic, epinephrine may cause spasm of the vasa nervorum and result in ischemic damage, or the pressure of injection may damage the nerve physically. The incidence of long-term injury remains extremely low, ranging 2 to 4 per 10,000 blocks.

**PROCEDURE**
In order to be valid or effective, nerve blocks need to be accurate. This involves placing the injection as close as possible to the target nerve. Several techniques are available to secure accurate placement. They differ for unaided (i.e., “blind”) techniques and for image-guided techniques.

**Blind Techniques**
For blind techniques, the oldest method of correct needle placement is to probe the nerve gently with the tip of the needle. This maneuver produces a paresthesia in the area of distribution of the nerve. Once paresthesia is elicited, the needle is held steady and the local anesthetic is injected. This technique, however, has now become obsolete. Probing some nerves (e.g., autonomic nerves) does not elicit paresthesia and, more importantly, probing nerves risks damaging them.

Mixed nerves, containing sensory and motor fibers, can be located by using an insulated needle connected to a peripheral nerve stimulator. By passing an electric current through the needle, the motor fibers in the nerve are stimulated, producing a twitch in the muscles supplied by the nerve.
This stimulation is usually not painful because motor fibers are activated at lower current intensity than sensory fibers. A typical setting is a frequency of 1 to 2 Hz and a current strength of 1 mA. At this setting, a twitch will be produced as the needle approaches the nerve but still lies some distance from it. Reducing the current to 0.4 to 0.5 mA allows the needle to be advanced further. A well-defined twitch at this intensity of current implies that the needle is close to the nerve.

Data from clinical anesthesia practice show a high success rate of blocks facilitated by a nerve stimulator. However, large volumes of local anesthetic are typically administered for operative anesthesia, and it is unclear if these data can be extrapolated to blocks in pain medicine, in which small volumes of local anesthetic are used in order to maximize the selectivity of the block. Although rare, neurologic complications may occur even when nerve stimulators are used.

For some blocks, palpable landmarks can be used to secure the accuracy of the block. A classic example is the intercostal block, for which the rib is an adequate landmark for the target site.

**Fluoroscopy-Guided Techniques**

When nerves and landmarks are not palpable and precision is required, unaided techniques do not ensure accuracy and selectivity of the block. In such circumstances, image guidance should be used to secure safety, accuracy, and selectivity.

Fluoroscopy is the most commonly used form of image guidance in pain medicine. Its main limitation is that fluoroscopy shows only bones. Therefore, it is suitable only for target nerves that bear a dependable relationship to a bony landmark. The accuracy of the block is achieved by directing the needle to the landmark. Safety is achieved both by choosing a course that does not incur intervening structures that should not be damaged and by having the needle not stray from the intended target. Selectivity is achieved by administering a test dose of contrast medium to establish that the injectate will flow into the region of the target nerve and will not flow onto other structures where anesthetization might compromise the selectivity of the block (Fig. 98.1). The advantages of fluoroscopy are that it demonstrates a wide field of view around the target.
region; with C-arm fluoroscopy, views of any orientation can be obtained in order to define the location of the needle during its course or at its target point; intermittent images are rapidly applied and continuous imaging is possible, if required; and the apparatus is not excessively expensive. A particular advantage of fluoroscopy is that in the event of intravascular injection, it will reveal rostral or caudal flow of contrast medium away from the target point. This facility is not available from devices that produce planar images.

**FIGURE 98.1** Steps in the execution of a C7 spinal nerve block. A: Oblique view showing a needle in position tangential to the superior articular process of C7. B: Anteroposterior view of the needle, showing its tip midway across the width of the articular pillars. C: Anteroposterior view of a test dose of contrast medium injected into the intervertebral foramen. D: Anteroposterior view after injection of sufficient contrast medium to reach the dural sac. (Radiographs provided by Dr. Paul Dreyfuss, Seattle, WA, and reproduced with permission from Bogduk N, ed. Guidelines for Spinal Diagnostic and Treatment Procedures. San Francisco, CA: International Spine Intervention Society; 2004.)
Computed Tomography–Guided Techniques
Some operators use computed tomography (CT) guidance instead of fluoroscopy. They are attracted by the definition that CT provides of viscera and vessels that should be avoided by the needle. Ostensibly, this allows for a safer placement of the needle. For injections into narrow joint cavities or irregularly orientated joints such as the sacroiliac joint, CT offers the virtue of depicting the cavity and its orientation directly. Consequently, a path for the needle can be planned to coincide directly with the joint. The disadvantages of CT guidance are numerous. Each time the needle position is checked, the patient must be rescanned. This interrupts the procedure, prolongs it, and involves considerable radiation exposure. More critically, planar image does not reveal flow of contrast medium in vessels that run out of the plane of view. Serial reconstruction does not compensate for this because by the time the images are acquired, the contrast medium will have left the field of view. Safety with respect to inadvertent intravascular injection has not been demonstrated for CT guidance. CT is far more expensive than fluoroscopy. For these reasons, fluoroscopic guidance remains preferable. Only in selected cases would CT guidance be justified.

Ultrasound-Guided Techniques
Ultrasound guidance is being increasingly used and explored in pain medicine. It demonstrates muscles, ligaments, vessels, joints, and bones (Fig. 98.2). Moreover, if high-resolution transducers are used, thin nerves can be directly visualized (Fig. 98.3). Ultrasound does not involve radiation exposure, either to the patient or to the operator, and continuous screening can be used. Fluid injected can be visualized in a real-time fashion. Ultrasound is less expensive than CT, and most ultrasound devices suitable for pain procedures are much less expensive than fluoroscopy. For these reasons, ultrasound guidance is emerging as an attractive alternative to other modalities of image guidance. Its main limitations, at present, are poor resolution of narrow-gauge needles (although, with experience, operators can infer the location of the needle from the movements of the soft tissues); echoes from overlying structures, such as bones, interfere with the image of the target area; decreasing image
resolution with increasing depth; and requirement of substantial training and experience to be able to perform the blocks effectively and safely.

**FIGURE 98.2** Ultrasound anatomy of the neck in the plane used for stellate ganglion block. Note how an anteroposterior approach, using either the traditional blind technique or fluoroscopy guidance, carries the risk of incurring the thyroid gland (Thy), common carotid artery (CCA), internal jugular vein (IJV), or esophagus (Oes). Under ultrasound guidance, an oblique approach lateral to the great vessels is possible. T, trachea; TP, transverse process of C6. (Illustration kindly provided by Dr. Urs Eichenberg, Balgrist University Hospital, Zurich, Switzerland.)

**FIGURE 98.3** Ultrasound image of the greater occipital nerve (arrow), visible as hypoechoic round structure posterior to the obliquus capitis inferior capitis muscle. The ultrasound anatomy and technique has been described by Greher et al. 114

From the first reports of ultrasound-guided nerve blocks in pain medicine,9 the number of published papers has skyrocketed and practice has expanded enormously. Most of the research has focused on techniques,
that is, on how to perform blocks of different nerves. More recently, randomized controlled trials have evaluated the value of ultrasound guidance in relation to patient-relevant outcomes. When comparing fluoroscopy-guided with ultrasound-assisted epidural steroid injections, the two techniques were found to be similar in terms of mean procedure time, number of needle insertion attempts or needle passes, mean pain intensity, and degree of disability scores at 1 and 3 months postprocedure.\(^\text{10}\) For perioperative thoracic epidural injections, the use of ultrasound to identify the epidural space resulted in a decreased number of needle punctures to achieve loss of resistance and in lower pain scores after surgery compared with the use of palpation.\(^\text{11}\) A systematic review on the use of ultrasound in lumbar spinal and epidural anesthesia found significant evidence supporting the role of ultrasound in improving the precision and efficacy of neuraxial anesthetic techniques.\(^\text{12}\) With fluoroscopy as reference standard, ultrasound imaging was found to be an accurate technique for performing cervical facet joint nerve blocks, with some improvements regarding time to perform the block.\(^\text{13–15}\) Ultrasound-guided piriformis injections provided similar outcomes to fluoroscopically guided injections without differences in imaging, needling, or overall procedural times.\(^\text{16}\) Similarly, there was no differences in patient-related outcomes at 7 days to 3 months between fluoroscopy- and ultrasound-guided sacroiliac joint injections.\(^\text{17}\) Although ultrasound guidance may decrease the risk of local anesthetic toxicity and of pneumothorax, the incidence of peripheral nerve damage is not decreased.\(^\text{18}\)

Taken together, these data indicate that ultrasound guidance has an emergent evidence-based role in pain medicine, representing for several procedures a valuable alternative to fluoroscopy. For procedures in which fluoroscopy has no role, such as nerve blocks of the extremities, ultrasound guidance is likely superior to nerve stimulation.

Test Blocks

Test blocks are ones that are not therapeutic injections, prognostic tests, or diagnostic tests in the strict and correct sense of those terms. They are performed simply to test if a particular nerve is involved in the patient’s
symptoms. A nerve is anesthetized and the response is either that the patient’s pain is relieved or not. The block is not prognostic because it is not used to predict the outcomes of any subsequent treatment. Nor is it diagnostic because the block is not used to distinguish one source of pain from another. It is used only to see if the nerve anesthetized is involved in the patient’s symptoms.

Virtually any nerve in the body can be blocked in this way. Examples include supraorbital blocks for headache; blocks of the median, ulnar, or radial nerves for pain in the hand; ilioinguinal and iliohypogastric nerve blocks for pain after herniorrhaphy; and tibial nerve blocks for pain in the foot.

The nature of the information derived by test blocks, and its utility, have been poorly elaborated. In some cases, the blocks are used to “confirm” the diagnosis, but the diagnosis will already be evident from other clinical information. The pivotal question—both clinically and philosophically—is what then.

If the patient’s response is used to predicate a subsequent treatment, the test must convert to a prognostic block (see following section). In that event, however, the block and the response to it need to be valid, and the treatment needs to be effective. If those requirements are not satisfied, the utility of the blocks remain unclear.

**Prognostic Blocks**

A prognostic block is one undertaken to test if a definitive treatment will be successful. The rationale is that if a nerve block with local anesthetic relieves the pain, then a treatment capable of interrupting conduction along the nerve should relieve the pain for a prolonged period, if not permanently.

For prognostic blocks to be valid, evidence is required to complete a table like that depicted in Table 98.1. There needs to be a strong association between a positive response to the block and a successful outcome from treatment and between a negative response to the block and failure of treatment. Such data are hard to produce and, to the authors’ knowledge, are not available. They would require a study in which patients
undergo treatment irrespective of their response to blocks. They also require a treatment that is dependably effective. Unless that is the case, failures may be due to the failure of treatment rather than an error in the response to blocks. Few such treatments exist.

In the absence of proper evidence, practitioners who use prognostic blocks assume that a positive response to a block should be predictive of a favorable outcome to treatment. This has not always proven to be the case. For instance, prognostic blocks of peripheral somatic nerves may be used to test the outcome of surgical neurectomy. However, there is no evidence for validity of these prognostic blocks to predict the efficacy of neurectomy. Furthermore, neuroma formation and deafferentation pain complicate the treatment, and worsening due to the treatment can occur also in the presence of positive prognostic blocks. Positive responses to sympathetic blocks are unclearly associated with favorable or sustained outcomes from sympathectomy—either surgical or chemical.

**SPINAL NERVE BLOCKS**

In some patients with radicular pain, medical imaging is not diagnostic. CT or magnetic resonance imaging (MRI) may show more than one spinal nerve affected by a disk herniation or by foraminal stenosis, and the clinical features do not help to determine which nerve is the source of symptoms. Spinal nerve blocks were developed to assist surgeons to determine the symptomatic level in such cases so that surgery could be directed at the correct segmental level.

Spinal nerve blocks involve placing a needle, under fluoroscopic guidance, into the intervertebral foramen that lodges the target nerve. If anesthetizing that nerve relieves the patient’s pain, then that nerve is implicated as the source of pain. If anesthetizing the nerve does not relieve
the pain, then that nerve is excluded as the source of pain, and investigations can be redirected to another nerve. Steps in the execution of a cervical spinal nerve blocks are shown in Figure 98.1. Because of the proximity of the medullary arteries and the spinal cord, and of the vertebral artery in the cervical spine, spinal nerve blocks require consummation skill in obtaining the correct view, delivering the needle, and checking its location. Guidelines for the safe conduct of the procedure have been published.19,20

Data on the validity of spinal nerve blocks are limited because of two factors. First, nerve blocks should be performed under controlled conditions in order to guard against false-positive responses, but only one study of spinal nerve blocks has used control blocks.21 Second, the predictive validity of blocks requires a study in which patients with positive responses to blocks and patients with negative responses both be submitted to treatment. Only such a study would provide proper data on the sensitivity and specificity of the blocks. Such studies are difficult to justify ethically and, to the authors’ knowledge, have not been conducted.

Partial data are available from studies that report the proportion of patients with positive responses to blocks in whom pathology is found at surgery. This proportion is not the sensitivity of the test but its positive predictive value in the sample tested. Because that value is dependent on the nature of the sample studied, it is not generalizable to other samples or to practice at large.

For lumbar spinal nerve blocks, various studies have reported positive predictive values that ranged between 80% and 100%.22,23 These high values imply that the false-positive rate of lumbar spinal nerve blocks is low and, therefore, that their specificity is likely to be high. In one study, a small number of patients with negative responses to blocks nevertheless underwent surgery.23 Pathology was found in all cases but not at the level tested; in no case did surgery find pathology at the level tested when the block had been negative. These patients proved to have multilevel disease or anomalous nerve roots. This implies that the false-negative rate of lumbar spinal nerve blocks is low and, therefore, that their sensitivity is high.

One study measured sensitivity by performing lumbar spinal nerve
blocks in 46 patients with clinical and radiologic evidence of nerve root compression, subsequently confirmed at surgery.\textsuperscript{24} The sensitivity was 100%, with 95% confidence intervals of 88% to 100%. That same study measured specificity by performing blocks in 23 patients at levels known by radiology not to be symptomatic. No false-positive responses were encountered, and the specificity of lumbar spinal nerve blocks was estimated at “around 90%.\textsuperscript{24}

The one study that used controlled blocks enlisted 18 patients with cervical radiculopathy and 83 with lumbar radiculopathy but did not stratify the results according to region investigated.\textsuperscript{21} Using a criterion standard of good outcome from surgery, it found a sensitivity of 93% but a specificity of only 33%. Spinal nerve blocks were no better than MRI in predicting good outcome, but the particular advantage of spinal nerve blocks demonstrated in this study was the ability of negative responses to blocks to predict poor outcome, particularly when MRI was negative or ambiguous.

**SYMPATHETIC BLOCKS**

Blocks of various elements of the sympathetic nervous system have a status somewhere intermediate between diagnostic and prognostic. They are not diagnostic in the strict sense of that adjective, for the cause of pain is usually evident from clinical assessment or other investigations. Fundamentally, they are used to test if the patient’s clinical features are mediated by sympathetic nerves. Knowing this does not affect management unless the response to blocks is used to prognosticate the response to neurolytic treatment of the sympathetic nerves.

Cervical sympathetic blocks have been used largely in the evaluation of patients with complex regional pain syndromes of the upper limb. Other applications have been for patients with pain in the face or head. The procedure requires delivering an aliquot of local anesthetic onto the stellate ganglion. The traditional approach has been a blind technique based on surface markings and palpation. The blind technique classically involved injecting a large volume of local anesthetic in order to ensure saturation of the ganglion. Large volumes compromise the validity of cervical sympathetic blocks because structures other than the target nerve are
anesthetized. In a study of eight volunteers, MRI showed that injectate was not delivered to the stellate ganglion but passed anterior to it.\textsuperscript{25} Several complications following stellate ganglion blocks have been described, mostly due to inadvertent puncture of sensitive structures.\textsuperscript{26–30} For these reasons, image-guided techniques are preferred.

Ultrasound guidance is an alternative to fluoroscopic guidance and offers certain advantages in this region. Ultrasound demonstrates the common carotid artery, internal jugular vein, thyroid gland, and esophagus—all of which need to be avoided during passage of the needle (Fig. 98.2). In a study that compared ultrasound guidance with the blind technique, the volume of local anesthetic required was reduced to 5 mL, the onset of block was sooner, and hematoma was avoided (but occurred in 3 out of 12 cases with the blind technique).\textsuperscript{31} A study in healthy volunteers showed that the esophagus, the vertebral artery, and other arteries are located in the needle path of the traditional blind technique and that manual dislocation did not displace these structures from the needle path in the majority of cases.\textsuperscript{32} Although comparative studies are lacking, it is reasonable to avoid the blind approach. Ultrasound seems preferable to fluoroscopy due to its ability to visualize structures that must be avoided during the needle passage.

Lumbar sympathetic blocks involve anesthetizing the lumbar sympathetic trunk, typically at the L3 level. They have traditionally been used to test if they relieve pain or other features of complex regional pain syndrome. The standard technique is fluoroscopically guided (Fig. 98.4).
The use of fluoroscopy or ultrasound establishes the face validity of sympathetic blocks (i.e., the sympathetic trunk is accurately and selectively infiltrated). Face validity can be confirmed physiologically by observing a rise in skin temperature in the limb of the target side, which suggests that the sympathetic trunk has indeed been anesthetized.

What has not been shown is that sympathetic blocks have construct validity (i.e., that the physiologic response is due to the effects of the local anesthetic and not to nonspecific factors such as placebo). This requires the execution of controlled blocks. Failing to use controlled blocks in the
past may have led to overestimates of so-called sympathetic-mediated pain. Unless and until studies are conducted using controlled blocks, its true prevalence will not be known. To the authors’ knowledge, no studies have tested the validity of lumbar sympathetic blocks. Nor has the prognostic validity of sympathetic blocks—cervical or lumbar—in predicting the outcomes of sympathectomy been demonstrated by rigorous research.

Other blocks of the sympathetic nervous system are practiced, ostensibly widely. These include blocks of the celiac plexus, splanchnic nerves, hypogastric plexuses, and blocks of the ganglion impar. However, there is no evidence on their validity as either diagnostic or prognostic procedures.

**Diagnostic Blocks**

Many conditions associated with chronic pain have no detectable anatomical correlate. The cause of pain is not evident on conventional medical imaging. For some such conditions, although the cause might not be evident, the source of pain can be established using diagnostic blocks.

The rationale for diagnostic, local anesthetic blocks is that if a structure is the source of pain, then anesthetizing it or its nerve supply should relieve the pain. If the suspected structure is not the source of pain, then anesthetizing it should not relieve the pain.

Two types of blocks have been used to pinpoint sources of pain: intra-articular blocks and nerve blocks. Intra-articular blocks involve injecting local anesthetic into a joint suspected of being the source of pain. Diagnostic nerve blocks are restricted to small nerves that have a limited and specific distribution. Blocks of larger nerves or of nerves that supply multiple tissues are not diagnostic of a particular source because of their widespread distribution; they fall under the category of test blocks.

**PRINCIPLES**

**Controls**

There are no objective tests for the presence of pain or for its relief. Investigators rely only on what the patient reports, but patients can report
relief of pain for reasons other than the effect of a local anesthetic injected during a diagnostic block. They may have an expectation that the block will relieve their pain, particularly if they have been coached or instructed to expect a positive response. Unprompted, they might want the response to be positive so that they qualify for the resultant treatment that promises to relieve their pain in the long term. Patients with medicolegal claims might choose to report relief in order to vindicate their claim.

Because of these extraneous, confounding factors, a positive response to a block cannot be summarily attributed to the effect of the local anesthetic injected. Some form of control is necessary if the response is to be valid and for the interpretation of the response to be correct. The most rigorous form of control is a placebo control in which an inactive agent is injected to test for spurious responses. However, for two reasons, placebos cannot be administered in an arbitrary manner. In the first instance, administering a placebo on a single-blind basis is considered unethical in some jurisdictions. Patients would need to be informed that they might receive an inactive agent. Furthermore, a positive response to placebo does not necessarily rule out that the tested structure is symptomatic.

Comparative local anesthetic blocks can be used as alternatives to placebo-controlled blocks. These involve administering a particular agent on the occasion of the first block but using a different agent on a second occasion. The agents advocated are lidocaine and bupivacaine. The paradigm maintains that a genuine patient will report short-lasting relief when lidocaine is used and long-lasting relief when bupivacaine is used. However, it is unclear whether a discordant response truly rules out a positive diagnosis. Patients may display prolonged pain relief after lidocaine for different reasons: The block may reduce central sensitization processes that contribute to pain intensity; the pain relief may have positive psychological effects, leading to long-lasting pain relief; the patient may experience prolonged pain relief because he or she will rest after the block, giving the false impression that the block is responsible for the absence of pain; etc.

Despite the limitations associated with placebo-controlled and comparative blocks, data on diagnostic blocks for zygapophysial joint pain presented in the following sections have shown that single blocks are
associated with high false-positive rates. Therefore, a form of control is currently an appropriate standard of care.

Criteria for Positive Response
For a response to a diagnostic block to be valid, certain criteria should be satisfied. On each occasion that the nerve is blocked, the patient should obtain substantial relief of pain. That should be validated by recording the intensity of pain before and after the block. Moreover, for the block to be physiologically and pharmacologically meaningful, the pain should return as the effect of the local anesthetic wears off. Recording the return of pain, therefore, becomes part of the assessment. A painful structure should resume being painful once the local anesthetic has ceased to operate. Prolonged relief of pain, lasting days, weeks, or months, occasionally occurs but is of difficult interpretation. Prolonged responses suggest either a placebo effect or some sort of modulatory effect on pain perception, the nature of which has not been determined.

A positive response to blocks should be corroborated by narrative and activity. The patients should volunteer that they feel distinctly better, and they should be able to undertake and demonstrate activities that previously were prevented or restricted by their pain. If activities are not restored, the utility of the block is questionable. If activities, ostensibly restricted by the pain, are not restored when pain is relieved, some factor other than the pain must still be responsible for the restriction.

APPLICATIONS
Nerve Blocks for Cervical Zygapophysial Joint Pain
The largest body of evidence on the validity of diagnostic nerve blocks has been produced in the context of zygapophysial (facet) joint pain. The cervical facet joints are supplied by the medial branches of the dorsal rami, with the exception of the C2–C3 joint that is supplied by the third occipital nerve. It has been shown that cervical medial branch blocks are target-specific. Material injected onto the target points floods the location of the target nerve but does not spread to adjacent nerves or the spinal nerves. Nor do cervical medial branch blocks anesthetize the posterior neck muscles in a nonspecific manner. The standard technique for cervical
medial branch blocks is fluoroscopy-guided (Figs. 98.5 and 98.6). Ultrasound-guided techniques have been described and validated, but only very experienced practitioners can safely and effectively perform them.13–15,35,36

**FIGURE 98.5** A lateral radiograph of the cervical spine on which the courses of the cervical medial branches and the target points for medial branch blocks have been depicted. **A:** The courses of the typical cervical medial branches are plotted by dotted lines. **B:** The dots mark the target points for medial branch blocks.

**FIGURE 98.6** A lateral fluoroscopic view of the cervical spine showing a needle in place on the articular pillar of C5 for a C5 medial branch block.

The construct validity of the comparative block paradigm has been tested in the context of diagnostic blocks of the medial branches. Concordant responses (i.e., effect lasting longer with bupivacaine than
with lidocaine) have a high specificity (88%) when compared with placebo-controlled blocks.\textsuperscript{37} This means that positive responses are very unlikely to be false. However, concordant responses have a low sensitivity (54%).\textsuperscript{37} This means that they do not detect all patients with cervical zygapophysial joint pain who do not have placebo responses. Discordant responses (i.e., effect lasting longer with lidocaine than with bupivacaine) have a high sensitivity (100%), implying that they detect all patients who have zygapophysial joint pain.\textsuperscript{37} However, their specificity is limited (65%), meaning that positive responses can include some placebo responses.\textsuperscript{37}

In studies using concordant comparative blocks as reference standard, single medial branch blocks had false-positive rates of 27%.\textsuperscript{38} However, as mentioned earlier (“Controls” section), it is unclear whether a discordant response truly rules out facet joint pain. The false-positive rate of single blocks may therefore be lower than 27%. Nevertheless, it is safe to say that single medial branch blocks are of questionable validity due to high false-positive rate and that the diagnostic confidence is improved by the practice of controlled blocks.

These different sensitivities and specificities make little difference in clinical practice because the prevalence of cervical zygapophysial joint pain is high, around 60%.\textsuperscript{39–41} Given a concordant response, a practitioner can be 88% confident that the positive response is true positive (Table 98.2). In comparison, although a discordant response has a lower specificity, its sensitivity is high, which means that the practitioner can be 81% confident that a positive response is true positive (see Table 98.2).\textsuperscript{42}

Diagnostic confidence is the measure of how confident the practitioner can be that the condition really is present when a test is positive. It amounts to the positive predictive value that applies for a particular prevalence and is derived from the specificity and sensitivity of the test by the equations:

\[
\text{posttest odds} = \frac{\text{pretest odds} \times \text{positive likelihood ratio}}{1 + \text{positive likelihood ratio}}
\]

\[
\text{positive likelihood ratio} = \frac{\text{sensitivity}}{1 - \text{specificity}}
\]

\[
\text{pretest odds} = \frac{\text{prevalence}}{1 - \text{prevalence}}
\]

\[
\text{diagnostic confidence} = \left(\frac{\text{posttest odds}}{1 + \text{posttest odds}}\right) \times 100\%
\]

Cervical medial branch blocks have established utility. They are the only means by which to diagnose the most common cause of chronic neck pain. Moreover, patients correctly diagnosed can be treated successfully with percutaneous radiofrequency neurotomy: Those patients who obtain complete relief from cervical medial branch blocks can expect a 70% chance of achieving complete relief of pain after cervical medial branch neurotomy.\(^43\text{–}48\)

The C2–C3 zygapophysial joint is innervated by the third occipital nerve, which is the superficial medial branch of the C3 dorsal ramus. Third occipital nerve blocks, therefore, are a particular subset of cervical medial branch blocks. They are used in patients with upper cervical pain and headache to test if the pain stems from the C2–C3 zygapophysial joint.

The utility of third occipital blocks lies in the investigation of cervicogenic headache. In patients with posttraumatic neck pain, in whom headache is the dominant complaint, the prevalence of pain from the C2–C3 zygapophysial joint is 53%.\(^49\) No other blocks and no other diagnostic tests have established any other source of cervicogenic headache with a prevalence that rivals this figure. A positive response to controlled, third occipital nerve blocks is prognostic of an 88% success rate for completely relieving headache by third occipital radiofrequency neurotomy.\(^44\)

**Nerve Blocks for Lumbar Zygapophysial Joint Pain**

Lumbar medial branch blocks are the only means available by which either to implicate or to refute the lumbar zygapophysial joints as the source of back pain. The validity of lumbar medial branch blocks has been studied more than any other diagnostic block in pain medicine. The blocks are target-specific. Provided that the correct target points are used and provided that small volumes are used, the injectate remains exclusively on
the target nerve.\textsuperscript{50} Placements more proximal along the nerve risk having the injectate spread into the intervertebral foramen.\textsuperscript{50} Construct validity has been demonstrated. Medial branch blocks protect normal volunteers from experimentally induced zygapophysial joint pain.\textsuperscript{51}

As for the cervical region, the standard technique for lumbar medial branch blocks is fluoroscopy-guided (Figs. 98.7 and 98.8). Ultrasound-guided techniques have been described and validated, but they require excellent expertise.\textsuperscript{52–54}

**FIGURE 98.7** Radiographs of the lower lumbar spine on which the courses of the medial branches (mb) of the lower lumbar dorsal rami and the L5 dorsal ramus (dr) have been depicted. A: Anteroposterior view. B: Oblique view.

**FIGURE 98.8** Radiographs of an L4 medial branch block. A: Oblique view showing a needle resting on the neck of the superior articular process of L5. B: Declined view showing the needle aiming obliquely onto the neck of the superior articular process at its junction with the transverse process.

In order to be valid in patients, the blocks should also be controlled.
Single blocks of the lumbar medial branches have false-positive rates of between 25% and 41%.\textsuperscript{55–57} This means that if the prevalence of lumbar zygapophysial joint pain is 15% (see the following text), for every three blocks that appear to be positive, two will be false positive. If the prevalence is 5%, five out of every six blocks will be false positive. A caveat applies to these calculations. As for cervical zygapophysial joint pain, the prevalence and false-positive rates have been computed based on concordant responses of comparative blocks, implying that only cases in which bupivacaine effects last longer than lidocaine effects are true positives. As mentioned earlier, we cannot rule out zygapophysial joint pain in the presence of discordant responses, that is, in those cases in which lidocaine duration of effect exceeds bupivacaine effect. This consideration suggests that the prevalence of lumbar zygapophysial joint pain may be higher than reported and, accordingly, the false-positive rates of single blocks may be lower than we currently estimate. Nevertheless, they likely remain clinically significant, indicating that a valid diagnosis cannot be made using a single diagnostic block.

Comparative local anesthetic blocks have been advocated and used as controls for lumbar medial branch blocks on the grounds that they have been validated for the cervical spine. In the cervical spine, comparative blocks have a specificity of either 65% or 88%, depending on the stringency of the criteria for a positive response.\textsuperscript{37} These values are acceptable for cervical medial branch blocks because cervical zygapophysial joint pain is so common. However, in the lumbar spine, where zygapophysial joint pain is far less common, comparative blocks result in inordinate numbers of false-positive results.

For a specificity of 65%, and a prevalence of 40%, the diagnostic confidence of positive comparative blocks is only 66% (Table 98.3). For a prevalence of 15%, this confidence drops to 32% and is even less for lower prevalence rates. For a specificity of 88% and a prevalence of 15%, the diagnostic confidence is only 60% but rises to 85% if the prevalence is 40% (see Table 98.3). These calculations show that for comparative blocks to be valid in the lumbar spine, the prevalence of zygapophysial joint pain must be substantial, and strict criteria for a positive response must be applied (e.g., the patient must have substantial relief of pain on each
occasion that the nerves are blocked and function has to be restored). Unless these conditions apply, the false-positive rates render the diagnostic confidence unacceptably low.

The calculations assume a sensitivity of 100%. Diagnostic confidence is the measure of how confident the practitioner can be that the condition really is present when a test is positive. It amounts to the positive predictive value that applies for a particular prevalence and is derived from the specificity and sensitivity of the test by the equations:

\[
\text{pretest odds} = \frac{\text{prevalence}}{1 - \text{prevalence}}
\]

\[
\text{positive likelihood ratio} = \frac{\text{sensitivity}}{1 - \text{specificity}}
\]

\[
\text{posttest odds} = \text{pretest odds} \times \text{positive likelihood ratio}
\]

\[
\text{diagnostic confidence} = \left[ \frac{\text{posttest odds}}{\text{posttest odds} + 1} \right] \times 100\%
\]

The available data on the prevalence of lumbar zygapophysial joint pain is mixed and contentious and differs according to the sample studied and the criteria used to define a positive response. Using the criterion of 50% relief of pain, the prevalence has been reported as 15% (10% to 20%) among younger, injured workers. Using a criterion of 75% relief of pain,
the prevalence was 45% (39% to 54%) in patients attending a pain clinic,\textsuperscript{57} and for a criterion of 90% relief, the prevalence was 40% (27% to 53%) in elderly patients with no history of trauma.\textsuperscript{59} These data leave the prevalence of lumbar zygapophysial joint pain in doubt. It appears to be low in injured young patients but may approach 40% in elderly patients.

Because of the relatively low prevalence of lumbar zygapophysial joint pain, the pretest likelihood is that the patient will have a negative response to lumbar medial branch blocks. Consequently, it would be inappropriate in most cases to test each joint one at a time. A more efficient use of lumbar medial branch blocks would be initially to perform a screening block, in which the L3 medial branch, L4 medial branch, and L5 dorsal ramus (supplying the L4–L5 and L5–S1 joint) are blocked simultaneously. If these blocks prove negative, zygapophysial joint pain is effectively refuted. Joints are most often symptomatic at L4–L5 and L5–S1,\textsuperscript{59} and an investigator would need good cause to test joints at higher segmental levels. If the screening blocks are positive, controlled blocks at single segments may be pursued to determine if the response is valid and to establish which particular joint is the source of pain.

Establishing a diagnosis of lumbar zygapophysial joint pain allows treatment to be offered in the form of lumbar radiofrequency medial branch neurotomy. If they are selected on the basis of positive responses to controlled blocks, 60% of patients so treated can expect to obtain at least 80% relief of pain lasting 12 months, and 80% can expect at least 60% relief.\textsuperscript{60} If pain recurs, neurotomy can be repeated in order to reinstate relief.\textsuperscript{61} A systematic review of randomized controlled trials that compared radiofrequency neurotomy with blockades, infiltrations, or placebo found low to moderate evidence in favor of radiofrequency neurotomy.\textsuperscript{62} Unfortunately, patient selection using controlled diagnostic blocks was not considered as criterion to include studies in the analysis, and therefore, several investigations enrolled patients who were unlikely to have zygapophysial joint pain. This has likely reduced the overall effect size of the procedure. A more recent randomized controlled trial found very limited benefit of adding radiofrequency neurotomy to an exercise program.\textsuperscript{63} However, the study has severe limitations that are summarized in a following commentary.\textsuperscript{64} A single diagnostic block was performed,
and the effect of the diagnostic block was based solely on pain relief (50%), with no evaluation of function. This practice likely resulted in high false-positive rates and therefore in the enrollment of patients with no pain stemming from the zygapophysial joints. Furthermore, based on the description of the technique, the radiofrequency electrode was not placed parallel to the nerve, which is essential to maximize the chances of coagulating the nerve. This technical flaw has likely prevented the procedure from being effective in patients with true zygapophysial joint pain. The results of this recent study are nevertheless important, as they confirm that lack of strict selection criteria and expeditious practice are not associated with successful outcomes of radiofrequency neurotomy.

The selection of patients for radiofrequency neurotomy is a crucial process. A multicenter randomized controlled trial compared the outcomes of lumbar radiofrequency medial branch neurotomy in patients selected with three different criteria: clinical findings (without diagnostic block), positive response to a single diagnostic block, and positive response to comparative blocks. Denervation success rates in the three groups were 33%, 39%, and 64%, respectively, indicating that controlled blocks led to better outcomes. However, the most cost-effective paradigm was proceeding to radiofrequency denervation without a diagnostic block. Due to the very low morbidity of radiofrequency denervation, economic considerations may encourage the practice of skipping diagnostic blocks and proceed directly to radiofrequency neurotomy. The authors of this chapter do not support this practice. A success rate of 33% is ethically unacceptable, considering that selection of patients with diagnostic blocks would substantially increase the chance of a positive outcome.

Which type of control an investigator chooses to use and which criteria should be used to assess comparative blocks is a matter of preference depending on the circumstances, that is, whether the blocks are performed for research or clinical purposes, the nature of the planned research, or the clinical circumstances. The choice ranges from placebo-controlled blocks to comparative blocks with more or less strict criteria regarding the relative duration of pain relief with the two different anesthetic agents. Substantial controversy exists regarding the amount of pain relief that has to be achieved by diagnostic blocks in order to categorize a response
as positive. In theory, zygapophysial joint pain is expected to be completely relieved by nerve blocks. However, there is widespread practice of considering 50% pain relief as sufficient to enroll patients for radiofrequency neurotomy. This approach may be associated with increased risk of false-positive responses and, consequently, failure of radiofrequency neurotomy. However, a study that evaluated the relationship between degree of pain relief after the blocks and denervation outcomes found no significant differences in radiofrequency outcomes based on any pain relief cutoff over 50% with the diagnostic blocks. Based on the results, the authors raised concerns that adopting the very stringent selection criterion of 80% to 100% pain relief as screening for radiofrequency ablation would result in withholding a beneficial procedure from a substantial number of patients.

Other Diagnostic Nerve Blocks
Unfortunately, most of the nerve blocks that can be technically performed have not been tested for their diagnostic utility. Therefore, despite wide use, the validity of most diagnostic nerve blocks remains undetermined. One example is the block of the greater occipital nerve for the diagnosis of occipital neuralgia. The causes of occipital neuralgia are mostly unclear, the most straightforward one being injury to the nerve caused by trauma or surgery. However, patients who fulfill the criteria for the clinical diagnosis of occipital neuralgia do not necessarily have a history of trauma or surgery. In these patients, the rationale for greater occipital nerve blocks as a diagnostic test is unclear. The block cannot establish or rule out the diagnosis of occipital neuralgia. At best, greater occipital nerve blocks can only be used to establish that afferent activity in this nerve, in some way, “modulates” the perception of pain. As mentioned in the section on therapeutic blocks, this modulatory effect can play a role also in forms of headache other than occipital neuralgia, such as migraine or cluster headache, which challenges the validity of occipital nerve blocks for the diagnosis of occipital neuralgia.

Diagnostic Intra-articular Blocks
Intra-articular injections are performed on joints of the appendicular
skeleton for a variety of reasons. These include therapeutic injections and diagnostic arthrography. However, diagnostic intra-articular blocks, using local anesthetic agents, are not common practice. The diagnosis of peripheral joint pain is established largely on the basis of physical examination and medical imaging, and there is no requirement for diagnostic blocks in routine practice. Some practitioners might use joint blocks in patients in whom the source of pain is ambiguous, such as hip joint blocks to distinguish hip joint pain from referred pain to the groin or buttock, but such practices are not widely used, and their validity and utility have still to be established.

Diagnostic joint blocks have a greater application in the diagnosis of spinal pain because the joints of the spine are less accessible to physical examination, and medical imaging is typically unhelpful in pinpointing a particular joint as the source of pain. In the past, intra-articular blocks of the zygapophysial joints were used as a means of diagnosing zygapophysial joint pain. The practice still continues in some circles. However, intra-articular blocks of the spine have never been validated and have not been shown to have therapeutic utility. They have been supplanted by medial branch blocks, which have been validated and which do have therapeutic utility.

It is unclear whether joint pain is the result of intra- or periarticular pathology or both. If periarticular lesions are involved, intra-articular blocks would not be sensitive for the diagnosis of joint pain. Periarticular infiltrations are performed in clinical practice, but their validity and therapeutic utility are unknown.

There are two spinal joints for which nerve blocks are not practical and for which intra-articular blocks remain the only means to determine if that joint is the source of pain. They are the lateral atlantoaxial joint and the sacroiliac joint.

Experimental studies in normal volunteers have shown that the lateral atlantoaxial joint (C1–C2) can produce pain in the upper cervical spine and in the head. In principle, therefore, this can be a source of cervicogenic headache and neck pain.

Lateral atlantoaxial joint blocks involve delivering a needle into the cavity of the joint. The technique involves a posterior approach, using
fluoroscopic guidance. The proximity of the target area to the dural sac, spinal cord, internal carotid artery, and vertebral artery poses significant risks during lateral atlantoaxial joint injection. Misplaced injections of local anesthetic could result in a high spinal block. Intra-arterial injection of depot corticosteroids could result in embolism and stroke. Therefore, the technique for lateral atlantoaxial joint blocks does not allow for any but minimal deviations of the needle from a straight course from the skin to the target point. These blocks should be performed only by operators who can use bevel control to restrict movements to less than a few millimeters from a straight course. Contrast medium is injected in order to establish that the injectate enters the joint cavity and does not escape from it (Fig. 98.9). This establishes the face validity of the injection. Once correct placement has been confirmed, about 1 mL of local anesthetic can be injected. A positive response is one in which the injection substantially relieves the patient’s pain.

![Anteroposterior fluoroscopy views of a lateral atlantoaxial joint injection. A: The needle has been advanced into the cavity of the joint. B: Contrast medium outlines the joint cavity and the internal surface of the lateral capsule.](image)

The validity of lateral atlantoaxial joints has not been tested. Single diagnostic blocks may have a false-positive rate which has not yet been measured. In principle, controlled blocks are required in order to maximize validity. Controls using comparative local anesthetic blocks might be used, but the validity of comparative blocks inside joints, where blood flow is low, has not been established. Anatomic controls might be an alternative, in which the control is to block an adjacent joint (e.g., C2–C3), but the results of such controls have not yet been reported.
There are few prevalence studies of lateral atlantoaxial joint pain, but the available data indicate a nonzero prevalence. One study, using single diagnostic blocks, found that at least 16% of patients presenting with headache responded to lateral atlantoaxial joint blocks. Another study found a prevalence of at least 13%. Each of these may be underestimates because not all eligible patients underwent diagnostic blocks. Conversely, the figures might be lower because controlled blocks were not used.

Lateral atlantoaxial joint blocks have therapeutic utility because patients can be treated by atlantoaxial arthrodesis. Follow-up studies have reported that arthrodesis succeeds in providing sustained relief of pain. Intra-articular injections of corticosteroids are a more conservative alternative but benefit only about 1 in 8 patients over the long term.

Sacroiliac joint blocks are a test for back pain stemming from a sacroiliac joint. They involve introducing a needle under fluoroscopic or ultrasound control into the lower end of the cavity of the joint. With fluoroscopy, a test dose of contrast medium establishes that the injectate lies within the joint cavity and does not escape from it. Ultrasound has emerged as an alternative to fluoroscopy as image guidance, with a randomized controlled trial showing that ultrasound-guided sacroiliac joint injection has similar accuracy and efficacy to fluoroscopy-guided injection. With either technique, a local anesthetic can be injected in order to anesthetize the joint. A positive response is substantial relief of the patient’s pain.
Two types of controls have been used in order to maximize the validity of sacroiliac joint blocks. One study used anatomic controls by previously anesthetizing lumbar zygapophysial joints.\textsuperscript{77} Another study used comparative local anesthetic blocks.\textsuperscript{78} Respectively, these studies found a prevalence (95% confidence intervals) of 13\% (6\% to 20\%) and 19\% (9\% to 29\%).

The lateral sacral branches contribute to the innervation of the sacroiliac joint\textsuperscript{79,80} and are therefore potential targets of diagnostic blocks. However, the intra-articular portion of the sacroiliac joint is innervated also from ventral nerves.\textsuperscript{79} Therefore, lateral sacral nerve blocks are unlikely suitable to diagnose sacroiliac joint pain. They should rather be considered a potential tool to predict the effect of lateral branch radiofrequency neurotomy.\textsuperscript{81} The block can be performed under either fluoroscopy or ultrasound guidance.\textsuperscript{82} A systematic review found some evidence for the face validity of sacral lateral branch blocks to diagnose posterior sacroiliac complex pain, and some evidence of moderate quality for the efficacy of lateral branch radiofrequency neurotomy.\textsuperscript{83} Three randomized controlled studies found lateral branch radiofrequency neurotomy to be superior to a
placebo treatment.\textsuperscript{84–87}

**Therapeutic Nerve Blocks**

Local anesthetics have a limited duration of action, and their effects are expected to wear off. Therefore, the most straightforward application of therapeutic nerve blocks is acute pain: The pain is treated while spontaneous healing is anticipated. Examples include femoral nerve blocks for a fractured femur,\textsuperscript{88} intercostal blocks to permit deeper breathing in patients with painful fractures of the ribs,\textsuperscript{89} and various nerve blocks, with or without indwelling catheter, for the management of postoperative pain.\textsuperscript{90,91} As mentioned in the introduction, these blocks are not the focus of this chapter.

For chronic pain, nerve blocks can be used to temporarily facilitate function or enhance the efficacy of other treatments. Examples include brachial plexus blocks to facilitate rehabilitation in patients with complex regional pain syndromes of the upper limb\textsuperscript{92} and suprascapular nerve blocks to facilitate mobilization of frozen shoulder.\textsuperscript{93} In these examples, it is recognized that the period of relief required is temporary and that other interventions will eventually treat the pain. If required, the blocks can be repeated to facilitate rehabilitation, but the blocks are not repeated ad infinitum.

In addition to serving as a complement to other treatments, nerve blocks have a long tradition as therapeutic tools per se in chronic pain conditions. The basis for this practice has been the anecdotal evidence that in some patients, repeating blocks can lead to prolonged periods of relief well beyond the duration of action of the agent used. This is supported by a systematic review that found the effect of local anesthetic injections to consistently exceed the duration of the conduction blockade.\textsuperscript{94} However, all the articles included in that review were single case reports or case series, preventing firm conclusions. As a matter of fact, neither the proportion of patients who respond with long-term benefits or the mechanism of this effect is known. It may be a peculiar effect of local anesthetic on open sodium channels in patients with chronic pain. It may be a placebo effect. It may be due to a settling effect on CNS pathways.
Notwithstanding this lack of information, therapeutic nerve blocks are an attractive option for some practitioners and for some patients when other options are not available or impractical.

To date, the best evidence for the efficacy of therapeutic nerve blocks is for blocks of the greater occipital nerve in the treatment of headache. Several studies using local anesthetics alone or in combination with a steroid have shown efficacy in reducing pain intensity and/or frequency of pain attacks in different forms of headache. The study design has been heterogenic. Most studies have been conducted as prospective case series or audits, using single injections or a series of procedures at variable intervals.\textsuperscript{95–97} An observational study on the effect of repeated greater occipital nerve and supraorbital nerve blocks with bupivacaine (without a steroid) for migraine found that 85\% of patients had a positive response during a 6-month observation period.\textsuperscript{98} One randomized controlled trial on cervicogenic headache found occipital nerve blocks with a mixture of local anesthetic, opioid, and clonidine to be superior to placebo at 2-week follow-up.\textsuperscript{99} A greater occipital nerve injection with steroid (without local anesthetic) was superior to placebo in preventing cluster headache attacks.\textsuperscript{100} Another randomized controlled trial in chronic daily headache found a significant reduction in pain up to 4 weeks after the injection, with no difference between local anesthetic alone and its combination with a steroid.\textsuperscript{101} Lastly, a more recent placebo-controlled trial on chronic headache showed superiority of a series of greater occipital nerve blocks with a local anesthetic at 4-week follow-up.\textsuperscript{102} A caveat applies to placebo-controlled trials on occipital nerve blocks, namely, the limited ability to blind patients to the group allocation due to the cutaneous numbness caused by the nerve block.

The mechanisms underlying long-term effects of occipital nerve blocks in headache are unclear. The nerve does not supply structures that are potential primary triggers of headache syndromes. The functional connections between cervical and trigeminal system\textsuperscript{103,104} may be involved in the effect of greater occipital nerve blocks in headache: Reducing the sensory input to the cervical system may lead to reduced nociceptive activity in the trigeminal system. This is supported by studies that explored the nociceptive trigeminal transmission with the nociceptive...
blink reflex, showing reduction in the reflex responses following nerve block.\textsuperscript{105,106} Furthermore, greater occipital nerve block reduces allodynia at both trigeminal and cervical areas not primarily supplied by the nerve,\textsuperscript{107} further supporting a modulatory effect of the block on central nociceptive pathways involved in headache.

The sphenopalatine ganglion is another potential target of local anesthetic blocks for the treatment of headache. The rationale is its anatomical connections with the trigeminal and parasympathetic system that are involved in symptoms associated with different forms of headache, in particular trigeminal autonomic cephalalgia. Block of the sphenopalatine ganglion has a long tradition in the treatment of headache.\textsuperscript{108} The ganglion can be blocked via either the transnasal route or infrazygomatic percutaneous puncture. Some evidence for efficacy has been produced. According to a recent review, the published data support efficacy of the block for cluster headache and migraine in both the short and long term, although the data are not very robust.\textsuperscript{108}

There are data on nerve blocks for the treatment of chronic shoulder pain. A randomized placebo-controlled trial on the treatment of shoulder pain after hemiplegic stroke found a single suprascapular nerve block with bupivacaine and steroid to be superior to placebo in terms of pain relief.\textsuperscript{109} The number-needed-to-treat for 50\% pain relief at 4 weeks was 4. Another randomized placebo-controlled trial studied the effect of suprascapular nerve block with bupivacaine, performed three times every 7 days, on frozen shoulder.\textsuperscript{93} Both the bupivacaine and placebo group underwent a home exercise program. After 1 month, the bupivacaine and placebo group displayed a 64\% and 13\% pain reduction, respectively, with 15.8\% improvement in shoulder function in the bupivacaine group versus 4\% in the placebo group. This reproduced the results of a previous randomized placebo-controlled trial on shoulder pain in rheumatoid arthritis and degenerative disease of the shoulder. This study found clinically and statistically significant improvements in pain scores, disability scores, and range of movement in the group receiving suprascapular nerve block, compared with the placebo group, at weeks 1, 4, and 12.\textsuperscript{110} A recent meta-analysis came to the conclusion that suprascapular nerve blocks provide better pain relief for 12 weeks compared with physical therapy and
placebo injections in patients with chronic shoulder pain but is not superior to intra-articular injections.\textsuperscript{111} The same review found evidence for better clinical outcomes when the block is performed under ultrasound guidance, compared to blind techniques and fluoroscopy guidance. In this regard, an ultrasound-guided technique of suprascapular nerve block has been developed that approaches the nerve at the supraclavicular region, resulting in better visualization of the nerve, compared with the traditional suprascapular technique.\textsuperscript{112}

Several caveats apply to the mentioned data on therapeutic blocks. Most of the studies have not been performed in a randomized controlled manner. The few randomized controlled trials are characterized by small sample sizes, heterogenic clinical regimens, and the aforementioned difficulty in ensuring blinding to the group allocation. These factors limit our ability to attribute the positive outcomes to a specific effect of the local anesthetic blocks. Factors other than the blocks may account for the positive outcome or contribute to them. They include placebo effects, spontaneous healing, and regression to the mean. Furthermore, the basic science supporting the therapeutic efficacy of nerve blocks is almost inexistent, making explanations of the underlying mechanisms largely speculative.

In these authors’ opinion, the earlier limitations should not prohibit the use of therapeutic blocks. The limited data available allow consideration of this practice for selected patients. Careful evaluation of alternative treatments, expected benefits, risks and costs associated with the procedure, and thorough patient information are mandatory. It is reasonable to predict that only a minority of patients have long-term relief of pain. Therefore, the indication for therapeutic nerve blocks should be restrictive. Alternative more evidence-based treatments must be tried or at least discussed with the patient before planning blocks. In the light of the weak literature and the small proportion of patients who benefit in the long term, the procedures should be of very low risk and performed by, or under supervision of, very experienced practitioners. This will minimize the risk–benefit ratio.

Realistic expectations have to be discussed with the patient. Nerve blocks cannot be expected to “fix” a chronic pain problem. Many patients will experience for the first time complete pain relief for few hours after
the block. This may generate the unrealistic expectation that pain can be cured in this way. Patients have to be informed that complete pain relief is very rarely achieved in the long term.

There is no purpose in performing repeated nerve blocks for a chronic condition if the effects are short lasting, and blocks should not be offered indefinitely in patients who do not display long-term benefits. Also, restoration of activities is an important goal, for if function does not improve, the risk–benefit or cost–benefit ratio may be considered as unfavorable.

The use of therapeutic nerve blocks is an area of pain medicine that has potential but suffers of very limited scientific background. The availability of more data presented in this chapter, compared with the previous edition of this book, is encouraging but far from providing solid support for an evidence-based practice. Hopefully, future research will provide further support to clinical decision making.

**Conclusion**

Anesthesiologists were prominent among those who founded the discipline of pain medicine. From their background and training in surgical anesthesia, they brought with them the art of local anesthetic blocks. In a new discipline, these blocks were a powerful tool: They could stop the symptom of which the patient complained. Over the last 40 years, however, the standards of science in medicine have escalated. The art of local anesthetic blocks has not kept pace with the science required of them.

Most of the publicity concerning evidence-based medicine has centered on the standards set and expected for studies of the efficacy of treatments. For such studies, rules apply concerning randomization, blinding, controls, follow-up, outcome measures, and intention-to-treat analysis. These same rules do not apply to diagnostic tests, but others do.

The rules for operative anesthesia are straightforward and easy to apply. In operative anesthesia, the objective is to protect the patient from feeling pain once the surgery commences. Adequacy of anesthesia can be tested by applying a noxious stimulus and asking the patient of any effect. If they are numb, the patient, the anesthetist, and the surgeon are all satisfied. At a
philosophical level, it does not matter if the patient had a placebo effect. The block, nevertheless, served its purpose.

A different set of rules applies to pain medicine. The situation differs in that the objective of local anesthetic blocks is to stop ongoing pain, be that for diagnostic, prognostic, or therapeutic purposes. This is a different idiom from that of securing surgical anesthesia.

Paramount is the validity of the local anesthetic block, and placebo effect is a serious, potential, confounding factor. It does matter if the patient has a placebo response when diagnostic and therapeutic decisions are based on that response. Notwithstanding the mysteries of the placebo response and what it means, a placebo response is likely a false-positive response. It means that any decision about diagnosis may not be correct and any decision about treatment may be wrong.

Because false-positive responses can occur, sometimes commonly, practitioners cannot assume that all positive responses to blocks are true positive. A block cannot be held to be valid unless it is subjected to some sort of control.

It is in this regard that the art of local anesthetic blocks has lagged behind the pace of contemporary science. Eminent authorities in the past have described a vast litany of the types of blocks that could be performed; some even implied that they should be done. At a scientific and clinical level, however, those recommendations pertained only to the execution of blocks. They did not address their validity and interpretation.

For prognostic blocks, the assumption has been that uncontrolled blocks will faithfully predict the outcome of treatment. This assumption may be convenient for expeditious practice, but it does not amount to evidence-based practice. Two confounding influences apply. The prediction of the blocks may be incorrect because the response to blocks is not valid, and the treatment may not work because its efficacy has not been established.

It is for these reasons that the present chapter does not resemble corresponding chapters in other books. Local anesthetic blocks have not been described just because they can be done. Instead, the present chapter has focused on why blocks might be done. Some degree of evidence is required to find the answer to that question. As a result, the present chapter does not describe blocks for which there is barely anecdotal evidence.
Prominence has been given to those blocks for which there is evidence and in proportion to the volume and quality of evidence available.

The foundations of pain medicine in general and interventional pain medicine in particular depend on the validity of local anesthetic blocks. The evidence, at present, would indicate that whereas diagnostic medial branch blocks are sound, all other diagnostic blocks have uncertain validity. Medial branch blocks have been shown to protect healthy volunteers from experimentally induced pain, they have been shown to have target specificity, their false-positive rates are known and are large but can be reduced by using controls, and positive responses are associated with successful outcomes of treatment. For no other local anesthetic block have these requirements been satisfied.

In comparison with the previous version of this chapter, some more evidence on the efficacy of therapeutic blocks has emerged, but the sparse data are in sobering contrast with the 8 years that have elapsed. The challenge, if not duty, of experts in this discipline is to make up the difference. It is often said that no evidence of efficacy is not evidence of no efficacy, but a retort applies. Assumption is not a substitute for evidence. Hopefully, future editions of this chapter can be enriched by a greater, appropriate body of evidence.

CHAPTER 99
Epidural Steroid Injections
TIMOTHY PHILIP MAUS and NIKOLAI BOGDUK

Definition
Lumbar epidural steroid injections (ESIs) are a minimally invasive procedure designed to treat lumbar radicular pain. They involve inserting a needle into a location from which medication can be delivered onto the affected spinal nerve, the dorsal root ganglion, or its roots. The medication delivered includes a corticosteroid preparation but variously may also contain a local anesthetic preparation or normal saline.

Steroid preparations are used in the belief that radicular pain is caused not just by compression but also by inflammation of the target nerve. There is both clinical and experimental evidence that an inflammatory component is necessary for the expression of radicular pain. Clinically, large disk herniations with significant neural compression may be asymptomatic, whereas severe radicular pain may exist without detectable root compression. The size or shape of a disk herniation, or change in size or shape over time, does not correlate with clinical presentation or course. Experimentally, it is well established that the natural history of disk herniation is resolution, mediated by macrophage-produced metalloproteases, abetted by neovascularization also induced by chemical signalling. The disk nucleus pulposus is known to be immunogenic with inflammatory mediators (phospholipase A$_2$, prostaglandin E$_2$, interleukins 1$\alpha$, 1$\beta$, 6; tumor necrosis factor, and nitric oxide) all detected in relationship to disk herniations. Available evidence suggests that both mechanical compression and an inflammatory component are necessary for radicular pain. This provides a rationale for the use of an anti-inflammatory corticosteroid preparation as a therapeutic agent.

Over the years, various steroid preparations, in various dosages, have
been used. The original agent was hydrocortisone. Subsequently, depot preparations were introduced, such as those of methylprednisolone, betamethasone, and triamcinolone. Of late, dexamethasone has enjoyed resurgence.

These preparations have typically been injected along with local anesthetic agents, but the rationale for using local anesthetics has never been expressly articulated. Ostensibly, early practitioners used local anesthetics in order to make the injection less painful, but modern experience shows that epidural injections are largely painless if performed carefully, and in those cases in which injection is painful, the sources of pain are not ones that are simply anesthetized by adding local anesthetic to the injected medication.

In some procedures, local anesthetic is used to provide what some practitioners call a “diagnostic phase.” The belief is that steroids do not take effect until days after their injection and that any immediate relief of pain must be due to the local anesthetic and, therefore, that relief serves as a diagnostic block that proves that the correct nerve was targeted. The rationale for this belief is mitigated by the reciprocal facts that steroids can have a local anesthetic effect and that local anesthetics have an anti-inflammatory effect. Consequently, the routine use of local anesthetic may not be well founded. Additionally, simultaneous optimization of diagnostic and therapeutic effects is not possible. Evidence supports greater therapeutic effect with central delivery of corticosteroids to the ventral epidural space. Centrally delivered injectate is not segment specific; true selective blocks must be performed at and peripheral to the neural foramen.

**Background**

The history of ESIs is characterized by tension. For a long time, the tension was between reported experience and evidence from controlled trials. Most recently, it has been tension between different types of systematic reviews of the evidence. At the heart of these tensions are driving forces and various differences.

A fundamental driving force is that many physicians want epidural
steroids to be an accepted treatment because it is an intervention that is simple to perform, is not time consuming, and which they can readily provide. Many observational studies fed this desire with reports of good success rates, so much so that ESI became entrenched as common, if not standard, practice. This established the basis for the first tension. The evidence from controlled trials did not corroborate the great success rates and in many instances questioned if steroids had any appreciable attributable effect.

The contemporary tension lies between reviews of the literature, both systematic and otherwise, that produce conflicting conclusions. Authors of reviews differ in the techniques that they apply, the literature that they retrieve, their interpretations of that literature, and the severity of their critical analysis. Whereas some reviews include all of the literature, others—including ones called Cochrane reviews—restrict their retrieval to randomized controlled trials (RCT), even though Cochrane himself called for reviews to include all studies, not just controlled trials.\(^{13}\)

A fundamental difference, however, is that many reviews lump the literature; they do not distinguish between procedures on technical grounds. Yet, there are at least seven different ways of delivering epidural steroids. Each differs by route of administration, the accuracy of needle placement, and the dispersal of injectate. Each of these factors can affect the effectiveness of the treatment, either potentially or actually. Furthermore, the available evidence for different procedures differs in quantity and quality.

**Techniques**

The various techniques for ESIs differ primarily according to target and route of administration. In the caudal route, the needle is inserted through the sacral hiatus, and the target is the epidural space. In the interlaminar route, the needle is inserted between consecutive laminae, and the target is the dorsal epidural space, with the hope for ventral distribution. In the transforaminal (TF) route, the needle is placed just inside an intervertebral foramen, and the target is the spinal nerve, the dorsal root ganglion, and its roots, which traverse that foramen.
A second distinction is whether the needle is inserted under image guidance or without imaging (i.e., “blind”). A third distinction is if that image guidance is fluoroscopy or computed tomography (CT).

As a result of these several technical distinctions, at least seven versions of “epidural steroids” can be recognized (Table 99.1). TF injections are performed only under image guidance; there is no “blind” version of this procedure. Caudal injections are performed blind or under fluoroscopy; although CT or ultrasound guidance might be used, there is no substantial literature on CT or ultrasound-guided caudal injections.

CAUDAL INJECTIONS: TECHNIQUE

The purported attraction of caudal injections is that they are easy to perform, and because the needle is placed distal to the dural sac, unintended penetration of the dural sac is avoided. Another advantage is that multiple nerves can be targeted with a single injection, if and when that is the desired outcome. The corollary of these advantages, however, is that the steroid preparation has to be propelled by a large volume of injectate in order to disperse it rostrally toward the target nerve or nerves, and hence, it will be of reduced concentration at a given epidural site.

When caudal injections are performed “blind,” the sacral hiatus is located by palpation, and the needle is introduced through the overlying skin until it is felt to penetrate the membrane that encloses the hiatus. Once the needle is placed, a steroid preparation mixed with local anesthetic or normal saline, is injected. Typical volumes are 10 to 15 mL, but volumes as large as 64 mL have been reported.\(^{14}\)

When caudal injections are performed under fluoroscopy, the sacral hiatus is visualized directly, and a needle is introduced into it. Correct
depth of penetration and entry into the sacral canal can be determined using a lateral view (Fig. 99.1). A test dose of contrast medium can then be injected in order to confirm flow into the sacral canal, exclude intravascular injection, and determine the volume of injection required to reach the target level. Thereafter, the therapeutic agent and its vehicle can be injected.

![Fluoroscopy images of a caudal injection of steroids.](image)

**FIGURE 99.1** Fluoroscopy images of a caudal injection of steroids. A: Posterior view showing a needle inserted into the sacral hiatus. B: Lateral view showing the needle correctly placed in the sacral canal. C: Posterior view after injection of contrast medium, showing flow of contrast medium as far as the L5 nerves. D: Lateral view after injection of contrast medium, showing flow of contrast medium within the sacral canal and epidural space. (Images kindly provided by Dr. Milton Landers, of Wichita, KS.)

The cardinal liability of the “blind” technique is that the physician has no means of verifying the final location of their needle. Consequently, caudal injections can fail to enter the sacral canal in up to 35% of cases.\textsuperscript{15–19} Injections can lie dorsal to the sacrum or coccyx (Fig. 99.2A), or be intravascular (Fig. 99.2B),\textsuperscript{20} the latter despite no blood appearing on aspiration before injection. For these reasons, many physicians now prefer to perform caudal injections under image guidance.
FIGURE 99.2  Fluoroscopy views of needles placed in the wrong location during the conduct of a caudal injection. A: Lateral view showing a needle that missed the sacral canal and passed dorsal to the sacrum. When injected, contrast medium forms a collection dorsal to the sacrum caudally, and the sacral canal is empty of contrast medium. B: Posterior view showing a needle correctly having entered the sacral canal but entering an epidural vein (vv). Subsequent injection of contrast medium is intravenous. (Images kindly provided by Dr. Paul Dreyfuss, of Seattle, WA.)

CAUDAL INJECTIONS: EVIDENCE

The evidentiary support for epidural steroid administration by the caudal route for radicular pain is limited and contradictory. Very few studies have used image guidance; hence, the unguided and image-guided evidence will be considered here collectively. In four nonimage-guided, randomized controlled explanatory trials with 12 months follow-up from 1971 to 2009, there was no long-term efficacy of caudal epidural injections.21–24 For example, a double-blind RCT of nonimage-guided caudal administration of steroid and local anesthetic versus saline (N = 23) showed an improvement in the steroid group in pain and function at 4 weeks relative to the control arm; at 1 year, there was no difference in pain and functional outcomes.22 A short-term, randomized trial of caudal epidural steroid plus local anesthetic versus local anesthetic alone (N = 48, unguided) showed no difference between the groups at follow-up of 1 to 3 months.25 In another randomized trial of steroid plus local anesthetic versus local anesthetic plus saline (N = 183, unguided), the corticosteroid group had greater improvements in functional recovery than the control arm out of 1 year, but the magnitude of the differential improvement was not clinically relevant.26

In the current decade, a randomized, double-blind, controlled trial of
caudal epidural steroid plus local anesthetic versus local anesthetic alone (N = 120, fluoroscopic guidance) showed both groups improved, and there was a significantly greater but quantitatively modest improvement in pain and functional recovery at 3 months for the steroid group, but no differences at 6 and 12 months, and no difference in opioid use at any time point. The improvement noted in both groups is confounded by multiple repeat injections over the year with no reporting of the temporal relationship between the repeat injections and the pain and functional assessments. A high-quality randomized controlled, blinded (patients, assessors) trial compared epidural corticosteroids versus epidural saline versus subcutaneous saline (N = 116, ultrasound guidance). There were no statistically nor clinically significant differences in pain, function, or quality of life (EuroQol) at 6 weeks, 12 weeks, or 52 weeks follow-up. All groups improved, in that at entry, all patients had a clinically documented radiculopathy; at 52 weeks, 27% of patients persisted with a radiculopathy, without difference between the groups. A short-term (12 weeks, N = 163, unguided) randomized trial compared three different steroid preparations plus local anesthetic versus local anesthetic alone. There were no differences in pain and functional recovery at 4 weeks, whereas measurements at 12 weeks favored the steroid groups.

A systematic review identified only one RCT addressing caudal ESIs in neurogenic claudication patients. This trial (N = 40, fluoroscopic guidance) compared caudal administration of steroid plus local anesthetic versus local anesthetic alone, with 1 year follow-up. Both groups improved, but there was no difference between the groups in pain relief, function recovery, or opioid use. This study is another confounded by multiple injections with uncertain temporal relationship to assessment. A retrospective study of neurogenic claudication patients (N = 95, fluoroscopic guidance, follow-up 5 to 76 months, mean 32 months) receiving caudal epidural injections showed very modest improvements, with only 35% of patients having a 50% improvement in pain and only 36% having a 2-point improvement in the Roland-Morris Disability Questionnaire. A small prospective cohort study (N = 34, follow-up 1 year, mean 2.2 fluoroscopically guided injections) reported 54% of patients had 50% pain relief and 51% had improved waking tolerance at 1
CAUDAL INJECTIONS: ADVERSE EVENTS

Adverse events with caudal ESIs are uncommon but do occur. In a series of 257 fluoroscopically guided injections in 139 patients, no major adverse events were noted. There were 15.6% minor adverse events per injection, primarily consisting of transient central steroid effects (flushing, nonpositional headache, insomnia). There were no dural punctures. An explanatory trial of 441 caudal injections in 120 patients reported no major adverse events; minor adverse events were not recorded. A more detailed reporting of minor adverse events in a series of 100 patients undergoing fluoroscopically guided caudal injections described minor complications in 24% of patients; the most commonly reported was soreness at the injection site (18%).

A recent single-center adverse event study reported 10,151 caudal injections over the span of a decade. There were three major adverse events in this series: one epidural hematoma, one paracoccygeal abscess, and one case of infectious spondylitis with epidural abscess. The most common minor adverse event was symptom aggravation in 11 patients (0.1%). Numerous case reports have described rare events, including transient blindness, retinal necrosis, chemical meningitis, arachnoiditis, epidural hematoma, and epidural abscess.

INTERLAMINAR INJECTIONS: TECHNIQUE

For interlaminar ESI, a needle is passed through an interlaminar space that is closest to the target nerve. The needle is inserted usually along the midline through the interspinous ligament or slightly to the side of this ligament. The procedure requires that the needle penetrates the ligamentum flavum to enter the epidural space but falls short of piercing the dural sac.

When performed “blind,” the physician relies on “loss of resistance” to detect entry into the epidural space. A syringe, filled with air or normal saline, or both, is attached to the needle and pressurized as the needle advances. When the tip of the needle is in the ligamentum flavum, the ligament resists injection, but once the tip enters the epidural space, the
resistance suddenly drops. Upon loss of resistance, the medication is injected. A steroid preparation can be injected alone or mixed with local anesthetic or normal saline, in total volumes of 2 mL to 43 mL,\textsuperscript{14} with volumes of 2 to 5 mL being typical.

When performed under fluoroscopy, interlaminar injection starts with inserting a needle, in a posterior view, onto the lower lamina of the interlaminar space that is the target segmental level.\textsuperscript{36} Noting the depth of this insertion serves to determine the depth of the ligamentum flavum. The needle is then readjusted to aim at the interlaminar space and is inserted as far as the previously noted depth plus a touch more, so that the tip engages the ligament (Fig. 99.3). This step guards against testing loss of resistance at too shallow depth. Final depth of insertion can then be determined by either of two methods.

If loss of resistance is used, a pressurized syringe is used as the needle is advanced through the ligamentum flavum. Once loss of resistance is felt, insertion is stopped, and the depth of insertion is checked on a lateral or contralateral oblique view. The tip of the needle should project just beyond the spinolaminar line or interlaminar line, respectively (see Fig. 99.3).

An alternative technique relies on imaging rather than loss of resistance. The needle is inserted while monitoring its progress on lateral screening. Insertion is stopped once the tip projects just past the spinolaminar line.

Once the tip of the needle is in the epidural space, aspiration is performed to check for cerebrospinal fluid (CSF). Thereafter, a test dose of contrast medium is injected to confirm that it spreads in the epidural space and is not intravascular (see Fig. 99.3). If correct placement is confirmed, the desired medication can be injected.
FIGURE 99.3 Stages in the conduct of an interlaminar injection under fluoroscopy. A: A posterior view showing a spinal needle inserted through an interlaminar space. B: A lateral view showing the tip of the needle just reaching the epidural space. C: A posterior view after injection of contrast medium showing correct spread of contrast medium across the epidural space. D: A lateral view showing spread of contrast medium across the epidural space. (Images kindly provided by Dr. Milton Landers, Wichita, KS and reproduced with permission from International Spine Intervention Society. Lumbar interlaminar access. In: Bogduk N, ed. Practice Guidelines for Spinal Diagnostic and Treatment Procedures. 2nd ed. San Francisco, CA: International Spine Intervention Society; 2013:443–456.)

Many physicians prefer fluoroscopic guidance because it avoids the liabilities of the blind technique. Without image guidance, injections can be subdural or superficial to the ligamentum flavum in some 17% of cases,\textsuperscript{15,37} or they can be intravascular (Fig. 99.4). Errors are more common in patients with large body mass index,\textsuperscript{18} when landmarks are difficult to palpate.\textsuperscript{17} Furthermore, even if the needle is accurately placed in the epidural space, the injectate can fail to reach the target level\textsuperscript{38,39} or can remain in the posterior epidural space and not reach the disk nerve root interface.\textsuperscript{38} Image guidance checks for these liabilities before any therapeutic agents are injected.
FIGURE 99.4  Fluoroscopy views of misplaced needles in the conduct of a lumbar interlaminar injection.  

A: Posterior view showing injection of contrast medium into the multifidus muscle (arrow).  

NONIMAGE-GUIDED INTERLAMINAR TECHNIQUE: EVIDENCE

A recent systematic review of nonimage-guided interlaminar injections examined 21 observational, 9 pragmatic, and 9 explanatory studies. There was no evidence supporting benefit for unguided injections beyond 3 to 6 weeks in either radicular pain or neurogenic claudication.\(^4^0\) An RCT (N = 228, radicular pain) series of three unguided steroid injections versus interspinous saline control injections showed an improvement in leg pain and a nonstatistically significant improvement in function, at 3 weeks only. There was no significant benefit in any pain or functional measure, return to work, or need for surgery from 6 to 52 weeks. There was no benefit of three over one injection.\(^4^1^, 4^2\) Another explanatory trial (N = 158, one to three injections, radicular pain) used epidural saline as the control. Mean leg pain scores improved at 6 weeks but not at 12 weeks. There was no difference in categorical outcomes of global improvement at any time point out of 12 weeks. Secondary outcomes were no different between the active and control groups at 12 weeks.\(^4^3\) A third RCT (N = 85, three injections, radicular pain) compared epidural steroid to epidural saline injections. The primary outcome was a semiquantitative global perceived effect measure, which was not different between the two groups at 35 days (study endpoint). Secondary measures of pain and functional improvement also did not differ between the groups.\(^4^4\)
The evidence supporting short-term benefit was conflicting and of low quality, culminating in a recommendation that nonimage-guided injections should be restricted to the rare settings where fluoroscopy is not available. This is in concert with the recommendations of the U.S. Food and Drug Administration (FDA) Safe Use Initiative on ESIs, that multiplanar image guidance is recommended for all epidural injections.

**IMAGE-GUIDED INTERLAMINAR TECHNIQUE: EVIDENCE**

Even image-guided interlaminar injections are challenged by the inability of the operator to control the distribution of delivered medications. This is particularly problematic with midline interlaminar injections, where spread from the insensate dorsal epidural space to the target of epidural injections, the ventral epidural space, lateral recess, and neural foramen may occur only infrequently and unpredictably. Injectate has been documented reaching the ventral epidural space in only 36% to 51% of injections.

A systematic review of fluoroscopically guided interlaminar injections revealed no explanatory trials and documented only modest short-term improvements in pain.

An RCT (N = 120, radicular pain) compared the interlaminar epidural injection of steroid plus local anesthetic versus local anesthetic alone. This was considered a pragmatic trial given the potential therapeutic effects of the local anesthetic. Both groups demonstrated significant improvement (50% decrement) over baseline in pain and function at 3, 6, and 12 months. There was no difference between the groups at 3 and 12 months; scores at 6 months favored the steroid group. This study allowed multiple injections and is again confounded by no reporting of the temporal relationship of the injections to the assessments.

A small observational trial (N = 21, radicular pain) noted that 28% of patients had complete pain relief at 3 months, whereas 38% achieved 50% pain relief. A retrospective trial (N = 40, radicular pain) compared interlaminar versus TF ESIs. There was more short-term improvement in pain in the TF group, and over 12-month follow-up, more interlaminar patients progressed to surgical intervention.

Four pragmatic studies addressed the efficacy of lateral parasagittal
interlaminar injections in comparison to midline injections or TF injections.\textsuperscript{52–55} The evidence suggests that parasagittal interlaminar injections have improved outcomes when compared to midline injections in radicular pain patients and approach the outcomes achieved with TF injections. This is likely due to the greater delivery of injectate to the ventral epidural space with parasagittal versus midline injections. This promotes parasagittal interlaminar injections as a useful strategy in the face of foraminal stenosis, which may make effective TF injections more difficult.

**INTERLAMINAR TECHNIQUE: ADVERSE EVENTS**

Adverse events may be segregated into major (neurologic injury, intraspinal hemorrhage, spinal infections) and minor events (vasovagal syncope, dural puncture, acute systemic steroid effects, contrast reactions). Serious adverse events have been limited to case reports, including intraspinal hematoma, spondylodiscitis with epidural abscess, chemical meningitis following inadvertent intrathecal delivery, paraplegia, and transient blindness.\textsuperscript{48} Fortunately, large prospective series reporting adverse event rates have identified few major complications. No major adverse events were seen in a multi-institutional cohort of >1,500 interlaminar injections.\textsuperscript{56} Dural punctures were seen in 0.2% of patients, vasovagal reactions in 0.5%, and a central steroid effect (transient flushing, sleeplessness, nonpositional headache) was observed in 2.6%. A recently reported single-center 12-year experience in >9,800 lumbar interlaminar injections identified single cases (0.01%) each of intraspinal hematoma, spondylodiscitis, and septic shock.\textsuperscript{35} Dural puncture with CSF leak was seen in six patients (0.06%); vasovagal reactions and systemic steroid effects were not described.

**TRANSFORAMINAL INJECTIONS**

Caudal and interlaminar injections rely on medication spreading to the target nerve or nerve roots from the point of injection. Because the spread of injectate into the epidural space is uncontrolled and unpredictable, only a fraction of the medication administered may actually reach the target nerve. TF injections differ in that the needle is placed next to the target
nerve, virtually or actually touching it. Thereby, all the medication is delivered onto the target nerve.

There is no “blind” version of TF injections. They are performed under image guidance.\textsuperscript{57} Image guidance is also critical for safety. The most serious danger of TF injections is injection into a radicular artery that reinforces the blood supply of the conus medullaris. Therefore, steps must be taken to guard against complications from such intra-arterial injections.

When lumbar spinal nerves are the target, the target zone is the intervertebral foramen that lodges that nerve. Along a posterior or posterior oblique view, a spinal needle is delivered into that foramen, at a location where the target spinal nerve does not lie (Fig. 99.5). The classical placement is subpedicular (i.e., tangential to the inferior surface of the pedicle) as deeply as the back of the vertebral body (see Fig. 99.5).

![FIGURE 99.5](https://example.com/figure995)

**FIGURE 99.5** Fluoroscopy views of stages in the conduct of a lumbar transforaminal injection. A: Posterior view showing a needle directed to a subpedicular position in a right L5–S1 intervertebral foramen. B: Lateral view showing the needle tangential to the pedicle, with its tip (arrow) resting on the back of the vertebral body. C: Posterior view after injection of contrast medium which outlines the parapedicular course of the L5 spinal nerve and the dural sleeve covering its roots. D: Lateral view after injection of contrast medium. The contrast medium (arrows) surrounds the nerve and flows rostrally, around the pedicle and under the lamina. (Images from International Spine Intervention Society. Lumbar interlaminar access. In: Bogduk N, ed. Practice Guidelines for Spinal Diagnostic and Treatment Procedures. 2nd ed. San Francisco, CA: International Spine Intervention Society; 2013:443–456.)

Alternative placements are supraneural, retroneural, and infraneural (Fig. 99.6). These can be used if and when the spinal nerve is displaced onto the pedicle, in patients with foraminal stenosis, or to avoid arteries in

4937
the rostral sectors of the foramen.

**FIGURE 99.6** Alternative placements of a needle in the intervertebral foramen for transforaminal injections. In the supraneural placement, the tip of the needle lies above the nerve. For the retroneural placement, the tip of the needle lies behind the nerve. For infraneural placement, the tip of the needle lies below the nerve, opposite the intervertebral disk. (Images reproduced with permission from International Spine Intervention Society. Lumbar interlaminar access. In: Bogduk N, ed. Practice Guidelines for Spinal Diagnostic and Treatment Procedures. 2nd ed. San Francisco, CA: International Spine Intervention Society; 2013:443–456.)

When sacral nerves are the target, a technique analogous to that for lumbar nerves is used. The needle is inserted through the posterior sacral foramen and placed in a retroneural position (Fig. 99.7).

**FIGURE 99.7** Fluoroscopy views of stages in the conduct of a sacral transforaminal injection. **A:** Posterior view showing a needle directed to a subpedicular position through a left S1 posterior sacral foramen. **B:** Lateral view showing the needle tangential to the pedicle, with its tip resting on the floor of the sacral canal. **C:** Posterior view after injection of contrast medium which outlines the parapedicular course of the S1 spinal nerve and the dural sleeve covering its roots. **D:** Lateral view
after injection of contrast medium showing contrast medium surrounding the nerve and flowing rostrally.

Once the needle has been placed, one or more safety checks are performed to avoid injection into a radicular artery. Such tests are necessary because infarction of the conus medullaris is the most catastrophic complication of TF injection of steroids, and circumstantial evidence implicates intra-arterial injection of particulate steroids as the cause.

Laboratory studies have shown that agents such as triamcinolone, betamethasone, and methylprednisolone form particles or aggregates that are large enough to block end arteries or capillaries. By implication, these particles could act as emboli if injected into an artery that supplies the spinal cord. More recent evidence suggests that particulate steroids may cause stasis in a microvascular bed due to red blood cell agglutination as a consequence of red cell membrane effects. Studies in animals have shown that injection of particulate steroids into cerebral arteries universally causes fatal stroke, whereas the nonparticulate steroid, dexamethasone, does not. In virtually all cases of spinal cord infarction after lumbar TF injection of steroids, a particulate steroid was used. Only one case report records this complication after the use of dexamethasone. Dexamethasone, however, is known to precipitate into particles if mixed with ropivacaine. Additionally, there is some evidence that steroid preparations can have a direct neurotoxic effect without forming emboli.

The foremost test for intra-arterial injection is the injection of a test dose of contrast medium. In the first instance, contrast medium is injected in order to show that injectate will flow in the appropriate direction, which is centrally, along the course of the target nerves and the dural sleeve that encloses its roots (see Fig. 99.5). It also serves to reveal aberrant flow if the needle has not been placed correctly. Aberrant flow can be into the subarachnoid space or the subdural space if the dural sleeve has been punctured; it may be externally, away from the nerve, if the intervertebral foramen is blocked or stenosed; or it may be into an epidural vein. Guidelines for what to do in the face of aberrant flow are elaborated elsewhere.
Notwithstanding normal flow, if the needle has punctured a radicular artery, the contrast medium will briefly flow within the artery before it is washed away. Intra-arterial injection is an indicated to terminate the procedure in order to avoid the risk of injecting potentially offensive medications into the artery and, therefore, into the circulation of the spinal cord. However, given that these arteries are tiny, it may be difficult to visualize arterial uptake of the contrast medium against a background of contrast medium in the epidural space (Fig. 99.8A). For this reason, some physicians repeat the injection of contrast medium under digital subtraction imaging (DSI). Under DSI, tiny arteries are brought into stark relief (Fig. 99.8B). Although adding DSI increases the amount of radiation to which the patient is exposed, the amount is small and well within notionally safe limits.66

**FIGURE 99.8** Injection into a radicular artery during a lumbar transforaminal injection. A: Posterior view during injection of contrast medium. The tiny artery (arrow) is difficult to see. B: Digital subtraction imaging brings the artery into starker relief (arrows). (Images kindly provided by Dr. Way Yin, Bellingham, WA and reproduced with permission from International Spine Intervention Society. Lumbar interlaminar access. In: Bogduk N, ed. Practice Guidelines for Spinal Diagnostic and Treatment Procedures. 2nd ed. San Francisco, CA: International Spine Intervention Society; 2013:443–456.)

Some physicians perform an additional test, although its validity is contentious. The test is to administer a small dose (1 mL) of lidocaine 2%; wait 2 minutes and examine the patient for sensory or motor loss in the lower limbs. The rationale for this test is that if the needle has punctured a radicular artery but the artery has not been noticed during the injection of contrast medium, the local anesthetic will be injected into the artery and will cause temporary neurologic deficits on the spinal cord being anesthetized. Incurring a temporary neurologic deficit protects the patient from permanent damage that would occur had hazardous medications been
administered. The test is loosely based on a single case report of temporary neurologic deficit after injection of local anesthetic during a cervical TF injection and a retrospective study of cervical TF injections that found that four patients in a series of 532 were positive to the local anesthetic test even though contrast medium had not shown arterial uptake.

Once the needle has been correctly placed and safety checks have reduced the likelihood of intra-arterial injection, the chosen medication can be administered. In the past, the agents used had been methylprednisolone (40 or 80 mg), triamcinolone (40, 50, or 80 mg), or betamethasone (5.7, 8.55, or 11.4 mg). Until recently, these particulate steroids were preferred over dexamethasone (6 or 7.5 mg) because they were regarded as being more effective. Indeed, the early literature supported this view because the studies with the best outcome data all used particulate steroids, whereas outcomes were poor in the few studies that used dexamethasone. However, that situation has changed.

Multiple large studies and reviews have shown that the success rates of TF injection of steroids are not significantly different statistically when dexamethasone is used instead of particulate steroids. This has promoted dexamethasone as a safer alternative for lumbar TF injections.

Concerned about the safety profile of TF injections, the FDA commissioned an expert panel to publish recommendations designed to reduce the risk of spinal cord injury. In the essence, those recommendations are the following:

- All lumbar interlaminar ESIs should be performed using image guidance, with appropriate anteroposterior (AP), lateral, or contralateral oblique views and a test dose of contrast medium.
- Lumbar TF ESIs should be performed by injecting contrast medium under real-time fluoroscopy and/or DSI, using an AP view, before injecting any substance that may be hazardous to the patient.
- A nonparticulate steroid (e.g., dexamethasone) should be used for the initial injection in lumbar TF epidural injections.
- There are situations where particulate steroids could be used in the performance of lumbar TF ESIs.

**TRANSFORAMINAL INJECTIONS UNDER**
FLUOROSCOPIC GUIDANCE: EVIDENCE
TF injections require image guidance, but fluoroscopy facilities are not generally available to pain physicians for relatively minor injections. Therefore, the practice of TF injections has not been as widespread as the practice of blind caudal injections or blind interlaminar injections. Nevertheless, there is an abundant literature on the outcomes of TF injections of steroids for radicular pain.

A systematic review reviewed all of the literature until 2013, covering observational studies as well as pragmatic trials and explanatory trials. It found that the evidence differed in volume and in conclusions for radicular pain due to disk herniation compared with neurogenic claudication associated with spinal stenosis.

For spinal stenosis, the literature and evidence were largely limited to observational studies. There was one pragmatic trial but no explanatory trials. Several observational studies did not provide meaningful evidence because, although they claimed success, they did not define successful relief of pain or because follow-up was only for 2 weeks. Two outcome studies respectively reported 26 of 48 patients and 6 of 10 patients having 50% relief of pain at 6 months. From the single, pragmatic trial data on success rates could not be calculated, but outcomes were not significantly different between patients treated with either TF injections or fluoroscopically guided interlaminar epidural injections of methylprednisolone.

For disk herniation, the review found that the literature is sufficiently abundant to show that lumbar TF injection of steroids is not universally effective but, nevertheless, benefits a substantial proportion of patients and is not a placebo.

The original study of TF steroids reported that 47% of 30 patients obtained complete relief of pain, which was maintained for 2 years, and only 20% of patients required surgery. The surgery-sparing effect was corroborated by a subsequent study in which 53 (77%) of 69 patients avoided surgery for 12 months after treatment.

Seven other observational studies provided reliable estimates of success rates for achieving at least 50% relief of pain at the times after treatment indicated: 100% of 53 patients at 1 month; 52% of 40 patients and 62%
of 41 patients at 90 days; 60% of 20 patients and 62% of 191 patients at 6 months; 75% of 69 patients at 12 months; and 78% of 40 patients at 1 month, reducing to 67% at 6 months and 55% at 12 months.

Although the review found several pragmatic studies, most did not provide data on success rates. Of the two that did, one reported 66% of patients achieved 50% relief of pain at 2 months, and the other reported 33% having this outcome at 6 months. These results are consistent with those of the observational studies.

Of the five explanatory trials, three used TF injection of bupivacaine as the comparison treatment, but it is not known if TF bupivacaine is strictly an inactive treatment. Ostensibly, local anesthetic might have only a temporary relieving effect on pain, but long-lasting effects have not been formally excluded.

A fourth study used intramuscular saline as the control treatment, which should be acceptable as a suitably inactive treatment for radicular pain, but this control treatment was administered in a different manner—as an office procedure—from that of fluoroscopically guided TF steroids. As well, patients were randomized according to patient choice. Both of these factors compromise the internal validity of the study and demote it to providing only weak evidence of efficacy of TF steroids.

A fifth study used TF normal saline as the control treatment. With respect to pharmacologic activity, this served as an appropriate, inactive control, but it does not control for possible irrigation effects of TF injections.

The sixth study addressed all of these concerns. It randomized patients to TF steroids or TF bupivacaine, TF normal saline, intramuscular steroids, or intramuscular normal saline, each performed in a fluoroscopy suite with intramuscular injections mimicking TF injections. Under these conditions, TF bupivacaine controlled for the addition of steroids to a TF injection, TF normal saline controlled for the possible effects of simply irrigating the affected nerve, intramuscular steroids controlled for systemic effects of steroids, and intramuscular saline served as a credible sham control.

The first explanatory study did not report on relief of pain or other conventional outcomes. It used avoidance of surgery as the single outcome measure. It showed that TF steroids spared patients from surgery
significantly more often than did TF bupivacaine alone. Only 29% (±17%) of 29 patients required surgery during the 13 months after treatment with TF steroids compared with 66% (±18%) of those treated with bupivacaine. Furthermore, the surgery-sparing effect was maintained during a subsequent 5-year follow-up.\textsuperscript{91}

The weak explanatory study\textsuperscript{88} found that 84% (±14%) of 25 patients treated with TF steroids achieved at least 50% reduction of pain, accompanied by improvements of at least 5 points on the Roland-Morris Disability Questionnaire, persisting for 12 months. In comparison, only 48% (±20%) achieved these outcomes after intramuscular injections of normal saline.

The double-blind trial that compared TF steroids and TF bupivacaine followed patients for 12 weeks\textsuperscript{86} and was supplemented by a 1-year follow-up.\textsuperscript{87} It found no differences in outcome, based on group scores, but success rates were not reported. However, patients who underwent surgery or a repeat injection before 3 months were excluded from the analysis, as were 16 patients who failed to attend for review at 3 months. It is not evident the extent to which these exclusions may have compromised the comparisons of outcomes.

The study that compared TF steroids with TF normal saline initially found no differences between outcomes based on group data.\textsuperscript{89} However, a later analysis revealed several features.\textsuperscript{92} First, TF steroids were not universally successful. They were no more effective than sham treatment in patients with extruded or sequestrated disk herniations, but they were effective in those patients with contained disk herniations. TF steroids were significantly more effective than control treatment for reducing leg pain at 2 weeks and 1 month. As well, patients treated with TF steroids tended to have fewer sick days, fewer resorted to surgery, and twice as many had at least 75% reduction in pain (44% ± 20% compared with 21% ± 16%), but for these latter differences, statistical significance did not emerge because of the small sample sizes involved (25 and 24). However, what did emerge is that for those patients with contained herniations, TF steroids were significantly cost-effective at 12 months, achieving a cost reduction of $12,666 per responder.

The sixth randomized, controlled study was designed primarily to test if
the effects of TF steroids could be attributed to placebo. For that purpose, it evaluated responses at 1 month after treatment, but it also provided subsequent 12-month data. It found that the various control treatments had success rates for providing at least 50% relief of pain that were statistically indistinguishable. Some 15% (8% to 22%) of patients obtained at least 50% relief after treatment with TF bupivacaine, TF normal saline, intramuscular steroids, or intramuscular saline. The success rate for TF steroids was significantly greater at 54% (36% to 72%). Furthermore, this study showed that successful relief of pain was accompanied by restoration of function and clinically significant reduction—or elimination—of the need for other health care for radicular pain. All patients recruited for the study came from a neurosurgery unit, and all were destined for surgical treatment. Successful relief of pain by transforaminal injection of steroid (TFIS) avoided the need for surgery. During the 12 months after treatment, the success rate from the initial treatment deteriorated, but at 12 months, 11% of patients still had at least 50% relief of pain and a further 14% still had complete relief.

This latter study also revealed a pertinent feature about reporting outcomes. The study clearly showed that TF steroids had a success rate that was significantly greater than those of any of the compared treatments, both statistically and clinically. However, the distribution of outcomes was distinctly bimodal: success or no success. Consequently, the group data did not produce a statistically significant difference because they camouflaged this bimodal distribution. Only if and when success rates were compared did significant differences appear. For these reasons, studies that report only group data may miss detecting statistically and clinically significant data.

Since the publication of this review, a systematic review reinforced the surgery-sparing effects of TF injection of steroids for radicular pain due to disk herniation, and several studies have corroborated the observed success rates. One study found success rates of 70% at 3 months and at 6 months, with success defined as greater than 50% reduction of pain, coupled with 50% reduction in disability. A large study of 2,634 patients had a success rate of 52% at 2 months and 50% reduction in pain, coupled with 40% improvement in disability. A companion study of
1,078 patients had a success rate of 45% for these same outcomes. An additional study demonstrated that repeat injection could increase the success rate of an initial injection that provided partial relief or could reinstate relief if initial relief waned. Importantly, this study also showed that if TF steroids were used in a disciplined manner, few patients actually required more than three injections per year in order to benefit from repeat injections.

In patients with neurogenic claudication due to spinal stenosis, a large double-blind multisite pragmatic trial (N = 400) compared epidural administration of corticosteroid plus lidocaine versus lidocaine alone by both TF and interlaminar routes. In this patient population, there was no detectable difference between the groups in pain reduction or functional recovery.

**TRANSFORAMINAL INJECTIONS: DETERMINANTS OF EFFICACY**

It would be clinically useful to identify patient, imaging, or procedural characteristics which are predictive of a positive response to TF ESIs. Spinal cord physiologic changes of central sensitization may amplify intensity and duration of perceived pain; pain chronicity may be a clinical marker of this process. A systematic review pooled data from three studies and noted a significant, although weak, association; patients having pain less than 6 months had better outcomes after TF injections. Another study of >2,000 lumbar TF injections had ~60% responders for pain and functional recovery in patients with pain <3 months. For patients with pain greater than 6 months, there were ~35% responders for both measures. Two studies on disk herniation patients demonstrated an association between the degree of neural compression and outcomes; patients with lesser degrees of neural compression on magnetic resonance imaging (MRI) had better outcomes. This was not, however, confirmed in a subsequent analysis of over 500 injections in a more heterogeneous population that includes fixed bony lesions as well as disk herniations. This study also demonstrated an association between the nature of the compressive lesion and outcomes; there were more responders in the entire cohort for functional recovery in disk herniation patients than in those with
a fixed lesion. When data was stratified by steroid preparation, however, patients with fixed lesions who received dexamethasone were indistinguishable from disk herniation patients. Patients with tandem lesions—a proximal zone of significant central canal compromise with a second lateral recess or foraminal lesion—did less well than those with single level lesions.

The targeted delivery of the steroid preparation to the site of neural compression, in the ventral epidural space, lateral recess, or foramen, has also been shown to be associated with better clinical outcomes after TF injections.\textsuperscript{11,100,101} The clinical assessment of response to an epidural injection, and hence further decision making, can occur at 2 weeks postinjection, as pain and functional recovery responses at this time are strongly associated with longer term response.\textsuperscript{102}

**TRANSFORAMINAL INJECTIONS: ADVERSE EVENTS**

The safety concerns leading to the adoption of the nonparticulate steroid dexamethasone are discussed earlier; it must be recalled that this was prompted by case reports of spinal cord infarction. All used particulate steroids except a recent report describing a cord infarct with dexamethasone, but this report\textsuperscript{63} is incomplete in its description of the injection procedure and the injectate.

More revealing are large prospective studies collecting adverse event data on consecutive patients. A multi-institutional study reported on 15,000 consecutive TF injections performed using Spine Intervention Society procedural guidelines; there were no neurologic events, intraspinal hematomas, or infections.\textsuperscript{56} The most common minor adverse events were vasovagal reactions (1.3%), central steroid effects (2.6%), and transient increased pain (2.1%). A single-center study reported on >22,000 lumbar TF injections; there were no major adverse events.\textsuperscript{35} Symptom aggravation was described in 0.43%. In another single-center study of 1,300 lumbar TF injections, there were no major adverse events; minor events, primarily vasovagal reactions, were reported in 11.5%.\textsuperscript{103} An additional single-center study reported on nearly 4,000 lumbar TF injections.\textsuperscript{104} There were no major adverse events; the most common minor adverse event was transient increase in pain in 0.01% of injections. Thus, despite the
concerns raised by case reports, TF injections are very safe when performed according to evidence-based procedural guidelines.

**TRANSFORAMINAL INJECTIONS UNDER COMPUTED TOMOGRAPHY GUIDANCE: EVIDENCE, ADVERSE EVENTS**

A systematic review found that, although there were several publications that promoted the use of TF injections under CT guidance, most did not provide evidence either of efficacy or of effectiveness.\(^{105}\) Variously, the published studies assessed several interventions but without stratifying outcomes, claimed success but without defining success, and claimed success but did not provide baseline data or numerical outcome data to corroborate that claim.

Of the four accepted studies, the first treated patients with radicular pain due to disk herniation\(^{106}\) and second treated patients with spinal stenosis.\(^{107}\) Both reported significant decreases in pain scores but did not provide any data on success rates. The third study treated patients with disk herniation or foraminal stenosis.\(^{108}\) It reported that 62% (±16%) had 50% relief at 6 months. The fourth study\(^{109}\) reported results in a confusing manner. A distillation of those results suggests the following:

- Of 49 patients with disk herniation, 24 obtained lasting relief, with 90% of these having at least 50% relief, which amounts to a success rate of 44% ± 14%.
- Of 59 patients with foraminal stenosis, 22 had lasting relief, with 90% of these having at least 50% relief, which amounts to a success rate of 34% ± 12%.
- Of those patients with lasting relief, only 78% also ceased medications. Thus, the success rate for relieving pain and also ceasing medications may be lower than the success rates for relieving pain alone.

Conspicuously, the review\(^{105}\) found no evidence to support the claims of proponents that CT-guided TF injections were “more accurate” and “safer” than fluoroscopically guided injections. Although CT shows the target nerve, this feature does not make the procedure “more accurate” than placing a needle under fluoroscopy. Meanwhile, the existing literature
actually refutes claims of CT guidance being safer.

In the first instance, CT guidance incurs radiation exposure that is some five times greater than that of fluoroscopic guidance.\textsuperscript{105} Secondly, CT guidance is not immune to serious vascular complications. At least half of the complications described in case reports have occurred under CT guidance, but all were prior to the recognition of the risks associated with particulate steroids. Critical to the avoidance of vascular complications is the administration of a test dose of contrast medium in order to check for arterial uptake. Conventional CT guidance does not allow for this safety check.\textsuperscript{105} The single-plane, axial view of conventional CT guidance does not show arteries running cephalad of the point of injection. However, if multislice CT fluoroscopy is employed, with image acquisition as the injection is performed, and immediately following cessation of the injection, vascular uptake can be evaluated under CT.\textsuperscript{110} When performed in this fashion, rates of detection of vascular uptake approached those seen with DSI. In a large prospective series of consecutive patients using this technique, in all spine segments, no major adverse events were noted.\textsuperscript{56}

**TRANSFORAMINAL EPIDURAL STEROID INJECTIONS: THEIR ROLE IN TREATING THE RADICULAR PAIN PATIENT**

ESIs can never be seen as an isolated therapeutic intervention; they must be part of a holistic spine care program. Their role in the disk herniation patient is to diminish the inflammatory response that causes neural irritation and to allow time for the natural history of involution of the herniated disk material to play out. TF ESIs have also been demonstrated to enable more vigorous and effective participation in a rehabilitation program. In a prospective cohort study, patients who had failed conservative therapy and were consented for surgery were offered up to two TF injections followed by a rigorous rehabilitation program.\textsuperscript{111} At 1 year, 78% had avoided surgery, and 62% had minimal pain (Visual Analog Scale [VAS] <10/100) and near complete functional recovery (Roland-Morris Disability Questionnaire <3/24).

Epidural corticosteroids may thus be effective in symptom control, but they do not treat the underlying lesion, whether it be disk herniation
causing radicular pain/radiculopathy, with a favorable natural history, or fixed stenotic lesions, causing radicular pain or neurogenic intermittent claudication, whose natural history is less favorable, and where outcomes with epidural steroids are accordingly less positive. When positive outcomes for pain and functional recovery are achieved, but prove to be temporary, epidural steroids can be used as part of a longer term management program, being mindful of the endocrine side effects of chronic steroid use.

Intrathecal Drug Delivery in the Management of Pain

EDGAR ROSS and DAVID ARCELLA

During the past 25 to 30 years, implantable drug delivery devices designed for long-term continuous infusion of medications have become an increasingly important part of the armamentarium for physicians involved in the treatment of patients with intractable pain. Intrathecal drug delivery systems (IDDSs) are an important and effective tool for use in the management of noncancer pain, spasticity, and cancer-related pain, and potentially for other central nervous system (CNS) disorders. Over the past several years, there has been a shift away from utilizing IDDS for nonmalignant pain, but recent studies suggesting the usefulness of far lower drug doses than previously employed (microdosing) might change the current trend.

History of the Development of Intrathecal Drug Delivery Systems

The development of IDDS devices represents one of the most significant advances of the past several decades in the field of chronic pain management. The advent of intraspinal opioid therapy is directly linked to the discovery and isolation of opioid receptors in the early 1970s and the discovery of their existence in both the brain and spinal cord. Yaksh and Rudy,\(^1\) discovered that direct application of morphine to the spinal cord in experimental animals produced measurable analgesic effects, and several years later, it was shown that the intraspinal injection of morphine, epidurally or intrathecally, produced effective analgesia in humans. In 1981, the first report describing the continuous infusion of intrathecal (IT) morphine in patients with intractable pain due to underlying malignancy
was published. Since this initial publication, a sizeable body of literature has amassed detailing the application, safety, and efficacy of intraspinal opiates in the management of both acute and chronic pain.

Basic Pharmacology of Intrathecal Drug Administration

The safe and effective use of IT infusion therapy is predicated on a thorough knowledge of the pharmacology of the individual drugs and an understanding of the pharmacodynamics of IT or epidural drug delivery.

The distribution and absorption of a drug delivered directly to the cerebrospinal fluid (CSF) within the IT space is based on multiple variables. These can be divided into patient characteristics (age, height, weight, gender, spinal anatomy, and CSF volume and circulation), drug characteristics (baricity, volume, dose, concentration, temperature of solution, viscosity, and additives), and injection technique (patient position, level of injection, needle type and alignment, use of an IT catheter, and fluid dynamics) (Fig. 100.1). When reviewing the patient characteristics, one must consider the nature of the patient’s pain complaint and the desired drug target. Central receptors within the spinal cord itself are the target for IT drug infusion, whereas brain receptors are the desired target in systemic drug therapy. CSF characteristics are also consequential. The choroid plexus produces CSF at a rate of about 0.3 to 0.4 mL per minute, and the CSF itself circulates through the cerebral ventricles and is ultimately reabsorbed into the venous system through the arachnoid villi. CSF drug distribution was once thought to be primarily through bulk flow but now is thought to be mixing within the CSF produced by pulsatile blood flow (Fig. 100.2). Because of the relatively small volume of CSF in the spinal canal (about 75 mL) and the relatively slow clearance of hydrophilic drugs from the CSF, infusions of even small doses of hydrophilic compounds can result in relatively high concentrations of that drug at the target site of action within the spinal cord as well as significant concentrations within the brain, potentially leading to side effects. Lipid solubility of drugs plays an important role in determining both the spread of the drug within the IT space and its rate of
clearance from the CSF. More water-soluble (hydrophilic) substances like morphine do not readily cross the blood–brain barrier, and infusion into the lumbar IT space produces high lumbar CSF concentrations of the infused agent in a gradient from the caudal to rostral direction. In contrast, compounds that are more lipid soluble (hydrophobic) will be preferentially absorbed into the substance of the spinal cord or diffuse across the subarachnoid-dural barrier into the epidural space. Lipophilic drugs like fentanyl and sufentanil usually do not reach significant concentrations within the CSF and may be useful in producing more segmental analgesia without the supraspinal effects that occasionally occur with more hydrophilic drugs.

FIGURE 100.1 Three-dimensional drug propagation in the lower thoraco-lumbar regions starting from a concentration distribution simulated in a separate injection analysis. Contour plots (scaled to 50% of the initial concentration) after 0 minutes (A), 20 minutes (B), and 20 minutes (C) show decreased and homogenized drug concentration levels. A continuous implanted IT drug infusion has significant theoretical and practical advantages over bolus administration. The use of an implanted continuous IT drug delivery system provides a continuously consistent concentration of drug within the CSF. This is advantageous because the concentration gradient is the primary driving force for diffusion of a drug to its target site in the spinal cord. This method also results in more predictable concentration gradient and is generally associated with fewer adverse side effects than intermittent bolus administration of the same drug.

Selection of Agents for Intrathecal Drug Delivery

Many drugs have been developed specifically for continuous IT delivery; however, only three have been approved by the U.S. Food and Drug Administration (FDA) for use with IDDS: morphine, ziconotide, and baclofen. Although there have been many scientific studies examining the use of other drugs published in the scientific literature, their use is considered “off label,” as they have not undergone the rigorous testing required for regulatory approval.
The Polyanalgesic Consensus Conference (PACC) is composed of a group of experts in the use of IDDS that convenes every several years to update recommendations about the evidence-based use of IT drugs for the treatment of pain. The most recent PACC recommendations on IT drug infusion systems were revised in May 2016. This group recommends selecting the appropriate agent based on the nature of each patient’s pain. Decision making should include an effort to differentiate nociceptive, neuropathic, spastic, or mixed pain syndromes. The PACC recommends that use of FDA-approved agents should precede any off-label drug use, alone or in combination with other agents; off-label use should be reserved for those patients who cannot tolerate or fail to respond to FDA-approved agents. In selecting a drug or drug combination, the PACC used the available scientific evidence and expert input to develop two distinct algorithms: one for neuropathic pain and one for nociceptive pain. The regimens are ranked from first-line recommended therapy (supported by extensive clinical experience and published literature) through fifth-line treatment approaches (anecdotal evidence alone). Neuropathic pain generally responds to ziconotide, opioid plus local anesthetic, local anesthetic alone, clonidine plus opioid, and clonidine alone. Nociceptive pain generally responds to opioid, ziconotide, opioid plus local anesthetic, and local anesthetic alone. Care should be given to selection of medication or compounded medications because granuloma formation has been associated with higher concentrations and total daily doses of all opioids except fentanyl.

The PACC further makes distinct recommendations to allow for variations including localized and diffuse pain, cancer or terminal illness, and noncancer pain. Thus, it is important to consider age, type of pain, and anticipated duration of therapy when selecting an agent. Table 100.1 details these recommendations.

Specific Agents for Intrathecal Drug Delivery

**OPIOIDS**

**Morphine**

The discovery of spinal opioid receptors in the 1970s represents the initial event that spawned interest in the IT administration of morphine. Several types of opioid receptors have been identified (μ, δ, κ). μ Receptors are the most important subtype in so far as the major clinical effects of morphine are concerned. Indeed, high concentration of μ receptors have been identified in the dorsal horn of the spinal cord, the presumed spinal site of action of morphine and other opioids used for IT infusion. IT morphine is considered to be about 10 times more potent than the same dose administered epidurally and approximately 100 times as potent as the same dose given IV. The most commonly used conversion values for morphine are 1 mg IT morphine = 10 mg epidural morphine = 100 mg IV morphine = 300 mg oral morphine. It should be clearly understood that these figures represent estimates and that the relative potency of morphine administered by different routes may not be the same in all patients or in patients who have been receiving chronic systemic therapy.

The advantages of IT drug administration include the lack of an absorption phase and essentially 100% bioavailability. Because of the small volume of distribution (spinal CSF volume is approximately 75 mL) of morphine when injected or infused into the CSF, a dose of IT morphine yields significantly higher CSF concentration than that which occurs when given epidurally where significant vascular absorption occurs. In addition,
because the rate of elimination of morphine from the CSF and plasma is similar, the duration of action of IT morphine is relatively long. Following IT administration, morphine is not detectable in serum for the first 2 hours. Because morphine is a hydrophilic compound, there is slow rostral spread of the drug through bulk flow of CSF, one factor responsible for clearance of morphine from the CSF. This slow rostral spread is also thought to be responsible for the delayed respiratory depression that can occur following IT administration, particularly in opioid-naive patients. Studies have indicated that following IT infusion of morphine in the upper lumbar region, a steady-state concentration gradient develops over a period of about 72 hours, with a lumbar:cervical concentration ratio of around 7 to 8:1. Elimination of IT morphine occurs through vascular absorption through the blood supply of the spinal cord. CSF elimination of opioids in general is biexponential and dependent on the lipid solubility of the drug. With a single bolus injection of morphine, there is thought to be little metabolism of the drug. However, with chronic infusion, morphine is metabolized to morphine-6-glucuronide (M6G) which has been shown in animal studies to have a potency 10 to 45 times that of morphine itself. Preservative-free morphine is currently the only opioid that is approved for IT use by the FDA.

**Hydromorphone**

Despite the paucity of clinical studies, the use of IT hydromorphone as an alternate opioid has steadily increased. Hydromorphone was initially utilized for IDDS in patients who manifested intolerable side effects to IT morphine or inadequate analgesia. Indeed, based on the large clinical experience with hydromorphone, this agent has been recommended as a “line 1” agent by the most recent Polyanalgesia Consensus Conference. IT hydromorphone is approximately 5 to 6 times more potent than IT morphine and is somewhat more lipophilic. Perhaps its main attraction is that IT hydromorphone is generally associated with fewer side effects than is IT morphine.

**Fentanyl and Sufentanil**

There has been considerable human and animal research regarding the IT

4964
use of both fentanyl and sufentanil. Both fentanyl and sufentanil are highly potent μ receptor agonists which are highly lipid soluble. Both have a rapid onset (approximately 10 minutes) and relatively long duration of action (1 to 4 hours for fentanyl, 2 to 6 hours for sufentanil) following acute IT administration. Because of the lipid solubility of these agents, it is important that the tip of the delivery catheter be positioned within a few spinal segments of the segmental pain level. Although this is not particularly critical for treatment of axial lumbar and/or lower extremity pain, it is important for treatment of pain at more rostral levels. In such cases, if the catheter is not located relatively close to the segmental level of pain, the drug will be absorbed into the spinal cord preventing the development of adequate concentration at the intended target site.

Overall, the analgesic response to long-term infusion to either agent was favorable and relatively well tolerated. Effective dosages have been in the microgram range: 10 to 115 µg per day for fentanyl and 12 to 77 µg per day for sufentanil.

**Opioid-Induced Hyperalgesia and Intrathecal Opioids**

Opioid-induced hyperalgesia is a condition that is manifest by a dramatically augmented sensitivity to stimuli and often appears in those receiving long-term IT therapy with opioids. This is manifest as hyperalgesia, an exaggerated pain response to a stimuli that would normally be considered mildly noxious, like a pinprick and allodynia, pain that is produced by a normally nonnoxious stimulus, like light touch. This phenomenon has been increasingly recognized in patients who have been treated with long-term opioid therapy and is yet another potential cause of loss of analgesia with IT drug infusion. Opioid-induced hyperalgesia is not simply an escalation of the patient’s original pain condition. Rather, the “abnormal” pain often originates from an area that is anatomically distinct from the original pain. In some patients, pain seems to increase and become more diffuse over time despite gradual escalation in their opioid doses. It has recently been shown that opioid-induced hyperalgesia may also develop in the context of short-term therapy in the absence of physical dependence or withdrawal.7
LOCAL ANESTHETICS
Local anesthetics have played a central role in the treatment of pain for decades, although it was not until the 1990s that continuous infusion of these agents was routinely used. Currently, local anesthetics such as bupivacaine are commonly given by continuous chronic IT infusion, often combined with opiates for the treatment of both cancer and nonmalignant pain. In low concentrations, local anesthetics such as bupivacaine are nontoxic and alter neurotransmission in a predictable and reversible fashion.

Bupivacaine is the most common local anesthetic used for continuous IT infusion. It appears to be most effective in patients with a neuropathic component of pain, although it may also provide some degree of benefit for patients with nociceptive pain. The utilization and dose escalation of bupivacaine is mainly limited by its side effects, which include sensorimotor blockade at higher doses and hemodynamic instability. Usually, clinically relevant side effects do not occur with doses less than 15 mg per day, although administration of doses as high as 118 mg per day has been reported with apparently no adverse effects. Optimal dosing is reached with progressive titration beginning with a daily dose of 3 to 5 mg per day. There has been some interest in liposomal encapsulation for local delivery by the IT route because this tends to reduce the toxicity and cardiovascular effects while increasing the anesthetic duration.

Ropivacaine is a long-acting amide type of local anesthetic that is unique in that it blocks sensory nerve fibers to a greater extent than motor fibers. It is similar to bupivacaine in onset and duration of sensory blockade. The potential advantage of ropivacaine is that it produces less motor block and has less cardiac toxicity than bupivacaine. As of yet, there have been no clinical studies published on the long-term use of IT ropivacaine for the management of chronic pain.

Tetracaine is another local anesthetic that acts through blockade of sodium channels. Unfortunately, tetracaine has been shown to have direct neurotoxicity in animals manifested by damage to both the dorsal and ventral roots, chromatolytic deterioration of motor neurons, and vacuolation of the spinal cord. Because of the potential neurotoxicity, tetracaine should not be used for long-term IT drug delivery.
**α₂-ADRENERGIC AGONISTS**

α₂-Adrenergic receptors play an important role in spinal antinociception. α₂-Receptor agonists in general, and clonidine in particular, are believed to produce their antinociceptive effects through inhibitory interactions with both pre- and postsynaptic primary afferent nociceptive projections onto secondary neurons in the spinal dorsal horn. Clonidine in particular has been felt to act by postsynaptic activation of descending noradrenergic inhibitory systems. It has also been suggested that the analgesic effects of this class of drugs might also be produced through the inhibition of substance P (SP) release.⁰⁰ Clonidine-induced spinal analgesia is reversed by α-adrenergic antagonists such as yohimbine but not by naloxone, providing further evidence of its mechanism of action.

Clonidine is one of the best studied of the nonopioid agents that have been adapted for intraspinal delivery. Clonidine has been shown to have analgesic action in both cancer and nonmalignant pain syndromes when administered intraspinally.⁴ Clonidine is a highly lipid-soluble drug that is rapidly absorbed and eliminated from CSF. Bolus administration of IT clonidine results in dose-dependent analgesia at doses of 150, 300, and 450 µg, and effective analgesia has also been shown with continuous IT infusion. Intraspinal clonidine appears to be devoid of any local neurotoxicity. The rapid onset of antinociceptive action when given intrathecally provides a strong argument that the major pharmacologic effects occur at the segmental spinal level. However, delayed supraspinal analgesic effects cannot be completely discounted because it has been shown that application of clonidine to the locus coeruleus results in analgesia. Because IT injection does not usually result in high cisternal concentrations of clonidine, these supraspinal effects might be explained by systemic absorption and central redistribution of the drug.

Although clonidine is the most common drug in this class to be used for spinal analgesia, other agents such as epinephrine, tizanidine, and dexmedetomidine continue to be studied for spinal infusion. Because the antinociceptive actions of the α₂-adrenergic agonists (and most of the other alternative agents discussed later) occur through a nonopioid mechanism, they are often effective in individuals who have become tolerant to morphine or other opiates. These agents (clonidine in particular) shift the
opioid dose–response curve to the left and appear to be synergistic with opioids; in other words, the analgesia produced by the combination of clonidine with an opiate often results in a magnitude of analgesia greater than that produced by either agent alone. The major side effects of spinal clonidine include hypotension, bradycardia, and sedation. The hypotensive effects most commonly occur with lower and moderate doses and are generally counteracted at higher doses by a direct peripheral vasoconstrictive effect. Unlike the opiates, clonidine does not cause respiratory depression. Clonidine has been studied in various animal models for possible neurotoxicity prior to its clinical use and has been found safe.

Clonidine has become a popular agent for spinal infusion in patients with reflex sympathetic dystrophy (RSD), now known as complex regional pain syndrome (CRPS) type I. Rauck et al. studied the efficacy of epidural clonidine in 26 patients with severe pain from CRPS I using a randomized, double-blind, placebo-controlled design. Cervical or lumbar catheters were placed in patients with upper or lower extremity RSD, respectively. Epidural clonidine (300 or 700 µg) and placebo were randomly administered on 3 consecutive days, and the analgesic response assessed at specified intervals for 6 hours following injection using Visual Analog Scale (VAS) scores and the McGill Pain Questionnaire (MPQ). Patients considered positive responders were offered entry into a trial of continuous epidural clonidine infusion. Within 20 minutes of injection, both doses of clonidine but not placebo-produced significant reductions in both VAS and MPQ scores that persisted for the 6-hour study period. Blood pressure was reduced by a similar amount with both clonidine doses. Nineteen patients were subsequently treated with continuous clonidine infusion (32 ± 6 µg per hour; range 14 to 50 µg per hour) for 43 ± 8 days (range 7 to 225 days). Their VAS scores, which were measured at weekly intervals during infusion, were significantly reduced compared with those recorded prior to clonidine therapy. Clonidine is currently approved by the FDA for continuous epidural infusion. Clonidine is not currently approved for IT infusion.

Although clonidine has been the most widely studied of the $\alpha_2$-agonists, several other agents have also received attention as potential spinal
analgesic agents. Tizanidine is another $\alpha_2$-agonist that has shown promise as a potential analgesic substance. Leiphart et al.\textsuperscript{14} studied the effects of tizanidine in a rat model of mononeuropathic pain that is believed to mimic the hyperalgesia and allodynia typical of many neuropathic pain syndromes in humans. Tizanidine increased the intensity of the mechanical stimulus required to induce paw withdrawal and reduced the duration of limb withdrawal from both normal temperature and cooled surfaces in a dose-dependent fashion. The effects of tizanidine were limited to the hyperalgesic limb and served only to normalize reactive latencies. However, morphine affected both the experimental and unaffected hind limb and increased withdrawal latencies to supernormal values. These findings suggest that IT tizanidine may be more specific for the hyperalgesia and allodynia associated with neuropathic pain states and perhaps may be valuable in managing patients that exhibit these findings.

Dexmedetomidine, another $\alpha_2$-agonist with a higher $\alpha_2$-receptor affinity than clonidine, has been studied experimentally for its effects on neuropathic pain.\textsuperscript{15} A dose of 1 µg of dexmedetomidine or 10 µg of clonidine administered intrathecally following sciatic nerve section resulted in a significant reduction in autotomy behavior (self-mutilation thought to be a sign of neuropathic pain) compared with both IT morphine and saline controls. Interestingly, morphine (but not $\alpha_2$-agonists) caused a significant reduction in autotomy behavior when given prophylactically or before sciatic nerve section. This finding suggests that morphine may prevent autotomy if administered prophylactically, whereas $\alpha_2$-agonists may be useful for treating established pain on a chronic basis. This observation could potentially have practical implications on the prevention or treatment of certain pain states such as pain following peripheral nerve injury or phantom pain. To date, there have been no studies in humans to investigate the efficacy or toxicity of this agent when given intrathecally.

**CALCIUM CHANNEL ANTAGONISTS**

Calcium is a critical element in the regulation of intracellular processes, including modulation of neuronal excitability, release of neurotransmitters, activation of second messenger systems, and gene transcription. Calcium has been found to play an important role in nociception and pain.
transmission. Regulation of calcium entry into cells is controlled by voltage-sensitive calcium channels (VSCCs) consisting of at least six neuronal subtypes (L, N, P, Q, R, and T). VSCCs are abundantly expressed on presynaptic nerve terminals where they regulate the calcium-dependent release of neurotransmitters that control synaptic transmission. N-type VSCCs are concentrated in the most superficial laminae of the dorsal horn of the spinal cord, where most primary nociceptive afferent fibers (Aδ and C fibers) terminate. Selective antagonists of N-type calcium channels such as ziconotide (also known as SNX-111), a synthetic agent derived from ω-conopeptide that selectively binds to N-type VSCC, have consistently been antinociceptive in animal models of acute, chronic, and neuropathic pain.\textsuperscript{16,17} Based on animal studies, numerous studies of ziconotide have been conducted in humans to determine both safety and efficacy. Based on these studies, ziconotide was ultimately approved by the FDA for IT use in humans.\textsuperscript{18,19}

The most common side effects included mental confusion, word-finding difficulties, nystagmus, gait, and balance problems. The frequent side effects associated with IT ziconotide have limited the overall use of this agent.

**N-METHYL-D-ASPARTATE RECEPTOR ANTAGONISTS**

The involvement of excitatory amino acids (EAAs) and the N-methyl-d-aspartate (NMDA) receptor system in nociceptive transmission, along with a clearer understanding of the development of central sensitization and wind-up phenomena, have generated considerable interest in developing antagonists of this receptor for the treatment of chronic pain, particularly neuropathic pain states. NMDA receptors alter opioid receptor sensitivity in a variety of pain states and have been implicated in the development of both opioid tolerance and opioid-induced hyperalgesia. Ketamine has been the most studied and has been used both epidurally and intrathecally for the treatment of postoperative and chronic pain.

To date, the use of NMDA receptor antagonists has been limited due to side effects. All of the NMDA receptor antagonists to some extent produce phencyclidine-like side effects such as disinhibition, hallucinations,
paranoid delusions, and rises in arterial blood pressure. There is also animal data suggesting that some of the NMDA antagonists may be neurotoxic when administered intrathecally. Using a sheep model for IT infusion, Hassenbusch et al. conducted a randomized, double-blind toxicity study of three NMDA antagonists: dextrophan, dextromethorphan, and memantine. Gross and histologic examination as well as neurologic measures demonstrated that all three agents produced a dose-dependent chronic inflammatory response of the spinal cord that led to necrosis. Although these agents are not currently suited for widespread use in humans, their beneficial effects, especially on wind-up pain and hyperalgesia, suggest that further efforts should be directed toward developing an agent that retains its analgesic properties while eliminating most of the side effects.

**γ-AMINOBUTYRIC ACID AGONISTS**

γ-Aminobutyric acid (GABA) and glycine are inhibitory neurotransmitters that are widely distributed throughout the nervous system. The beneficial effects of GABA agonists such as baclofen in reducing both spinal- and cerebral-origin spasticity have been well chronicled. Less well known are the potential analgesic effects of these agents. GABA can be readily found within the pain transmission system, particularly in Lissauer’s tract, and in laminae I, II, and III of the dorsal horn of the spinal cord. Baclofen is a GABA-B agonist and has been shown to be analgesic when administered intrathecally in animals. The antinociceptive effects of GABA agonists are not reversed by naloxone, suggesting that GABA-aminergic analgesia is not mediated through endogenous opiates. IT baclofen diminished allodynic behavioral responses following IT administration of prostaglandin (PG) F\textsubscript{2α} and reduced c-fos gene expression in an animal model of neurogenic pain.

**GABAPENTIN**

The use of IT gabapentin has been evaluated in a number of rodent models. Injection of an IT bolus of gabapentin resulted in reduction in mechanical allodynia and thermal hyperalgesia. There was no demonstrable effect on acute nociceptive pain assessed by the formalin or
hot plate test. IT gabapentin produced no deleterious hemodynamic effects but did lead to mild neurologic dysfunction when dose in excess of 300 µg were used.

SOMATOSTATIN AND SOMATOSTATIN ANALOGUES

Somatostatin is a tetradecapeptide that is widely distributed throughout the CNS. Somatostatin was initially discovered by virtue of its ability to inhibit the secretion of growth hormone from the pituitary gland. However, its distribution is not limited to the pituitary axis. Indeed, somatostatinergic neurons can be found in the spinal cord, primarily in the substantia gelatinosa where they seem to exert inhibitory effects on nociceptive neurons. Somatostatin is also present in other areas of the CNS concerned with pain transmission and modulation such as the periaqueductal gray (PAG) and both ascending and descending pain-modulating systems in the brainstem. The presence of somatostatin in primary afferent axons that terminate in lamina II of the dorsal horn of the spinal cord, spinal interneurons, descending inhibitory pathways, and PAG presents a strong circumstantial argument for an antinociceptive role of this substance. Single cell recordings have indicated that somatostatin inhibits the responses of dorsal horn neurons to noxious stimulation. Somatostatin has been shown to elevate pain thresholds in experimental animals and has been reported to produce analgesia in humans when administered by either an epidural or IT route. The exact mechanism of action is unclear, although it does not appear to be opioid-mediated because the antinociceptive effects of somatostatin are not antagonized by naloxone.

Octreotide, a stable, nonenzymatically degraded, nontoxic analogue of somatostatin, has yielded promising results as a spinal analgesic for cancer pain. Penn et al. reported the efficacy and preclinical neurotoxicity of IT octreotide in six patients with terminal cancer. At a concentration of 500 µg/mL, octreotide was found to be stable within the SynchroMed model 8611 programmable infusion pump (Medtronic Neurological, Minneapolis, Minnesota) over a 4-week period. Insignificant concentration changes were measured at the catheter tip and within the pump drug reservoir. Preclinical toxicity testing in dogs showed no evidence of histopathologic
changes. Based on the stability and toxicity studies, six patients were treated with IT octreotide. Dosing was initiated at 2.5 to 5.0 µg per hour and increased by increments of 2.5 to 5.0 µg per hour to a maximum dose of 20 µg per hour or 240 µg per day as necessary to achieve pain control. Treatment was continued for periods of 13 to 91 days (mean duration 45.5 days). Baseline mean VAS scores of 9.7 were significantly reduced to 1.7 after 1 week of treatment. Although VAS scores increased to 3.6 at 1 month, the improvements remained statistically significant. The same authors have reported long-term experience with octreotide in two patients with nonmalignant pain. Although this experience is modest if not anecdotal, it nevertheless provides additional evidence for a sustained analgesic effect of IT octreotide in nonmalignant disease states.

There does appear to be some element of tolerance, necessitating upward titration of the dose over time. Although octreotide does in fact produce analgesia, many factors currently make this agent impractical for widespread clinical use. First, the commercially available preservative-free preparation comes at a concentration of 500 µg/mL, necessitating frequent refills. Additionally, in order to avoid damaging the infusion device, the pH must be adjusted. Perhaps the most important factor is the extreme cost—in excess of $20,000 per year—which makes this agent unsuitable. Notwithstanding the limitations of octreotide, these results should prompt further investigation into the development of other somatostatin analogues that might be equally effective but more practical for clinical development.

**TRICYCLIC ANTIDEPRESSANTS**

Tricyclic antidepressants (TCAs) have long been known to participate in the modulation of pain transmission. The analgesic effects of TCAs are believed to be mediated through effects on monoaminergic and serotonergic pathways in the CNS, specifically, prevention of reuptake of these transmitters. In vitro testing has also shown that the TCAs bind with the NMDA receptor complex, possibly meaning that the antiallodynic and hyperalgesic effects of the TCAs are mediated via an NMDA receptor mechanism. The effect of IT TCAs on pain behavior has been studied in several animal models. Presently, IT administration of TCAs in humans is not possible due to the lack of preclinical toxicity data, the observed
development of motor impairment at high doses in rat experiments, and the unavailability of preservative-free preparations. However, the profound reduction in hyperalgesia and the synergistic effect with opiates provide ample reason to pursue and develop this class of agents as an effective mode of pain control.

ACETYLCOLINESTERASE INHIBITORS
Acetylcholine (ACH) is a ubiquitous neurotransmitter in all parts of both the central and peripheral nervous systems. Choline acetyltransferase, the rate-limiting enzyme in the synthesis of ACH, is abundant in nerve terminals within the dorsal horn of the spinal cord. Moreover, the presence of acetylcholinesterase in certain descending raphe-spinal projections implies that ACH may be implicated in the modulation of nociception. ACH diminishes the response of dorsal horn interneurons to EAAs. Some neurons are depolarized by cholinergic substances, whereas others become hyperpolarized. IT administration of both muscarinic and nicotinic agents has indicated that analgesic effects are mediated only through muscarinic receptors. Animal studies have shown that spinal neostigmine produces analgesia (albeit transiently) and also enhances the analgesia provided by IT clonidine but with fewer side effects.

Based on animal data, human applications of the use of IT neostigmine have been performed. Hood et al. studied the effects of IT neostigmine in 28 healthy volunteers. Although IT administration of neostigmine was antinociceptive to a noxious cold stimulus, significant side effects occurred, including nausea, vomiting, reversible lower extremity weakness, and, at larger doses, tachycardia and hypertension. Although neostigmine alone is probably not suitable based on the side-effect profile, further studies may be warranted using this agent in patients who have become tolerant to opiates.

ADENOSINE
Although the results have been conflicting, some studies have demonstrated that adenosine, an endogenous nucleoside, and its analogues may participate in pain modulation. Belfrage et al. performed an open-label trial to determine the safety and efficacy of IT adenosine in 14
patients with neuropathic pain accompanied by tactile hyperalgesia or allodynia.\textsuperscript{31} Patients were given IT injections of either 500 or 1,000 $\mu$g of adenosine ($n = 9$), and areas of tactile pain were mapped. Spontaneous and evoked pain were assessed (VAS scale of 0 to 100) before and 1 hour after injection. Median VAS scores for spontaneous and evoked pain were reduced from 65 to 24 ($P < .01$) and 71 to 12 ($P < .01$), respectively. Parallel increases in tactile pain thresholds in areas of allodynia were also observed. The median reduction in the area of tactile hyperalgesia/allodynia was 90\% ($P < .001$). Twelve of the 14 patients experienced pain relief for a median of 24 hours. The only noted side effect was transient lumbar pain at the site of injection.

**NITRIC OXIDE**

Nitric oxide (NO) is synthesized from L-arginine by activation of NO synthase. Because NO easily penetrates cell membranes, it has been identified as a substance that may potentially act like a neurotransmitter. Because synthesis of NO is induced through an NMDA receptor mechanism, and because NMDA receptors have been implicated in the wind-up phenomenon, NO may in fact participate in the development of this pathologic state. There is evidence of increased synthesis of NO in the dorsal root ganglion animal models of neuropathic pain. Malmberg and Yaksh\textsuperscript{32} have injected arginine analogues that functionally inhibit NO synthesis intrathecally and found that they induce a dose-dependent reduction in the formation of the hyperalgesic state. Although there are currently no human trials to evaluate the role of NO synthesis inhibitors, this may represent fertile ground for future research.

**PROSTAGLANDIN INHIBITORS**

PGs are another well-known group of substances that participate as neurotransmitters. PGs are synthesized at the spinal cord level in the identical way to that which occurs systemically. Activation of the NMDA receptor and subsequent calcium influx are thought to lead to activation of phospholipase A\textsubscript{2} and ultimately to the formation of cyclooxygenase products. PGs increase calcium conductance in dorsal root ganglion cells, thereby increasing the release of SP and other peptides. Potentially,
inhibition of IT PG formation might result in a reduction in neurotransmitters such as SP, thereby decreasing nociception. The effects of nonsteroidal anti-inflammatory agents are mediated through inhibition of PG synthesis. In fact, recent attention has been directed toward evaluating the analgesic effects of IT nonsteroidal agents. Malmberg and Yaksh have studied the effects of IT ketorolac on nociception. IT ketorolac was found to inhibit the development of hyperalgesia in a rat model of neuropathic pain, but it had minimal effect on the acute phase of pain. When administered concomitantly with morphine, ketorolac produced a synergistic analgesic effect on both the fast and slow components of pain. Further research is obviously needed to define the exact role of the various PG substances as they relate to pain transmission as well as to study the potential for spinal toxicity.

**CALCITONIN GENE-RELATED PEPTIDE ANTAGONISTS**

Calcitonin gene-related peptide (CGRP) is another neuropeptide found in dorsal root ganglion cells, Aδ and C fibers, Lissauer’s tract, and the terminals of primary afferents in laminae I, II, and V of the dorsal horn. There are two types of CGRP and perhaps as many as four receptor subtypes. A noxious thermal stimulus has been shown to result in increased levels of CGRP in lamina II or the substantia gelatinosa. Moreover, some studies have shown that IT administration of CGRP actually increases nociceptive transmission, although the data on this are conflicting. It has been suggested that CGRP may enhance the effects of SP by either inhibition of the enzyme that degrades SP or augmentation of SP release. Yu et al. showed that, although IT administration of CGRP does not produce any apparent effect on pain transmission, IT injection of CGRP 8-37, a known CGRP receptor antagonist, does induce a dose-dependent reduction in nociception. Notwithstanding the work of Yu et al., the conflicting evidence regarding CGRP indicates that the role of this substance needs to be more clearly defined before human trials of CGRP antagonists can be conducted.

**SUBSTANCE P ANTAGONISTS**
SP belongs to the family of substances known as the tachykinins. It is believed to be involved in the transmission or modulation of nociceptive information. SP is stored in synaptic vesicles in primary afferents located in laminae I and II of the dorsal horn and preferentially binds to the NK1 receptor. Based on SP’s presumed role in pain transmission, studies have focused on whether antagonists of SP may be effective in producing analgesia. Again, data are conflicting regarding the effects of IT SP antagonists. Unfortunately, further studies have been hampered by the fact that these substances are neurotoxic and subject to rapid biodegradation, thus hindering application to human clinical trials.

**Patient Selection for Intrathecal Drug Delivery**

In selecting appropriate patients to undergo trial and ultimately permanent implantation of an IT drug delivery device and continuous IT infusion therapy, appropriate patient selection is critical to success. Proper patient selection includes consideration of disease-specific indications, comorbid disease, previous systemic medication use, sustainability, economics and anticipated duration of IT therapy, patient goals of care, as well as psychological assessment and social support evaluation. When assessing potential candidacy for implantation, one needs to ensure that the patient candidate has already participated in multidisciplinary care and has tried the maximum oral therapeutic medications available. Of these patients, potential implantation candidates are those who have failed optimization of oral therapy or are not able to tolerate the adverse side effects of systemic medications.

Disease-specific indications include patients who have chronic intractable axial neck or back pain and are not candidates for surgical intervention and patients with failed back surgery syndrome, abdominal/pelvic pain, extremity pain, CRPS, trunk pain, or cancer pain either caused by direct invasion of tumor or as a result of therapy directed against malignancy. Patients may also be considered for IT drug delivery if they receive moderate pain relief with use of systemic opioids but are not able to tolerate the adverse effects of systemic therapy. Table 100.2 lists some of these common diagnosis.
TABLE 100.2 Common Diagnosis Treated with Intrathecal Therapy

- Axial neck or back pain; not a surgical candidate
  - Multiple compression fractures
  - Discogenic pain
  - Spinal stenosis
  - Diffuse multiple-level spondylosis
- Failed back surgery syndrome
- Abdominal/pelvic pain
  - Visceral
  - Somatic
- Extremity pain
  - Radicular pain
  - Joint pain
- Complex regional pain syndrome (CRPS)
- Trunk pain
  - Postherpetic neuralgia
  - Postthoracotomy syndromes
- Cancer pain, direct invasion, and chemotherapy related
- Analgesic efficacy with systemic opioid delivery complicated by intolerable side effects

Comorbid conditions should be carefully considered in patient selection. Patients who are undergoing radiation or chemotherapy for treatment of malignancy may exhibit poor wound healing or be more susceptible to infection from therapy-induced neutropenia. A patient may be a good candidate for implanted IT drug delivery but may require coordination of implantation timing to coincide with a break in other therapies to allow for optimal conditions to undergo the surgery of implantation itself. Presence of coagulopathy or concomitant use of anticoagulants must be closely considered (e.g., a patient who has an extensive history of thrombotic events with any cessation or decrease in anticoagulation therapy might not be a candidate for implantation), as the risks of stopping anticoagulation might exceed the potential benefit of IT pain therapy. Care must also be given to the review of a candidate’s medication list and various comorbidities. Specifically, one must assess any perturbations in the cardiopulmonary system that may be impacted by the introduction of sedating and respiratory depressant IT medications as well as their interactions with the patient’s current regimen.

Previous systemic medication use comes into play in assessing the potential efficacy of utilizing implanted IT drug delivery systems. If a
The patient has shown evidence of analgesia with the use of a systemic opioid medication but is intolerant of the systemic adverse effects of opioid medication, they may be considered a stronger candidate than one who has not shown any relief with the use of systemic opioid medications. The patient’s previous systemic medication usage also comes into play when attempting to determine dosing for both the trial phase and after implantation.

Sustainability, economics, and anticipated duration of therapy are important considerations in patient selection. The upfront cost of implantation of IDDS can be quite significant. The combined cost of the implanted device itself, along with operating room time and associated staff costs and the total hospital stay all figures into determining the total financial impact of employing this therapy. Hasselbusch et al. in 2013 determined that when treating cancer pain, implanted IDDS achieved cost equivalence at an average of 7.4 months when compared to high-cost conventional therapies including high-dose opioids, nongeneric drugs, and parenteral drug administration. Kumar et al. determined that the crossover point where conventional therapy exceeded IDDS in treating nonmalignant pain was at 28 months.

Patient goals of care, psychological assessment, and social support evaluation are important to consider in evaluating a patient for potential implantation. With most patients treating malignant pain, the goals are usually palliative and in line with improving the patient’s quality of life in their remaining time. An implanted IT drug delivery device should strongly be considered if a patient’s main goal of care is to remain at home in the company of their family, as it can aid in achieving this goal. In patients with intractable pain associated with advanced illness, detailed psychological screening is often omitted. However, in selecting patients with nonmalignant pain, it is important to perform careful psychological screening while discussing and defining clear patient expectations of treatment and making clear the need for ongoing close follow-up for IDDS refill and management (see Chapter 76 for a detailed discussion of psychological screening in selecting patients for IDDS). It should be emphasized that the purpose of the psychological evaluation is not to simply “clear” or, for that matter, exclude the patient for an implant but
rather to gain an understanding of the psychological factors that might influence the outcome in a particular patient. It is also important to realize that although a given patient might initially be noted to have an unfavorable psychological profile, this does not necessarily constitute an absolute contraindication to implantation at some time in the future. Patients who are willing to work with a psychologist and/or psychiatrist can progress to the point where they are appropriate candidate for IDDS at some point in the future. Table 76.3 lists referral guidelines for presurgical psychological screening.

Each patient should undergo a detailed pain history that includes a review of all prior pain treatments and the results of such treatments. A history of lack of benefit from all prior treatment is a poor prognostic sign. A relatively recent spinal imaging study should be reviewed to exclude obvious, surgically correctable conditions such as spinal stenosis or spinal instability and to assure that there is no pathology that would otherwise preclude safe placement of an IT catheter.

Contraindications to pump implantation include the presence of systemic infection, local cutaneous infection near the potential surgical sites, uncorrectable coagulopathy, known allergies to components of either the pump or catheter, and active IV drug use. Further challenges include emaciation or patients with a body habitus that may not be conducive to an implant in standard locations (i.e., inadequate subcutaneous tissue to create a pocket for the implanted pump). Careful consideration must be given to patients receiving anticoagulation therapy. Although implantation is not contraindicated in these patients, all anticoagulations must be reversed prior to any type of invasive procedure. Patients with an unfavorable psychological profile should not be considered for IDDS until any psychological concerns have been addressed and resolved. Although recovering drug addiction is not an absolute contraindication, these patients need careful assessment prior to proceeding with this therapy; it is important to understand that placement of an IDDS device does not lead directly or inevitably to cessation of all oral opioids.

Trialing Techniques for Intrathecal Drug Delivery
Prior to implantation of a permanent IDDS device, patients should undergo some type of screening trial to determine the effectiveness and potential drug-related side effects. Even before proceeding with the trial, it is imperative that the patient and physician establish the specific goals for determining success of the trial. Goals are not necessarily uniform across all patients but must be individualized on a case-by-case basis, depending on the particular circumstances. One of the goals, and probably the most important goal from the patient’s point of view, is pain reduction. Most of the published literature defines a successful trial as a 50% reduction in the patient’s pain. Although 50% pain reduction would seem to be a reasonable achievement in the chronic pain population, this figure should not be used as the sole determining factor of the success or failure of an individual trial. There are patients for whom a lesser reduction in pain is sufficient and results in improvement in activities, reduction in medication use, and other beneficial effects. There are also patients who will be disappointed with the outcome if they experience anything short of complete pain resolution. Some patients have difficulty with the realization that they will have some degree of pain for the duration of their life. These patients often struggle with discontinuing systemic opioids following pump implantation, demand frequent increases in their IT drug dose, and generally do not demonstrate the kind of improvement in function commensurate with their stated degree of pain reduction. Such patients often pose difficult long-term management problems; thus, it is imperative that the implanting physician clearly outlines the reasonable benefits and expectations of the therapy before proceeding with the trial. By establishing reasonable goals and expectations at the outset, future problems can often be avoided. Clinicians who fail to follow this basic principle will, more often than not, be left to deal with an unhappy and frustrated patient.

Although pain reduction is important, perhaps the more important and revealing outcome measure is improvement in function. The type and degree of functional improvement will vary between patients. Nonetheless, it is important to establish reasonable goals for functional improvement that can be measured and confirmed after institution of IT drug delivery. Physical and occupational therapists can be quite valuable in assisting the
clinician in developing achievable goals and monitoring the patient during therapy. These individuals also provide an independent evaluator in evaluating the outcome of treatment. Besides improvement in physical function, other important and useful measures of outcome include improvements in vocational activity (i.e., return to work, increase in social and vocational activities, improvement in sleep patterns, improvement in mood/affect, reduction in adjuvant medication use, and reduction in health care utilization). There exist a number of valuable standardized and validated measurement tools that can be utilized to assess outcomes. These include tools such as Short Form Health Survey (SF-36), the Brief Pain Inventory (BPI), various mood scales, etc. These questionnaires can be administered prior to treatment and at various intervals thereafter to provide objective measurements that can then be correlated with the patient’s reported degree of pain reduction. Careful patient selection is the key to success of IDDS. Table 100.3 lists various approaches and doses for IT or epidural trials.

</table>
Aside from the criteria that will be used to determine the success or failure of the trial, there are a number of issues to consider in designing an IT trial, including (1) the method that will be used for screening, (2) duration of the trial, (3) which drug to use and what starting dose, (4) the potential use of a placebo, and (5) what to do with systemic opioids during the trial. There are several accepted screening methods available for IT trials including single IT bolus injection, multiple IT boluses, continuous epidural, or IT infusion.

There is currently no clear consensus among clinicians as to the ideal trial technique. Each has its advantages and disadvantages. The single IT bolus represents the simplest, most cost-effective method of screening for IT drug delivery. However, depending on the dose injected, bolus injection may result in subanalgesic drug levels, thus producing a “false-negative trial.” Additionally, drug-related adverse side effects are generally more common following bolus injection than continuous infusion, and these side effects may obscure the analgesic response. There is also a higher likelihood of a placebo response when using a single injection technique. Even though a single low-dose bolus of opioid produces a positive response, it is difficult to determine an accurate starting dose for the implanted pump. Finally, although single shot bolus trials are simple to perform, they do not provide the ability to evaluate the effect of the therapy on function as well as some of the other outcome measures that have been discussed. Although multiple IT boluses are more costly and time-consuming, they do provide the ability to titrate the dose and establish a dose–response curve. It is also possible to employ placebo injections for comparison with active drug administration using multiple boluses during the trial. On the other hand, multiple boluses are often associated with an increased incidence of side effects, lack of correlation with the results of continuous infusion, and require multiple dural punctures unless a temporary IT catheter is used.

The continuous or functional trial is probably the one preferred by the majority of implanters. In fact, in a survey of implanters at academic teaching institutions conducted in 1999, 52% indicated they preferred continuous infusion for performing screening trials. Fifty-nine percent of
Implanters utilized the IT route, 17% used epidural infusion, and 22% employed both routes at various times.\textsuperscript{38} Intuitively, it would seem that continuous infusion would have clear advantages over bolus techniques. Continuous infusion can be performed using either the IT or epidural route. Although either is acceptable, it is important to understand the difference between IT and epidural drug delivery (Table 100.4).

Regardless of the route chosen, continuous infusion allows for controlled dose titration and assessment of a reasonable starting dose once the pump is implanted. On balance, there is a lower risk of side effects with continuous infusion. There is also less chance of a placebo response because continuous infusion allows for the placebo response to dissipate over time as the trial is continued. Perhaps, most importantly, a continuous trial, particularly if continued for a sufficient period of time, allows for assessment of functional outcome which is perhaps the most important determining factor of success. Notwithstanding the advantages, there are some relative disadvantages to continuous infusion. It is more complicated and requires greater expertise for placement of a tunneled catheter and is obviously more costly to perform than a bolus trial.

LP, lumbar puncture.

For opioid-naive patients or those on relatively low oral doses, a tunneled externalized IT catheter can be placed in the operating room and a continuous functional outpatient trial conducted for anywhere between 2 and 4 weeks. By providing the patient a drug holiday, it is possible to begin the IT infusion at very low doses (usually around 0.25 to 0.5 mg per
day of IT morphine) of medication. For patients with nociceptive pain or mixed nociceptive/neuropathic pain, an opioid is typically used. If the pain is predominantly neuropathic, bupivacaine or clonidine is added to the infusion. The patient is evaluated at least three times per week to determine the analgesic response, degree of functional improvement, and the development of side effects. Incremental dose escalation is performed and if a significant degree of pain reduction or functional improvement is not realized by the time the patient reaches 2 to 4 mg of IT morphine (or its equivalent) per day, the trial is terminated and the catheter is removed. The success or failure of the trial is based on the goals that have been agreed on by the clinician and patient prior to proceeding with the trial. If the trial is deemed a success, the patient is then returned to the operating room for revision of the catheter and implantation of the pump. Patients are provided short-acting opioids during the immediate postoperative period for management of surgical pain and these are weaned and discontinued over a 2-week period. Patients are routinely counseled that they may experience incident pain that will typically be transient depending on their daily activities and are provided with nonpharmacologic coping strategies for managing these situations.

Of note, the 2017 PACC consensus guidelines on IT drug delivery states that no single study has shown that a continuous IT trial is superior to other methods of IT trialing in noncancer pain.\textsuperscript{39} There are equal levels of evidence for single shot trialing, bolus trialing, and continuous infusion. Other issues that need to be addressed include the duration of the trial, the specific medication(s) and dosages administered, and the handling of baseline systemic opiates during the trial.

There is currently no standard protocol that defines the optimal trial duration, trialing with specific medications, or how to handle baseline opioids during the trial. According to the 2017 PACC consensus guidelines, there are four possible scenarios for managing oral/systemic opioids during and after the IT drug trial.\textsuperscript{39} The first scenario is that the patient remains on oral systemic opioids throughout the trial and implantation of the IT drug delivery device. The second scenario is that systemic opioids are eliminated prior to trialing and implantation. The third scenario is that the systemic opioids are reduced during the
trial/implant. The fourth scenario is that the systemic opioids are reduced during the trial and eliminated after the implant. There are advocates for employing each of these strategies, but great caution should be employed when considering concurrent use of IT and systemic opioid medications as there is an increased risk for adverse effects from additive effects. Ideally, patients should be positioned for dose reduction and or elimination of systemic opioids when considered for implanted IT drug delivery. The majority of patients being considered for implanted IT drug devices have been on or are currently taking chronic systemic opioid medication, and many will have opioid tolerance and hyperalgesia. In this set of patients, it may be very difficult to assess the efficacy of therapy during the trial, and consideration should be given to weaning or eliminating systemic opioid medications prior to trial.

**Implantable Pump Technology**

Fully implantable infusion pumps were first used for the continuous delivery of heparin, insulin, and intraarterial chemotherapy and later applied to intraspinal drug infusion. There are two basic types of fully implantable devices for continuous delivery of IT medications: constant flow pumps and programmable pumps.\(^{40,41}\)

The first-generation pumps were constant flow devices preprogrammed to deliver medication at a single, fixed, constant rate. The initial prototype of the constant flow pump consists of a hollow titanium two-chambered device which consists of a drug reservoir and a chamber that contains a volatile two-phase fluorinated hydrocarbon (FHC) which functions as a propellant. Installation of medication into the drug reservoir results in compression of the propellant which transforms it to a liquid state. As the propellant is warmed by the patient’s body temperature, the FHC is transformed from liquid to vapor which then exerts continuous pressure on a system of bellows which expand and force the drug out of the reservoir and into the IT catheter. The standard pump holds a volume just under 50 mL and is filled by puncturing a special inlet septum with a noncoring Huber needle. Flow rates designed to deliver 1.0 to 6.0 mL per day are preset and calibrated at the factory. Although this pump is relatively
simple and inexpensive compared to fully programmable devices, the
major disadvantage is that dosage alterations require the pump to be
drained and refilled with a different concentration of drug. Also, flow rates
can be altered by certain physical and physiologic factors, and these
fluctuations in drug delivery rate can result in parallel fluctuations in
analgesia (Table 100.5).

The second type of fully implanted drug delivery device is a fully
programmable pump such as the SynchroMed infusion system (Medtronic
Neurological, Minneapolis, Minnesota) or a Flowonix infusion system
(Mt. Olive Township, New Jersey). The current model (SynchroMed II)
consists of a collapsible drug reservoir into which the drug is injected
through a self-sealing septum. The pump is powered by a lithium–
cadmium battery which drives an internal peristaltic pump. The pump
contains an electronic module with a computer chip which allows one to
program variable infusion rates, bolus injections, etc. A small
radiofrequency antenna allows the pump to be noninvasively interrogated
by telemetry and programmed with an external handheld programmer. The
pump can be programmed for a variety of delivery modes which can be
tailored to the individual circumstances. The pump comes with a catheter
access port (CAP) side port which is extremely valuable for
troubleshooting catheter-related problems.

**SURGICAL TECHNIQUE OF PUMP IMPLANTATION**

Implantation of an IDDS system is usually a straightforward procedure for the properly trained and experienced implanter. Despite the perceived simplicity of the implant procedure, there are numerous pitfalls that can lead to complications. Many complications can be avoided through attention to meticulous aseptic operative technique, gentle tissue handling, and adherence to certain technical points during catheter insertion and pump implantation.\(^{42}\)

Implantation of an IDDS can be performed either under local anesthesia with IV sedation or general anesthesia, depending on the clinician’s preference and the overall condition of the patient. All patients should receive a single dose of prophylactic antibiotics directed toward the normal skin flora within 30 minutes of incision. Typically cefazolin 1 to 3 g based on the patient’s weight (clindamycin 600 mg IV if they have an allergy to β-lactam medication) is sufficient for prophylaxis. The patient is positioned and secured in a lateral decubitus position taking care to pad the patient’s pressure points and using an axially roll to alleviate pressure to the dependent brachial plexus. The pump can be placed on either side, either in the subcostal region or lower quadrant of the abdomen. It is important to position the pump such that it does not impinge on or sit directly over any bony prominence (e.g., iliac crest, or rib cage, as this is likely to result in local pain and the need for revision of the pump pocket site). Other factors that occasionally need to be taken into account include the presence of either current or expected ostomies and body habitus. Although implantation of a pump is not absolutely contraindicated in those with ostomies, there is likely a higher risk of infection and every effort should be made to implant the pump as far from these sites as possible.

Prior to pump implantation, all patients should undergo an appropriate imaging study of the spine (computed tomography [CT] with IV contrast, CT myelography, or magnetic resonance imaging [MRI]) to ensure there is no anatomical obstruction that might preclude safe catheter insertion. The first step is to insert and properly position the catheter in the subarachnoid space.\(^{42}\) This should always be performed with the use of intraoperative C-
arm fluoroscopy to verify the correct position of the catheter. A small stab incision is made in the midlower lumbar region based on fluoroscopic imaging. Keeping in mind that the spinal cord terminates at the T12 or L1 vertebral level, needle entry should be caudal to this level, ideally at L2–L3 or L3–L4. The exact insertion site may vary depending on the spinal anatomy and the presence of spinal instrumentation. A lumbar puncture is performed using a paramedian approach with a shallow insertion angle (the angle between the plane of the skin’s surface and the axis of the needle shaft) to facilitate catheter advancement and reduce the chance of kinking and fracture. After obtaining good flow of CSF, the catheter is inserted through the needle and is threaded rostrally. Either a one- or two-piece catheter can be used, depending on the clinical situation and the preference of the implanter. The catheter should pass easily with minimal resistance. Under no circumstances should the catheter be forced passed the point of an apparent obstruction or withdrawn. Advancing the catheter against resistance can lead to inadvertent entry of the catheter into the substance of the spinal cord, resulting in serious neurologic sequelae; withdrawing the catheter through the needle can lead to shearing of the catheter. The tip of the catheter should generally be positioned in the uppermost portion of the lumbar cistern (Fig. 100.3). The guide wire is then removed by straightening the catheter and applying gentle traction to the guide wire. CSF should be flow spontaneously from the end of the catheter; occasionally, it is necessary and to insert a blunt-bevel needle in to the catheter and attach a syringe to, then gently aspirate to establish CSF flow. Once CSF flow is confirmed, the tubing is temporarily occluded with an atraumatic clamp to prevent CSF loss.
The Tuohy needle is left in place to prevent inadvertent damage to the catheter during dissection. A skin incision is made incorporating the needle, and dissection is carried down to the lumbodorsal fascia. A small pocket is then fashioned to accommodate a loop of catheter in the subcutaneous tissue of the lumbar region. This loop prevents kinking and reduces strain between the distal and proximal portions of the catheter that can occur as the patient flexes and extends the lumbar region after implantation. The needle is then withdrawn leaving the catheter in place. The catheter is anchored using a standard anchoring devices close to where the catheter enters the fascia to prevent migration using nonabsorbable suture.

With the catheter secured in place, the next step is to create a
subcutaneous pocket in the abdominal region to accommodate the pump. The pocket should be sufficiently large to easily accommodate the pump and allow closure of the wound without any significant tension. Care should be taken to avoid making the pocket too large as this can lead to the pump inverting within the pocket. Once an adequate pocket has been created, a tunneling device is passed through the subcutaneous tissues from the pocket to the lumbar paraspinal incision. Care must be taken to palpate the tip as the tunneling device is advanced to prevent the device from penetrating in to the abdominal cavity. The catheter is then passed through the hollow tunneling device and the device is removed, leaving the catheter in the subcutaneous tunnel with the tip now exiting from the abdominal pocket. Continued flow of CSF should be confirmed from the end of the catheter. If a two-piece catheter is used, the distal (i.e., IT) catheter is trimmed by an appropriate amount (if so desired) and then connected to the proximal catheter using a pin connector; this connection is then covered with a strain relief sleeve to prevent kinking at the connection site. This pin connector is then used as a second anchoring site, thereby creating a gentle strain relief loop between the fascial anchor and the pin connector. The amount of the distal catheter that is trimmed should be measured and recorded to be able to accurately calculate the catheter volume for subsequent drug delivery programming. Once the pump has been prepared and filled with drug (the technique will vary depending on the type of pump), it is brought onto the surgical field and connected to the catheter. The pump is then placed into the subcutaneous pocket, ensuring that the refill side is toward the skin and secured in place with nonabsorbable sutures, utilizing either the suture loops attached to the pump or by placing the pump into a Dacron pouch and securing the pouch to the fascia. Securing the pump to the fascia significantly reduces the chance of the pump inverting. Any excess proximal catheter should be gently beneath the pump, taking care to avoid kinking the catheter. A generous amount of catheter should be left in the pouch, as this will create an additional strain relief loop in the system. After securing the catheter and anchoring the pump, the CAP (if there is one) should be entered with a 24-gauge noncoring needle and CSF aspirated. A small amount of nonionic preservative-free contrast can be injected to confirm patency of
the system. If contrast is used, it should be flushed from the catheter using preservative-free saline. The surgical wounds are then closed in anatomical layers. The pump can then be programmed to infuse a bolus to bring active drug to the tip of the catheter.

Complications of Spinal Drug Delivery

A thorough understanding of the potential complications that might occur during the course of device placement and long-term use of spinal drug infusion is essential for any clinician involved in the implantation and/or management of spinal drug delivery systems. Although complications can and do occur, early detection can minimize the harm that results. Complications associated with IDDS can be divided into surgical complications related to the implant procedure, device-related complications, and pharmacologic complications (Table 100.6).

Complications Associated with Pump Refill

| Contamination of pump reservoir |
SURGICAL COMPLICATIONS

Wound Hematoma/Seroma and Epidural Hematoma

Bleeding is an obvious risk for any surgical procedure and can occur intraoperatively or in the postoperative period. The bleeding can be superficial or deep and related to either surgical or systemic factors. Severe bleeding is rare. Prior to proceeding with insertion of a catheter for screening or implantation of an IDDS, all patients should be screened for risk factors that could cause intraoperative or postoperative bleeding. A careful medical history including family history of bleeding, screening for coagulation disorders should be conducted. Laboratory studies such as prothrombin and partial thromboplastin times, platelet function assays, and specialized bleeding tests should be reserved for those patients where a specific bleeding disorder is suspected. If the patient is being treated with anticoagulant medications, they should be stopped for a sufficient period of time prior to the procedure based on the pharmacology of each drug. It is important to coordinate cessation of anticoagulant therapy with each patient’s treating physician to assure that the risks and benefits of discontinuing therapy have been carefully weighed.

Intraoperative bleeding is rare as the degree of tissue dissection necessary to place IDDS is minimal, and the anatomical areas that are involved are not particularly vascular. Most of the bleeding problems associated with IDDSs involve the subcutaneous tissues, particularly the pump pocket. Failure to assure hemostasis in the subcutaneous tissues can lead to complications wound hematoma, seroma, and/or infection. Infiltration of the surgical sites with local anesthetic containing 1:200,000 epinephrine can be helpful to reduce superficial bleeding. Use of electrocautery for the majority of the dissection will also minimize bleeding. Excessive use of electrocautery in any one location can destroy and devitalize tissue making it a potential nidus for infection. Electrocautery should be avoided near skin edges and the IT access. This can lead to poor wound healing and subsequent wound breakdown and/or infection or spinal cord injury.

Clinically significant intraspinal bleeding related to needle or catheter
insertion is rare. The risk of intraspinal bleeding can be reduced by minimizing the number of needle passes. Tumors can be vascular and should be avoided. A small amount of epidural bleeding is unlikely to be clinically significant. However, accumulation of sufficient blood in the epidural space as an epidural hematoma can lead to the development of neurologic injury. Epidural hematoma should be suspected in a patient who reports severe, escalating back pain and progressive symptoms of neurologic dysfunction. Any patient who develops neurologic symptoms or signs in the immediate postoperative period should undergo an immediate imaging study (CT or MRI) of the spine, and neurosurgical consultation should be obtained.

Wound hematoma and/or seroma are more common and usually due to inadequate hemostasis. A wound hematoma is usually manifest by local pain, pressure, and swelling over the surgical wound and may or may not be accompanied serous or serosanguineous drainage. Most wound hematomas or seromas can be managed conservatively and will resolve spontaneously. However, in the event of a large collection, either surgical evacuation or percutaneous aspiration may be necessary. In the event of a wound hematoma or seroma, early pump refills should be limited because puncture of the skin may increase the risk of infection. A large hematoma overlying the pump will make accessing the refill port more difficult and increase the chances of subcutaneous injection of the medication.

**Infectious Complications**

The incidence of infection following implantation of an IDDS is low, and the presence of an active systemic infection or localized soft tissue infection near the site of implantation may increase the risk of a surgical site infection. Most wound infections present early, typically within 1 to 4 weeks after implantation. The usual presentation includes pain, swelling, erythema, and tenderness over the surgical incision, sometimes accompanied by purulent drainage. Although fever may be present, absence of fever should not rule out an infection. In the absence of systemic symptoms and/or signs of infection, a period of conservative management for several weeks, including percutaneous aspiration, IV antibiotics, and, in some cases, instillation of antibiotics directly into the
pump pocket should be considered. However, if an infection of the pump pocket occurs involving more than the superficial tissues, explantation of the device (including the catheter) is typically required. If there is no evidence of extension of the infection from the subcutaneous tissues surrounding the pump toward the lumbar catheter insertion site, it is possible to remove just the pump and leave the IT catheter in situ. The catheter is exposed in the lumbar paraspinal region far from the site of the pocket infection, cut and occluded just above the fascial insertion site. In this way, once the infection has resolved, the catheter can be revised without having to replace the IT segment of the original catheter and a new pump implanted in a site remote from the previous infection. However, the safest approach is to remove the entire system and consider reimplantation once the infection has resolved. Once the pump has been explanted, systemic analgesics must be started to prevent withdrawal.

Meningitis is another rare infectious complication that has been reported after IDDS placement. The clinical presentation of bacterial meningitis includes fever, chills, intractable headache, malaise, nausea/vomiting, neck/back pain, and nuchal rigidity. Most patients who develop meningitis look ill, and progression can be extremely rapid. The key to treatment is early recognition of clinical signs followed by a lumbar puncture and early institution of broad-spectrum antibiotics. Urgent removal of the IT infusion system should be strongly considered.

Epidural abscess is rare following IDDS implantation, although there are numerous case reports of epidural abscess following insertion of epidural catheters. The clinical presentation of epidural abscess is similar to that of an epidural hematoma, although the onset is generally more delayed and the progression of symptoms may be slower. Early diagnosis requires a high degree of suspicion; any patient who develops unexplained neurologic signs or symptoms should undergo an imaging study to exclude this problem. If an epidural abscess is confirmed and the patient demonstrates signs of neurologic dysfunction, neurosurgical consultation should be obtained immediately and consideration given toward surgical decompression. Although epidural abscess has traditionally been considered a neurosurgical emergency, an increasing number of reports of nonoperative management of this condition have appeared in recent years.
If the patient has no sign of neurologic dysfunction, it may be possible to manage the patient with an epidural abscess with antibiotics combined with close clinical observation. This approach is probably most applicable to abscesses that occur in the lumbar region since the cauda equina, where expansion of the abscess is less likely to produce immediate neurologic compromise. As is the case with more superficial infections, the most conservative approach regarding the implant is removal. Most postoperative epidural abscesses are due to Staphylococcus aureus and should be treated with at least 6 weeks of IV antibiotics.

**Cerebrospinal Fluid Leak and Postdural Puncture Headache**

Insertion of the IT catheter requires performing a lumbar puncture with large Tuohy needle. CSF leak and postdural puncture headache (PDPH) are risks associated with pump implantation. This problem may occur as a result of multiple dural punctures or as a result of a CSF leak around the catheter where it enters the dura. Some implanters try to minimize this risk by placing a purse-string suture around the catheter below the fascial insertion site. If this technique is employed, one must be careful to avoid occlusion of the IT catheter that can result if the purse-string suture is cinched too tightly, occluding the catheter.

PDPH is classically described as a severe postural headache, but this postural change is not always present. Initial management includes bed rest, fluids including caffeinated beverages, and the use of an abdominal binder. If conservative measures fail to eliminate the problem, an epidural blood patch can be considered. Placing a blood patch in a patient with an IDDS requires fluoroscopic guidance in order to avoid damaging the IT catheter. If the leak persists, surgical exploration to seal the leak may be required.

Occasionally, patients will present with a CSF hygroma beneath the lumbar incision. In most cases, this will resolve spontaneously with time. It is usually not necessary nor recommended that these collections be aspirated as there is risk of infection or damage to the catheter. If the collection is large and/or the patient is symptomatic, then surgical exploration to close the leak around the catheter might be required.
Neurologic Injury

Neurologic injury during and after IDDS placement is most commonly associated with the development of an epidural hematoma or abscess. Although uncommon, direct neurologic injury can also occur from insertion of the needle or IT catheter. Neurologic injury can be minimized by preoperative imaging study of the spine, preferably an MRI, to ensure that the spinal canal is patent and that the catheter can be inserted safely. This is especially important in patients with cancer and spinal metastases. Imaging will also exclude the presence of problems such as a low-lying or tethered cord. To minimize the risk of neural injury, the needle should be inserted in the lower to midlumbar region in order to avoid direct injury to the conus medullaris (which usually terminates around T12 or L1) or the spinal cord itself. Once the needle has been inserted and free flow of CSF confirmed, the catheter should be inserted and positioned using fluoroscopy. The catheter should be gently advanced; under no circumstance should the catheter be forced if undue resistance is met. If this occurs, the entire catheter and needle assembly should be removed and the process repeated. The position of the catheter tip should be confirmed with fluoroscopy. Ideally, the catheter tip should be positioned in the upper portion of the lumbar cistern. By keeping the catheter caudal to the conus medullaris, the risk of cord compression due to subsequent development of an IT granuloma will be minimized. If the catheter passes retrograde toward the sacrum, it should be removed and repositioned with the introducer needle to avoid shearing of the catheter. If the catheter remains low in the lumbar region, it can potentially “knot” and damage the nerve roots of the cauda equina in the event it needs to be removed. It is not uncommon for the catheter to cause transient nerve root irritation that is usually manifest by radicular symptoms. This is usually self-limited and resolves over several days to weeks. In the event it persists, it may become necessary to remove the catheter.

DEVICE-RELATED COMPLICATIONS

Catheter and Pump Problems

Complications related to the catheter system represent a considerable source of morbidity in patients with IDDS. Catheter-related problems
include fracture, migration, kinking, occlusion, and dislodgment. In three separate clinical trials conducted by Medtronic, catheter-related complications were reported in 20% to 25% of patients who received an implant. This included both one- and two-piece catheters. During a 1- to 2-year follow-up period, approximately 80% of the catheters remained complication-free. Correction of a catheter complication not only requires additional surgery but also results in interruption of therapy with the possibility that withdrawal symptoms will develop. The device-manufacturing companies consistently maintain that only the FDA-approved IT pump medications should be used with their devices, which reduces pump failure rates. When a patient presents with a sudden loss of pain relief after an IDDS has been functioning well, a sequential and systematic approach will usually identify the problem. First, proper function of the pump itself can generally be confirmed using telemetry. The pump should be interrogated to ensure that the information is as expected from prior records and accurate. The accuracy of the pump prescription is checked, and the device is refilled with new medication. The residual drug volume is checked against that predicted by the telemetry, and these volumes should agree. Plain radiographs that include the entire catheter and pump system are then obtained to exclude disconnection of the catheter from the pump as well as fracture, migration, or kinking of the catheter. Although most catheter fractures can be seen with plain radiographs, some leaks are small and cannot be seen with plain x-rays. MRI imaging can be ordered to exclude the presence of a catheter granuloma, especially where new neurologic signs or symptoms are noted or large pump volume discrepancies are evident. If this evaluation fails to reveal the source of the problem, then a contrast study can be done to further evaluate the catheter. The CAP (Fig. 100.4) is accessed using either a 24- or 25-gauge needle provided in the CAP kit. Prior to anything being injected, the catheter should be aspirated to confirm CSF flow and several milliliters of CSF should be removed. Remember, the length of the catheter extending from the CAP on the pump to the distal tip within the CSF is filled with highly concentrated drug. When CSF cannot be aspirated, injection is likely to push drug within the catheter directly into the CSF, resulting in a drug overdose. Assuming one can easily aspirate
CSF, a small amount of nonionic, radiographic contrast can then be slowly injected and the spread observed under fluoroscopy. If the catheter is patent and there is no obstruction at the tip, contrast should be seen to flow from the catheter and then dissipate quickly in the subarachnoid space. It is also possible to study the catheter by placing a radioisotope such as indium-111 in the drug reservoir and imaging the system over a sufficient period of time to allow for tracer movement into the CSF based on the flow rate of the pump.

Complications in Regional Anesthesia and Pain Medicine. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2013:278. Figure 25-6.)

**Complications Associated with Refill of the Pump Reservoir**

Complications related to refilling a drug delivery device include inadvertent subcutaneous administration, accidental IT injection, and pump programming errors. All of these complications are avoidable by adhering to a strict protocol for pump refills. The danger during initiation of IDDS and refilling of the reservoir is apparent from a recent postmarketing study carried out by Medtronic. This report revealed that mortality after initiation of IDDS or device interventions (reprogramming,
refilling of the drug reservoir) typically occurred as a result of multiple factors, including excessive IT morphine dosing during initiation of IDDS, lack of close supervision of concomitant opioid or respiratory depressant drug intake, and early hospital discharge preventing monitoring for respiratory depression early after initiation of IDDS. Before refilling any drug delivery device, one should check to ensure that the drug prescription matches that currently in the pump. Refills should be performed sterilely to avoid contamination of the drug reservoir. Refills should only be performed with the appropriate needles provided in the manufacturer’s pump refill kit. The drug reservoir is accessed with 22-gauge Huber needle and the CAP with a 24- or 25-gauge needle, depending on the model of the pump. The needle intended for entering the CAP should never be utilized for accessing the drug reservoir. If the smaller needle is used and accidentally inserted into the CAP, the entire volume of medication can be directly injected into the IT space. The CAP bypasses the drug reservoir and pump and cannot be accessed with the larger 22-gauge needle. If there is any question that the needle is in the appropriate port, it is prudent to confirm this with fluoroscopy. The provider performing the refill should confirm that the residual volume of the reservoir matches that predicted by telemetry. Once the refill has been completed and the pump reprogrammed, the pump prescription should again be rechecked for accuracy.

Inadvertent injection into the subcutaneous tissues around the pump as well as injection through the CAP directly into the IT space have both been reported. This can lead to significant respiratory depression, which is likely to be delayed in onset and occur after the patient has left the office. If subcutaneous injection occurs in patients already receiving chronic opioid therapy, treatment with an opioid antagonist should be instituted, with careful observation with incremental doses to avoid excessive reversal; overly aggressive reversal could precipitate acute withdrawal leading to hypertension, cardiac arrhythmias, and pulmonary edema. In the event that direct injection into the CSF does occur and it is recognized, the drug infusion should be stopped and the patient admitted to the hospital for observation and close monitoring for signs of respiratory or hemodynamic compromise. Judicious use of opioid antagonists as described is warranted.
If the patient develops signs of respiratory compromise, there should be no hesitation in proceeding with endotracheal intubation of the patient and providing mechanical ventilatory support until the drug effects have dissipated. If subcutaneous injection occurs in patients receiving baclofen, the patient may exhibit signs of overdose including CNS depression, somnolence, hallucinations, agitation, mydriasis, nausea and vomiting and may progress to severe bradycardia, hypotension, and respiratory failure. If baclofen overdose is suspected, immediate admission to the hospital is warranted. These patients should be closely monitored and can require supportive care to maintain hemodynamic and respiratory function. A nonspecific reversal agent for baclofen overdose is physostigmine which should be administered in incremental doses.

**PHARMACOLOGIC COMPLICATIONS AND DRUG-RELATED SIDE EFFECTS**

**Side Effects of Intrathecal Opioids**

It is commonly held misconception that switching from systemic to IT delivery of opioids alleviates all of the clinically significant side effects. However, IT opioid infusion is commonly associated with side effects. Often, these side effects are mild and well tolerated and do not interfere with therapy. As patients develop tolerance to the analgesic effects of the drug, they also tend to develop tolerance to the side effects. Nonetheless, some patients develop side effects that may be so bothersome as to have a significant impact on the treatment. The most common side effects experienced by patients receiving IDDS include respiratory depression, gastrointestinal symptoms, urinary dysfunction, hormonal alterations, and itching.

Aside from true anaphylaxis, which is rare with the use of opioids, respiratory depression is the most clinically concerning drug-related side effect. Respiratory depression results from the supraspinal interaction of the drug with µ-opioid receptors in the brainstem. It can occur from rostral spread of the drug and is probably more common when using hydrophilic agents which can attain significant concentrations in the CSF. Respiratory depression can also occur with systemic absorption from the CSF into the blood and redistribution to the CNS. It is most likely to occur in patients
who are opioid naive. There are relatively few reports of clinically significant respiratory depression in patients who have been exposed to opioids before instituting IDDS. Additional risk factors for development of respiratory depression include advanced age, absence of severe pain, debilitated physical condition, preexisting pulmonary disease, sleep apnea, and use of additional opioids delivered by alternative routes. Respiratory depression can occur as early as 4 hours following IT dosing, although it is often delayed in onset up to 24 hours. Treatment consists of support of respiration and the judicious use of a µ-receptor antagonist such as naloxone and employing appropriate precautions as outlined previously in this chapter.45

Urinary retention is another common side effect of IT opioids, reported in 20% to 40% of patients. It is a direct spinal side effect caused by reduction in detrusor muscle tone and detrusor-urethral sphincter dyssynergia. It does occur with the intraventricular administration of morphine. It is believed to be mediated primarily through µ- and δ-receptors. It is more common in males and rare in women and individuals who are opioid tolerant. It is often self-limited and usually resolves within 24 to 48 hours. Treatment entails intermittent bladder catheterization until the problem resolves. One can also consider adjunct pharmacologic treatment with opioid antagonists and/or phenoxybenzamine. If the problem persists, an alternative strategy involves switching to another opioid.45

Gastrointestinal side effects such as nausea, vomiting, and constipation are less common than with systemic delivery. However, they still occur in up to 25% to 30% of patients, especially those who are opioid naive. Nausea and vomiting are mediated by the interaction of opioids with the chemoreceptor trigger zone. Treatment is usually symptomatic with antiemetic agents.

Pruritus occurs in about 25% of patients exposed to IT opioids and may be more common in opioid-naive individuals. It is more common with morphine than other opioids and is believed to result from degranulation of mast cells. The problem is usually self-limited and can be managed with antihistamines albeit with mixed results. In the case of severe persistent itching, the best approach is to switch to an alternative opioid such as...
hydromorphone or fentanyl. It is important to differentiate opioid-induced pruritus from true allergy. Most patients and many clinicians not familiar with the actions of IT opioids will misconstrue itching as an allergic reaction. In fact, true allergic reactions to morphine or its congeners is unusual.\textsuperscript{45}

Finally, there is compelling evidence that opioids can have a negative effect on neuroendocrine function.\textsuperscript{46} Morphine has been shown to inhibit the release of gonadotropin- and corticotrophin-releasing hormones from the hypothalamus, resulting in reduced circulating levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), adrenocorticotropic hormone (ACTH), and β-endorphin. The end result is reduction in serum levels of cortisol and testosterone. Clinically, the end effect is reduction in libido and/or impotency. In men, reductions in testosterone can also result in decreased muscle mass and increased fat mass. In addition to these effects, IT morphine administration can also produce significant fluid retention, likely due to alterations in antidiuretic hormone function.

**Opioid Tolerance**

Tolerance can be defined as the requirement for progressively escalating doses of medication in order to achieve the same degree of clinical effect. In pharmacologic terms, tolerance represents a pharmacodynamic effect manifested by a rightward shift in the dose–response curve. Two mechanisms for opioid tolerance have been proposed: desensitization (i.e., decreased activation) of opioid receptors following prolonged exposure to opioids and opioid receptor downregulation.\textsuperscript{7} Desensitization involves changes in opioid receptor physiology that are believed to result from alterations in G-protein coupled receptor (GPCR) function. The end result is a decrease in analgesia. Like many other GPCRs, downregulation, the second mechanism believed to produce opioid tolerance occurs when opioid receptors are internalized from the cell membrane by endocytosis, is mediated through the β-arrestin pathway.

Although tolerance is discussed mostly in terms of loss of analgesia, it should be noted that tolerance also occurs to other effects of a given drug. Tolerance is believed to be an important causal factor in the loss or complete failure of analgesia in patients with implanted drug delivery systems.
systems, particularly those patients primarily receiving opioid medications. Tolerance usually develops over the course of time, and the rate at which tolerance develops may vary between individuals. Moreover, tolerance does not usually develop equally to all effects of a given drug at the same rate. Before concluding that loss of analgesia is indeed related to tolerance, it is important for the clinician to exclude other reasons such as problems with the delivery system or progression of disease.

Management of tolerance depends to large degree on the baseline treatment protocol for a given patient. In some cases, simple dose titration by 10% to 30% per day will overcome the problem. If indeed the problem is simply a tolerance issue, then increasing the dose should result in demonstrably improved pain control, at least for some period of time. Depending on the delivery system, dose escalation will be limited by the volume that can be safely infused. The maximum infusion rate generally recommended for an epidural infusion is around 10 to 15 mL per hour; for IT infusion, the rate should not exceed more than 10% of the patient’s calculated CSF volume (typically 75 mL total, limiting the daily infusion to 7.5 mL per day). These limitations can make restoration of analgesia impossible by dose titration alone unless the infusion prescription can be prepared in a higher concentration, although there are also limits to this (Table 100.7).

It has been suggested that continuous drug delivery is less likely or will less rapidly lead to the development of tolerance, although there are no studies that clearly demonstrate this to be the case. Switching to a more potent opioid may result in a slower development of tolerance by reducing the rate of receptor downregulation. One can also consider switching to a different opioid assuming there is incomplete cross tolerance between the two drugs. Another strategy is to add other agents such as clonidine that act through alternative spinal modulating systems and therefore might have some opiate-sparing effects. Finally, some experts have suggested that a local anesthetic be substituted for the opioid to provide for an opioid-free interval.

**Intrathecal Inflammatory Masses (Intrathecal Granuloma)**

Inflammatory masses associated with the tip of an IT catheter is a potentially serious complication that, if not promptly recognized and managed, can result in neurologic injury. IT granuloma was first reported in 1991 and, over the course of time, additional case reports and small case series appeared in the literature. By 2000, 41 cases had been reported. Due to growing concern about this problem, a consensus panel met and subsequently published recommendations on the management of catheter-tip inflammatory masses. A similar consensus panel was reconvened in 2007 and the recommendations and guidelines of this panel were recently published. The panel reviewed the pertinent literature including preclinical data, information on pathophysiology of inflammatory mass formation, and clinical data, and ultimately developed an algorithm for prevention, early detection, and treatment.

An inflammatory catheter tip mass typically is composed of both acute and chronic reactive inflammatory cells derived from the arachnoid and/or fibrosis that does not directly involve the spinal cord parenchyma. Although these masses represent a buildup of granulation tissue and have been termed “granulomas,” they do not fit the classical histopathologic description of a true granuloma. An infectious agent has never been associated with these inflammatory masses. There are a number of preclinical studies in both dogs and sheep that demonstrate that catheter-tip...
inflammatory masses occur predictably in animals receiving IT morphine infusions. Based on preclinical studies, the panel concluded that these masses likely occurred as a result of infusion of high concentrations and/or high daily doses of IT morphine.

Although most of the preclinical evidence implicated the use of morphine, more recent data indicate that other opioid infusions may be associated with inflammatory catheter tip masses. There has also been a more recent report implicating IT baclofen as a potential causative agent.

Although the occurrence of inflammatory masses in humans is less predictable than in animal models, it is believed that the incidence in humans increases with the duration of IT therapy, ranging between 0.4% after 2 years of treatment up to 1.16% after 6 years of treatment. Moreover, animal data fails to clarify whether there is dose in humans below which granuloma formation will not occur. Available data do support the concept that both concentration and total dose of all opioids, with the exception of fentanyl, are important in the development of inflammatory masses. Based on the available data, the 2007 consensus panel has published recommendations for maximum doses and concentrations of the currently used IT agents (see Table 100.7).

The first clinical clue of the development of an inflammatory catheter tip mass in a patient who has otherwise been doing well is often an increase in the patient’s pain and the requirement for repeated and rapid dose escalations. In such cases, absent an obvious progression of disease, one should begin to consider that diagnosis of an inflammatory mass. Any patient who develops new neurologic symptoms should be evaluated with spinal imaging, preferably MRI. A catheter-tip inflammatory mass can usually be detected with MRI (Fig. 100.5).
Management of the patient with an inflammatory catheter tip mass depends on the clinical situation but is primarily related to the presence or absence of neurologic signs and/or symptoms. If a mass is detected and the patient does not have neurologic symptoms, it is possible to retract the catheter caudally a few centimeters out of the granuloma and reduce the drug dose and/or concentration. One additional suggestion has been to switch to a “safer” medication such as fentanyl or ziconotide. If symptoms persist despite these changes, the patient should be rapidly weaned off all IT opioids, the medication should be removed from the pump, and the pump filled with saline. One needs to pay close attention to signs of withdrawal, not only from opioids but also from adjuvant medications that may also be in the pump such as clonidine and/or baclofen. If the symptoms resolve after removing the catheter from the mass, the patient should be reimaged in 6 months to confirm resolution of the granuloma before reinstituting the therapy. If a small granuloma is still evident, one must decide between further retraction or removal of the catheter. If neurologic signs and symptoms persist or in the event that a granuloma is detected that is producing significant neural compression, then the system should be removed. In patients with a large granuloma compressing the spinal cord and producing neurologic dysfunction, consultation with a
neurosurgeon should be obtained to determine whether removal of the granuloma itself is warranted.

Drug Withdrawal
Disruption of the IT catheter, pump battery failure, and human error during refill and reprogramming can all lead to sudden cessation of drug delivery and result in drug withdrawal. Of the medications that are currently used for IT delivery, distinct abstinence syndromes are most commonly associated with opioids, baclofen, and clonidine. There are currently no reports of withdrawal associated with the use of IT ziconotide.

The clinical symptoms and signs associated with opioid withdrawal include any or all of the following: increased lacrimation and rhinorrhea, diaphoresis, mydriasis, pilomotor erection, restlessness, irritability or agitation, gastrointestinal symptoms (nausea, vomiting, diarrhea), tremor, abdominal cramping, and, of course, increased pain levels. In severe cases, acute opioid withdrawal can lead to pulmonary edema or cardiovascular collapse resulting in death. The most common causes of opioid withdrawal are catheter disruption and pump refill/programming errors. Because of the risk of opioid withdrawal, antagonist medication must be used with caution in patients undergoing chronic opioid therapy. Treatment should be aimed at respiratory and hemodynamic support with restoration of the drug infusion as soon as possible.

Baclofen withdrawal is a serious complication that, if unrecognized, can be life-threatening. It is usually heralded by increase in spasticity, sometimes to the point of rigidity, pruritus, hyperthermia, drowsiness progressing to obtundation, respiratory depression, rhabdomyolysis, acute renal failure, acute multiorgan failure, and even death. Early recognition is the key to treatment. The treatment of baclofen withdrawal requires urgent attention, the goal being restoration of the IT baclofen infusion as soon as possible. For patients with signs of severe baclofen withdrawal, it is not sufficient to merely provide oral medication until the problem can be fixed. In such cases, it may be prudent to place a temporary lumbar drain and restart the infusion until such time as the problem can be correctly diagnosed and treated. Abrupt cessation of clonidine can also be associated with adverse effects such as rebound hypertension, particularly in patients
receiving higher doses. All patients receiving clonidine should be provided a prescription for either oral or transdermal clonidine and advised to contact the implanting physician should they develop any symptoms or signs of clonidine withdrawal.

Patient Outcomes and Intrathecal Drug Infusion

CANCER PAIN

Continuous IT infusion of opioids was first used for the management of cancer pain in the early 1980s and, over the next decade, remained the single most common indication for IDDS. During the past several years, it seems the use of IT opioids for cancer pain has declined due in large measure to the development of more effective long-acting oral opioids as well as the development of less expensive drug infusion reservoirs. Nevertheless, continuous IT opiate infusion remains one of the most effective methods of controlling cancer pain and affording patients, maximal independence.

IT opioids are indicated for the management of cancer pain in two circumstances: (1) in patients whose pain is refractory to reasonable doses of oral opioids and (2) in patients who are unable to tolerate sufficient doses of oral medications needed to adequately treat their pain due to undesirable systemic side effects, mainly sedation. Although appropriate management of the patient is the paramount goal, the current climate of health care in the United States has dictated an ever increasing recognition of the cost of care. In order to justify the cost of an implanted system, potential candidates for pump implantation should have a life expectancy of at least 3 to 6 months. Cost analysis studies comparing implanted programmable pumps to external infusion systems have shown that for patients requiring treatment more than 3 months, an IDDS is the more cost-effective device.48,49

Continuous infusion of IT opiates has proven to be an effective and safe method for controlling cancer pain.2,50–52 Adequate pain control that results in significant reduction in oral narcotic intake and increase in activity can be achieved in the majority of patients. A retrospective multicenter survey regarding intraspinal opiate therapy revealed the
average reduction in pain to be just over 60% (n = 382) regardless of etiology. Increase in activity was noted in nearly 82% of patients (n = 399) with 59% realizing moderate to significant increases in activities of daily living (ADL). Just over 95% of patients reported either good (42.9%) or excellent (52.4%) pain relief. There were no significant differences in the level of pain relief reported between patients with cancer and those with nonmalignant pain syndromes. Complications related to the delivery system occurred in 21.6% of patients (n = 380) and were most often related to the catheter. Adverse drug effects were reported in approximately one quarter of the patients. The most common adverse effects were nausea and vomiting (25.2%) and pruritus (13.3%).

Perhaps the best evidence for the use of IDDS in patients with cancer pain comes from the study of Smith et al. The authors performed a randomized controlled trial of IDDS versus conventional medical management (CMM) in a cohort of 202 patients. Entry criteria include inadequately controlled pain of 5 or greater (0 to 10 VAS scale). Clinical success was defined as either a 20% reduction in baseline VAS score or equivalent VAS score accompanied by at least a 20% reduction in toxicity following 4 full weeks of treatment. Nearly 85% (60 of 71) of patients randomized to IDDS achieved clinical success compared to 70% (51 of 72) of patients who received CMM (P = .05). Mean pain scores fell from 7.8 to 3.7 (52%) for the IDDS group compared to 7.8 to 4.8 in the CMM group (P = .055). Toxicity scores fell 50% for the IDDS group compared with only 17% for the CMM group (P = .004). Interestingly, the IDDS also showed improved survival, with 54% alive at 6 months compared with 37% in the CMM group.

INTRATHecal DRUG DELIVERY FOR CHRONIC NONCANCER PAIN
During the past two decades, there has been an increasing trend toward the use of chronic IT opiates in the management of refractory noncancer pain syndromes. Noncancer pain related to failed back surgery syndrome is now the most common indication for the use of IDDS. However, in spite of encouraging results in carefully selected patients with noncancer-related pain, the use of intraspinal opiates for these chronic pain
conditions has remained a controversial issue among clinicians, lay persons, and government regulators. Indeed, much of the fear regarding this issue has been born of the belief that the use of opioids in noncancer pain invariably leads to tolerance and drug abuse. However, numerous retrospective and prospective studies suggest that these previously held beliefs may have been overly critical. Noncancer pain syndromes for which IT opiates have been and might be used are outlined in Table 100.8.

The treatment strategy in patients with noncancer pain syndromes should obey the principle that the least invasive and least costly interventions should be attempted first, reserving more invasive and expensive therapies for patients who fail the former. Unfortunately, patient selection for IT administered opiates is not as straightforward as in patients with cancer. Although there are ample reports of significant pain reduction using IDDS, translation of pain reduction into functional improvement has been more difficult to achieve.

Winkelmüller and Winkelmüller\textsuperscript{56} reported on 120 patients with noncancer pain syndromes managed with long-term IT opiates with an average follow-up of more than 3 years. Nearly three-quarters (74.2\%) of the patients derived benefit from the therapy, with a mean pain reduction of 58\%. Overall, 92\% of patients were satisfied with the treatment and

81% reported an improvement in their quality of life. The incidence of tolerance was low, only 5.8% (seven patients) and was successfully managed in four patients by means of “drug holidays.” Anderson and Burchiel\textsuperscript{57} investigated the long-term efficacy and safety of IT morphine in 33 patients with noncancer pain. These investigators noted a significant reduction in pain which persisted up to 2 years. Although the daily IT of morphine appeared to increase for the initial months of treatment, this tended to stabilize and remain constant after 1 year.

Roberts et al.\textsuperscript{58} reported their results of IDDS for noncancer pain in 84 patients who were followed on average for 3 years. Nearly two-thirds of their patients suffered from low back and/or radicular pain. Mean pain reduction was around 60%, and 74% of patients self-reported increased activity levels as well as significant reduction in oral medication. These gains were not accompanied by change in work status. Technical complications requiring an additional surgical procedure occurred in 40% of patients. These patients were initially receiving relatively high doses of morphine (9.95 mg per day) and by the end of 6 months, the mean daily dose had escalated to 15.3 mg per day.

Finally, Deer et al.\textsuperscript{59} reported the results of IDDS for the treatment of low back pain from the National Outcomes Registry for Low Back Pain. Out of 166 patients enrolled to be trialed for an IDDS system, 136 (82%) received a permanent implant. Scores for back and leg pain fell by an average of 47% and 31% respectively at 12 months follow-up for those who received an implant. In addition, more than 65% of patients demonstrated reduction in Oswestry scores by at least one level compared with baseline. At 1-year follow-up, 80% of patients indicated they were “satisfied” with the therapy, and 87% said they would undergo the procedure again for the same outcome.

**Conclusion**

IT drug delivery has evolved since its inception more than 30 years ago. This technique represents a viable option for patients with intractable pain conditions. Although once viewed solely as a salvage treatment, this is no longer the case. The surgical procedure for IDDS placement is relatively
simple, yet the management of patients with IDDS is has many associated challenges. IDDS, particularly for patients with noncancer pain, represents a long-term commitment on the part of both the patient and clinician. Multiple problems will inevitably develop over the course of treatment, including drug-related side effects and system complications that must be addressed. Consequently, this therapy should be reserved for those who do not respond to less invasive treatments. In spite of the potential problems associated with this therapy, IDDS can be useful and beneficial to patients who fail to respond to simpler pain treatments, so long as one adheres to the principles of judicious patient selection, meticulous surgical technique, and diligent patient management.

ACKNOWLEDGMENT

The authors would like to thank Richard K. Osenbach for his contributions to the previous edition of this chapter.

Intradiscal therapies are interventions in which agents—physical or chemical—are delivered into an intervertebral disk, either to stop pain or to reverse or remove processes responsible for the pain. Fundamental to the use of such interventions is the belief that the lumbar intervertebral disks are a common source of chronic low back pain. This belief has a long history and is based on a variety of circumstantial and direct evidence.

**Discogenic Pain**

The proposition that lumbar disks could be a source of back pain has been espoused at least since as long ago as 1940.\(^1\) Over the ensuing years, opponents have raised various arguments against the concept. However, each of these arguments has been systematically refuted.\(^1\)

Originally, the argument was that disks could not hurt because they lacked a nerve supply. This argument was maintained as recently as 1980\(^2,3\) despite the fact that studies published in 1940\(^4\) and 1959\(^5\) had shown that the lumbar disks were, indeed, innervated. Studies in 1980\(^6\) and 1981\(^7\) confirmed that innervation and established its source. Later studies, using modern techniques, confirmed the presence of nociceptive nerves in the outer third of the anulus fibrosus of normal disks.\(^8\)–\(^11\) Other studies showed that, in addition to their normal innervation, damaged or degenerated disks can attract an ingrowth of new nerves, which follow blood vessels and granulation tissue.\(^12\)–\(^14\)

The second argument was that, although disks might be innervated, they did not hurt (the innervation being vasomotor or serving some function...
other than nociception). This was refuted by observations that back pain could be provoked by noxious stimulation of disks. When discography was developed as a diagnostic test for disk herniation, investigators noted that injections of contrast medium into affected disks reproduced the patients’ low back pain.\textsuperscript{15–18} Others, when operating on patients under local anesthesia, observed that probing the disk evoked back pain.\textsuperscript{19,20} A modern study found that, of all the structures in the lumbar spine submitted to mechanical provocation, the disks were the most potent source of back pain.\textsuperscript{21}

The third argument was that, although disks might hurt, there are no means of diagnosing the condition. This argument is correct if the diagnostic test relies on detecting degenerative changes on imaging of the disk. So-called degenerative changes are almost as prevalent in patients with back pain as in asymptomatic subjects and have no clinically significant, statistical association with pain.\textsuperscript{22} For this reason, those who pursue discogenic pain rely on disk stimulation as the diagnostic test.

Disk stimulation is an adaptation of discography.\textsuperscript{23} Discography was originally developed in order to demonstrate the internal morphology of the disk, but this is largely irrelevant to diagnosis. Disk stimulation differs in that its emphasis is on the patient’s response to stimulation of the disk with injections of contrast medium or normal saline. Morphologic changes are of secondary importance.

The operational guidelines for disk stimulation\textsuperscript{23} are that for a disk to be deemed to be the source of pain:

- Stimulating the disk must reproduce the patient’s pain (known as a concordant response).
- Stimulation of adjacent disks does not reproduce pain.
- Pain is evoked at low thresholds of stimulation: less than 20 psi (0.14 kPa).
- The evoked pain is clinically significant, that is, rated as greater than 7 out of 10 on a numerical pain rating scale or its equivalent.

These guidelines were developed on the basis of various studies that were performed in order to ensure consistency of practice and interpretation and to minimize false-positive rates caused by excessive stimulation or by hyperalgesia.\textsuperscript{1}
The validity of disk stimulation was challenged by studies that reported purportedly high false-positive rates. However, when the data of those studies were analyzed according to operational guidelines, the false-positive rates all but disappeared. A systematic review showed that the false-positive rate of disk stimulation was less than 10% and probably closer to 6%, which is a tolerably low rate.

The final argument against lumbar discogenic pain has been that there is no pathology that renders the disk painful. This has now been comprehensively refuted, as shown in the following section.

### Pathology

It is now evident that the lumbar disk responds to a variety of nutritional, metabolic, and mechanical insults in a similar manner. Those responses are expressed as what, to date, have been called degenerative changes.

The disk matrix is produced by chondrocytes in the nucleus pulposus, and synthesis is promoted by factors such as transforming growth factor (TGF) and insulin-like growth factor (IGF), which reside in the matrix (Fig. 101.1). Under normal conditions, the matrix is continually renewed. For this to occur, old matrix has to be degraded. The chondrocyte produces enzymes—known as matrix metalloproteinases (MMPs), which degrade the matrix. These enzymes are controlled by tissue inhibitors of matrix metalloproteinases (TIMMPs).
Injury disturbs the normal balance between synthesis and degradation toward degradation\textsuperscript{26,27} (see Fig. 101.1). Injury results in the liberation of phospholipases (PLAs), which in turn act on arachidonic acid to produce prostaglandins (PGs) and leukotrienes (LTs). LTs are chemotactic and attract macrophages. Macrophages release superoxide and cytokines such as tumor necrosis factor alpha (TNF\(\alpha\)), interleukins (IL), and interferon (IFN). These cytokines stimulate the chondrocyte to produce more MMPs and, thereby, promote matrix degradation. The cytokines also stimulate nitric oxide synthetase to produce nitric oxide (NO). NO not only inhibits the chondrocyte but also combines with superoxide to produce peroxynitrite, which inhibits the tissue inhibitors of MMPs, thereby promoting matrix degradation. Superoxide itself inhibits the chondrocyte and directly degrades the matrix.
As the nucleus degrades, it is no longer able to retain water and loses its hydrostatic properties. Pressures within the nucleus become irregular and reduced\textsuperscript{28,29} (Fig. 101.2), and the nucleus is less able to sustain compression loads. Meanwhile, compression loads are increasingly borne by the posterior anulus, which is subjected to loads substantially above normal\textsuperscript{28,29} (see Fig. 101.2). Irregular pressures in the nucleus and increased stresses in the posterior anulus are each independently associated with the disk being painful\textsuperscript{30}.

\textbf{FIGURE 101.2}  The internal stress profile across a diameter of an injured intervertebral disk. Stresses are normal in the anterior anulus, decreased and irregular across the nucleus, and raised in the posterior anulus.

The depressurized nucleus is unable to brace the anulus internally. As a result, the inner anulus buckles and delaminates. Progressive disruption of the anulus leads to the development of radial fissures, which are characteristic of the condition known as internal disk disruption\textsuperscript{31–33}. The severity of disruption can be graded according to the extent to which fissures penetrate the anulus (Fig. 101.3). Grade III fissures reach the outer third of the anulus and become grade IV fissures if they extend circumferentially around the outer anulus. These fissures are the hallmark of internal disk disruption. They do not represent age changes\textsuperscript{34} and are most likely features of previous injury. Grade III or grade IV fissures are imperfectly but nonetheless significantly associated with the disk being painful on disk stimulation.\textsuperscript{1,34–39}
Experimental studies have now produced internal disk disruption in laboratory animals. The initiating injury was fracture of the vertebral endplate. This injury precipitates the biochemical and morphologic changes of internal disk disruption. Biomechanics studies in cadavers have shown that endplate fractures can be precipitated by fatigue failure. Immediately after fracture of the endplate, the disk expresses the biophysical features of internal disk disruption. Endplate fractures are caused by repeated compression loading and can occur after as few as 100 cycles of compression at 50% to 80% of ultimate tensile strength of the endplate. This level of stress is well within the range experienced during normal occupational heavy lifting.

Internal disk disruption can be diagnosed in patients. Radial and circumferential fissures can be demonstrated by computed tomography (CT) discography, in which a CT scan is obtained after contrast medium has been injected into the disk (Fig. 101.4). Demonstrating such fissures converts the diagnosis from discogenic pain to painful internal disk disruption. Otherwise, certain features evident on magnetic resonance imaging (MRI) are consistent with features of internal disk disruption.
Postdiscography computed tomography scans showing Grade 0 and a Grade IV internal disk disruption. In the Grade 0 disk, the contrast medium is contained in the nucleus pulposus, with a regular, smooth perimeter. In the Grade IV disk, a Grade III radial fissure has penetrated the anulus fibrosus and has spread circumferentially to become a Grade IV fissure. (Images kindly provided by Dr. Milton Landers, Wichita, Kansas.)

High-intensity zones (HIZ) in the posterior anulus (Fig. 101.5) represent the cross-sectional appearance of a circumferential fissure. They occur in 20% to 30% of patients with chronic low back pain and correlate with the affected disk being painful. Although figures differ between studies (Table 101.1), the pooled data show that an HIZ has a positive likelihood ratio greater than 3 for the affected disk being the source of pain.

Modic lesions occur in the spongiosa of the vertebral body above an abnormal disk (Fig. 101.6). Type 1 lesions appear dark on T1-weighted images but bright on T2-weighted images and represent bone marrow edema. Type 2 lesions appear bright both on T1-weighted images and T2-weighted images and represent fat deposition (implicitly postinflammatory). They occur in about 33% of patients with chronic back pain and correlate significantly with the affected disk being painful, the pooled data indicating a positive likelihood ratio of about 3 (Table 101.2).

95% CI, 95% confidence interval of likelihood ratio, the prevalence represents the number of disks studied that showed the sign.

In patients with chronic low back pain, the prevalence of internal disk disruption is about least 40%.\(^{56,57}\) The diagnostic features are reproduction of the patient’s pain by disk stimulation and demonstration of a radial fissure on postdiscography CT scan.\(^1\)

The mechanism of pain in internal disk disruption appears to be a combination of mechanical and chemical factors. The increased pressures in the posterior anulus provide a basis for mechanical pain. The inordinate pressures in the posterior anulus would stimulate the nociceptive nerve endings in the outer anulus. Inflammatory mediators from the degraded nucleus provide a basis for chemical pain. Mediators that track through the radial fissure would reach the nerve endings in the outer anulus. They could stimulate the nerve endings to produce chemical nociception or they could sensitize the endings and lower their threshold to mechanical stimulation. Both mechanisms could be amplified if new nerve fibers are attracted into the disk by the radial fissure.\(^{12–14}\)

### Therapies

The recognition of lumbar discogenic pain and internal disk disruption has attracted the exploration of a number of therapies that specifically target
this condition. Variously they involve ablating the nerves that mediate the pain, injecting drugs or chemicals to suppress chemical nociception, or injecting agents intended to reverse the degradative processes within the disk.

**ABLATION**

Attempts have been made to denervate painful disks at a variety of sites, using a variety of means. Most have proved unsuccessful.

**Ramus Communicans Lesions**

A prospective, controlled study compared the effects of thermal radiofrequency lesioning in the region of the ramus communicans with those of injections of lidocaine over the same site. Statistically, significant differences arose in favor of radiofrequency treatment, at 4 months following intervention. However, the degree of relief afforded by radiofrequency therapy was modest, amounting to only a 46% mean decrease in pain, and the authors did not report the number of patients experiencing high-grade relief (75% to 100%). Moreover, the study was confounded because patients who received radiofrequency therapy also received an injection of triamcinolone (40 mg) at the site treated, which the control group did not receive. It is, therefore, not evident if the modest improvements seen in the study group arose from the radiofrequency lesion created, or the injection of corticosteroids.

**Intranuclear Radiofrequency**

The nucleus pulposus is normally devoid of nerve endings. Therefore, placing radiofrequency lesions in the nucleus has no prospect of coagulating nerves in the immediate vicinity of the electrode. However, proponents of intranuclear radiofrequency argued that the electric field produced around the electrode would be sufficient to heat and destroy nerve fibers in the outer anulus fibrosus, and thereby provide relief of pain; but cadaver studies have dispelled this notion. Significant heating does not occur in the outer anulus. A controlled trial demonstrated that intranuclear radiofrequency achieved no greater relief of pain than sham therapy. What were promoted as successful outcomes in earlier
observational studies amounted to no more than placebo responses.

**PERCUTANEOUS INTRADISCAL RADIOFREQUENCY THERMOCOAGULATION**

Percutaneous intradiscal radiofrequency thermocoagulation (PIRFT) involves inserting a flexible radiofrequency electrode into the posterior anulus fibrosus in order to coagulate fissures and nociceptors with a heat lesion.\(^6^3\) Good results were reported in a pilot study, with some 40% of patients achieving at least 50% relief of pain, coupled with improvement in disability.\(^6^3\) However, a controlled trial later found minimal improvements in pain and no differences in outcome between active and sham treatment.\(^6^4\)

**Intradiscal Electrothermal Therapy**

Intradiscal electrothermal therapy (IDET) was a treatment developed in the mid-1990s that involved threading a flexible heating element into the posterior anulus fibrosus or along the nucleus–anulus boundary in order to ablate nociceptors in the posterior anulus and to seal fissures.\(^6^5\)–\(^6^9\) The procedure attracted attention in the form of observational and controlled studies.\(^6^9\)–\(^7^4\)

In observational studies, the proportion of patients who achieved greater than 50% relief ranged from 50%\(^7^5\)–\(^7^7\) to 70%,\(^7^8,7^9\) and up to 20% of patients achieved complete relief.\(^7^5,7^6\) In some studies, outcomes were maintained for 2 years.\(^7^6,8^0,8^1\)

Two randomized, placebo-controlled trials had different results.\(^8^2,8^3\) In one trial, a clear difference was demonstrated between placebo and experimental groups, although success rates were modest.\(^8^2\) Greater than 50% relief was achieved in 40% of patients, among whom 22% experienced 75% to 100% relief of pain. These outcomes were consonant with those reported from observational studies. The other controlled study\(^8^3\) found no effect, either from active treatment or from sham treatment. This lack of any response is dissonant with the outcomes of observational studies, and the lack of any placebo effect is curious and unexplained. However, because no placebo effects were demonstrated, this study does not provide evidence that the responses in other studies were
due to placebo effects.

Despite these data, the popularity of IDET has all but evaporated. To some extent, that could be because successful outcomes occurred in only a modest proportion of patients or because many patients suffer exacerbation of the pain rather than relief. The principal factor, however, seems to be the failure of the procedure to attract reimbursement in the US health system.

**L’DISQ**

L’DISQ is the proprietary name for a flexible and navigable electrode that can be used to deliver thermal lesions into an anulus fibrosus. It differs from its predecessors in that the tip of the electrode can be bent by an internal mechanical device in order to change its course as it is pushed across the anulus. A single case series reported that 11 of 20 patients treated with this device achieved 50% relief of pain at 24 weeks and 48 weeks after treatment. From the data published, it is not clear the extent to which these same patients reduced their disability or improved their function.

**Coblation**

Coblation is a procedure that uses an electrode bathed in saline that produces a so-called “plasma field” around the tip of the electrode consisting of ionized particles. The electrode can be used to dissolve and remove (“coblate”) tissues. When used for discogenic pain, the electrode is inserted into the outer anulus fibrosus ostensibly to remove material in radial fissures. One study reported that 10 of 17 patients so treated achieved at least 50% reduction in pain, but no outcome data were reported on restoration of function or continuing health care.

**Biacuplasty**

Intradiscal biacuplasty is a procedure in which cooled, radiofrequency electrodes are inserted into opposite, posterolateral corners of the anulus fibrosus of the target disk ([Fig. 101.7](#)). The rationale for the procedure is that arcing a heat lesion between the electrodes will ablate nociceptors in the posterior anulus or around fissures traversing the anulus. This
A pilot study of 15 patients reported that 6 had greater than 50% relief of pain at 6 months, coupled with improvement in physical function.\textsuperscript{86} A subsequent letter reported that 7 patients had this same response at 12 months.\textsuperscript{87} In a randomized study, biaocuplasty was shown to be more effective than sham therapy,\textsuperscript{88} but success rates were modest. With success being defined as a reduction of pain by 2 points out of 10 and improvement in physical function by 15 points out of 100, 8 of 27 patients (30\%) achieved a successful outcome after biaocuplasty compared with
only 1 of 30 after sham treatment. At 12 months follow-up of 22 patients, group scores for pain and physical function continued to improve, but only 4 patients (18% of those followed, or 15% of those originally treated) satisfied the criteria for successful outcome.89

Similar, modest outcomes have been reported by others. In one study, 8 of 15 patients had 50% relief of pain or better.90 In another study, 4 of 14 patients had greater than 60% relief at 6 months, sustained for 12 months, with 1 having complete relief over this period.91

Although the outcomes of biacuplasty appear to be modest, they can be viewed in the context of alternatives for patients with discogenic pain. A randomized controlled study showed that, despite modest success rates, biacuplasty coupled with conventional medical management was clearly superior to conventional medical management alone, in terms of group scores for pain and function.92,93 Some 42% of patients treated with biacuplasty had at least 50% relief of pain at 6 months, compared with only 7% treated by conventional medical management.92 This outcome was largely sustained at 12 months.93 Furthermore, the group scores for relief of pain and improvement in function were not appreciably different from those for surgery for the same condition.93

Taken in context, the outcomes of biacuplasty make it an entertainable option for patients with discogenic pain. It is a remarkably safe procedure that is easy to perform and tolerated by patients. No alternatives have proven to offer better prospects of relief. A technical issue limits the efficacy of biacuplasty. The iliac crests can prevent optimal placement of electrodes into L5–S1 disks, such that not all of the posterior anulus can be adequately encompassed by the thermal lesion delivered. If this can be overcome, success rates might be improved.

CHEMICAL THERAPIES
Various chemicals have been used for discogenic pain. For some, there is a reasonable rationale because the drug administered targets one or other of the agents involved in disk degradation. For others, a solid rationale is lacking.

Intradiscal Steroids
Because phospholipase A\(_2\) (PLA\(_2\)) has been implicated in disk degeneration and disk injury, intradiscal injection of corticosteroids has a rationale. By inhibiting PLA\(_2\), steroids prevent the arachidonic acid cascade and the production of PGs and LTs (see Fig. 101.1).

In early studies, investigators claimed good results when they used intradiscal steroids to treat patients with a variety of complaints described as back pain and/or sciatic but without a diagnosis of discogenic pain having been made objectively.\(^94\)–\(^97\) In later studies, a diagnosis of discogenic pain was established by discography, and therapeutic injections were performed at the time of discography.\(^98\)–\(^100\)

Two controlled trials have refuted any attributable effect from intradiscal steroids for discogenic pain diagnosed solely by disk stimulation. The first compared the therapeutic effects of intradiscal methylprednisolone (80 mg) with those of 1.5 mL intradiscal bupivacaine (0.5%).\(^98\) At 10 to 14 days after treatment, improvements in pain and disability occurred in similar, small proportions of patients in both groups. In the second trial, responses to intradiscal injections of either 40-mg methylprednisolone or 1-mL normal saline were compared. At 1-year follow-up, there were no discernible improvements in disability or pain scores in either group.\(^99\)

A different picture has emerged for the treatment of painful disks that exhibit Modic changes. In one study at 1 month after intradiscal injection of 25 mg prednisolone, 1 of 11 patients with type 2 lesions reported greater than 50% relief of pain, whereas 18 of 33 patients with type 1 lesions and 13 of 25 patients with combined lesions reported that degree of relief.\(^101\) Another study found significant improvements in pain 1 day after intradiscal injection of steroids in patients with type 1 lesions,\(^102\) but improvements attenuated over 12 months or longer follow-up. However, a controlled trial has provided support for intradiscal steroids in such patients.

Patients with Modic type 1 or Modic type 2 lesions were randomized to receive intradiscal injections of saline, betamethasone, or betamethasone mixed with a Chinese medicine extract.\(^103\) No significant improvements occurred in patients treated with normal saline, but at 3 and 6 months, significant improvements in pain scores and in disability occurred in all
groups treated with betamethasone, with or without extract, and regardless of lesions being type 1 or type 2. In those groups, no significant differences arose according to type of treatment or type of Modic lesion. At 6 months, mean pain scores dropped from 7 to 2, and disability scores dropped from 35 to 15. However, the authors did not report the success rates for any given definition of success.

Had there been no placebo-controlled trial, the observational studies of intradiscal steroids for Modic lesions could be dismissed as showing no more than placebo responses. However, there being a positive, placebo-controlled trial, the treatment cannot be summarily dismissed as a placebo. What is still required, however, is evidence that this treatment obviates need for other health care and evidence either that it has long-term effects or can be repeated safely in order to reinstate relief if it wanes.

**Etanercept**

Because TNFα is involved in the degradation of lumbar disks (see Fig. 101.1), there is a rationale for using TNF-blocking agents to treat discogenic pain. One such agent is etanercept, which binds TNF receptors.

A placebo-controlled study assessed the efficacy of intradiscal injection of etanercept in doses increasing from 0.1 to 1.5 mg. No differences were found at 1 month, either within or between patients treated with etanercept or normal saline, with respect to relief of pain or disability. A second controlled trial compared the effects of 10 mg etanercept plus bupivacaine with those of bupivacaine alone. At 4 weeks after treatment, improvements in pain scores and disability were significantly greater in the etanercept group. Moreover, 56% of patients treated with etanercept achieved at least 50% relief of pain, compared with only 23% of those treated with bupivacaine alone. However, at 8 weeks, the therapeutic benefits had extinguished.

Thus, there is evidence that a high dose of etanercept has therapeutic effects beyond those of placebo, but those effects occur only in some patients and are not lasting. By inference, it seems that etanercept can block the inflammatory processes of internal disk disruption, but a single dose is not enough to overcome continued production of TNFα.
**Methylene Blue**

Methylene blue has weak neurolytic effects and inhibits guanylate cyclase and nitric oxide synthesis. The latter property affords it a role in the treatment of discogenic pain by blocking the degradative effects of NO (see Fig. 101.1).

In a pilot study, a team of investigators in China reported astounding results from the use of intradiscal methylene blue for discogenic back pain.\(^\text{106}\) They subsequently published a sham-controlled trial that corroborated these results. At 24 months, 19% of the patients treated with methylene blue had complete relief of pain and no restriction in activities; a further 72% had only slight pain and mild restriction of activities.\(^\text{107}\) Of the sham control group, only 15% had slight pain; the remainder had continuing pain. Later, another study from China echoed these results but published only group data that showed improvements in pain scores and disability.\(^\text{108}\)

These results have not been reproduced in open-label studies by others. One study had only 1 patient out of 8 who obtained complete relief of pain, which continued for 12 months; the other 7 patients had no relief or various grades of relief that lasted no longer than 6 months.\(^\text{109}\) A second study reported success rates based on 2 points reduction of pain but did not report the proportions of patients achieving 50% relief or complete relief.\(^\text{110}\) A third study provided 50% relief to 5 of 15 patients.\(^\text{111}\) A fourth study had 3 of 16 patients achieve 50% relief or greater at 2 months, dwindling to 1 of 16 patients at 6 months.\(^\text{112}\)

Observational studies are considered a low level of evidence when results are positive, but when results are negative, such studies constitute strong evidence. In the process of scientific enquiry, reproduction of results is essential for credibility. The failure to match the results of the original studies from China is enigmatic, if not curious.

**Antibiotics**

A group of investigators explored the conjecture that back pain in patients with Modic lesions was due to infection of the disk by anaerobic organisms. On this assumption, they conducted a pilot study, followed by a placebo-controlled trial of antibiotic therapy for back pain in patients with
disk herniations and Modic lesions affecting the same level. Their group data showed significantly greater improvements in pain and disability in those patients treated with antibiotics. Despite these results, however, some 67% of their patients still had pain at 1 year. Although heralded as a major breakthrough in the treatment of back pain, this study has attracted criticism on several counts. A later study, using ribosomal assays of herniated disk material, found no evidence of bacterial infection.

**Proliferants**

Some investigators have sought to ameliorate disk pain through the injection of substances purported to enhance healing of diseased disk tissue. Typically, solutions have been used that contain chondroitin sulfate, glucosamine hydrochloride, dimethyl sulfoxide (DMSO), bupivacaine, and hypertonic dextrose or hypertonic dextrose alone.

The literature on using these agents is limited to isolated publications that claimed good outcomes but which provided little objective data. Although they reported various degrees of relief of pain, for various durations, none provided data on function or subsequent use of other health care. So, it is not evident from the literature if these interventions make any impact on the burden of illness.

Although authors have referred to injection of these agents as “regenerative” or “proliferative” therapies, chondroitin and glucosamine have not been shown to have any specific anabolic effect on the disk, and DMSO is neurolytic rather than restorative. The term regenerative seems more appropriate for emerging intradiscal therapies that have a known positive effect on connective tissue metabolism.

**BIOLOGICS**

The term biologics is used to refer to elements, naturally found in blood or bone marrow as cells or proteins, that are known from studies in vitro and in laboratory animals to promote healing of connective tissues or to inhibit cytokines or degradative enzymes. Jointly or severally, such elements have been used extensively to treat musculoskeletal disorders such as tendon injuries and osteoarthritis. Based on their reputed success in these conditions, they have been explored for the treatment of discogenic pain.
Sealant
A proprietary preparation of fibrinogen, referred to as a sealant, has been used to control bleeding in neurosurgery, but it also inhibits cytokines and MMPs. These properties made it an attractive agent ostensibly to seal radial fissures and inhibit the degradative processes of internal disk disruption. A pilot study of intradiscal injection of sealant in 15 patients provided 7 patients with greater than 50% relief of pain, accompanied with improvements in disability, at 1 year after treatment, with 6 maintaining this response to 2 years.\textsuperscript{120}

Platelet-Rich Plasma
Platelet-rich plasma (PRP) contains high concentrations of TGF, IGF, basic fibroblast growth factor, and platelet-derived growth factor, which promote matrix synthesis (see Fig. 101.1) and connective tissue healing.\textsuperscript{121} It has, therefore, been used in attempts to produce these responses in internal disk disruption.

The first study compared the effects of intradiscal PRP with those of a control injection of contrast medium.\textsuperscript{122} Statistically significant differences in favor of PRP were found in some outcome measures, although not for “current pain” or physical function. Success rates of treatment were not reported. An open-label study provided 9 out of 22 patients with greater than 50% relief of pain, coupled with greater than 30% improvement in disability, at 6 months after treatment.\textsuperscript{123}

$\alpha_2$ Macroglobulin
Fibronectin-aggreca complex (FAC) is a marker of cartilage degradation. Its formation is inhibited by $\alpha_2$ macroglobulin (A2M). A study explored the effects of intradiscal injection of plasma rich in A2M in 24 patients in whom disk lavage detected FAC or not.\textsuperscript{124} At 6 months after treatment, significantly greater improvements in pain and in disability were found in those patients who were FAC positive.

Stem Cells
Of all the biologics, intradiscal stem cell therapy has attracted the greatest amount of attention. There is an abundant literature on the effects of stem
cells on disk tissue in vitro and in laboratory animals. In these models, stem cells suppress genes for synthesis of degradative enzymes, increase proteoglycan content and extracellular matrix, improve the histologic appearance of the disk, increase disk height, and improve MRI appearance. Several small studies have established the feasibility and safety of intradiscal injection of stem cells in humans.

With respect to effectiveness, an observational study found that 16 of 26 patients achieved greater than 50% relief of pain at 12 months after intradiscal stem cells, with 2 of these patients being completely pain free. Relief was accompanied by improvements in disability. These outcomes were largely sustained at 2 years.

An earlier study compared the outcomes from intradiscal stem cells with those of sham therapy. It claimed that stem cell therapy was effective on the grounds that patients had greater and more sustained relief of pain after treatment with intradiscal stem cells. However, pain scores and disability scores were not compared statistically between groups. Inspection of the published data suggests that stem cell therapy reduced the mean values of pain scores to levels slightly lower than those achieved by sham therapy at 6 months after treatment but not at 3 or 12 months. Furthermore, although 5 of 12 treated patients had good relief of pain, so did 4 of 12 control patients. The authors were concerned that active treatment appeared to work in only 40% of patients and were not able to explain this phenomenon.

A leading possibility stems from the fact that all of the preliminary and subsequent studies of intradiscal injection of stem cells selected patients on the basis of MRI features of disk degeneration, but disk degeneration occurs commonly in asymptomatic subjects and has no clinically significant association with the affected disk being painful. Therefore, the disks that were treated may not have been the source of pain in many of the patients treated. The prospect arises that the success rates of intradiscal stem cell therapy might be substantially improved if the treatment was applied to disks shown to be painful by disk stimulation or likely to be painful on the basis of Modic changes or HIZs on MRI.

Discussion
A common theme in most of the studies of treatments for discogenic pain is that many investigators seem intent on discovering a cure for discogenic pain. Some have affiliations with or proprietary interests in the device, technique, or agent that they have investigated or promoted.

Another theme is “50% relief in 50% of patients.” This seems to be offered as sufficient evidence that the treatment is successful. However, what is missing from the literature is any evidence that such outcomes actually reduce the burden of illness: that patients return to normal function or near normal but satisfying function and require no continuing health care for their back pain.

These themes create points of resistance among consumers of research data. Tutored consumers would be wary of reporting bias and generous definitions of success. Developments in this field would be more compelling if and once independent, third parties conducted replication studies to determine how well a new treatment works, for how long, and in which types of patients.

A parallel theme is the hope that ablating parts of a disk, or injecting something into it, will be enough to produce a cure. This overlooks the fact that disrupted disks continue to be subject to offending compression loads during normal activities of daily living. Biomechanics continues to drive degradative processes and threatens to overwhelm the effects of single-shot interventions. Thus, although thermal interventions might temporarily ablate fissures and degrade cytokines, continued compression threatens to create new fissures and cytokines. Thermal interventions might destroy nociceptors, but they will likely regenerate. Chemicals might inhibit agents currently active in the disk, but the dose will not be enough to antagonize newly secreted agents. Biologics might promote synthesis of new matrix, but will they be strong enough to overcome continued degradation? In that regard, what is seen in a Petri dish is not what happens in vivo. Cells that benefit from biologics in a Petri dish are not constantly subjected to offensive compression loads. These considerations warn that the current battery of interventions for discogenic pain might have partial or temporary effects, but none are designed to stop permanently the biochemical and morphologic responses to biomechanical injury.

CHAPTER 102
Neurolytic Blockade for Noncancer Pain

JOHN MACVICAR and NIKOLAI BOGDUK

Introduction

DEFINITION
Stedman’s Medical Dictionary defines neurolysis as either the selective, iatrogenic destruction of neural tissue to secure the relief of pain, or a procedure in which the nerve is electively freed surgically from inflammatory tissue. This chapter deals with the former half of this definition. It covers using chemical or physical means to damage peripheral nerves focally in order to prevent the transmission of nociceptive information along the target nerve in order to provide relief of pain. Surgical interventions are described in Chapters 103–105.

Etymologically, the term neurolysis actually means teasing apart or dissolving a nerve, and neurotomy means opening a nerve, but no superior term has been advanced and accepted to refer to producing focal damage to a nerve while leaving it intact. In this chapter, the term neurolytic blockade has been adopted, as a general term, to refer to all procedures whose intent is to prevent the conduction of nociceptive traffic along it. Reflecting convention, rather than good etymologic practice, “neurolysis” has been retained in the context of chemical procedures and “neurotomy” in the context of physical procedures.

PRINCIPLES
Neurolytic blockade is a therapeutic option when the actual source of pain cannot be treated. The objective is to relieve the pain by blocking the nerves that transmit nociception from its source.

The primary indication for neurolytic blockade is complete relief of pain.
when the target nerve is anesthetized temporarily with controlled, local anesthetics (see Chapter 98). Longer lasting relief can then putatively be achieved by neurolysis or neurotomy.

Of the chemical agents, phenol and alcohol are the most commonly used, and there are no comparative outcome data by which to choose between the two. Glycerol has a special application in the management of trigeminal neuralgia.

Of the physical modalities, heat and cold have both been used to interrupt conduction along peripheral nerves. In both instances, a probe or an electrode is placed on the nerve and is used to produce a small lesion that incorporates a segment of the nerve. Cold lesions (cryoneurotomy) are produced by passing carbon dioxide through a probe. Thermal lesion (thermal neurotomy) are produced by passing a radiofrequency (RF) current through an electrode. Variants of RF neurotomy have been developed in which the emphasis lies in the frequency and modulation of the current applied rather than the heat that it generates.

HISTORY AND TRENDS

The earliest form of neurolytic blockade was surgical neurectomy, in which the nerves from a source of pain were simply transected. This approach has largely been abandoned for several reasons. Neurectomy did not achieve long-term results, and when pain returned, the procedure could not be repeated, painful neuromas could develop on the proximal stump of transected nerve, and transecting large nerves could result in deafferentation pain.

Chemical and physical neurolytic blockades were developed to overcome or circumvent these problems. Neuroma formation could be avoided by not transecting the nerve. If the nerve recovered, and pain recurred, the neurolytic procedure could be repeated. Small nerves, not readily accessed surgically, could be targeted with electrodes or injections in order to avoid having to target their larger, parent nerves.

LIMITATIONS

Classical pathology teaching describes how nerves recover after they have been transected. Wallerian degeneration occurs in the distal stump and is
completed within 24 hours in small nerve fibers and in 48 hours in larger nerve fibers. In the proximal stump, regeneration of axon tubules occurs within hours of the transection. The process is driven by neurotrophic agents, such as tumor necrosis factor α (TNF-α), T cells, macrophages, leukocyte inhibitory factor (LIF), and cell adhesion molecules, which are expressed in a highly coordinated fashion. A growth cone, containing mitochondria, vesicular elements, neurofilaments, and endoplasmic reticulum, emerges from the proximal stump and proceeds into the distal stump, if it is accessible; Schwann cells undergo mitotic activity and form a framework for developing fibers. Regeneration occurs at a rate of approximately 1 mm per day so that reinnervation of a structure 5 cm away would take approximately 50 days. This process requires an intact dorsal root ganglion to synthesize the regenerative proteins and other nutrients.

Neurolytic blockade involves a different pathology, much of which has not been explored and explained. The differences arise according to where in the nerve the lesion is made, the nature of the lesion, and its size.

If the dorsal root ganglion is destroyed, regeneration will not occur because the cell nucleus is not available to drive the process. Consequently, not only permanent relief of pain but also permanent side effects and complications can be expected from neurolytic procedures that target a dorsal root ganglion.

If a peripheral nerve is targeted, chemical neurolysis does not destroy it. Instead, the chemical applied denatures the components of the axons, in one way or another, and only focally. Chemicals can bind to membrane proteins or other elements, or they can exert an osmotic effect which focally desiccates the nerve. From such processes, the nerve can recover. All that is required is that the damaged elements be replaced in the normal course of endocellular maintenance of the cell membrane or other constituents. The rate at which this happens, however, has not been established.

Cryoneurotomy works by freezing intracellular water; the ice expands and essentially fractures the nerve membrane, thereby preventing conduction along it. From this effect, the nerve can recover by reconstituting the damaged segment of membrane. Based on the duration
of relief of pain following cryoneurotomy, this recovery process appears to be relatively fast: measurable in weeks.

Thermal RF neurotomy denatures all the proteins in the segment of nerve incorporated in the lesion made. Nevertheless, the nerve remains macroscopically intact. Regeneration does not occur by classical processes because the nerve is sealed by the coagulated proteins, not transected, and left open. Therefore, growth cones cannot emerge. Before the nerve can regenerate, the coagulated material has to be removed by endocellular repair mechanisms. The rate of this process has not been determined but appears to be measurable in months based on the duration of effect of thermal RF neurotomy. Critical in this regard is the length of nerve affected. It is axiomatic that, if a short segment (1 to 2 mm) is coagulated, recovery will be faster than if a longer segment (10 to 15 mm) is coagulated. An appropriate simile is that endocellular repair is like tunneling a mineshaft that has caved in; it takes longer to tunnel a longer length of caved-in shaft.

Chemical Neurolytic Blockade

**PRINCIPLES**

Phenol, alcohol, and glycerol are locally neurotoxic in a dose-dependent manner. These dehydrating agents cause a nonselective destruction of neuronal tissues followed by necrosis, nonsegmental demyelination, wallerian degeneration, and complete conduction block occurs within 10 minutes of application.\(^5\)–\(^{12}\)

**PHENOL**

First introduced by Lister in 1867 as an antiseptic, phenol (carbolic acid) is a neurolytic agent with local anesthetic properties. Concentrations of less than 1% produce local anesthesia without toxicity or neurolysis and may be used as a topical anesthetic. Phenol can be injected directly onto peripheral nerves or into the subarachnoid space in order to target dorsal root ganglia. Nonselective neuronal destruction leading to wallerian degeneration is its principle mode of action.
ALCOHOL

Alcohol (absolute alcohol, ethanol, ethyl alcohol) is a clear volatile hygroscopic liquid that exerts its analgesic effect by nonselective neuronal destruction.\textsuperscript{8–10} Because of its irritant effect, alcohol may exacerbate local pain on injection and may produce dose-dependent burning and dysesthesia. Prior injection of local anesthetic may minimize this effect. Alcohol has produced variable results, and some consider that the risk of complications outweighs its benefits.\textsuperscript{8}

APPLICATIONS

Alcohol or phenol has been widely used to perform neurolytic blockades of various parts of the sympathetic nervous system of the abdomen. Targets have included the lumbar sympathetic trunks and the splanchnic nerves but most commonly the celiac plexus and ganglia.

In patients with visceral disorders, neurolytic blocks of the celiac ganglion or plexus are most commonly used to treat the pain of carcinoma of the pancreas. Various techniques are available by which to block the celiac plexus, ranging between anterior or posterior approaches, using fluoroscopy, computed tomography (CT), or endoscopic ultrasound, for guidance.\textsuperscript{13} For carcinoma of the pancreas, neurolytic blocks are often helpful to reduce pain\textsuperscript{14–17} but are not necessarily more effective than treatment with analgesics and opioids.\textsuperscript{17–20}

For the pain of chronic pancreatitis, the evidence is less robust and less heartening. Response rates are low,\textsuperscript{13,15} and unequivocal data on efficacy, and long-term outcomes are lacking.\textsuperscript{21}

Descriptive studies promoted neurolytic lumbar sympathetic blocks as a worthwhile treatment for rest pain in patients with peripheral vascular disease, particularly those in whom surgery could not be performed.\textsuperscript{22–24} A controlled trial showed that neurolytic blocks were far more effective than local anesthetic blocks,\textsuperscript{25} but higher levels of evidence have not appeared.

Phenol or alcohol can be injected intrathecally in order to target particular nerve roots. Mixing the neurolytic agent with glycerine produces a hyperbaric solution, which can be guided under gravity to the target nerve or nerves. Adding contrast medium to the solution allows the movement of the solution to be monitored. With skillful technique, the
solution can even be guided into a single nerve root pouch by appropriately tilting the patient. In case reports and book chapters, such injections have been promoted as a treatment for cancer pain, but there have been no controlled trials. The treatment provides complete relief of pain in up to half of the patients treated. The duration of effect is measurable in weeks or months, which may be sufficient for patients with short life expectancy. Intrathecal injections of phenol have not been promoted for the treatment of noncancer pain.

Neurolytic blocks of the lumbar or cervical sympathetic chains have been used, at times, for the treatment of complex regional pain syndromes, albeit on the basis of very little published evidence. A systematic review concluded that there is no good evidence for the effectiveness of sympathectomy—particularly with regard to long-term effectiveness outcomes—and it should be used with great caution if at all outside a research context, in carefully selected patients after thorough assessment and probably only after failure of other treatment options. A narrative review concluded that no high-level evidence exists to support the widespread use of neurolytic blocks for complex regional pain syndromes, particularly because there is evidence to support other forms of treatment.

Although injections of phenol have been used to treat lumbar zygapophysial joint pain, this treatment has not been widely adopted by others and has neither been corroborated nor validated by controlled trials.

GLYCEROL
Propane-1,2,3 triol, or glycerol, is a colorless hygroscopic, syrupy liquid that has a unique application in the management of trigeminal neuralgia. Percutaneous retrogasserian glycerol rhizolysis is achieved by the instilling, under fluoroscopic guidance, no more than 0.3 mL of glycerol into the gasserian cistern. Glycerol nonselectively damages both the axons and the myelin sheath, and 30% to 76% of patients suffer sensory loss. Some achieve good pain relief without detectable facial numbness. Onset of analgesia takes about 1 to 10 days to occur but can be delayed for up to 6 weeks. It provides excellent pain relief while largely sparing trigeminal nerve function in most patients. As many as 72% of patients can be
totally free of pain for 3 years, and in one series, 60% remained pain-free for more than 10 years after a single injection.\textsuperscript{31} Within the first year, 10% to 53% recur,\textsuperscript{32} whereas 25% to 83% recur between 2 and 5 years.\textsuperscript{33} These long durations of effect are concordant with the trigeminal ganglion being the target of the treatment. Damaging ganglion cells prevents or impedes regeneration of the peripheral nerve fibers that they subtend.

Glycerol is preferred when pain is localized to the first division as it rarely produces corneal anesthesia, but the overall effectiveness is less than for RF neurotomy.\textsuperscript{34} In the elderly or where microvascular decompression is contraindicated, glycerol ganglion lysis is safer, more effective than stereotactic surgery and is more cost-effective.\textsuperscript{35} Head-to-head comparisons of effectiveness indicate that glycerol is at least as effective as RF neurotomy,\textsuperscript{36} but balloon compression may be slightly more effective than either of these procedures.\textsuperscript{37}

### Cryoneurotomy

Cryoneurotomy relieves pain by causing a variable degree of nerve injury. Freezing is achieved by a simultaneous reduction in pressure and temperature as expanding carbon dioxide is forced through a specialized probe. An ice ball averaging 3.5 to 5.5 mm in diameter rapidly forms at temperatures as low as $-50^\circ\text{C}$ to $-70^\circ\text{C}$. Subzero temperatures cause nonselective but reversible conduction block, and the effect is prolonged when the intracellular contents are crystallized. There is little clinical difference provided that the temperature is maintained below $-20^\circ\text{C}$ for 1 minute.\textsuperscript{38,39}

Nerve injury is dose dependent and ranges from a mild “neurapraxia” to changes of wallerian degeneration, associated with very minimal inflammatory reaction. Within a few days of freezing, the lesion is seen as a dense cellular matrix of macrophages.\textsuperscript{40} In contrast to chemical neurolysis, painful neuromas, neuritis or dysesthesia is avoided as exact regeneration is facilitated by an intact epineurium and perineurium.\textsuperscript{38,39} The duration of the block depends on the rate of nerve regeneration at the proximal stump, which averages 1 to 3 mm per day.\textsuperscript{38,39} Cryolesioning is a safe, simple, and repeatable procedure: It produces a temporary block, and
Its therapeutic effect may last for many weeks. The main disadvantage is that the relief of pain is often of short duration and unpredictable.\textsuperscript{41}

Cryotherapy has been used by some as an effective adjunct to the pharmacologic management of trigeminal neuralgia when other more invasive treatments are contraindicated. In most patients, the relief of pain is immediate, and in one series, at least 58\% remained pain free for 12 months with a mean time to recurrence of 20 months.\textsuperscript{42}

For chronic lumbar zygapophysial joint pain, modest outcomes have been noted in two studies. One study claimed a 72\% success rate 6 weeks after cryotherapy.\textsuperscript{43} The other found that 62\% of patients reported at least 50\% relief of pain for 12 months, with parallel improvements in activities of daily living.\textsuperscript{44}

Cryoneurotomy has been reported as useful for the management of postthoracotomy pain and intercostal neuralgia.\textsuperscript{45} In these conditions, the short duration of relief obtained may be enough to render patients comfortable while natural healing occurs or other measures are implemented.

**Thermal Radiofrequency**

**INTRODUCTION**
Thermal (continuous) percutaneous RF procedures have now evolved as one of the better and more practical neurosurgical procedures for the management of chronic disabling pain. With modern imaging and the development of sophisticated equipment, precise ablation of neural pathways is possible. When meticulously executed in correctly selected patients, RF neurotomy with temperature monitoring has proven itself to be safer and more effective than any other procedure. The technique required principally depends on the source of nociception and the accessibility of the nerves that innervate it. Critical to its correct application is an understanding and appreciation of its limitations, the pathophysiology of the primary condition, and a valid diagnosis.

**PHYSICS**
Thermal RF should not be confused with electrocautery. Tissues are not
burned or oxidized. Rather, they are coagulated in situ by the application of a high-frequency, alternating electric field. The objective of RF lesioning is to deliver sufficient heating power into biologic tissue such that the tissue temperature is raised above the “lethal temperature” range of 45° to 50° C. Neural cells exposed to these temperatures for 20 seconds or more will be destroyed by heat. This requires an RF generator, an insulated electrode with an exposed (“active”) tip of 2 to 10 mm, and a ground or dispersive (“passive”) plate with a large surface area. The electrode is placed either into (central nervous system) or onto (peripheral nerve) the target structure. The larger dispersive plate is placed at a convenient location of the body remote from the electrode. The patient completes the electrical circuit, and the generator delivers the alternating current between exposed tip of the insulated electrode and the large dispersive plate.

The passage of low-energy, high-frequency alternating current (100,000 to 500,000 Hz) causes intense oscillation of ions. This oscillation heats charged molecules, notably proteins. The exposed, active tip of the electrode acts as an antenna, around which the current concentrates into a greater density. Consequently, greater heating occurs in the tissues around the electrode, and it is the tissue about the electrode tip, rather than the electrode itself, that becomes the source of heat. The tissues heat the electrode, and a thermocouple, built into the electrode, monitors the temperature generated. Once a certain temperature is reached, lesion formation (“coagulation”) occurs.

Tissue temperature (T) is related directly to current density (I) but inversely to the fourth power of the radius (R) from the electrode, that is, $T = IR^{-4}$. Current density is less at the distal tip of the electrode than at its sides. Therefore, the lesion extends little, if at all, in a longitudinal direction from the tip. Rather, it extends radially around the circumference of the exposed shaft and generally assumes the shape of a prolate spheroid (football). However, because the tissue temperature drops rapidly with distance from the electrode, the lesion is limited in size, to 2 mm or less beyond the surface of the electrode (Fig. 102.1).
FIGURE 102.1 Longitudinal sections through thermal radiofrequency electrodes, showing the geometry of the lesions that they produce. The lesion has a transverse radius \( r \) that is proportional to the width \( w \) of the electrode. Less lesion is produced distally \( d \). For the same electrode on different occasions, the size of the lesion varies around a mean value in a normal distribution. Smaller electrodes generate smaller lesions. Smaller lesion may fail to incorporate a target nerve \( n \) completely, even if the electrode is placed close to the nerve.

The physical variables that govern lesion size include current density, its rate of application, lesioning temperature, electrode size, the duration of heating, and impedance.\(^{48,50–52}\) Temperature is the fundamental lesioning parameter, and temperature monitoring remains central to the safety of the procedure and quantification of lesion size.\(^{53,54}\) Because there is no consistent relation between temperature and voltage, temperature-controlled RF lesioning is preferred to voltage-controlled lesioning in order to create reproducible and well-defined lesion sizes.\(^{55}\) The use of lower temperatures may not be acceptable in the clinical setting because it may not produce a permanent or long-term or sufficiently extensive lesion. Above 60° C,\(^{56,57}\) soft tissues generally will coagulate, and if the surface temperature of the electrode is elevated to 80° to 85° C, then tissues within a short distance from the surface will be heated to 60° to 65° C or more. Once the electrode surface temperature reaches 80° C, lesion size increases with time as the temperature is maintained. Most of the increase in size occurs within 60 seconds, but an appreciable growth continues between 60 and 90 seconds.\(^{57}\) After 90 seconds, further growth is prevented because the coagulated tissues present an increasing impedance (resistance) to flow of current and, therefore, the generation of any further lesion.

The lesion should be generated by increasing the temperature by about
1°C per second. This avoids cavitation, steam formation, microexplosions, and charring, but more critically in the event that the patient experiences adverse sensations, heating can be aborted promptly, before the temperature rises too high and any damage is done.49

The size of the lesion is directly proportional to the diameter (width) of the electrode. Because lesions develop from the surface of the electrode, those formed by a larger electrode will reach further away from its center. Lesions made by small-diameter electrodes will extend only a short distance from their surface (see Fig. 102.1). In practice, the radius of a lesion is equal in length to between 1 and 2 times the width of the electrode used. Beyond this range, tissues may escape coagulation.49,57

Because electrodes generate lesions radially, they must be placed close and parallel to the target nerve in order for the lesion to be optimally effective.49,56 If the electrode is placed perpendicular to the nerve, the lesion made may fail to incorporate the target nerve (Fig. 102.2). Throughout the lesioning process, the electrode must be held in place lest it dislodges, and its proper placement should be checked by periodic fluoroscopic monitoring.

**FIGURE 102.2** The influence of orientation on the effects of thermal radiofrequency neurotomy. **A:** If an electrode is placed perpendicular to the target nerve, it may coagulate the nerve only partially and for a short length because of the limited range over which the electrode generates a lesion distally. **B:** If an electrode is placed parallel to a nerve, it incorporates a large volume of the nerve along a greater length.

**PATHOLOGY**

Heating by RF causes many cells to die rapidly at temperatures greater
than 45° C. Similar effects are produced irrespective of whether the electrode is placed either inside the dorsal root ganglion or onto a peripheral nerve. Above 55° C, there is an indiscriminate destruction of both small and large myelinated fibers, focal necrosis, hemorrhages, extensive edema, and features of wallerian degeneration. Even with a low voltage of 0.1 V, an electrode placed inside a dorsal root ganglion and heated to 67° C causes a total loss of myelinated fibers, with hemorrhages.

**PHYSIOLOGY**

The study by Letcher and Goldring is often misrepresented as showing that RF neurotomy selectively destroys small-diameter fibers while preserving large-diameter fibers. Rather, what the study showed was that depression of C-fiber and Aδ-fiber action potentials preceded depression of the potentials of Aβ fibers, but, within a short time, all fibers were ultimately and equally affected, and the disappearance of action potentials was independent of fiber size. No class of fiber was exempt from the effects of heat. These findings were confirmed in two independent clinical studies which showed that RF neurotomy of the medial branches of the lumbar dorsal rami resulted in electromyographic abnormalities in over 80% of patients. These abnormalities indicated that large-diameter α motor neurons were not spared by RF neurotomy.

**APPLICATIONS**

In general medicine, thermal RF is widely used for the treatment of supraventricular tachyarrhythmias. Water-cooled electrodes permit the generation of larger lesions to ablate thick ventricular muscle effectively. In pain medicine, thermal RF has been used to treat trigeminal neuralgia, to interrupt pain pathways in the spinal cord or brainstem, and to treat various types of spinal pain and miscellaneous other types of pain.

**Trigeminal Neuralgia**

For the symptomatic treatment of trigeminal neuralgia, various descriptors, such as RF trigeminal neurolysis, RF thermocoagulation of the gasserian ganglion, or retrogasserian thermorhizotomy, each refer to the generation
of thermal lesions in an area between the trigeminal ganglion and its sensory root. Under fluoroscopic guidance, the electrode is introduced via the foramen ovale until the active tip sits at the posterior end of Meckel’s cave, the average depth of insertion being 5 to 6 cm. Once the electrode appears to be adequately placed, a test electric stimulus is delivered to the nerve. If the electrode has been accurately placed, test stimulation will evoke pain in the area in which the patient normally experiences pain. Lesioning temperature may range between 55° and 90° C, and the current may be applied either continuously for up to 300 seconds or in 45- to 90-second cycles.

The evidence of effectiveness for trigeminal RF neurotomy consists of several, large, observational studies, some encompassing over 1,000 patients. In one series, 41% of patients sustained relief for 20 years. However, because of methodologic inconsistencies, a systematic review found only four studies on which sound conclusions could be based. Nevertheless, collectively, these studies reaffirmed the general, favorable impression conveyed by the literature at large. Compared with other, commonly used, ablative techniques, RF neurotomy provided the highest rate of complete pain relief: Some 75% of patients were free of all pain for at least 6 months. At 12 months, RF provided a higher rate of complete pain relief than stereotactic radiosurgery. In a later, unrelated study, 90% of patients reported complete pain relief from their first RF, and a significant proportion continued to enjoy excellent relief some 15 years later. Presumably due to neuronal regeneration, the success rate diminishes and pain returns such that just over 50% remain completely relieved at 5 years with a 14-year recurrence rate of 25% in one series.

Common side effects are sensory loss, sufficient to affect quality of life, in more than 30% of patients; keratitis in some 10%; and dysesthesia in 4% to 10%. Although rare, reported complications include cranial nerve palsies, brainstem injury, meningitis, and vascular fistula formations.

Central Ablative Procedures
In conditions where pain is intractable and refractory to most forms of nonsurgical and minimally invasive interventions, relief may be secured by
interrupting pathways in the spinal cord. The most common target sites are the dorsal root entry zones, the spinothalamic tract, and trigeminal pathways.

Dorsal Root Entry Zone Lesions
Dorsal root entry zone (DREZ) lesioning is performed for the relief of central (deafferentation) and peripheral (neuropathic) pain caused by disease of peripheral nerves or injuries to them. In these conditions, deafferentation results in spontaneous activity in the apical neurons of the dorsal gray column of the segments to which the affected nerves relay. DREZ lesioning involves inserting a small electrode into this region in order to ablate the spontaneously active cells. Multiple lesions are usually required in order to capture all the active neurons. Better outcomes are obtained when the dorsal root and the dorsal horn are primarily affected by the injury and both the pain and the pathology are topographically well defined. Conversely, DREZ lesioning is contraindicated where pain is poorly localized because identifying the level at which the operation should be performed is difficult. The ablative process includes the central portion of the dorsal root, the tract of Lissauer, and layers I to V of the dorsal horn. In this manner, the lateral portion of the dorsal horn, where C fibers predominate, is destroyed. By sparing the medial portion of the dorsal horn, tactile and proprioception senses are preserved.

Better outcomes are obtained if test electrical stimulation is used. Stimulation not only confirms the relevant segments but also identifies additional zones of dorsal horn electrical hyperactivity which would have been missed if topographical landmarks alone are used.

Controlled trials have not been performed, but this may be understandable given the nature of the disorder and the nature of the intervention. Advocacy is based on multiple observational studies in which significant proportions of recipients report remarkable relief. DREZ lesioning has been particularly effective for the pain of brachial plexus avulsion with 66% and 87% patients affirming more than 70% relief, and an appreciable proportion not requiring supplementary medication. For traumatic spinal cord injuries, percentage relief of pain can range from
at least 50% to complete relief with no limitation of activity or the need for opioids, but a recent review found the published evidence to be limited. With respect to postamputation pain, the outcomes are better for phantom pain than for stump pain alone. DREZ lesioning has not been particularly effective for postherpetic neuralgia. Some 18% to 47% report complete pain relief, but such relief is not consistently maintained. The close neuroanatomical relationship between the site of DREZ lesioning, the lateral corticospinal tract, and the dorsal column can lead to severe neurologic complications such as motor weakness, bladder or sexual dysfunction, and dysesthesia (see Chapter 107).

Brainstem Procedures
Pain subtended by the nucleus caudalis of the trigeminal nerve can be treated by ablating various sites within the brainstem, such as the descending trigeminal tract (trigeminal tractotomy), the nucleus caudalis (trigeminal nucleotomy), or all of the substantia gelatinosa of the nucleus caudalis (nucleus caudalis dorsal root entry zone, NCDrez). Nociceptive type pain is most sensitive to NCDrez ablation. Indications have included severe glossopharyngeal neuralgia, craniofacial dysesthesia, posttraumatic neuropathy, atypical facial pain, complex craniofacial pain, and anesthesia dolorosa. For intractable facial pain, such as “end-stage” trigeminal neuralgia that has failed all other means of treatment including microvascular decompression, DREZ lesioning of the nucleus caudalis has been successful in 60% to 70% of cases.

Cordotomy
Percutaneous cordotomy can be used to treat unilateral intractable pain transmitted by the lateral spinothalamic tract. A lesion made in the anterolateral segment of the spinal cord totally abolishes pain and temperature in one-half of the body below the lesion. The procedure is typically performed percutaneously at the C1–C2 level, using a lateral approach to insert the electrode. Indications for these procedures have included severe neuropathic pain arising from brachial plexus root avulsion imitating phantom pain, electric burns, postherpetic neuralgia, and cancer pain. In patients with cancer pain, some 70% or
more\textsuperscript{106,107} initially obtain worthwhile relief. This relief wanes with time but persists in most for the duration of remaining life.

\textbf{Medial Branch Neurotomy}

Medial branch neurotomy is a procedure in which an RF electrode is used to coagulate one or more medial branches of the dorsal rami of the spinal nerves.\textsuperscript{108,109} The strictest, taxonomically purest definition of the indication for the procedure is that it is used to treat pain mediated by one or more medial branches. A corollary of this definition is that the indication requires complete relief of pain when the target nerve or nerves is anesthetized using controlled diagnostic blocks (see Chapter 98). However, the medial branches of the dorsal rami have a restricted distribution. They supply the zygapophysial joints and certain of the posterior spinal muscles. These muscles, however, are innervated in a myotomal fashion such that only those fascicles stemming from a particular spinous process are innervated by the nerve of the same segmental number. There are no known disorders that affect selectively only particular myotomes of the back muscles.\textsuperscript{110,111} Therefore, the most likely sources of pain mediated by medial branches are the zygapophysial joints. Consequently, medial branch neurotomy has come to be regarded as a treatment for zygapophysial joint pain. However, stipulating the actual source of pain is immaterial, for the indication for treatment is relief of pain after blocking the nerve or nerves that mediate the pain.

\textbf{Lumbar Medial Branch Neurotomy}

\textbf{Background.} The history of lumbar medial branch neurotomy is replete with misconceptions, errors, and misrepresentations. These apply both to surgical technique and to patient selection.

The original version of the procedure—known as “facet denervation”\textsuperscript{112–115}—was based on the concept that coagulating articular nerves would relieve pain from the zygapophysial (“facet”) joints. An abundant literature followed, with many studies claiming remarkable success for relieving back pain.\textsuperscript{108} However, it was subsequently shown that there were no nerves in the location where electrodes were placed.\textsuperscript{116,117} This converted the procedure to a sham.
At the same time, it was shown that the only suitable targets for denervating a zygapophysial joint were the medial branches that supplied the joint.\textsuperscript{116,117} Consequently, the procedure was renamed medial branch neurotomy.\textsuperscript{117} Furthermore, the practice became to place the electrode perpendicular to the nerve.\textsuperscript{118} However, some 7 years later, it was shown that perpendicular placements risked missing the nerve, or capturing it only partially (see Fig. 102.2).\textsuperscript{56} The resultant revision was to place the electrode parallel to the nerve in order to capture a maximal thickness of the nerve and a maximal length of it in the lesion created by the electrode.\textsuperscript{56}

Studies showed\textsuperscript{56,57,119} that large-gauge (16 gauge) electrodes made larger lesions and were more likely to capture the target nerve than would small-gauge (20- to 22-gauge) electrodes. If smaller electrodes were used, they had to be in direct contact with the nerve in order to capture it. Displacements as little as 1 mm could result in failure to capture the nerve.

Furthermore, it became apparent that the exact location of the nerve could vary, by up to a few millimeters.\textsuperscript{119} Therefore, a single target point could not be used. Instead, in order to capture the nerve, multiple lesions need to be made across the target zone in which the nerve could lie. The smaller the gauge of the electrode used, the greater the number of lesions that needed to be made in order to fully coagulate the target zone.\textsuperscript{108}

Despite the research over 20 years that established these principles, not all surgeons have heeded them. They have developed, used, and continue to use flawed techniques, despite warnings publicizing these flaws.\textsuperscript{120,121} Electrodes have been placed in locations where nerves are not located, which renders the procedure a sham. Electrodes have continued to be placed perpendicular to the nerve, which risks coagulating the nerve inadequately and, therefore, lowering the success rate, the degree of relief, and its duration.

A different set of confounding influences pertains to patient selection. They relate to the validity of diagnosis and its subsequent effects on the success of treatment.

The paradigm of medial branch neurotomy is that the patient’s pain must be relieved by prior diagnostic blocks.\textsuperscript{108} If the pain is not relieved, there is no logic using medial branch neurotomy to treat the pain, for the
patient does not have the condition for which the treatment is designed.

The strictest operational criteria for diagnostic medial branch blocks are that the patient’s pain must be completely relieved by double-blind controlled blocks and that relief is accompanied by restoration of activities of daily living previously impeded by the pain. Any deviation from these criteria threatens the validity of the blocks.

Single diagnostic blocks are not valid. Not only do single blocks fail to identify the 34% or so of patients who fail to get any relief when a block is repeated, they also have false-positive rates that range between 25% and 45%. Depending on the prevalence of the condition, such false-positive rates mean that even if the patient reports complete relief of pain, up to 60% or more of patients will not actually have the condition being tested. In turn, that means that up to 60% of patients will not respond to treatment, except perhaps through a placebo effect.

For diagnosis to be valid, diagnostic blocks must be controlled. Vexatious, however, is the type of control that should be used. That, too, depends on the prevalence of the condition. For common conditions, such as cervical zygapophyssial joint pain, lesser controls are adequate. For less common conditions, such as lumbar zygapophyssial joint pain, tighter controls are required in order to ensure validity.

For common conditions, comparative local anesthetic blocks are practical. They provide a credibility of 75% if agents are fully randomized or 50% if agents are only routinely alternated. For less common conditions, diagnostic confidence plummets such that when the prevalence is only 30% or less, as many as two-thirds of positive responses to comparative blocks will be false. For those conditions, placebo-controlled blocks are required for consummate diagnostic accuracy.

The degree of relief from a diagnostic block is also critical. Optimally, the relief should be complete. In that regard, nuances apply. In a patient with pain stemming from consecutive zygapophyssial joints, a physician might have initiated investigations by anesthetizing the upper of the two levels. In that event, the patient may report complete relief but only in the upper part of his or her region of pain. Reciprocally, if the physician anesthetizes the lower of the two joints, the patient may report complete relief but only in the lower region of his or her pain. However, once both
sources of pain have been correctly identified, complete relief can be achieved by performing diagnostic blocks simultaneously of both sources of pain. Detailed protocols for these situations are available elsewhere.122,132

That situation is different from a patient reporting only, say, 50% relief of all of his or her pain. Without further information, such a response is uninterpretable. A physician cannot tell if the patient is reporting some sort of placebo response; is uncertain of the effect of the block; does not understand the purpose and significance of the block; or has some other, unknown, concurrent source of pain. Although it might be convenient to assume that the patient has a concurrent source of pain, that assumption cannot be held to be true unless and until that other source of pain is identified in a valid manner. However, regardless of the reason, 50% relief pain from a diagnostic block means that, at best, the patient could not expect better than 50% relief following treatment.

Witnessing restoration of activities of daily living is a critical requirement of diagnostic blocks. Relief of pain is a subjective phenomenon, but restoration of activities previously limited by pain renders the response to a block objective122 For example, seeing a patient being able to move freely without pain serves to confirm the positive response to the block. Not being able to move is incongruous with a positive response to the block.

If these various requirements are not satisfied, the validity of a block is compromised, and poorer outcomes from medial branch neurotomy can be expected. If blocks are not repeated in order to confirm the response, or if controlled blocks are not used, the resultant false-positive responses mean that large proportions of patients will not respond to medial branch neurotomy because they do not have the condition that the treatment is designed to treat or they will have only placebo responses to treatment. If the patient does not get complete relief from a block, they cannot expect complete relief from the treatment. If a block does not restore the patient’s activities of daily living, they cannot expect the treatment to do so. These various features have confounded much of the literature concerning the evidence for the effectiveness of medial branch neurotomy.
Technique. The one technique for lumbar medial branch neurotomy that is based on the research literature concerning the anatomical basis for this procedure, and for which there is evidence of effectiveness, is that described by the Practice Guidelines of the International Spine Intervention Society. Details for the conduct of that procedure are provided in those guidelines. Figure 102.3 illustrates the critical features.

**FIGURE 102.3** Fluoroscopy views of an electrode in place for an L4 medial branch radiofrequency neurotomy. A: Declined (pillar) view showing the tip of the electrode lodged in the notch between the superior articular process and transverse process of L5. B: Oblique view showing the tip of the electrode crossing the junction of the superior articular process and transverse process. C: Posteroanterior view showing the electrode orientated obliquely, cephalad and medially, against the lateral surface of the superior articular process. D: Lateral view showing the active tip of the electrode lying opposite the middle two-fourths of the neck of the superior articular process.

The electrode must be inserted so that its tip lies parallel to the target nerve. This requires an insertion from below, along a ventroorostral trajectory (Fig. 102.3A). The electrode must also avoid the mamilloaccessory ligament. Therefore, the trajectory must also be slightly abducted (Fig. 102.3C). The electrode is inserted until its tip enters the target zone for the medial branch, which lies opposite the middle two-quarters of the neck of the superior articular process.\(^{108,119}\)

Because of idiosyncrasies in anatomy, for the L1–L4 nerves, the target
is the medial branch. At L5, the target is actually the L5 dorsal ramus itself. It is the L5 dorsal ramus, rather than the L5 medial branch, that crosses the target zone opposite the middle two-quarters of the neck of the S1 superior articular process.108,110,119

Once the electrode has been placed, the tissues surrounding its tip are coagulated by raising the temperature of the electrode to 80° to 85° C for 90 seconds. However, for optimal outcomes, adjustments have to be made to cater for the gauge of the electrode and the length of its exposed tip. A single lesion may not be adequate to ensure capturing the entire nerve. Because the nerve may lie slightly higher or slightly lower on the neck of the superior articular process, lesions may need to be placed high and low in the target zone. This is less of an issue if large-gauge electrodes are used, for such electrodes form large lesions that can encompass the entire height of the target zone, but if smaller electrodes are used, two or three placements may be required in order to encompass the entire target zone.108 If the exposed tip of the electrode is only 5 mm, lesions may need to be made both distally and proximally along any given insertion, in order to capture a maximal length of the nerve.108 If these precautions are not taken, either the nerve may escape coagulation or be only partially coagulated, either of which consequence compromises the outcome of the treatment.

**Effectiveness.** The effectiveness of this technique of lumbar medial branch neurotomy was benchmarked by two studies. Both studies selected patients for treatment on the basis of responses to comparative local anesthetic blocks. Both placed large-gauge electrodes parallel to the target nerves, across the target zone for each nerve.

The earlier study selected patients on the basis of greater than 80% relief from pain following each of two diagnostic blocks.66 Anatomical success in coagulating the target nerves was confirmed by postoperative electromyography of the myotomes of the nerves coagulated. At 12 months after treatment, 80% of patients continued to have at least 60% relief of pain, and 80% had at least 60% relief.

The later study was conducted in two neighboring practices.133 The data from each practice differed only in that one practice performed treatments
over a longer period of survey and performed more repeat treatments when pain recurred. Patients were selected on the basis of complete relief of pain following comparative local anesthetic blocks. Successful outcome was defined as complete relief of pain for at least 6 months, accompanied by restoration of activities of daily living and no need for continuing care for back pain. In the two practices, the initial success rates were 58% (44% to 72%) and 53% (40% to 66%). In the first practice, the median duration of relief from the first treatment was 15 months, with an interquartile range of 10 to 28 months. In the second practice, the corresponding figures were 15 (10 to 29) months. Repeat treatments were performed to reinstate relief if pain recurred after the first treatment. A total of 35 treatments in 29 patients were performed in the first practice, and 66 treatments in 30 patients in the second practice, resulting in a median duration of relief, per treatment, of 13 months, over a 5-year period.

These data established that good outcomes could be achieved if patients were correctly selected using controlled diagnostic blocks and if meticulous surgical technique was used. Moreover, a success rate of over 50% for achieving complete relief of pain, with restoration of activities of daily living and no need for continuing care is unprecedented in the treatment of back pain.

Other studies, including controlled trials, have not matched these outcomes, but nor have they applied the same discipline and rigor, either for selection of patients, for surgical technique, or both. Consequently, none of the other literature constitutes legitimate evidence concerning the effectiveness or efficacy of lumbar medial branch neurotomy as prescribed by the International Spine Intervention Society. Any evidence that other studies provide pertain to other variants of this procedure.

This distinction has been overlooked or ignored by authors of systematic reviews. Any objective appraisal of the evidence requires stratifying the data according patient selection and surgical technique, for variations in those domains seriously compromises the outcomes achieved. Not making the distinctions creates a false impression of the effectiveness of lumbar medial branch neurotomy.

Relying on single blocks to select patients and not using controlled blocks does not provide a valid diagnosis. The high false-positive rates of
single blocks means that the study sample will be contaminated by patients who are unlikely to have the condition that lumbar medial branch neurotomy is designed to treat. Indeed, it has been shown that success rates are significantly lower in patients selected by single blocks, than in those selected by controlled blocks.\textsuperscript{134} This flaw does not compromise the outcomes on those patients who do have the condition, but it reduces the power of the study, particularly if it is a controlled trial. Genuine responses to treatment will be swamped and obscured by patients with no response or placebo responses.

Using less-than-complete relief of pain as a selection criterion compromises the validity of diagnosis and the outcomes achieved by treatment. A criterion of 50% relief means that no patient can be expected to achieve the benchmark standard of complete relief of pain. Nor can they be expected to restore activities of daily living or cease health care, which are also the benchmark standards for lumbar medial branch neurotomy. For statistical purposes, this may or may not be a fatal problem in controlled trials. The trial could still show that a greater proportion of patients achieved 50% relief after active treatment, but such an outcome would be of questionable value if it does not reduce the burden of illness, that is, the patients still have a complaint that requires continuing treatment.

Placing the electrode perpendicular to the target nerve incurs the risk of not coagulating the nerve adequately. In turn, this risks reducing the success rate for achieving complete relief of pain or reducing the duration of relief. Likewise, creating a single lesion at a single target site, rather than coagulating an entire target zone, risks inadequate coagulation of the target nerve. The same applies to using small-gauge electrodes. In both instances, both the success rate and the duration of relief can be compromised.

A fatal flaw applies to techniques in which the electrode is placed at locations remote from any known nerve or insufficiently close to the target nerve to capture it. Such techniques, by definition, constitute a sham procedure. Neurotomy cannot be a genuine procedure if no nerve is coagulated.

Throughout the literature, outcomes inferior to those of the benchmark...
studies can be traced to one or more of these flaws. In some instances, the flaws disqualify the study from providing any evidence. In others, certain conclusions can be drawn but not others.

In two explanatory controlled trials, electrodes for active treatment were placed remote from any target nerve.\textsuperscript{135,136} These studies constitute comparing one sham with another. The authors of one of these studies later acknowledge this flaw.\textsuperscript{137}

Perpendicular placement of electrodes is characteristic of studies emanating from The Netherlands or influenced by them. The earliest of these studies described but did not illustrate the technique used,\textsuperscript{138} so it is not exactly clear where the electrode was placed. Nevertheless, sham treatment was rigorously compared with active treatment. The success rate of active treatment was low, ostensibly because single blocks were used to select patients or because a single lesion was made perpendicular to the target nerve, using a small electrode. Consequently, it was difficult to show statistically significant difference by a simple comparison of success rates. However, survival analysis clearly showed that success over time was significantly greater after active treatment.\textsuperscript{138}

Another explanatory study from The Netherlands found no significant difference in favor of active treatment.\textsuperscript{139} However, small-gauge electrodes were used; single lesions were made, perpendicular to the target nerve; and the illustration of the technique showed that electrodes were not placed sufficiently near to the target nerve.\textsuperscript{121} The authors acknowledged these limitations but explained that they tested how RF neurotomy was performed in their community, that is, The Netherlands.\textsuperscript{140} Therefore, the conclusions from this study cannot be generalized to other techniques of lumbar medial branch neurotomy; they expressly apply only to how it is practiced in The Netherlands.

A second explanatory study from The Netherlands found no attributable effect from active RF neurotomy compared with sham.\textsuperscript{141} However, patients were selected on the basis of a decrease in pain of only 2/10 following a single diagnostic block, small-gauge electrodes were placed perpendicular to the target nerve, and only a single lesion was made at each site.

A more recent study from The Netherlands reported that adding
neurotomy to conservative treatment did not improve outcomes.\textsuperscript{142} However, patients were selected by single blocks, and although the surgical technique used was not illustrated, the authors—when challenged\textsuperscript{143–145}—responded that they studied how neurotomy was practiced in The Netherlands.\textsuperscript{146} Therefore, although their conclusion might apply to practice in The Netherlands, they do not apply to other techniques of lumbar medial branch neurotomy.

One controlled study used correct surgical technique but selected patients by single blocks only.\textsuperscript{147} Consequently, the data do not lack validity but are compromised by less than optimal success rates. Even so, the study showed that lumbar medial branch neurotomy was significantly more often effective than a credible sham comparator.

Two studies selected patients by comparative local anesthetic blocks, and each used correct surgical technique. The first was an observational study.\textsuperscript{148} Patients were selected if they reported at least 70\% relief of pain following comparative medial branch blocks. Of 174 patients reviewed over a 10-year period, 35\% (29\% to 41\%) of patients had at least 50\% relief of pain, and a further 22\% (16\% to 28\%) had 80\% relief of pain, at 6 months after treatment. The proportions of patients with enduring relief decreased between 6 months and 2 years after treatment, but the median duration of relief was 12 months. A later, placebo-controlled trial\textsuperscript{149} showed that patients reported significantly greater relief of back pain after active treatment, but this study was compromised because patients had other complaints of pain, such as radicular pain. Consequently, a success rate for complete elimination of pain could not be determined.

No controlled trial has shown that the results of lumbar medial branch neurotomy—when performed correctly—are attributable to placebo. Yet, a small number of controlled trials, with limitations, have shown that the outcomes of lumbar medial branch neurotomy cannot be attributed to placebo. Those controlled trials that claim no benefit beyond that of placebo are all compromised by suboptimal selection of patients and discredited surgical technique.

Cervical Medial Branch Neurotomy

\textbf{Background.} The principles of surgical precision that beset lumbar medial
branch neurotomy were established before cervical medial branch neurotomy was extensively used. Therefore, its literature is less affected by errors and misrepresentations. Nonetheless, some problems still apply.

In strictest terms, cervical medial branch neurotomy is used to treat pain mediated by one or more of the medial branches of the cervical dorsal rami. In practical terms, it is used to treat cervical zygapophysial joint pain. At typical cervical levels, each zygapophysial joint is supplied by the two medial branches with the same segmental numbers as the joint. The C2–C3 joint is supplied by one nerve: the third occipital nerve, which is the superficial medial branch of the C3 dorsal ramus.

The singular indication for cervical medial branch neurotomy is complete relief of pain when one or more medial branches is anesthetized by controlled diagnostic blocks. Typically, this means both of the nerves that innervate a particular zygapophysial joint or the third occipital nerve when the C2–C3 joint is the source of pain.

**Technique.** A particular idiosyncrasy that affects cervical medial branch neurotomy is that cervical medial branches follow a curved path around the waist of the cervical articular pillars. Therefore, in order to capture fully a long length of the target nerve, electrodes have to be placed along each of two paths: a sagittal path to capture the nerve on the lateral aspect of the articular pillar and an oblique path to capture it on the anterolateral aspect.

The one technique that has been based on original anatomical and laboratory research is that promoted in the Practice Guidelines of the International Spine Intervention Society. It is also the only technique that has been validated in clinical studies and trials. The Practice Guidelines describe in detail how cervical medial branch neurotomy should be performed. Figure 102.4 illustrates the key features.
FIGURE 102.4 Fluoroscopy view of electrode placements in the execution of a C5 medial branch radiofrequency (RF) neurotomy. A: Lateral view of an oblique insertion. The tip of the electrode lies over the anterolateral surface of the C5 articular pillar. (A block needle remains in place over the target area, in case supplementary local anesthesia is required.) B: Posteroanterior view of an oblique insertion. The tip of the electrode lies just medial to lateral margin of the silhouette of the C5 articular pillar. C: Lateral view of a sagittal insertion. The tip of the electrode lies over the lateral surface of the C5 articular pillar. D: Posteroanterior view of a sagittal insertion. The tip of the electrode lies tangential to the lateral surface of the C5 articular pillar.

In order to reach the proximal end of the target nerve, the electrode is inserted along a 30-degree oblique path so that its tip lies against the anterolateral aspect of the articular pillar (see Figs. 102.3A and 102.3B). That portion of the nerve is coagulated by raising the temperature around the tip of the electrode to 80°C for 90s. In order to reach the next section of the nerve, the electrode is inserted along a sagittal path so that its tip lies tangential to the lateral aspect of the articular pillar (see Figs. 102.3C and
For nerves at different segmental levels the target zone differs.\textsuperscript{57,109} At the C4 and C5 levels, the target zone lies opposite the central half of the articular pillar. At higher and lower segmental levels, the target zones lie progressively higher on the pillar.

**Efficacy.** This technique was developed initially on the basis of anatomical studies\textsuperscript{111} but subsequently refined in the light of pilot clinical studies.\textsuperscript{150} Once perfected, it was rapidly subjected to a placebo-controlled trial.\textsuperscript{151} That trial showed that active treatment was significantly more effective than sham treatment both in terms of success rate and duration of relief. In that study, and in those that followed, the definition of success was complete relief of pain, accompanied by restoration of activities of daily living and no need for other health care.

Subsequent studies performed long-term follow-up of the patients treated in the placebo-controlled trial and patients treated after the trial.\textsuperscript{152} Other studies corroborated the outcomes and provided additional details.\textsuperscript{153,154}

Complete relief of pain is achieved in some 70\% of patients treated.\textsuperscript{150–154} Errors in diagnosis account for the failures. Some patients have false-positive responses to diagnostic blocks, even when these are controlled. In other patients, neurotomy unmasks latent or previously undiagnosed sources of pain, for example, at adjacent segmental levels.

The pooled data indicate that about 60\% of patients maintain complete relief of pain at 6 months, and between 30\% and 50\% do so at 12 months.\textsuperscript{155} Success rates are not demonstrably different between patients with legal claims and those without.\textsuperscript{151–154} Recurrence of pain is to be expected because the treated nerves regenerate, but repeat neurotomy reinstates relief. Repetition has been reported to reinstate relief up to seven times, with the average duration of relief ranging between 8 and 18 months per repetition.\textsuperscript{57,152–154}

Complete relief of pain is accompanied by restoration of activities of daily living and no need for other health care.\textsuperscript{57,154,155} These outcomes occur only if the technique recommended by the International Spine Intervention Society\textsuperscript{109} is used and only if the selection criteria are
complete relief of pain following controlled diagnostic blocks of the medial branches to be targeted.\textsuperscript{155} If lesser diagnostic criteria are used, success rates and the degree of relief are substantially lower.\textsuperscript{156,157}

Conspicuously, RF medial branch neurotomy is the only treatment that has been shown to provide complete relief of chronic neck pain, with restoration of activities of daily living and no other need for health care.\textsuperscript{57,151,155} Moreover, it also resolves psychological distress immediately upon relieving pain\textsuperscript{158,159} and reduces central sensitization and hyperalgesia.\textsuperscript{160} No other treatment for chronic neck pain has been shown to have these properties. A Cochrane review found that the evidence for cervical RF neurotomy was limited, but only in the sense that there have not been more controlled trials; there was no dispute concerning the quality of the published studies.\textsuperscript{161} An independent review reported that RF neurotomy sets a benchmark for the treatment of chronic neck pain.\textsuperscript{162}

The rare side effects of cervical medial branch neurotomy include vasovagal syncope, dermoid cyst, Koebner phenomenon, and so-called neuritis: ostensibly, irritation of one of the target nerves.\textsuperscript{57,163} More common side effects are numbness or dysesthesia in the cutaneous territory of one of the target nerves.\textsuperscript{57,163} These have been self-limiting and not requiring treatment. None is permanent because the target nerve regenerates.

Skin burns are avoided by using a firmly applied dispersive/ground plate with a large surface area rather than a spinal needle to dissipate electrical energy. Meticulous technique and strict asepsis should guard against infection and hematoma formation. Neurologic complications are avoided by ensuring that electrodes always remain external to the vertebral column and do not reach either the vertebral artery or the intervertebral foramen.\textsuperscript{109}

Concerns that denervating a zygapophysial joint could cause Charcot joints\textsuperscript{164,165} are unfounded. There are no published reports of Charcot arthropathy directly attributable to RF neurotomy. Modern pathophysiology implicates a neurovascular mechanism, and diabetes has replaced tertiary syphilis as the most common cause of Charcot arthropathy,\textsuperscript{166} and arthropathy can occur in advance of abnormal
Charcot joints classically occur in weight-bearing joints of the lower limb in which all the surrounding muscles are insensate, resulting in instability. This does not occur with spinal RF neurotomy. The medial branches innervate only the deep paramedian muscles. The superficial and lateral muscles are spared. Thus, the spinal motion segment is not rendered insensate. Meanwhile, the disk and articular processes maintain stability passively.

Catastrophic, spinal cord injuries have occurred only when electrodes have been egregiously misplaced. They are avoided by careful placement of electrodes into the correct target zone and monitoring their location during the generation of lesions.

Third Occipital Neurotomy
RF third occipital neurotomy is a companion procedure to conventional cervical medial branch neurotomy. Its distinction is that the target nerve is the third occipital nerve (see Fig. 102.4), and the pain problem treated is cervicogenic headache. The singular indication for the procedure is complete relief of headache after controlled blocks of the third occipital nerve.

The Practice Guidelines of the International Spine Intervention Society describe in detail how third occipital neurotomy should be performed. Figure 102.5 illustrates the key features.
The third occipital nerve wraps around the waist or lower half of the C2–C3 zygapophysial joint.\textsuperscript{111} It furnishes articular branches to the joint from its deep aspect. The location of the third occipital nerve is quite variable but in a predictable area.\textsuperscript{57} Most often, it lies along the equator of the C2–C3 zygapophysial joint, but it can also lie low on the joint, toward the waist of the C3 articular pillar. Consequently, there is no single target point for neurotomy. Rather, a target zone has to be coagulated, in order to accommodate variations in the exact location of the nerve.\textsuperscript{109}

In order to reach the proximal end of the third occipital nerve, the electrode is inserted along a 30-degree oblique path so that its tip tucks across the ventrolateral aspect of the joint (see Fig. 102.5). To reach the
more distal segment of the nerve, the electrode is inserted along a sagittal path so that its tip rests tangential to the lateral aspect of the joint (see Fig. 102.5).

Along each path, the tip of the electrode has to be adjusted into two or more, higher or lower locations so that the entire target zone is coagulated. Fewer such adjustments are required if large-gauge (16G) electrodes are used, but more lesions need to be made if small-gauge electrodes are used. At each location, the target zone is coagulated by holding the electrode temperature at 80 to 85°C for 90 seconds.¹⁰⁹

This intervention has not been subjected to a placebo-controlled trial because it is not possible to mask the procedure. Active treatment produces a patch of anesthesia in the cutaneous territory of the third occipital nerve. However, the procedure has been benchmarked by an observational study. That study showed that when patients were selected on the basis of complete relief of headache following controlled blocks of the third occipital nerve and when third occipital neurotomy was performed according to prescribed standards,¹⁰⁹ complete relief of headache was achieved in 88% of patients, for a median duration of some 297 days.¹⁷² That relief was associated with restoration of activities of daily living and no need for other health care. Such results have been corroborated by other studies,¹⁵²–¹⁵⁴ which included patients with cervicogenic headache but did not focus explicitly on them. For patients in whom headaches recur, relief can be reinstated by repeating the neurotomy. By repeating neurotomy as required, some patients have been able to maintain relief of their headache for longer than 2 years,¹⁷² for up to 5 years,¹⁵⁴ and beyond.¹⁵²

Others who have purported to study cervicogenic headache in controlled trials have not matched these benchmarks,¹⁷³–¹⁷⁵ but in those studies,

- Patients were selected simply on the basis of clinical criteria.
- Nerves were indiscriminately targeted, without having been subjected previously to controlled blocks.
- None of the surgical techniques has ever been validated anatomically or clinically.

So, there was no evidence in these controlled trials that any of the patients had third occipital headache and no evidence that the technique used could successfully and thoroughly coagulate the third occipital nerve.
Consequently, these controlled trials do not contribute any evidence concerning the efficacy or effectiveness of third occipital neurotomy when performed correctly.

Third occipital neurotomy is associated with distinctive side effects: notably numbness, ataxia, and dysesthesia. Numbness is to be expected because the third occipital nerve has a cutaneous distribution that is larger and more constant than that of typical cervical medial branches. Touch-evoked hypersensitivity and dysesthesia typically resolve spontaneously, usually within a fortnight, but may last up to 6 weeks. The third occipital nerve also innervates the semispinalis capitis and contributes substantially to cervical proprioception and tonic neck reflexes. Therefore, neurotomy is commonly associated with a mild ataxia. Generally, this ataxia is not disabling, for patients can rely on visual cues to locate horizontal objects and thereby stabilize the orientation of their head. No long-term effects have been reported.

Because of possible problems with ataxia, presumptive bilateral neurotomy is not recommended in patients with bilateral third occipital headache. If bilateral neurotomy is indicated, it is recommended that one side be treated first and the other side be tested with a prognostic block to test that subsequent neurotomy on this side does not produce disabling ataxia.

Sacral Lateral Branch Neurotomy

Sacral lateral branch neurotomy is a procedure devised for the treatment of sacroiliac pain. It involves coagulating the lateral branches of the S1–S3 dorsal rami where they emerge from their dorsal sacral foramina.

A variety of methods have been used to coagulate these nerves, ranging from conventional, monopolar electrodes to bipolar electrodes, cooled electrodes, and special multipronged electrodes. None has emerged as the preferred method, and outcomes have been less than impressive. Moreover, the indications for the procedure have not been rigorous.

The most unambiguous indication for lateral branch neurotomy would be complete relief of pain from controlled, diagnostic blocks of the sacral lateral branches, but no one has followed this paradigm. Instead, a variety of other indications have been used.
One indication has been a positive response to intra-articular blocks of the sacroiliac joint, in the belief that lateral branch neurotomy should be a treatment for sacroiliac joint pain. Indeed, a recent Appropriate Use Criteria listed relief from intra-articular blocks as a prime indication for lateral branch neurotomy. However, this belief is inconsistent with the available evidence. Anesthetizing the lateral branches does not protect normal volunteers from experimental pain from the sacroiliac joint. Consequently, lateral branch neurotomy cannot be a logical treatment for sacroiliac joint pain, and positive sacroiliac joint blocks cannot be a logical indication for lateral branch neurotomy.

Anesthetizing the lateral branches protects normal volunteers from experimental pain from the posterior sacroiliac ligaments. Therefore, a logical indication for lateral branch neurotomy would be sacroiliac ligament pain, for which the diagnostic test would be controlled blocks of the sacral lateral branches. However, in that regard, several problems arise.

No one has systematically determined the prevalence of sacroiliac ligament pain. So, we do not know if this is a common or a rare condition. No one has determined if the condition occurs in isolation or concurrently with sacroiliac joint pain. The previously conventional technique, using single-site blocks, has been shown to be flawed, in that it often fails to capture the target nerves. More accurate is a multisite, multidepth technique, but no one has applied this technique to determine the prevalence of sacroiliac ligament pain. In principle, single blocks—by any technique—would be liable to false-positive responses, but no one has reported using controlled diagnostic blocks of the sacral lateral branches, and the false-positive rate is not known, either for single blocks or controlled blocks.

For these various reasons, sacral lateral branch neurotomy lacks a firm foundation. Although a rationale for lateral branch neurotomy can be formulated, data consistent with this rationale are few.

Most studies selected patients on the ill-founded basis of positive responses to one or two intra-articular blocks. For achieving at least 50% relief of pain, they variously reported success rates of 50% to 80% at 2 or 3 months, reducing to 30% to 60% at 6 and 9 months.

One study selected patients on the basis of an initial intra-articular
block, supplemented by a single lateral branch block.\textsuperscript{189} It reported 50% of patients having at least 50% relief at 9 months.

The only study that used lateral branch blocks alone, selected patients who had at least 75% relief from each of two blocks that were not in any way controlled.\textsuperscript{190} At 6 months after lateral branch neurotomy, 27% of patients had greater than 50% relief of pain, and 18% reported being totally free of pain. At 9 months, these figures were 52% and 15%. The proportion of patients who achieved good outcomes at 1 month was nearly six times greater than that of patients who underwent sham therapy, but the small sample size prevented demonstrating an absolute statistically significant difference.

Although the development of sacral lateral branch neurotomy was inspired by the success of cervical and lumbar medial branch neurotomy, the outcomes of lateral branch neurotomy have not mirrored those achieved by medial branch neurotomy. Most studies have reported only the achievement of 50% relief of pain. No evidence has appeared that such an outcome is sufficient to reduce the burden of illness.

The one study that most closely adhered to the rationale for lateral branch neurotomy\textsuperscript{191} achieved complete relief of pain in only 18% of patients. The reason for this low yield is not known. There may be limitations to surgical technique, or it may be that 75% relief from diagnostic blocks is not a sufficiently rigorous selection criterion. For medial branch neurotomy, the best outcomes have been achieved after complete relief of pain following controlled diagnostic blocks.

**Discussion**

The published evidence shows that of all the neurolytic procedures, thermal RF neurotomy is the most widely successful in terms of the diversity of pain problems for which it can be used, its success rate for achieving complete or near-complete relief of pain, and the duration of effect than can be achieved, either from a single application or by repeating the treatment in order to reinstate relief.

The effectiveness of RF neurotomy for trigeminal neuralgia has not been questioned despite no placebo-controlled trials having been
RF medial branch neurotomy has also been shown to be successful. Of all treatments for any form of spinal pain, it is the only one that has been shown to be capable of achieving complete relief of pain accompanied by restoration of function and eliminating the need for other health care. In that regard, it is the only treatment for spinal pain that has been shown to reduce the burden of illness.

However, RF medial branch neurotomy is not a treatment for nonspecific spinal pain. It is applicable only for pain mediated by one or more medial branches of the dorsal rami. For the treatment of that condition, the diagnosis must be rigorously established using controlled diagnostic blocks, and the treatment must be performed meticulously. Only under those conditions can optimal outcomes be achieved.

Unfortunately, both in the published literature and in practice, these conditions are not always met. Taking shortcuts in diagnosis, and imprecision of surgical technique, decrease the success rate and effectiveness of medial branch neurotomy, which gives the procedure a poor reputation. These problems, however, are an indictment of how the treatment is practiced but not an indictment of its effectiveness.

180. Buijs EJ, Kamphuis ET, Groen GJ. Radiofrequency treatment of sacroiliac joint-related pain

In this chapter, we consider ablative and decompressive surgical approaches to pain that target the peripheral nervous system. Ablative procedures interrupt signal flow between pain generators in the periphery and brain. For example, cutting a peripheral nerve may prevent transmission of pain-encoding signals from an injured region to the spinal cord. By contrast, nonablative procedures may relieve pain due to compression of nerves by adjacent connective tissue.

There are five major categories of pain surgery involving the peripheral nervous system: peripheral neurectomy, nerve entrapment release, dorsal rhizotomy and ganglionectomy, sympathectomy, and neurostimulation. The treatment of trigeminal neuralgia, one of the most prevalent pain diseases successfully treated with surgery, is presented in Chapter 104. Ablative procedures aimed at the spinal cord, such as the dorsal root entry zone operation for brachial plexus avulsion or cordotomy for cancer pain, are presented in Chapter 105. Neurostimulation procedures, including dorsal column stimulation, nerve root stimulation, and peripheral nerve/field stimulation, are presented in Chapter 96.

There are two fundamental approaches to control intractable pain: attempts to palliate symptoms and attempts to eliminate pain definitively. Pharmacologic, psychological, physiotherapeutic, neuromodulation, and neurointerventional approaches each attempt to reduce the severity of pain symptoms. Surgical approaches have great appeal for their potential to eliminate pain altogether. In fact, nerve decompressions are among the most common peripheral nerve surgeries. By contrast, ablative procedures such as neurectomy and ganglionectomy are notorious for achieving only
short-term benefits, a reputation that undermines their appeal. In support of such skepticism, animal research suggests that axotomy alone may be sufficient to induce pain.\textsuperscript{1} However, regardless of the perception that inappropriate patient selection may lead to considerable morbidity, the experience of some clinicians remains that ablative procedures have the capacity to relieve pain enduringly and that ablative procedures are useful therapeutic ventures in properly selected patients.

Peripheral Neurectomy

BASIC CONSIDERATIONS
There are two reasons that a nerve may be cut to eliminate pain. One reason is to denervate a peripheral pain-producing structure to treat nociceptive pain. For example, facet rhizotomy denervates the facet joint as a treatment for axial spine pain. A second reason to cut a nerve is to remove an abnormal focus of nerve injury (e.g., excision of a neuroma). In this case, there is some irony in the use of neurectomy to treat pain, as transection of a somatic nerve may have been the original cause of the pain. To understand how neurectomy may relieve pain, we must consider some aspects of the pathophysiology of neuropathic pain.

Pathophysiology of Neuropathic Pain
When sensory nerve fibers are severed, the proximal axons remain in continuity with cell bodies in the dorsal root ganglion. These axons sprout and seek Schwann-cell guides. Schwann cells are believed to upregulate expression of neurotrophic factors, which induce axonal growth.\textsuperscript{2–5} If the perineurium of the injured nerve has remained intact, as in the case of crush or certain thermal injuries, the sprouts may successfully reinnervate the target tissue. Successful regeneration may also occur when the transected ends of the nerve are surgically reapproximated (neurorrhaphy). However, when Schwann-cell guides are not present, the axon sprouts are unable to reach the target tissue and randomly double back on themselves. This disordered process of growth ultimately results in a densely packed cluster of nerve sprouts known as a neuroma.

Weir Mitchell\textsuperscript{6} brought attention to the problem of painful nerve injury
after caring for wounded soldiers during the American Civil War. A century later, Denny-Brown and Kirk\textsuperscript{2} presented one of the first studies demonstrating that axotomy can induce behavioral signs of pain in an animal model. More recent studies have suggested that axotomy of a major nerve, by itself, may induce hyperalgesia in animals. Although nontraumatic neuropathies may induce pain in diverse ways, the single nerve lesion offers a useful model through which to understand the mechanisms of neuropathic pain.

At least four pathophysiologic mechanisms appear to play a role in nerve injury pain.

**Ectopic generation of action potentials:** Although normally silent, nociceptive afferents may become spontaneously active following nerve injury, producing action-potential activity in the absence of a stimulus.\textsuperscript{3} This activity may be experienced as spontaneous pain. In addition to abnormal signaling in the nerve itself, the activity may sensitize central neurons, such that inputs from nonnociceptive, tactile afferents produce pain (allodynia).\textsuperscript{7}

**Ectopic excitability:** Uninjured nerve trunks are minimally sensitive to mechanical stimuli. Gentle percussion over a nerve is not painful. Following injury, however, regenerating fibers may abnormally respond to mild, mechanical stimuli. Such ectopic mechanical excitability gives rise to Tinel sign, an electrical sensation in the nerve’s original target distribution, elicited by mechanical stimulation at the location of regenerating axons. Furthermore, ectopic excitability to mechanical stimuli may be accompanied by chemical sensitization. For example, injured nociceptive axons may become abnormally sensitive to catecholamines. As a result, the physiologic release of norepinephrine from sympathetic terminals may induce pain (sympathetically maintained pain [SMP]).\textsuperscript{4,5}

**Nervi nervorum:** Nerves themselves appear to be innervated by nociceptive fibers. These nervi nervorum fibers may be sensitized to mechanical stimuli following nerve injury. Such a mechanism may explain, for example, the local tenderness and mechanical hyperalgesia of the ulnar nerve when it is entrapped at the elbow or the local tenderness of nerves entrapped by scar tissue.\textsuperscript{8}

**Ephaptic conduction:** Under normal conditions, signals in adjacent
afferent nerve fibers are insulated from each other. Activity in an injured nerve fiber may cross to a nearby fiber, through a direct electrical connection between the two. During such ephaptic transmission, or cross-talk, a nonnoxious sensory stimulus may evoke activity in nociceptive fibers and thereby cause pain.

Some of the mechanisms of ectopic generation of action potentials and ectopic excitability have been described. When an axon is severed, the axonal transport of sodium channels and other ion channels from the neuronal cell body to the sensory terminal is interrupted. As a result, channels may be expressed ectopically in the neuroma formed at the nerve injury site. Nociceptive fibers in the neuroma thereby become sensitive to normally nonpainful stimuli, producing pain when these stimuli are present.\(^9,10\) In addition, nerve injury may lead to profound changes in gene expression, promoting ectopic excitability.\(^11\)

Other mechanisms may also contribute to neuropathic pain. Although inflammatory and neuropathic pain syndromes are traditionally considered separately, immunologic studies have implicated several pathways through which inflammatory responses may alter nociceptive processing, resulting in neuropathic pain.\(^12\) Evidence supports what may be termed the wallerian degeneration hypothesis.\(^13\) According to this hypothesis, uninjured nociceptors that are adjacent to nerves undergoing wallerian degeneration may become spontaneously active and develop sensitivity to catecholamines, resulting in spontaneous pain and SMP. To the extent that neuropathic pain results from these mechanisms, peripheral neurectomy may be expected to worsen pain because the nerve undergoes wallerian degeneration distal to the site of neurectomy.

**Rationale for Neuroma Relocation Surgery**
The concept of surgery to remove a neuroma as a treatment of nerve injury pain is a flawed one. Neuromas arise from nerve fibers proximal to a region of transection or severe injury, which remain in continuity with their cell bodies in the dorsal root ganglia. Cutting the nerve at a location that is proximal to the site of nerve injury to remove the neuroma results in the formation of a new neuroma at the proximal location. Surgery in which neuromas are “removed” should therefore be termed neuroma relocation.
surgery.

Not all neuromas are painful. The tissue milieu surrounding the nerve may determine whether a neuroma becomes painful or remains painless. The use of peripheral neurectomy as a treatment for painful neuromas is therefore predicated on the hope that relocation of the neuroma may convert it from a painful one to a painless one. For example, relocating a neuroma to a non–pressure-sensitive area may alleviate pain in some patients. Relocation of neuromas into muscle was first described in 1918. Since that time, the identification of anatomic locations appropriate for nerve relocation has improved outcomes substantially. \(^{14–22}\)

Thus, an important consideration in peripheral neurectomy is the role of location in the production of pain. If the location of nerve injury contributes to pain, then relocating the neuroma to a mechanically favorable area may be advantageous. However, to the extent that there is location-independent ectopic generation of action potentials in the neuroma, neuroma relocation surgery will fail. Additionally, some investigators have argued that central mechanisms may account for pain in many nerve injuries. \(^{23}\) In this circumstance, neuroma relocation surgery may also fail. However, our observations as well as those of other experienced clinicians suggest that in patients with nerve injury pain, where anesthetic block of the injured nerve relieves pain, peripheral neurectomy may provide significant pain relief.

**CLINICAL CONSIDERATIONS**

**Preoperative Evaluation**

Clinical scenarios favoring peripheral neurectomy may be broadly divided into two circumstances: neuropathic pain resulting from nerve injury and nociceptive pain from a diseased tissue other than nerve. Nerve injury pain is characterized by numbness, burning, and allodynia. Tinel sign may be present at the site of a painful neuroma. Candidates for neuroma relocation surgery should respond to local anesthetic blockade.

Successful anesthetic blockade is an important prerequisite for effective neuroma relocation surgery. If blockade of the putative, pain-generating neuroma fails to relieve pain nearly entirely, the rationale for neuroma relocation surgery is precarious. The decision to operate may be made with
more confidence if more than one block is done. Once candidate nerves are identified, local anesthetic blocks indicate the level of benefit that can be obtained following nerve ablation. A successfully applied block should induce anesthesia in the distribution of each target nerve, but not beyond, to indicate the specificity of the blockade. Injection of saline or injections away from the nerve may enhance blockade specificity by identifying nonspecific responses (e.g., placebo responses).

Findings associated with complex regional pain syndrome (CRPS), such as edema, hyperalgesia, and trophic changes, also suggest that neurectomy will not alleviate pain. Notably in such cases, peripheral nerve blockade typically produces little relief. Patients should be additionally assessed for hyperalgesia to cooling stimuli. This finding is suggestive of SMP, discussed in the following text. Finally, local tenderness in combination with Tinel sign suggests nerve entrapment. In this instance, nerve decompression would be indicated rather than neurectomy. It is important to note that even subtle entrapments without significant motor or sensory loss may induce severe pain.

Even after one has identified a specific nerve as the pain generator, and one has determined that there are no contraindications to neuroma relocation surgery, a wait-and-see approach may remain most appropriate. For example, where injury is relatively recent and the nerve relatively minor, one may choose to observe. The pain may resolve spontaneously. Where there is only partial nerve injury with remaining function, neurectomy may sacrifice function without any assurance that the new neuroma will be less painful than the old one. In this circumstance, nerve repair should be considered before performing neuroma relocation surgery.

Nerve repair has the potential to relocate neuromas with the advantage of restoring neurologic function. The clinician sometimes faces the ironic situation that to repair an injured nerve, a normal nerve (e.g., sural nerve) may be sacrificed to provide donor grafts. In effect, nerve repair is, in a sense, still a neuroma relocation operation—the neuroma is relocated to the donor nerve. Repair of an injured nerve, when feasible, is generally preferable to permanent transection. By contrast, if a nerve has already been completely severed, the risk of relocating the neuroma is low. Thus, in a case of a well-defined neuroma, when an anesthetic block relieves
Careful analysis may lead to rewarding outcomes. The following case presents the history, preoperative evaluation, and treatment of a patient with neuropathic pain.

A 44-year-old woman presented with a chief complaint of right vaginal pain. This problem had been present for 3 years and originated with an excisional biopsy of a right-sided vaginal ulcer near the introitus. The pain was always present, but especially disturbing were lightning attacks of pain that occurred unpredictably several times a day. Examination disclosed a subtle sensory loss in the right vulvar area. Medication trials were minimally helpful. An anesthetic block of the right pudendal nerve led to 50% pain relief. A combined ilioinguinal and genitofemoral nerve block also led to 50% pain relief. A local anesthetic block of all three nerves together led to 100% pain relief. As treatment, the right pudendal nerve was severed distal to the sacral spinous ligament through a perivulvar approach, and the patient, predictably, had 50% of her pain relieved. At a separate surgery, the right ilioinguinal and genitofemoral nerves were severed through a retroperitoneal approach. At 3-year follow-up, the patient had complete relief. There were no adverse sequelae.

In this case, both lumbosacral neural segments provided innervation to the painful neuromas. Failure to appreciate this would have led to a less than satisfactory result. This case underscores the need for complete blockade of pain during the application of local anesthetic to ensure that all involved nerves are identified.

Operative Technique
Once peripheral neurectomy has been selected as the treatment of choice, the primary surgical issue is where to relocate the neuroma. Troublesome neuromas typically are in areas near joints, scars, and structures that may tether the nerve. The idea of surgery is to relocate the neuroma to a new location where tethering does not occur. Nerves may be cut back to locations such that the ends can be placed in healthy, well-vascularized muscle. Some have also advocated that neuromas be placed in holes in bone. Placement of a cut nerve into these environments does not change
the fact that the cut ends of the nerve will sprout and that a neuroma will form. However, with relocation of the neuroma into muscle or bone, chances are reduced that the new neuroma will be subject to the tension and shearing forces likely to play a role in pain generation.

Alternatives to neuroma relocation exist. The nerves may be cauterized, frozen, burned, or injected with toxic chemicals. These options have been reported to be successful, but their advantages over surgical neurectomy have not been demonstrated. A surgical procedure where the neurectomy is done sharply, with limited damage to the surrounding environment of the nerve, is most appealing from a mechanistic perspective. Damage to the surrounding tissues, such as necrosis due to phenol injection, may create a new focus for pain generation.²⁴

**INDICATIONS AND OUTCOMES FOR TREATMENT OF NEUROPATHIC PAIN**

Ordinarily, neurectomy should be reserved for those situations in which nerve decompression is unlikely to provide a satisfactory result and nerve repair is not possible. Division of major nerves can cause significant motor deficits, sensory deficits, and pain. Ablation of such nerves as a treatment of pain should ordinarily be considered only if the nerve is already divided. Nerve graft repair should be considered as an alternative to repeat transection. Neurectomy of minor nerves has a role in pain treatment, and the risk–reward ratio may be favorable.

**Amputation Stump Pain**

In cases of stump pain, it is worthwhile to examine the patient for tender neuromas. A prosthetic device, for example, may apply pressure to the neuroma, causing pain. Surgical relocation of neuromas to more proximal or protected locations, often in conjunction with nerve wrapping, may provide significant benefit in these cases.²⁵,²⁶

**Intercostal and Intercostobrachial Pain**

Chest trauma or thoracotomy may damage intercostal nerves. Shoulder trauma and axillary node dissection may damage the intercostobrachial nerve. Motor deficits associated with intercostal and intercostobrachial
neurectomy are clinically insignificant. Hence, neurectomy is usually without significant drawbacks. This procedure can be safely accomplished through video-assisted thoracoscopy as well as through an open procedure.27

**Perineal and Inguinal Pain**
Injuries to the pudendal, ilioinguinal, iliohypogastric, and genitofemoral nerves may result in severe pain. These injuries are often due to abdominal and pelvic surgery, episiotomy, hernia repair, entrapment, or blunt trauma. For example, the Pfannenstiel transverse incision may injure the ilioinguinal/iliohypogastric nerves. Groin pain from inguinal herniorrhaphy is not uncommon. Stulz and Pfeiffer28 reported relief of pain with neurectomy in 70% (16 of 23) of patients with ilioinguinal and iliohypogastric neuralgia as a complication of prior surgery. Starling and Harms29 reported similar rates of success: 89% (17 of 19) for ilioinguinal neuralgia and 71% (12 of 17) for genitofemoral neuralgia. In the largest series to date, Amid30 reported 95% improvement in pain among 225 patients. Our own experience supports the use of neurectomy, but the incidence of long-term favorable outcomes is much more modest.31 Recently, Chen and colleagues32 reported that patients who underwent a laparoscopic retroperitoneal triple neurectomy for inguinal pain over open and standard procedures for inguinal herniorrhaphy showed superior outcomes in terms of postoperative pain scores and recovery time.

**Meralgia Paresthetica**
Entrapment or injury of the lateral femoral cutaneous nerve, meralgia paresthetica, may result in pain and dysesthesia in the anterolateral thigh. In cases where the diagnosis is unclear, local anesthetic blockade may be helpful. Transection should ordinarily be considered as a backup procedure when decompression is not feasible and nonsurgical approaches, such as weight loss, have failed.33 A study comparing neurolysis to neurectomy for the treatment of meralgia paresthetica found that only 60% of patients who underwent neurolysis reported being pain free compared to 87.5% of patients treated with neurectomy.34
Saphenous Neuralgia

Entrapment of the saphenous nerve in the subsartorial canal may occur with or without a history of trauma. Damage to the saphenous nerve may occur when the saphenous vein is harvested during revascularization procedures. Risk factors associated with the development of saphenous neuralgia after saphenous vein harvest include younger age, female sex, diabetes mellitus, higher body mass index, distal-to-proximal dissection of the saphenous vein, and closure of the leg wound in two layers. The condition is associated with pain (with or without numbness) along the anterior and medial leg and the dorsum of the foot. Proximal neurectomy may be used if the nerve has been directly injured. Otherwise, in our experience, the nerve should be decompressed as the first-line treatment.

Morton’s Neuroma

This condition involves compression of the digital nerve, typically between the third and fourth tarsal bones. The compression leads to a swelling of the nerve, which is mistakenly called a neuroma. Patients present with pain in this region worsened by wearing shoes and walking. If conservative measures (e.g., orthotics) fail, neurectomy may be offered. Indeed, this operation is a common procedure for this condition. Johnson et al. reported relief of pain in 67% (22 of 33) of patients, with 6 years average follow-up, following excision of the plantar interdigital neuroma. Others have reported surgical success rates of up to 90%. A recent consecutive cohort study reported that ultrasound-guided radiofrequency ablation of Morton’s neuroma provided pain relief in 25 out of 30 patients. This procedure can be completed on an outpatient basis and is less invasive than traditional neurectomy.

General Results of Neurectomy for Neuropathic Pain

What are the predicted results of neurectomy for nerve injury pain? The question is difficult to answer because the patients undergoing this treatment are heterogeneous. In addition, measurement of patient outcome varies greatly among studies with regard to methodologic rigor, length of follow-up, and technique. As suggested by the studies cited earlier, success rates vary from modest to high.
Burchiel and colleagues\textsuperscript{42} have taken a systematic approach to the treatment of nerve injury pain, moving the field toward a definition of the indications for neuroma surgery. In their study, 42 patients with nerve injury pain were divided into four treatment groups:

- Patients with distal sensory neuromas treated by excision of the neuroma and implantation of the proximal nerve into muscle or bone marrow
- Patients with suspected distal sensory neuromas in which the involved nerve was sectioned proximal to the injury site and implanted into muscle or bone
- Patients with proximal neuromas-in-continuity of major sensorimotor nerves treated by neuroplasty, which frees a nerve from adjacent tissue
- Patients with nerve injuries at points of anatomic entrapment treated by neuroplasty and transposition

Surgical success (rated as a greater than 50\% subjective improvement in pain levels, subjectively rated pain relief as “good” or “excellent,” and no postoperative narcotic usage) varied between the groups. In the 40 patients who received postoperative follow-up care over 2 to 32 months (average of 11 months), 16 (40\%) met these criteria. By group, successful pain relief was accomplished in 44\% (8 of 18) of group 1, 40\% (4 of 10) of group 2, 0\% (0 of 5) of group 3, and 57\% (4 of 7) of group 4.

After obtaining these results, Burchiel et al.\textsuperscript{42} attempted to determine retrospectively the extent to which indicators of nerve injury predicted surgical success. Such indicators included Tinel sign, hyperalgesia, a “discrete nerve syndrome,” litigation, and prior procedures. Some predictors showed promise. For example, a discrete nerve syndrome, defined as a condition in which a single nerve could account for all the neurologic findings and pain distribution, tended to predict success. However, none of the relationships between preoperative diagnostic variables and treatment success achieved statistical significance at the P < .05 level. Another prospective study found that employment status, duration of pain, CRPS, smoking, and improvement with nerve block were all prognostic factors for surgical management of neuroma pain.\textsuperscript{43}

One can only speculate why the results of this series differ substantially
from those of other series. Perhaps patient selection accounts for differences, yet Burchiel and colleagues\textsuperscript{42} appeared to discriminate patients at high risk for failure. Surgical technique could also play a role, but there is no evidence on which to base such a statement. In some cases, neuromas are innervated by more than one nerve. For example, proximal resection of the superficial radial nerve to treat dorsoradial wrist neuromas often relieves pain only temporarily. Further inspection reveals that the lateral antebrachial cutaneous nerve may also innervate these neuromas, and thus, success may require sectioning this nerve as well.\textsuperscript{44}

Another reason for failure in neuroma relocation surgery may relate to the discovery that the distal side of a severed nerve may also form a neuroma at the site of injury. Plexus formation distal to the neurectomy may allow intact nerve fibers from other nerves to sprout in retrograde fashion to innervate this distal site. This retrograde sprouting may create a potentially painful neuroma on the “wrong” side.\textsuperscript{45} Neuroma relocation surgery should perhaps attend to neuroma formation on both sides of a severed nerve.

INDICATIONS AND OUTCOMES FOR TREATMENT OF NOCICEPTIVE PAIN

Neurectomy may be performed to interrupt the flow of pain signals through intact nerves from a diseased, pain-generating tissue to the spinal cord. In these cases, a balance is sought between elimination of input from the pain-generating tissue and the potential formation of a painful neuroma. Following neurectomy, regrowth of the transected nerve and invasion of the diseased tissue by surrounding nerves may result in a return of pain. In addition, intact and otherwise “normal” nerve fibers may be sensitized by the release of growth factors in partially denervated tissues. Progression of the underlying disease process may also enlarge the injured tissue region, producing pain beyond the region of surgery. In spite of these considerations, in the following disease processes, neurectomy may be an effective treatment of nociceptive pain.

Axial Spine Pain

The medial branches of dorsal rami innervate the paraspinal muscles, the
interspinous ligament, and the zygapophyseal (facet) joints. Pain associated with movement of the lower back, which is relieved by rest and is not attributable to other spine pathology, may be relieved through bilateral, percutaneous radiofrequency or chemical ablation of these branches in the lumbar spine.\textsuperscript{46,47} A success rate of 85% with mean duration of relief of 10.5 months was reported by Schofferman and Kine\textsuperscript{48} through this procedure. In addition, neck pain associated with whiplash injury may benefit from a similar procedure in the cervical spine.\textsuperscript{49} The mechanism of pain relief is thought to relate to denervation of the facet joint. Because the dorsal ramus innervates several structures, other mechanisms are possible. Evidence is indeterminate for similar pain of thoracic origin.

Many experts suggest diagnostic anesthetic blocks of the facets prior to a facet denervation procedure. Good results are expected only in patients who get excellent benefit from the blocks. Patients who have axial pain in addition to radicular symptoms tend not to benefit from facet denervation procedures alone. Among preexisting symptoms, only paraspinal tenderness has been shown to predict treatment success, whereas increased pain with facet loading maneuvers predicts less favorable outcomes.\textsuperscript{50,51} The procedure is performed percutaneously with radiofrequency heat lesions. The advantages of this procedure are that it can be done on an outpatient basis and morbidity is low. The disadvantage is that the procedure often confers only temporary relief or often no relief at all regardless of the temporary effects of diagnostic facet blocks. In addition to continuous, high-temperature radiofrequency medial branch ablation, pulsed radiofrequency, cryodenervation, and phenol neurolysis have also been used to provide intermediate to long-term pain relief.

In patients with no prior spine surgery, these procedures have been reported to provide initial relief for 60% to 70% of patients.\textsuperscript{36,49,50,52} Rates are reported to be considerably lower, 20% to 50%, for patients with prior spine surgery.\textsuperscript{36,52,53} However, a history of spine surgery is associated with treatment failure not only for radiofrequency denervation but other interventions as well, including epidural steroid injection and open surgery. Our view is that this is a low-morbidity procedure that can provide effective, albeit impermanent, pain relief for patients with axial pain.
spine pain. Recurrence of pain following denervation can be treated with repeated neurotomy with comparable efficacy. See Chapter 102 for a detailed discussion of neurolytic blocks, including radiofrequency neurolysis.

**Extremity Joint Pain**
Denervation procedures aim to eliminate pain arising from degenerative processes in the joint while preserving functions that may be lost after other forms of joint surgery. Buck-Gramcko\textsuperscript{54} reported retention of wrist mobility with substantial reduction of pain in 69\% (135 of 195) of patients following wrist denervation surgery. Wilhelm\textsuperscript{55} reported success in 90\% of patients with tennis elbow treated by denervation. Dellon et al.\textsuperscript{56} reported satisfaction in 86\% (60 of 70) of patients following partial denervation surgery for persistent, postoperative knee pain. Pulsed radiofrequency denervation has also been used to provide relief although generally with shorter effect when compared to conventional radiofrequency ablation and limited evidence to support the efficacy of this approach.\textsuperscript{57}

**Pelvic Pain**
Neurectomy of the superior hypogastric (presacral) plexus has been advocated as a treatment for medically refractory pelvic pain. In 1948, Ingersoll and Meigs\textsuperscript{58} reported complete relief of primary dysmenorrhea in 81\% (72 of 89) of women treated with neurectomy. More recently, with the development of more effective analgesics, ablative approaches to pelvic pain have been largely limited to patients with secondary dysmenorrhea associated with endometriosis. Nezhat et al.\textsuperscript{59} reported at least 50\% relief from pain in 70\% to 85\% of patients with various stages of endometriosis, with 1-year follow-up, following presacral neurectomy combined with excision and vaporization of endometriotic lesions. Debate over the proper role of presacral neurectomy has been ongoing for well over 50 years. Introduction of the biopsychosocial model of chronic pain has potential to spare many women from surgery.

**Cancer Pain**
Peripheral neurectomy is infrequently used in the treatment of pain due to cancer. This is due to the availability of alternative strategies with low morbidity and higher success rates, such as spinal opiates or percutaneous radiofrequency cordotomy.\textsuperscript{60,61} Transecting a peripheral nerve may fail to relieve pain because of overlapping receptive fields of adjacent nerves or central plasticity. Sectioning major peripheral nerves results not only in numbness but also in unacceptable motor loss. Peripheral neurectomies are rarely indicated in the extremities. However, localized chest or abdominal wall pain can successfully be treated with intercostal neurectomies. Alcohol injection, cryoprobe, or radiofrequency lesions provide similar success to open surgery and lowered morbidity for the treatment of cancer pain.

**Nerve Entrapment Release**

**BASIC CONSIDERATIONS**

**Pathophysiology of Nerve Entrapment Pain**

Nerve entrapment syndromes result from pressure applied directly to a nerve, causing pain, paresthesias, or weakness in the sensory distribution of the nerve.\textsuperscript{44,62,63} Entrapment commonly develops where peripheral nerves traverse confined anatomic spaces, rest in superficial locations or in proximity to joints, or become tethered to adjacent tissues. Structural factors such as anomalous nerves, cervical ribs, muscles, or connective tissue bands also may contribute. Repetitive motion, nerve traction due to joint position, chronic vibration, and high force constitute physical stressors that increase the risk of symptomatic entrapment.

Although the degree of compression required to cause nerve injury may vary, axonal degeneration follows pressure in a dose-dependent relationship.\textsuperscript{64} Symptoms can arise following a few significant events or after a longer period of repetitive mild insults. The time course and force of injury are just two of the prognostic considerations. The length of the affected nerve region as well as the presence and severity of nerve ischemia are important factors in the development of symptomatic nerve entrapment. Finally, nerves become more vulnerable to injury in the presence of concurrent systemic metabolic disease, and nerves lose their
Several pathophysiologic mechanisms have been proposed to explain pain associated with peripheral nerve entrapment at the cellular level. Evidence for these mechanisms arises from studies of animal models. Following local nerve compression, internodes along myelinated fibers distort in shape. Demyelination appears earliest in the segment nearest to the point of compression. Eventually, segmental demyelination leads to diffuse demyelination and, ultimately, axonal degradation. Compressive injury usually affects larger, more peripherally located myelinated nerves as opposed to smaller or unmyelinated fibers.

Nerve ischemia may also play an important role in nerve entrapment pain syndromes. Focal pressures of 20 to 30 mm Hg may impede venous blood flow, whereas higher pressures may reduce arterial supply. Within 4 hours of extraneural compression, increasing permeability of the blood–nerve barrier leads to development of subperineurial edema. As there is no lymphatic drainage of the endoneurial space, sustained intraneural pressure elevations persist for at least 24 hours after compressive forces are removed. Following such injury, reactive inflammation, fibrin deposition, and proliferation of endoneurial fibroblasts and capillary endothelial cells lead to intraneural fibrosis of perineurial and epineurial tissues.

Ischemia does not appear to play a role in the initial demyelination associated with acute compressive injury. Rather, nodes of Ranvier adjacent to the point of compression are outwardly displaced and disrupt the myelin sheath. Segmental demyelination follows, stemming from these sites of myelin invagination. Disruption of anterograde axoplasmic flow of vital nutrient proteins reduces terminal membrane excitability. Long-standing ischemia thereby results in replacement of funicular contents with fibrotic tissue, producing derangements in electrical conductivity.

**Nerve Entrapment and Systemic Disease**

Several endocrine and rheumatologic diseases show an association with increased risk for nerve entrapment. Approximately 15% of upper extremity nerve entrapment patients have diabetes. This may result from...
an increased association of peripheral neuropathies with entrapment. Both hypo- and hyperthyroidism have been shown to pose an increased risk for nerve entrapment, which is thought to result from glycogen deposition in Schwann cells. Up to 30% of acromegalics are diagnosed with nerve entrapment syndromes, which often resolve with treatment of the underlying acromegaly. Obesity and pregnancy have well-documented associations with entrapment syndromes, with as many as two-thirds of pregnant women experiencing temporary symptoms. Rheumatoid arthritis is also thought to contribute to entrapment in anatomic locations where synovial overgrowth can produce compression of a nerve. There is an estimated 45% incidence of entrapment neuropathy in rheumatoid arthritis patients. Amyloidosis, carcinomatosis, gout, mucopolysaccharide storage diseases, and polymyalgia rheumatica are all suspected to pose an increased risk for exacerbation of nerve entrapment.

**CLINICAL CONSIDERATIONS**

**Preoperative Evaluation**

**Clinical findings:** Patients suffering from nerve entrapment syndromes present with pain, paresthesias, or motor weakness along a specific nerve distribution. Nocturnal pain, either sharp or burning, classically develops before the onset of daytime or persistent symptoms. Muscular changes, such as atrophy or fasciculation, as well as sensory alterations, such as altered two-point discrimination or temperature sensation, can occur in advanced cases. Specific symptoms result from the location and severity of compression.

On physical examination, Tinel sign may be present. Tinel sign is an electric radiating sensation in the distribution of the nerve, produced by percussion over the nerve. Tinel sign represents ectopic excitability, a hallmark of nerve entrapment, and may be accompanied by local tenderness. Provocative maneuvers may reproduce or exacerbate symptoms and have significantly positive predictive value in the diagnosis of entrapment syndromes.

In many cases, diagnosis of a specific entrapment syndrome may be difficult to make. Compensation of one muscle group by another may create uncertainty in identifying etiology of the entrapment. Furthermore,
entrapment syndromes may be accompanied by concurrent radiculopathy, producing synergistic pain, thereby adding to the diagnostic challenge. In addition, pain associated with entrapment syndromes may not be well localized. For example, radial nerve entrapment may present with global arm pain. Finally, results of electrodiagnostic studies may be normal in some cases, further increasing the diagnostic dilemma.

**Electrodiagnostic studies:** Physical findings may be supported by electrodiagnostic studies. Nerve conduction studies (NCS) measure action potentials along axons, whereas electromyography studies (EMG) measure muscle fiber activity. In sensory NCS, a stimulus is applied to the nerve and a sensory nerve action potential (SNAP) is measured at various distal points along the nerve. Alterations in axon number, diameter, myelination, or temperature all affect the magnitude and temporal profile of the SNAP. In motor NCS, a stimulus is applied to the nerve and a compound motor action potential (CMAP) is measured from the innervated muscle. Changes in conduction velocity, amplitude of CMAP, and distal motor latency suggest that conduction inhibition exists between the point of initial stimulation and the site of recording. Needle EMG examines the spontaneous electrical activity of individual muscle fibers resulting from denervation, reinnervation, or acute muscle injury.

These studies aid in the differentiation of peripheral nerve entrapments from brachial plexopathy and radiculopathy by defining the nature and extent of neurologic dysfunction. For example, although NCS cannot be performed in structures like the brachial plexus due to an inability to record and stimulate across the region of compression, a plexus lesion would be expected to affect the function of multiple peripheral nerves. In entrapment neuropathy, large myelinated sensory fibers are typically affected before motor fibers. Hence, NCS are more often effective earlier in the disease than motor conduction studies (ulnar compression at the elbow is a notable exception to this rule). Entrapment is represented by abnormal recordings of evoked SNAPs along a short nerve segment. Prolonged latency or reduced motor conduction velocity is also indicative of injury, although they are less sensitive measures. Fibrillation seen on EMG occurs as a result of wallerian degeneration of distal nerve segments and suggests advanced entrapment. In general, a combination of studies
and measurement points yields the best information with which to form a diagnosis.

Comparison among the nerves of interest and a nearby unaffected nerve is often more accurate than comparison of a nerve with normal reference values. Cooler temperature, increasing age, and patient size all serve to prolong sensory latencies, confounding reference values. As a result, and to avoid such confounding factors, it is common to perform sensory latency comparisons at as many as three sites (median-ulnar midpalmar, median-ulnar ring finger, and median-radial thumb) in the diagnosis of carpal tunnel syndrome (CTS). Although the greater number of studies increases the likelihood of false-positive results, summation of the latencies of these three studies has proven to be the most sensitive and specific test for CTS.

Following entrapment release, it is notable that clinical improvement may not correlate reliably with electrodiagnostic studies. However, in patients with persistent symptoms following treatment, comparison with pretreatment studies may be helpful. If earlier studies are unavailable, a series of postoperative studies over several months should be obtained.

**Imaging studies:** Developments in ultrasonography and magnetic resonance imaging (MRI) have resulted in a potentially expanded role for imaging in the diagnosis of entrapment neuropathies. Ultrasonography now offers the highest available resolution for visualizing the location of entrapment (Fig. 103.1). However, ultrasound is unable to show pathologic changes within nerves. In contrast, signal and configuration characteristics seen in chronically compressed or tethered peripheral nerves have been well characterized by MRI (Fig. 103.2). On MRI, indicators for nerve abnormality include focal enlargement, T2 hyperintensity, and an indistinguishable or nonuniform fascicular pattern. In addition, MRI simultaneously visualizes muscular alterations due to atrophy and neurogenic edema.
FIGURE 103.1  Series of transverse 17.5 MHz sonography images obtained from proximal to distal over palmar cutaneous branch of median nerve (MN) in 35-year-old healthy man with corresponding diagrams. Relationships of palmar cutaneous branch of MN (thin arrows) with MN (thick arrows), flexor carpi radialis tendon (curved arrow in A, C, E, and G; fcr in B, D, F, and H), and antebrachial fascia (arrowheads, E–H) are shown. A,B: Palmar cutaneous branch of MN detaches from MN as one of its most radial fascicles. C,D: Palmar cutaneous branch of MN gradually deflects to approach flexor carpi radialis tendon. E,F: Palmar cutaneous branch of MN runs slightly deep in relation to antebrachial fascia. G,H: Palmar cutaneous branch of MN lies adjacent to flexor carpi radialis tendon after piercing fascia. (From Tagliafico A, Pugliese F, Bianchi S, et al. High-resolution sonography of the palmar cutaneous branch of the median nerve. Am J Roentgen 2008;191[1]:107–114. Reprinted with permission from the American Journal of...
Specific MRI findings have been correlated with clinical findings, electrodiagnostic findings, and postoperative outcomes for several nerve entrapment syndromes. With current technology, MRI may be a useful adjunct in the diagnosis of entrapment. Specific indications for MRI may include ulnar entrapment, entrapment in the presence of superimposed neuropathy, entrapment where other tests are equivocal, and postoperative evaluation of entrapment. The value of MRI imaging in the setting of uncommon entrapments is less clear.
Operative Technique
Substantial experimental evidence supports three treatments of peripheral nerve entrapment: splinting, local corticosteroid injection, and surgical release. Splinting reduces the offending stimulus through postural correction and reduction of repetitive injury, thereby decreasing reactive inflammation. Local corticosteroid injections have been shown to be helpful in mild cases. Surgical release of anatomic compression is the mainstay of treatment in more advanced cases of peripheral nerve entrapment.95

In general, operative release of entrapment can be quite rewarding, as the risks of surgery are typically low and pain improvement is often dramatic. Avoidance of additional trauma to the compressed nerve is of great importance to surgical outcome. Occasionally, unexpected sources of entrapment may be found during surgical exposure, such as cysts, soft tissue masses, and bony prominences. Choices of surgical approach and operative technique are based largely on individual surgeon preferences.96 Rates of success and complications vary with the location of entrapment and the etiology of pain.

INDICATIONS AND OUTCOMES
Entrapments of the Median Nerve
Carpal tunnel syndrome: CTS results from compression of the median nerve between bones of the wrist and the flexor retinaculum. CTS is the most common nerve compression syndrome, with an annual incidence of 150 per 100,000 population and a 2:1 female predominance.97,98 Patients with CTS present with pain along the radial half of the hand, particularly at night, and weakness of median innervated muscles. Phalen’s sign—recreation of pain through complete wrist flexion for 30 to 60 seconds—is a sensitive and specific marker of mild to moderate CTS.99,100 Electrodiagnostic studies typically demonstrate decreased median-nerve conduction velocity at the wrist. Imaging findings on MRI, when performed, may demonstrate increased signal intensity in the nerve, volar bowing of the flexor retinaculum, and flattening of the median nerve at the level of the hamate.101

Initial therapy includes splinting, activity modification, and nonsteroidal
anti-inflammatory medications for mild disease. Corticosteroid injections offer nearly a 70% positive response initially, although eventual recurrence of symptoms is high.\textsuperscript{102}

Surgical decompression of the carpal tunnel is indicated in cases that have failed conservative management or in cases with severe or rapid onset of symptoms. Some 80\% of patients achieve excellent pain relief with surgery, whereas another 10\% achieve partial relief; less than 1\% of patients experience worsening of their pain symptoms. For patients with motor weakness, similar results have been reported with 84\% of patients returning to baseline function and another 9\% experiencing some improvement.\textsuperscript{100,103–105} Early surgery in patients with ongoing pain has been associated with improved resolution of symptoms.

Incomplete decompression of the nerve is seen in the majority of cases in which pain relief is incomplete, absent, or transient. Another cause of recurrent pain includes postoperative fibrosis. Failure to appreciate the path of the recurrent motor (thenar) branch of the nerve can result in postoperative weakness following release. Injury to the palmar cutaneous branch can result in postoperative pain in the wrist and proximal thenar eminence.\textsuperscript{106,107} A 2010 review attempted to identify optimal outcome prognostic factors for patients undergoing carpal tunnel release. They discovered that having comorbid conditions such as diabetes, poor health status, thoracic outlet syndrome (TOS), double crush, alcohol, and smoking led to a worse prognosis. However, they were unable to identify any positive prognostic indicators that would predict an optimal outcome in patients with CTS undergoing carpal tunnel release.\textsuperscript{108}

\textbf{Anterior interosseus syndrome:} Anterior interosseus syndrome results from isolated injury or entrapment of this largely motor branch of the median nerve.\textsuperscript{109} The nerve arises distal to the medial epicondyle and is vulnerable to injury in supracondylar and forearm fractures.\textsuperscript{110–112} In severe cases, there may be weakness of flexor pollicis longus, flexor digitorum profundus to the index finger, and pronator quadratus.

Patients with anterior interosseus syndrome may present with a characteristic pinch as compensation for weakness in the long flexors of the index finger and thumb. The condition may also present with pain in the forearm associated with tenderness in the proximal volar forearm.
EMG may confirm changes associated with muscular denervation. Surgical exploration with neuroplasty is most commonly performed for patients whose pain does not respond to anti-inflammatory medications or avoidance of repetitive pronation/supination activity.\textsuperscript{113–117}

**Entrapment by the ligament of Struthers:** Struthers’ ligament can cause compression of the median nerve, brachial artery, or brachial vein as they pass beneath it, proximal to the medial epicondyle. A variant bony spicule (supracondylar process) arising from the humerus at this level can place the nerve at risk for entrapment.\textsuperscript{118} A rare disorder, this pathology can potentially be mistaken for CTS.\textsuperscript{119} Motor weakness of the pronator teres, flexor carpi radialis, and flexor digitorum profundus (to the first two digits), although not always present, indicate a point of compression proximal to the carpal tunnel. Release of the ligament and excision of the supracondylar process typically provides pain relief.

**Pronator syndrome:** Pronator syndrome presents as a vague, aching pain in the volar aspect of the elbow and forearm that is exacerbated by activities involving grasping or pronation of the forearm.\textsuperscript{120} On physical examination, tenderness can usually be elicited by deep palpation over the pronator teres. Compression occurs at the lacertus fibrosus, within the muscle between the two heads of pronator teres, or beneath the flexor superficialis tendon at its origin. Avoiding maneuvers that exacerbate the pain and intra-muscular injection of corticosteroids may be attempted prior to surgical release.

**Entrapments of the Ulnar Nerve**

**Ulnar nerve entrapment at the elbow:** Ulnar nerve entrapment at the elbow (UNEE) is the second most common peripheral nerve entrapment syndrome after CTS. At the elbow, the ulnar nerve is bounded medially and anteriorly by the medial epicondyle and laterally by the olecranon. A dense fascial layer overlies this space, forming the cubital tunnel. Entrapment may occur at the cubital tunnel, in the epicondylar groove, beneath the arcade of Struthers, or at the medial intermuscular septum.\textsuperscript{121} Antecedent trauma, inflammatory change, and mass lesions increase the risk of UNEE. Subluxation of a hypermobile ulnar nerve over the medial epicondyle may lead to traumatic injury. An anomalous and potentially
compressive anconeus epitrochlearis muscle may be found in up to 30% of patients.\textsuperscript{122–124}

UNE typically presents insidiously with paresthesias in the ulnar distribution of the forearm, wrist, and hand. Muscle weakness leads to impaired grip and clumsiness in the hand and, in more severe cases, atrophy of intrinsic hand muscles. Tinel sign and the elbow flexion-pressure test, which is done with manual compression of the ulnar nerve just proximal to the cubital tunnel for 30 seconds, offer significant sensitivity and specificity for UNE.\textsuperscript{125,126} Electrodiagnostic studies may demonstrate reduced sensory and motor conduction velocity across the elbow.

The optimal surgical technique for entrapment release in UNE has not been established. Options include transposition of the nerve and in situ decompression. For transposition, the ulnar nerve is displaced anterolaterally in order to shorten its course around the medial epicondyle. Transposition may be subcutaneous, intramuscular, or submuscular, with respect to the flexor-pronator muscle mass.\textsuperscript{127–135} Among the larger case series, successful surgical results of 90% have been reported regardless of technique.\textsuperscript{136–140} Many surgeons favor in situ decompression as an initial surgical treatment, particularly when patients have milder symptoms and isolated compression at only one site.\textsuperscript{141–145}

Traumatic etiology, chronic symptoms, absence of sensory potentials, and severe muscular weakness are among the indicators of poor prognosis for surgical outcome. Pain symptoms more often resolve, whereas motor symptoms may only partially improve, after surgery. Persistent pain following ulnar nerve decompression at the elbow may be due to injury of the medial antebrachial cutaneous nerve.

**Ulnar nerve entrapment at the wrist:** The ulnar nerve and artery course through Guyon’s canal and may become entrapped there.\textsuperscript{146} This canal is bounded by the volar and transverse carpal ligaments and palmaris brevis muscle, with the pisiform bone proximally and medially and the hook of the hamate laterally and distally. Common causes of entrapment include local masses, such as ganglion formation, lipomas, and uremic tumoral calcinosis, or anatomic variants, such as the presence of abductor digit minimi within the canal.\textsuperscript{147} Evaluation is typically based on physical
examination and electrodiagnostic studies. MRI, when a dedicated wrist coil is utilized, offers noninvasive visualization of Guyon’s canal.\textsuperscript{148} Surgical decompression involves unroofing of the canal and removal of any masses.\textsuperscript{149,150}

**Entrapments of the Radial Nerve**

Compression neuropathy of the radial nerve occurs at the radial tunnel, a 5-cm space extending from the capitulum of the humerus to the distal edge of the supinator muscle. It is bounded anteromedially by the brachialis muscle, anterolaterally by brachioradialis and extensor carpi radialis brevis, and posteriorly by the capitulum. Just distal to the lateral epicondyle, the radial nerve divides into a purely sensory superficial branch and a deep branch, the posterior interosseous nerve.

Whereas the superficial branch passes superior to the supinator muscle, the posterior interosseous nerve courses in a plane between the two heads of the supinator muscle as they both continue into the forearm. Potential sources of compression at this level include the fibrous bands that anchor the radial nerve to the elbow, the recurrent radial artery and its associated vessels and branches (collectively known as the leash of Henry), and the arcade of Frohse at the fibrous origin of the supinator and other muscles.\textsuperscript{149,151–153}

**Radial tunnel syndrome and posterior interosseous nerve syndrome:** Classically, there are two distinct clinical syndromes involving this pathology—one primarily involving pain, and the other, motor dysfunction. Radial tunnel syndrome itself is a frequently cited, yet somewhat controversial diagnosis, as some argue against its existence. It consists of pain symptoms including deep aching pain, often worse at night, in the extensor muscle mass at the lateral elbow. On physical examination, several particular maneuvers are suggestive of this diagnosis: (1) reproduction of pain by resisting extension of the third digit, with the elbow and wrist in full extension; (2) tenderness to palpation over the entry of the posterior interosseous nerve into the supinator muscle, approximately 5 cm distal to the radial head; and (3) reproduction of pain with the application of a tourniquet at this level.\textsuperscript{154–157}

In contrast to radial tunnel syndrome, posterior interosseous nerve
syndrome is defined primarily by motor symptoms, including progressive weakness of the wrist and digit extensor muscle group. Due to the relatively distal point of compression, innervation to the brachioradialis, extensor carpi radialis muscles, and supinator are typically unaffected. Weakness in wrist extension is incomplete, such that there is radial deviation. Pain, when present, is secondary in this constellation of symptoms.

Development of this entrapment syndrome is associated with repetitive forceful movements involving elbow extension and forearm pronation and supination. Mass lesions, elbow dislocation, vascular malformations, and synovial inflammation are other potential etiologies of compression, and MRI or ultrasound may be useful in the identification of compression. Electrodiagnostic studies are of limited utility for most patients. Hence, the diagnosis is typically clinical.

Operative release of entrapment includes an exploration of all the branches of the radial nerve, such that the posterior interosseous branch can be fully liberated. Few large case series have been analyzed, and reported outcomes vary in the region of 70%. In some series, however, improved functional outcomes have been reported in over 90% of treated patients.

**Superficial sensory branch entrapment:** Entrapment of the superficial sensory branch of the radial nerve can occur through externally compressive apparel such as watchbands. Chronic intermittent compression tends to cause numbness and dysesthesias over the dorsal surface of the hand, whereas blunt injury at this location typically causes highly refractory pain. Operative neuroplasty has yielded significant improvement of symptoms in 74% to 86% of patients. Of note, superficial sensory branch entrapment may be associated with De Quervain’s tenosynovitis, and release of the extensor compartment is sometimes performed in combination with neuroplasty.

**Entrapment of the Suprascapular Nerve**
Suprascapular nerve entrapment presents with shoulder pain along the border of the trapezius muscle and often denervation of the associated musculature. On physical examination, it is exacerbated with
abduction and external rotation of the arm. The suprascapular nerve passes through the suprascapular notch and beneath the suprascapular ligament before entering the supraspinatus fossa. Compression at the suprascapular ligament is common, and thus, a palsy involving both supraspinatus and infraspinatus is more frequently seen than an isolated infraspinatus denervation on EMG. History of trauma such as shoulder dislocation or scapular fracture is usually present. When this is absent, suprascapular ligament compression, tumor, ganglion, or Parsonage-Turner neuritis should be considered. Reported pain relief and strength increase after surgery have been excellent, with improvement in over 90% of patients. Early surgical treatment appears to yield better results than a delayed operation. This is thought to primarily to prevent the progression of nerve injury as well as muscle atrophy; however, a true association between nerve injury and muscle atrophy reversibility and latency from symptom onset to treatment has yet to be shown. Additionally, the approach to decompression of the suprascapular nerve is still hotly debated among physicians.

Thoracic Outlet Syndrome
The term “thoracic outlet syndrome” (TOS) was coined by Peet to describe compression at the thoracic inlet of the neurovascular bundle composed of the brachial plexus, subclavian vein, and subclavian artery. TOS is most commonly neurogenic in origin. In TOS, unlike other upper extremity entrapments, NCS across the putative entrapment site are not feasible. The diagnosis is therefore typically based on clinical criteria.

TOS has been subdivided into three syndromic zones, according to likelihood of entrapment of the brachial plexus, subclavian artery, and subclavian veins. Anterior scalene syndrome occurs with brachial plexus or subclavian artery compression in the interscalene triangle. Costoclavicular syndrome occurs with compression of any nearby structures in the space between the clavicle and the first rib. Retropectoralis minor syndrome can involve any adjacent structure as well, and compression occurs at the attachment site of pectoralis minor at the coracoid process (the subcoracoid tunnel).

In cases of pure peripheral nerve compression, insidious onset of pain
and paresthesias in the neck, shoulder, arm, or hand is typical, whereas motor weakness occurs in just 10% of patients. Nearly 90% of cases involve the ulnar nerve distribution. Symptoms may be reproduced when assuming a spear-throwing position or with downward pressure on the shoulder. Tenderness (with or without Tinel sign) over the anterior scalene muscle in the supraclavicular fossa may also be present.

Diagnosis can be aided by imaging and electrodiagnostic studies. In particular, a radiograph demonstrating anomalous bony findings, such as a cervical rib, in the presence of corresponding symptoms is highly predictive of good surgical outcome. Comparing MRIs of the thoracic outlet in the standard anatomic position and following hyperabduction and external rotation of the arm may reveal significant narrowing of the costoclavicular space in patients with TOS compared to normal healthy subjects.

With careful attention to patient selection and surgical technique, good results have been reported with surgical management. Surgery can involve first rib resection, anterior scalenectomy, resection of the costoclavicular ligament, or neuroplasty, depending on suspected pathology. The majority of surgeons employ a transaxillary or supraclavicular approach.

In general, immediate pain relief with surgery is good, although results often deteriorate over time. Numerous outcome studies for the transaxillary approach report greater than 90% of patients enjoy initial symptomatic relief. However, long-term follow-up has revealed that less than 50% of patients sustain relief at 5 years, and less than 10% of patients have relief persisting at 20 years. Although reported in fewer numbers and with shorter follow-up, outcomes for the supraclavicular approach appear to be equally good in terms of initial results. Complications of surgery for TOS are unfortunately common and include vascular injury, brachial plexus injury, and thoracic wall injury.

**Entrapments of the Lower Extremities**

Of the entrapment syndromes seen in the lower extremities, meralgia paresthetica (symptoms along the lateral femoral cutaneous nerve) is the most common. Inciting factors are many, including trauma, weight gain, and clothing. Indeed, trauma is the foremost cause of peripheral nerve
injury in the lower extremities, particularly around the pelvic, inguinal, and ankle regions, often involving the femoral, obturator, ilioinguinal, iliohypogastric, genitofemoral, and posterior tibial nerves. Described chronic compressive syndromes include entrapment of the lateral femoral cutaneous, sciatic, saphenous, posterior tibial, common peroneal, deep peroneal, and plantar digital nerves. Results from surgical management of meralgia paresthetica and Morton’s neuroma (of a plantar digital nerve) are discussed with other pathologies treated by neurectomy and will be omitted here.

**Sciatic nerve entrapment:** The posterior L4–S3 sacral plexus nerve roots typically give rise to the sciatic nerve, which travels anterior to the piriformis muscle before passing beneath its inferior border to exit the pelvis through the greater sciatic foramen posterior to the piriformis muscle, along with the superior and inferior gluteal vessels and nerves. When the sciatic nerve instead travels above or even through the piriformis muscle, a syndrome of gluteal region pain, weakness in hip abduction resulting in a lurching gait, and tenderness to palpation just lateral to the greater sciatic notch can be induced.\(^{188}\) Weakness in knee flexion in the absence of paraspinal muscle weakness can be suggestive of this peripheral injury as well, and there is often discrete tenderness between the greater trochanter and ischium.

This entrapment syndrome is six times more common in women than in men and often associated with repetitive trauma such as horseback riding, muscular hypertrophy or ossification, or with iatrogenic injury to the sciatic nerve.\(^{189}\) It can closely mimic the sciatica caused by lumbar disk herniation or spinal stenosis, and MRI is particularly helpful in determining the likelihood of a peripheral nerve entrapment in relation to the far more common spinal etiologies. Electrodiagnostic tests are very difficult to perform reliably in this region and are generally of little utility. Focal tenderness directly over the piriformis muscle, together with normal MRI of lumbar spine, is suggestive of sciatic nerve entrapment.

Surgical management involves sectioning of the overlying piriformis muscle and has provided excellent relief in a limited number of reported cases.\(^{190,191}\) A feared complication of this procedure is complete sectioning of one of the associated gluteal vessels, which can retract into
the pelvis, necessitating laparotomy for hemostasis.\textsuperscript{192} There have been case reports of spontaneous entrapment neuropathies involving the distal portions of the sciatic nerve in the thigh.\textsuperscript{193,194} Endoscopic release of the piriformis muscle has also been shown to be an effective approach to improving pain symptoms for patients with sciatic nerve entrapment.\textsuperscript{195}

**Saphenous nerve entrapment:** Iatrogenic saphenous nerve injury is commonly a result of saphenous vein harvesting. A similar syndrome that also presents as dysesthesias and pain involving the medial aspect of the knee and anterior tibial region has been treated successfully with surgical release in the subsartorial (Hunter’s) canal.\textsuperscript{35,196} A fascial band between the abductor magnus and vastus medialis muscles is the offending factor, and pain can typically be elicited on examination with palpation over the canal.

**Tibial nerve entrapment:** Tibial nerve entrapment at the popliteal fossa results from compression by the tendinous arch of the origin of the soleus muscle as well as from nerve tumors, Baker’s cyst, and trauma. As it crosses medially in the popliteal fossa, the tibial nerve travels superficially to the popliteus muscle while passing under the tendinous arch of the soleus muscle before entering the space between the heads of the gastrocnemius and plantaris muscles.\textsuperscript{197,198}

Symptoms of tarsal tunnel syndrome result from compression of the posterior tibial nerve at the medial malleolus. The tarsal tunnel itself refers to the deep posterior compartments of the distal leg as they pass beneath the flexor retinaculum, which is formed from the superficial and deep aponeuroses of the leg.\textsuperscript{199} Symptoms typically include pain and dysesthesias involving the plantar surface of the foot and sometimes the heel, depending on whether the posterior tibial nerve trifurcates and gives rise to the medial calcaneus sensory branch proximal to the point of compression. Tinel sign over the flexor retinaculum is quite sensitive and specific in the diagnosis of entrapment, particularly when combined with the dorsiflexion–eversion maneuver.\textsuperscript{200} In fact, a recent study in 2012 found that a positive Tinel sign over the tibial nerve at the tarsal tunnel in a diabetic patient with chronic nerve condition at the aforementioned location predicts significant pain relief and improvement in plantar sensibility.\textsuperscript{201} Both MRI and electrodiagnostic studies are extremely
helpful in confirming and assessing severity of the pathology, particularly in recurrent cases and in those rare instances refractory to conservative management.\textsuperscript{202–206} The differential diagnosis is wide and includes such common etiologies as CRPS, plantar fasciitis, and Achilles tendonitis.

Surgical sectioning of the flexor retinaculum and release of the nerve has demonstrated only moderate success, perhaps in part due to the success of conservative management in such a large proportion of cases.\textsuperscript{207–209} Pfeiffer and Cracchiolo\textsuperscript{210} reported 44\% of patients received significant improvement after decompression, and two subsequent studies showed similar overall benefit. Sammarco and Chang\textsuperscript{211} later reported significantly better surgical outcomes in patients with duration of symptoms lasting less than 1 year, compared with disease present for greater than 1 year. Still, Turan et al.\textsuperscript{212} demonstrated that surgical management is still of benefit in those with long-standing symptoms, providing excellent results in 61\% of patients who experienced symptoms for more than 5 years.

**Peroneal nerve entrapment:** Once the sciatic nerve reaches the popliteal fossa, it gives rise to the common peroneal nerve, which then wraps around the fibular head and passes into the peroneal tunnel alongside the peroneus longus tendon. There, it trifurcates, giving off superficial and deep peroneal nerve branches as well as a sensory branch to the tibiofibular joint and knee.\textsuperscript{213} Entrapment syndromes typically arise due to compression in the knee (due to fatty tissue deposition or Baker’s cyst) or at the peroneal tunnel, but the superficial and deep branches can be compressed at the fascial exit of the superficial branch over the anterolateral aspect of the lower shin\textsuperscript{214} and at the anterior tarsal tunnel bounded by the fascial layers over the talus and the inferior extensor retinaculum, respectively. Several small series of patients undergoing decompression of the superficial and deep branches have shown the efficacy of surgical treatment, but large reports guiding decision making in surgical decompression are lacking.\textsuperscript{215–219}

The common peroneal nerve rests in a particularly superficial position at the fibular neck and thus is susceptible to external compression as well as to traction injury. It is also a common site of intraneural ganglia.\textsuperscript{213} Neuropathy is commonly found in women who habitually sit in a cross-
legged position. Similarly, prolonged squatting or kneeling can cause compressive symptoms. Repetitive plantarflexion and inversion of the foot is often the mechanism of traction on the nerve, and a constricting band at the level of the fibular head is often found at the time of operation. Symptoms most commonly include foot drop, weakness of ankle, dorsiflexion and eversion, and pain in the peroneal nerve dermatome along the lateral leg. The pain symptoms can be easily confused with such common ailments as shin splints or tibial stress fracture as well as with an L5 radiculopathy or compartment syndrome. Electrodiagnostic studies are helpful in isolating the region of entrapment.\textsuperscript{220}

Surgical decompression must not be delayed, although conservative management is successful in approximately one-third of cases.\textsuperscript{221} In one analysis, 87\% of patients with motor dysfunction obtained good improvement, whereas only 54\% of patients with purely sensory deficits experienced long-term relief.\textsuperscript{222} However, the average time between onset of symptoms and operation was 14 months in this study. In another series, surgical intervention was shown to yield a 97\% immediate success rate when performed within 2 months of onset of injury, whereas in cases lasting 4 to 8 months, only a 38\% benefit was found.\textsuperscript{223}

Dorsal Rhizotomy and Ganglionectomy

**BASIC CONSIDERATIONS**

The Bell-Magendie model describes a dorsal root composed solely of primary afferent fibers, whereas the ventral root contains only efferent fibers. Dorsal rhizotomy and ganglionectomy procedures seek to take advantage of this apparent physiologic segregation to halt the inflow of nociceptive signals to the spinal cord at particular levels while sparing motor outputs. Injury to motor fibers in the ventral root is avoided (Fig. 103.3). No neuroma forms at the cut ends of the rootlets, as nerve fibers that enter the spinal cord are deprived of their cell body and hence degenerate.\textsuperscript{224}
Theoretically an appealing treatment option for pain, rhizotomy in practice often fails to confer the lasting benefit that one might expect. Early surgeons performed dorsal rhizotomy for a broad range of conditions including stump pain, intercostal neuralgia, angina, visceral pain, and spastic hemiplegia. After comparing operative results for pain with those for spasticity in 1911, Groves \(^225\) remarked, “Strangely enough, the division of the posterior spinal roots has given the least satisfactory results in those very cases where we should have expected it to be the most efficient . . . the relief of pain.”

An important problem with rhizotomy is that the sensory afferents that arise from a region of the body may provide contributions to multiple spinal nerves. Conversely, fibers from a single spinal nerve may innervate multiple segments of the spinal cord. As a result, sensory dermatomes overlap considerably, so that ablation of a single dorsal root produces little sensory deficit.\(^226\) The earliest studies\(^227,228\) of the dermatomes appreciated this complexity, and early surgeons performed rhizotomy at two to three levels or more to achieve pain control.\(^225\) Extensive remodeling of sensory dermatomes, attributed to intraspinal sprouting of dorsal root axons,\(^229\) functional reorganization of existing sensory pathways,\(^230\) and other mechanisms, has since been described.

A second potential explanation of surgical failure involves the presence of unmyelinated sensory fibers in the ventral roots. In 1894, Sherrington...
noted degeneration of fibers on the cord side of a transected ventral root.\textsuperscript{231,232} He suggested that these fibers, which he presumed would double back and reenter the cord through the dorsal root, might provide a physiologic basis for the observation that stimulation of the ventral root results in pain. Microscopy has demonstrated that some fibers do, in fact, enter the cord through ventral roots, cross the ventral horn, and synapse within the dorsal horn or enter the dorsal columns.\textsuperscript{233} Thus, dorsal rhizotomy may fail ultimately because of the presence of afferents that reach the spinal cord via the ventral root. However, the actual frequency of ventral root sensory nerves is not known.

To obviate this problem, consideration may be given to performance of a sensory ganglionectomy. The cell body for all primary afferents is believed to reside in the dorsal root ganglion regardless of whether the fibers reach the spinal cord via the dorsal or ventral roots. One report cites a patient with recurrent pain following dorsal rhizotomy that experienced enduring pain relief following removal of the dorsal root ganglia at the same level,\textsuperscript{234} providing further evidence that afferents concerned with pain may enter the spinal cord through ventral roots. Ganglionectomy has gained acceptance in the treatment of certain pain disorders.\textsuperscript{235} However, including ganglionectomy in a dorsal rhizotomy has not been demonstrated to yield better long-term results, although late recurrence with ganglionectomy is also common.

\textbf{CLINICAL CONSIDERATIONS}

\textbf{Preoperative Evaluation}

Dorsal rhizotomy or sensory ganglionectomy may be attempted for treatment of both nociceptive and neuropathic pain, although in our experience, pain often recurs within a few years. Prediction of the potential effect of an operation can be fairly simple, if only a single level is affected. A number of confounding anatomic situations, such as root-to-root anastomosis or overlap of root innervation, must be considered.\textsuperscript{236} Identification of the appropriate spinal level and roots or ganglia for ablation is accomplished through paravertebral local anesthetic nerve blocks. Spinal epidural or subarachnoid blocks can be used for screening purposes when considering sacral rhizotomy. For greater accuracy in
diagnosis, these blocks should be performed at multiple levels, with placebo controls. There is a tendency for the anesthetic to leak into the epidural space, and this may lead to a false-positive result.

Although rhizotomies are now done infrequently for pain, some patients do gain enduring pain relief from rhizotomy or ganglionectomy, with acceptable morbidity. The challenge is to select the patients most likely to benefit. Feasibility dictates the appropriate procedures to some extent. If the clinical problem is limited to one root, ganglionectomy has appeal in order to avoid the problem of ventral root afferents. Unfortunately, surgical ganglionectomy involves destruction of a substantial portion of the facet and therefore may not be practical if two or more roots are involved. Rhizotomy may be preferable in this instance; however, the problem of pain recurrence may be higher. No clinical studies directly compare rhizotomy and ganglionectomy, and differences in outcome between the two procedures are not well understood.

Dorsal rhizotomy and sensory ganglionectomy spare motor efferents and do not lead to the formation of neuromas. However, careful attention must be given to the potential complications of dorsal root surgery. Ablations of the dorsal roots attenuate not only pain but also vibratory, temperature, and proprioceptive inputs. Loss of these sensory functions may be troublesome particularly in the extremities. In addition, with the ablation of the highly vascularized dorsal roots, blood supply to the spinal cord can be jeopardized. Ablation of more than six dorsal roots increases this risk considerably.\textsuperscript{226} Finally, dorsal rhizotomy and ganglionectomy, if unsuccessful, preclude the use of dorsal column stimulation as a means of pain treatment because the primary afferents on which the stimulator acts undergo wallerian degeneration.

The following case presents evaluation and treatment of a patient with neuropathic pain, in an ideal setting for performance of a ganglionectomy, although with eventual pain recurrence.

A 42-year-old woman underwent an anterior cervical discectomy and fusion with harvesting of a bone graft from the left iliac crest. An anterior abdominal wall hernia developed at the site of bone harvest. This defect was repaired with mesh, and the patient developed severe pain at the repair site. Eventually, the repair site was explored, and injury to the subcostal
nerve (T12) was noted. The neuroma was resected back and relocated to a healthy muscular bed away from scar. Pain was relieved for several weeks and then returned. An additional attempt at neuroma relocation surgery met with the same fate. Opioid treatments as well as other pharmacologic approaches failed to provide satisfactory relief. Nerve root blocks of T12 but not of T11 or L1 led to complete pain relief. A ganglionectomy was performed at T12, and the patient had sustained pain relief for 2 years.

In this case, pain was limited to a single, clearly defined spinal level. The return of pain following neurectomy demonstrated the high likelihood of reformation of a painful neuroma. A single ganglionectomy both eliminated the pain and precluded the reformation of a painful neuroma. However, the pain recurred after 2 years. In our experience, peripheral nerve stimulation, spinal cord stimulation, and intrathecal pain pumps may be preferable and nondestructive first-line therapies for radicular pain prior to performance of sensory rhizotomy or ganglionectomy.

Operative Technique
Dorsal rhizotomy is performed using either an intradural or extradural approach, whereas ganglionectomy is by extradural approach. For intradural rhizotomy, a laminectomy is performed at the levels of interest and the dura is opened, where sensory rootlets are then identified at the intervertebral foramina, followed proximally, and divided. For extradural rhizotomy, the lateral facet is removed and the appropriate nerve roots are exposed laterally. The proximal spinal root is dissected free, and the dorsal rootlet is identified and divided. For ganglionectomy, the dorsal root ganglion is also dissected free and removed. In some cases, separation of the ganglion from the motor root is difficult, and there may be resections of this structure as well, a factor to be borne in mind when selecting the ablative approach. Ganglionectomy can also be performed from a foraminal approach with minor disruption of the facet. Sacral rhizotomy may be accomplished through sacral laminectomy and division of the thecal sac between the S1 and S2 roots.237

INDICATIONS AND OUTCOMES
Indications for dorsal rhizotomy or ganglionectomy may be broadly
divided into procedures for cancer and noncancer pain and are outlined by the Joint Section on Pain in its 1994 recommendations. In addition, dorsal rhizotomy can be a useful therapy in treatment of certain spasticity disorders, including spastic cerebral palsy. Barrash and Leavens reported success in 70% (50 of 71) of patients with cancer, with 10.5-month average follow-up. By contrast, Onofrio and Campa reported an overall success rate of 41% (46 of 112) in patients with localized idiopathic pain. Wilkinson and Chan reported excellent pain reduction in 74% of patients with dorsal root ganglionectomy alone, with no adverse complications, for pain refractory to other treatments. The differences in success rate between cancer and noncancer pain could potentially result from earlier mortality among patients with cancer-related pain, given the significant incidence of late-recurring pain.

Cranial and Cervical Pain

Rhizotomy of C1–C4 in combination with cranial nerves V, IX, and X may provide effective pain relief from extensive head and neck cancers. In considering such a procedure, one would have to consider the morbidity of such an extensive operation in terms of sensory loss. In some cancer victims, however, sensory loss is already extensive. Dorsal cervical rhizotomy may also be combined with trigeminal tractotomy. Cancers of the lung or breast with brachial plexus involvement, with loss of function in the upper limb, may also benefit from cervical rhizotomy.

Occipital Neuralgia

The greater occipital nerve, formed by the posterior primary ramus of C2, and the lesser occipital nerve, formed by the C2 and C3 roots in the cervical plexus, jointly innervate the occipital region of the scalp. Occipital neuralgia is headache, characterized by severe paroxysmal lancinating or continuous pain, localized to this innervated region. Occipital neuralgia may be due to migraine, compression of the C2 root, entrapment of greater occipital nerve at the superior nuchal line, or nerve injury. 

C2 or C3 ganglionectomy, as well as upper intradural cervical rhizotomy, have been used successfully in treatment of occipital neuralgia. Stechison and Mullin reported success in 4 of 4 patients with idiopathic
greater occipital neuralgia, with 2-year average follow-up. Lozano et al. reported that patients with occipital neuropathic pain due to trauma are more likely to experience significant pain reduction following C2 ganglionectomy than other patient groups with occipital pain. Onofrio and Campa reported relief from occipital neuralgia in 64% (9 of 14) of patients immediately and 50% (7 of 14) of patients following ablation of 1 to 3 cervical roots. Dubuisson reported success in 71% (10 of 14) of patients, with 33-month average follow-up, following partial posterior rhizotomy at C1–C3. Cervical nerve block has been shown to be useful for confirmation of occipital neuralgia and possibly as a patient selection tool for rhizotomy. In a recent study, Acar and colleagues reported the return of pain within a year in 65% (13 of 20) of patients undergoing C2 or C3 ganglionectomy. Occipital nerve stimulation may be considered a favorable alternative to C2 or C3 ganglionectomy. However, future work must be completed to further optimize this technology.

All other recent studies recapitulate what is already been said.

Thoracic Pain
Pain associated with chest wall invasion of pleural-based or chest wall malignancies, as well as localized thoracic pain secondary to nerve invasion or compression, can be an indication for dorsal rhizotomy or ganglionectomy. Arbit et al. reported complete pain relief in 64% (9 of 14) and 50% to 100% pain relief in an additional 29% (4 of 14) of patients with cancer pain, with 22-month median follow-up, following thoracic dorsal and ventral rhizotomy. Smith reported success in 10 of 10 patients with intercostal pain due to thoracotomy (7), herpes zoster (2), and cancer (1), following thoracic ganglionectomy.

Postsurgical Truncal Pain
Persistent pain following thoracotomy or laparotomy may be responsive to dorsal rhizotomy. White and Kjellberg reported successful treatment of intercostal neuralgia in 3 of 4 patients, with 8-month median follow-up, following thoracic rhizotomy. Loeser reported success in 33% (1 of 3) of patients at more than 3 months. By contrast, Onofrio and Campa
reported on 18 patients with postthoracotomy pain and 5 patients with postlaparotomy pain, none of whom obtained benefit. White and Kjellberg\textsuperscript{226} also reported successful treatment of postherniorrhaphy neuralgia in 3 of 4 patients, with 2-year median follow-up, following thoracolumbar rhizotomy. There are no large series of patients on which to base management decisions.

One case report demonstrated complete resolution of pain symptoms from postthoracotomy pain syndrome using spinal cord stimulation at 4-month follow-up. However, the authors cite that this technique must be further researched and refined.\textsuperscript{254}

**Sacral Pain**

Cancers of the colon, rectum, urinary tract, cervix, and prostate may result in pain attributable to sacral roots. Unfortunately, ablation of the second and third sacral roots may affect bladder, sphincter, and sexual function. Thus, sacral root division is indicated in cases of pelvic cancer pain, where patients have already lost bladder and bowel function. It is a simple procedure that may confer striking benefit. Saris et al.\textsuperscript{255} reported success in 47% (7 of 15) of patients with colorectal cancer presenting with perianal pain, with 1-year median follow-up, following bilateral S3–S5 rhizotomy. Felsoory and Crue\textsuperscript{237} reported satisfactory results in 69% (20 of 28) of patients with colorectal (17), cervical (5), anal (3), and other (3) cancers, with unstated follow-up duration, following transection of the cauda equina at L5/S1. The surgical anatomy is depicted in Figure 103.4.
A 14-year single-center study showed an 87.5%, 84.8%, and 73% improvement in patients with idiopathic urinary retention, urgency urinary incontinence, and painful bladder syndrome with sacral neuromodulation. This technology has, however, been studied and used more in the treatment of fecal incontinence.
Extremity Pain

Rhizotomy or ganglionectomy is indicated for denervation of a functionally useless limb. There are few other indications in the treatment of extremity pain. That multiple roots may be involved, the morbidity of sensory loss, and the problem of frequent pain recurrence, lead to infrequent use of these procedures for extremity pain. Ganglionectomy for monoradicular extremity pain has been proposed but remains unproven. North et al. reported greater than 50% relief from failed back surgery syndrome in none of the 13 patients they studied, with 5.5-year average follow-up. By contrast, Taub et al. reported success in 59% (36 of 61) of patients with intractable monoradicular sciatica following dorsal root ganglionectomy, with 5- to 9-year median follow-up. This unusually high rate of success likely reflects very careful patient selection.

The choice of rhizotomy or ganglionectomy for treatment of extremity pain requires a balance between compromise of function due to elimination of sensation and the elimination of pain. For the upper extremity, White and Kjellberg reported successful treatment of diffuse upper extremity pain in 50% (7 of 14) of patients, with 3-year median follow-up, following rhizotomy at various levels. Following the procedure, none of the patients complained of unpleasant numbness or clumsiness of the hand, perhaps reflecting the seriousness of the preoperative condition. In the lower extremity, they reported successful treatment of lateral femoral cutaneous neuralgia in 67% (4 of 6) of patients, with 3-year median follow-up, following L2–L3 rhizotomy. Spinal cord stimulation may offer a nondestructive alternative to rhizotomy or ganglionectomy for the treatment of extremity pain. In addition, recent work has shown that stimulation of the dorsal root ganglion at certain spinal levels provides longer lasting relief than does traditional spinal cord stimulation. Yang and Hunter reported successful treatment of traditional spinal cord stimulator failed CRPS in two patients with the use of dorsal root ganglion stimulation. Huygen and colleagues reported 50% improvement in patients with failed back surgery syndrome who had undergone L2–L3 dorsal root ganglion stimulation. Although this technology is continuing to be refined and studied, these nonablative and modifiable methods of improving pain outcomes may indeed show promising outcomes over
more traditional ablative procedures.

**Visceral Pain**

Although rarely used today due to the advent of other techniques, dorsal rhizotomy has been reported to be highly effective in controlling visceral pain. White and Kjellberg\textsuperscript{226} reported successful treatment of medically intractable angina in 75% (3 of 4) of patients, with 14-month median follow-up, following T1–T4 rhizotomy. Success was 50% (3 of 6) for treatment of other forms of visceral pain.\textsuperscript{226}

Peripheral subcutaneous nerve stimulation has been recently introduced as a new technology to improve the symptoms of abdominal pain from a variety of sources including hernia repair and painful surgical scars. However, no long-term trails have been completed to prove its effectiveness.

**Axial Spine Pain**

Lumbar median branch rhizotomy via percutaneous radiofrequency ablation is indicated for treatment of facet arthropathy pain and is discussed in detail in Chapter 102. Local and radicular pain due to lumbar spine disease is largely unresponsive, in the longer term, to dorsal rhizotomy. Loeser\textsuperscript{238} reported success in 75% (12 of 16) at up to 3 months but only 14% (2 of 14) at more than 3 months for patients with disk disease. Onofrio and Campa\textsuperscript{240} reported improvement in 17% (11 of 64) of patients with lumbosacral pain following rhizotomy, with unstated follow-up. Wetzel et al.\textsuperscript{262} reported success in 55% (28 of 51) at up to 6 months and 19% (7 of 37) at 2 years for patients with lumbar radiculopathy after lumbar surgery.

Taub and colleagues\textsuperscript{259} reported similar findings in that patients with intractable radicular pain who underwent ganglionectomy, 59% achieved reduced or eliminated pain symptoms. However, dysesthesias developed in a significant number (60%) of these patients. Therefore, there may be a role for ganglionectomy in the treatment of axial spine pain, but it must be weighed against the development of other painful symptoms (dorsal root ganglion for intractable monoradicular sciatica).
**Postherpetic Neuralgia**

Dermatomal pain following herpetic infection responds poorly to dorsal rhizotomy. Loeser\(^\text{238}\) reported failure in 2 of 2 patients. Onofrio and Campa\(^\text{240}\) reported success in only 20% (1 of 5) of patients, with 5-year follow-up, following unilateral rhizotomy. The treatment of postherpetic neuralgia is discussed in Chapter 27. A 2002 study showed 82% of patients with postherpetic neuralgia treated with spinal cord stimulation showed long-term pain relief and significant improvement in pain-limiting activities of daily living. In fact, 8 patients in the study had their stimulators removed between 3 and 66 months postimplantation because of complete pain relief, possibly suggesting that the stimulation induces some form of plasticity within the central nervous system to achieve complete resolution of pain symptoms.\(^\text{263}\)

**Sympathectomy**

**BASIC CONSIDERATIONS**

**Sympathetic Efferents**

Sympathetic efferents reach their target structures in two steps. Preganglionic sympathetic efferents arise in the intermediolateral cell column of the spinal cord at T1–L3. Thinly myelinated fibers emerge in the ventral roots and transit briefly through the spinal nerve before exiting to form the white rami communicantes, leading to the paravertebral sympathetic ganglia. Some preganglionic fibers form synapses in the sympathetic chain with postganglionic neurons, from which unmyelinated fibers return to the spinal nerves, forming the gray rami communicantes. These postganglionic efferents provide sympathetic innervation to blood vessels, sweat glands, and other structures. Other preganglionic fibers pass through the paravertebral sympathetic chain without forming synapses and continue to the prevertebral ganglia. In the prevertebral ganglia, these efferents synapse with postganglionic effector neurons. From the prevertebral ganglia, unmyelinated fibers innervate the abdominal and pelvic viscera. Sympathectomy has been used in the treatment of pain from the limbs, the heart, and abdominal viscera. Presacral neurectomy and thoracic sympathectomy for cardiac pain are discussed earlier in this
chapter and are not further addressed here.

**Sympathetically Maintained Pain**

In some patients with chronic pain syndromes, the pain depends on the activity of sympathetic efferents in the painful area. This pain, termed sympathetically maintained pain (SMP), is defined as that aspect of pain that is relieved by blockade of sympathetic efferents. Pain that is unaffected by the activity of sympathetic efferents is termed sympathetically independent pain. The diagnosis of SMP is empiric; that is, it is made based on response to treatment. In any pain syndrome, a portion may be sympathetically maintained, although another part is sympathetically independent. Notably, CRPS and other neuropathic conditions may or may not be associated with SMP.

Traditionally, three distinct mechanisms have been considered as ways through which ablation of sympathetic nerves or ganglia may lead to pain relief:

1. The sympathetic efferents in T1–L3 that pass through paravertebral sympathetic ganglia to abdominal and pelvic viscera do not travel alone. They are accompanied by afferents, with cell bodies in the dorsal root ganglia of T1–L3, which convey sensory information about distension and inflammation of visceral organs to the central nervous system. As a result of this colocalization, ablation of prevertebral ganglia (or the nerves originating from them) interrupts the flow of nociceptive signals from visceral structures to brain, thereby producing pain relief. Hence, as a treatment for visceral pain, sympathectomy is a form of sensory neurectomy.

2. Sympathectomy may improve pain associated with ischemia. Sympathetic efferents maintain arterial tone. In vasospastic and vasoocclusive conditions, the vasodilation consequent to sympathectomy may ameliorate ischemia, thereby decreasing pain.

3. Finally, sympathectomy may eliminate norepinephrine-mediated activation of nociceptors and thereby relieve SMP. In this section, we concentrate on this latter mechanism and extremity pain related to CRPS in which a component of pain has been demonstrated to be
sympathetically maintained.

Understanding of the pathophysiologic mechanisms underlying SMP continues to increase. The involvement of both A and polymodal C nociceptors is evident although incompletely elucidated.\textsuperscript{266,267} Immunologically mediated mechanisms involving prostaglandin, bradykinin, substance P, neuropeptide Y, and calcitonin gene-related peptide have also been proposed in treatment-resistant patients.\textsuperscript{268,269} Increased expression of class I and II human leukocyte antigen in patients diagnosed with reflex sympathetic dystrophy suggests a genetic predisposition to poor treatment response,\textsuperscript{270} although a relationship to SMP has not been defined.

By definition, SMP is eliminated by blockade of sympathetic efferent innervation of the painful area. Thus, anesthetic blockade of the relevant sympathetic ganglia relieves pain in patients with SMP. Stimulation of the sympathetic chain evokes pain in patients with SMP but not in those without SMP.\textsuperscript{25} Moreover, Walker and Nulson\textsuperscript{271} noted that stimulation of the severed distal end of the sympathetic chain evokes pain in those diagnosed with SMP but not in other patients. Thus, the central connections of sympathetic efferent fibers are not required for stimulation of the sympathetic system to evoke pain. These observations establish that efferent sympathetic fibers, rather than afferent sensory fibers that may travel with sympathetic fibers, account for SMP in nonvisceral pain syndromes.

Several independent lines of pharmacologic evidence support the claim that norepinephrine released from sympathetic fibers is critical in SMP. First, regional infusion of guanethidine, which acts to deplete norepinephrine from sympathetic terminals, relieves pain in patients with SMP.\textsuperscript{272} Second, in patients whose pain had been relieved by either sympathetic block or sympathectomy, a cutaneous injection of norepinephrine into the previously painful area rekindles the pain and hyperalgesia. However, norepinephrine injected intracutaneously into normal subjects induces less pain and less hyperalgesia.\textsuperscript{273,274} Finally, administration of sympathetic β-adrenergic antagonists, such as prazosin, phenoxybenzamine, or phentolamine, relieves SMP.\textsuperscript{273,275–277}

Following nerve injury, neuromas that form may acquire sensitivity to
norepinephrine. Injection of pH-balanced norepinephrine solution into normal subcutaneous tissues causes little pain. However, injection of norepinephrine onto painful neuromas does induce pain. Thus, nerve injury may be associated with the induction of SMP.

These observations suggest that an abnormal increase in the amount of norepinephrine released from sympathetic terminals is not likely to be the mechanism of SMP. Rather, it is the response to norepinephrine that appears to be critical. Studies continue to support this theory, demonstrating the benefit of perioperative pharmacologic sympathetic block in reducing recurrence. Whether this change is due to an upregulation of \( \beta \)-adrenergic receptors or increased receptor sensitivity is unknown.

**CLINICAL CONSIDERATIONS**

**Preoperative Evaluation**

SMP cannot be diagnosed purely from history and physical examination of the patient. However, it must be differentiated from similar-appearing chronic pain syndromes, particularly peripheral nerve injury. A number of clinical features are helpful: (1) In general, SMP does not occur in places other than the extremities or face. As a rule, the likelihood of developing SMP parallels the density of sympathetic innervation of the skin. Hence, truncal pain is far less likely to be due to SMP than is extremity pain. (2) Signs that may be inferred to represent increased sympathetic activity in the painful area do not necessarily denote the presence of SMP. For example, limbs associated with SMP may be warmer, cooler, or the same temperature as unaffected limbs. Similarly, differences in sweating, nail growth, and muscle tone do not reliably contribute to the diagnosis of SMP. Nonetheless, sweating abnormalities in particular, as well as temperature alterations in general, may have some diagnostic utility.

We have found that among patients with traumatic nerve or soft tissue injury with touch-evoked pain, all patients with SMP and 50% of patients with sympathetically independent pain have striking sensitivity to mild cooling stimuli.

Due to adverse effects and lack of definitive supporting evidence, surgical sympathectomy is typically reserved for medically refractory
SMP. Careful patient selection is critical to success. Thus, preoperative evaluation is of great importance. Mechanical allodynia with temperature change and cooling hyperalgesia together form an indication for sympathetic blockade. The effect of sympathetic blockade via regional blockade or systemic infusion, in turn, plays an important role in identifying patients who might benefit from sympathectomy. High rates of recurrence, either due to sympathetic chain regeneration or new-onset CRPS, as well as significant adverse effects of the operation, serve to further highlight the need for discriminating patient selection. Finally, early intervention is important to optimize patient outcomes.

Quantitative sensory testing: Essentially all patients with SMP have cooling hyperalgesia. In fact, patients with SMP often spontaneously volunteer that the one stimulus that they most dread is cooling of the painful area. Cooling hyperalgesia occurs less frequently in patients with sympathetically independent pain. This suggests that cooling hyperalgesia is a highly sensitive although not specific, indicator of SMP.

Local anesthetic sympathetic ganglion blocks: The traditional procedure to diagnose SMP is percutaneous injection of local anesthetic onto the sympathetic ganglia serving the painful region. In local anesthetic sympathetic ganglion blocks (LASB), ganglia are localized through anatomic landmarks, ideally under fluoroscopic guidance, and local anesthetic is injected into the region. The presence of local anesthetic at the ganglia prevents norepinephrine from being released into peripheral tissues. Although frequently used to diagnose SMP, LASB results must be interpreted with care: (1) Incomplete block of individual ganglia may falsely underestimate the contribution of SMP to a painful condition. The extent of sympathetic block must be evaluated by assaying for effects of sympathetic block, such as changes in skin temperature. (2) Spread of local anesthetic onto somatic afferents in the nerve roots, or blockade of sensory afferents that accompany sympathetic efferents, may induce pain relief by way of somatic block rather than sympathetic block. Careful sensory examination must be performed to ensure that somatic afferents are not affected by injection of local anesthetic. (3) LASB may evoke a placebo response, causing overestimation of pain relief. In addition to these interpretive issues, LASB has some risk. Complications reported
with LASB include pneumothorax, phrenic and laryngeal nerve block, cardiac arrhythmia, kidney injury, hemorrhage, and inadvertent intravascular or epidural injections (see Chapter 98 for a detailed discussion of the role of local anesthetic blocks in the diagnosis of SMP).

**Systemic phentolamine infusion:** An alternative strategy to assess the potential efficacy of sympathectomy involves intravenous infusion of phentolamine, a short-acting antagonist of α-adrenergic receptors.\(^{273,276}\) There is good correlation between pain relief with LASB and that with systemic phentolamine infusion (SPI).\(^{281,285}\) As a systemic infusion, phentolamine does not provide any information about anatomic localization, as is available with LASB. However, SPI has a number of advantages over LASB: (1) The test is painless in that the phentolamine is delivered systemically and does not require fluoroscopy or needles to be placed in the paravertebral space; (2) with SPI, a significant observation period can be used prior to the administration of the drug, and the patient can be blinded to the time of drug administration, allowing a placebo-control period in every trial; and (3) SPI appears to be safer than LASB, with only nasal stuffiness and peripheral vasodilation reported as side effects.\(^{286}\) Furthermore, because the activity of nearby sensory afferents is preserved, SPI appears to be a more specific diagnostic test for SMP.\(^{281,285}\)

**Intravenous regional block:** A third method to detect SMP involves regional intravenous infusion of an agent that impedes peripheral release of norepinephrine,\(^{272}\) known as a Bier block. Sympatholytic agents studied include bretylium, reserpine, and guanethidine.\(^{284}\) To avoid systemic circulation of the sympatholytic agent, a tourniquet is applied to the limb during the test. The central advantage of intravenous regional block (IRB) is localization of sympathetic block to the limb of interest. However, there are shortcomings: (1) Some patients poorly tolerate the required tourniquet application; (2) the dramatic release of sympathetic neurotransmitter accompanying infusion of guanethidine in SMP patients may be severely painful; (3) the blocking agent may leak beyond the tourniquet, in some instances with significant hemodynamic effects; (4) the need for a tourniquet makes IRB difficult to perform either in the trunk or in the lower extremity; and (5) it is difficult to evaluate placebo responses with IRB. Although frequently mentioned as a means to diagnose and to treat
SMP, we believe that IRB has few advantages. The same degree of β-receptor blockade can be achieved with systemic phentolamine.

**Medical treatment of sympathetically maintained pain:** Once the diagnosis of SMP is made, the mainstay of treatment is medical sympatholysis, with surgical intervention reserved for refractory cases. A remarkable feature of SMP is that extended sympathetic blockade may lead to long-term or permanent relief from the disorder. When the goal of blockade is diagnosis, the diagnostic technique should be specific to the sympathetic nervous system. By contrast, when the goal is treatment, there need not be specificity. There are several medical and interventional means by which to achieve sympatholysis. The choice of technique should be based on considerations of safety, comfort, and efficacy.

Multiple sympathetic ganglion blocks with local anesthetics have, in the past, served as the criterion standard for treatment. However, local anesthetic treatment of peripheral nerves may work as well by inducing similar blockade of the distal sympathetic fibers. For example, SMP in the upper extremity could be treated either by LASB of thoracic sympathetic ganglia or by local anesthetic application to the appropriate nerves.

Alternatively, although epidural administration of anesthetic may lack specificity as a means to diagnose SMP, it may provide an effective treatment regimen. Epidural clonidine, although limited by hemodynamic effects, provides extensive analgesia.\(^{287}\) SPI has been used successfully to treat SMP in a patient with pain in all extremities due to Sjögren’s associated polyneuropathy.\(^{288}\)

When episodic treatments fail to provide adequate relief, chronic treatment with oral sympatholytics may reduce SMP. Both phenoxybenzamine and prazosin have been used in this manner.\(^{275,277}\) However, the systemic hypotension that frequently accompanies the use of these agents may preclude adequate sympathetic blockade. Finally, topical clonidine, which is likely to inhibit local norepinephrine release, may be a low-morbidity treatment of SMP in some patients, albeit locally.\(^{273,289}\) If well tolerated, this and other medical techniques could substantially reduce the need for surgical sympathectomy; indeed the role for surgical sympathectomy remains in question.
Operative Techniques

To achieve sympathectomy of the upper extremity, it is necessary to resect the T2, T3, and T4 sympathetic ganglia. Removal of less than all three ganglia risks inadequate sympathectomy for pain. One of our patients required extension of the sympathectomy to T5. This is best achieved through a thoracoendoscopic technique, although the data on this operation have been acquired through open supraclavicular transaxillary or posterior costotransversectomy approaches. By contrast, the lumbar sympathetic chain, most commonly involving L2 and L3 ganglia, is generally accessed through an anterolateral retroperitoneal surgical approach. Percutaneous approaches have been suggested, but these procedures often do not achieve enduring results. In addition, the scarring produced by these approaches makes later surgical treatment more difficult.

Many clinicians have reported limited success in the treatment of pain by surgical sympathectomy. Failure of sympathectomy may reflect inadequacies either of the preoperative evaluation, as discussed earlier, or of the extent of the sympathectomy. For example, sympathetic outflow to the arm derives predominantly from the T2 and T3 ganglia and not from the stellate ganglion. Failure to remove the T2 ganglion, at a minimum, will result in continued sympathetic innervation of the hand. An important feature in the lower extremity is that sympathetic innervation is often bilateral. Bilateral lumbar sympathectomy of L2–L4 is typically necessary (Fig. 103.5). A typical patient history is one of impressive relief of pain lasting several weeks following an ipsilateral lumbar sympathectomy. The pain then returns, and at that time, the pain may be relieved by a contralateral block of the lumbar sympathetic ganglia. Patients will typically have enduring relief of pain following contralateral lumbar sympathectomy. As in the upper extremity, complete sympathectomy is required for pain relief; the partial denervation that is successful for vascular diseases is not adequate as a treatment for pain.

**INDICATIONS AND OUTCOMES**

Ulmer and Mayfield\(^{294}\) reported successful treatment of 96% (67 of 70) of soldiers with burning pain due to nerve injury by surgical sympathectomy of appropriate ganglia. In studies of a civilian population, Manart et al.\(^{295}\) reported a “good” response to thoracic sympathectomy in 59% (13 of 22) of patients with burning posttraumatic pain, even when diagnostic blockades were not typically performed. For patients selected for preoperative diagnostic sympathetic block, Mockus et al.\(^{296}\) reported improvement in 94% (29 of 31) of patients, with 3.4 years average follow-up. AbuRahma et al.\(^{297}\) reported 1-year satisfactory improvement of pain in 20 of 21 patients. Overall success rates of 90% or greater with surgical sympathectomy have been reported by several groups.\(^{298}\) Thompson\(^{299}\) reported successful surgical treatment in 46% (55 of 120) of patients with SMP following minor trauma, who were unresponsive to medical therapy. Overall, long-term successful outcomes in 70% to 85% of cases of thoracic, and slightly less in lumbar sympathectomy, can be expected.

As noted, results of sympathectomy largely depend on careful patient selection.\(^{277}\) Our experience has been that patients do extremely well if the
pain responds dramatically to sympathetic ganglion block and systemic infusion of phentolamine, and there is provocation of pain with injection of norepinephrine when the patient is under the influence of LASB. Although our conclusions are preliminary, it appears that if one or more of these elements are missing, the patient does not fare as well. The modest response rates to sympathectomy in earlier series may reflect improper patient selection and inadequate sympathectomy (e.g., bilateral sympathectomy required for lower extremity pain) or more extensive unilateral ganglionectomy for total denervation of an extremity.

**POSTOPERATIVE COMPLICATIONS**

Surgical sympathectomy may be associated with idiosyncratic complications. One frequent complication, affecting up to 20% to 50% of patients, is postsympathectomy pain. This condition is characterized by the sudden onset, a few weeks after the procedure, of superficial burning pain, deep aching pain, and cutaneous hyperalgesia. The pain arises in the proximal regions of limbs and the trunk despite surgical ablation of sympathetic innervation to the distal limbs. Fortunately for the majority of patients, postsympathectomy pain resolves spontaneously in several weeks to a few months, and no further surgical intervention is warranted.

Ablation of sympathetic input to a region of skin results in sudomotor paralysis. In the upper extremity, the resultant dryness can be uncomfortable. In the lower extremity, dryness is better tolerated. Postural hypotension also can be a transient problem. However, even in patients with sympathectomy of all four extremities, this problem is usually not enduring. Compensatory hyperhidrosis, as well as pathologic gustatory sweating, may be found in patients following sympathectomy. Two additional complications of sympathectomy include paradoxical vasoconstriction and ileus. Sympathetic fibers arising from the celiac and mesenteric ganglia modulate gastrointestinal motility. Both complications are generally transient.

CRPS is defined as a chronic pain disorder that has a propensity to affect only one limb (arm, leg, etc.) and is disproportionate in terms of how long the pain lasts or how intense the pain is compared to any known
trauma or other lesion. It is also a progressive disease that is not confined to a certain nerve territory or dermatome and has a predilection for producing distal sensory and motor symptoms including burning sensations, allodynia, and hyperalgesia.\textsuperscript{304}

SCS has been shown to be beneficial in the treatment of CRPS. Although traditional SCS is the primary type of SCS that is used clinically, one study showed that dorsal root ganglion SCS is superior to traditional SCS for the treatment of CRPS.\textsuperscript{305} However, traditional SCS has been shown to be superior to other treatments for CRPS. Kemler and Furnee\textsuperscript{306} studied a population of patients who were initially unable to work due to severe pain and disability and were refractory to physical therapy (PT) and other medical treatments. These patients were then either randomized to a control group that received only PT or the experimental group that received SCS and PT. The study showed that the patients who were randomized to the SCS-with-PT group had a greater than 50\% decrease in their pain at 6 months compared to the PT-only group. Additionally, the study showed that at 1 year, patients in the SCS-with-PT group had a marked improvement in their quality of life compared to the PT-only group. They did not, however, observe any difference in functional status or psychological depression between the two studied groups.\textsuperscript{306,307} Another study showed that pain caused by CRPS decreased on average by 45\% after treatment with SCS.\textsuperscript{308} These studies and others demonstrate that using SCS for medically refractory CRPS is beneficial.

Conclusion

The peripheral nervous system offers a number of attractive strategies for treatment of pain. Peripheral nerves may be transected or released from regions of entrapment. Where regional pain control is required, sensory roots or ganglia may be the targets of therapy. In cases where pain has a significant sympathetically maintained component, sympathectomy may offer significant and long-lasting pain relief.

As for all surgical procedures, careful patient selection and clear establishment of the etiology of the painful condition is critical to ensure successful analgesia. Enthusiasm for these surgical procedures must be
tempered by a keen appreciation of potential complications.

Nerve transection may either produce or eliminate pain. This leaves the clinician with the sometimes daunting task of deciding if, when, and how to perform neurectomy. Each patient must be carefully evaluated. In the case of minor nerves previously transected, the clinician should not labor over the decision to relocate the neuroma to a protected, unscarred site. In this instance, there is little to lose.

Pain due to mechanical compression may be relieved through release of nerve root entrapments. Carpal tunnel release and release of UNEE are among the most commonly performed peripheral nerve procedures. However, many less common forms of nerve root entrapment may be overlooked or misdiagnosed. A systematic understanding of peripheral neuroanatomy on the part of the pain clinician is essential to accurate diagnosis and treatment of these pain syndromes.

Dorsal rhizotomy is seldom used in modern practice, but a survey of the existing literature reveals that patients certainly exist in whom rhizotomy conferred long-term benefit. Today’s pain clinician does well to keep this option in mind in properly selected cases. Ganglionectomy has certain theoretical advantages over rhizotomy and neurectomy and is still another technique that should be considered in certain cases. However, recurrence of pain several years after surgery may be quite common.

Sympathectomy is helpful in patients with persistent SMP who are refractory to medical management. Recognition of the clinical symptoms of SMP, such as cold allodynia, and appropriate selection of sympathetic blockade modalities are required to make the diagnosis and to provide a successful treatment strategy. Hence, the key to success with this procedure, as with most surgery, is meticulous patient selection and proper execution of the operation.

Peripheral electrical neuromodulation, a nonablative surgical intervention for the treatment of pain, is emerging as a promising therapeutic approach for well-selected patients. This technology is still evolving, and further research will need to be conducted to objectively show improvements in the quality of pain improvement as well as the exact mechanism by which this technique works on a cellular and network basis.

Trigeminal neuralgia (TN), formerly known as tic douloureux, is a chronic pain disorder affecting the trigeminal nerve. Clinically, TN is characterized by bouts of severe, lancinating pain in a trigeminal distribution, often triggered by light touch or facial movement. A variety of effective medical and surgical therapies exist for TN. Carbamazepine (Tegretol) is considered the first-line treatment; second-line medications include oxcarbazepine and lamotrigine, among others. Opiates are not particularly effective. Surgical therapies include microvascular decompression (MVD), percutaneous rhizotomy, and radiosurgery. In this chapter, we review the surgical management of TN.

Patient Presentation

TN is rare, with an incidence of 2 to 5 per 100,000 per year and a prevalence of 0.03% to 0.3%. Patients typically present in their 60s, although some develop symptoms as early as their late 30s. There is a female preponderance (3:2), and some studies suggest an association with arterial hypertension. Case reports have identified familial forms of TN; these appear to be rare, are sometimes bilateral, and may follow an autosomal dominant inheritance pattern.

Patients typically present with one of two clinical syndromes. Type 1 TN (“typical TN”) is characterized by a predominance of brief, lancinating, or electrical unilateral pain. Type 1 TN most frequently occurs in the V2 or V3 division, and it does not cross the midline. Triggers may include tactile stimuli or facial movements such as talking or chewing, and
there is usually a refractory period during which pain cannot be elicited. The duration of pain is often brief, lasting seconds, but there may be up to several minutes of paroxysms before the pain-free refractory period. The International Headache Society diagnostic criteria for TN are outlined in Table 104.1.9

### TABLE 104.1 Diagnostic Criteria for Trigeminal Neuralgia from the International Headache Society

<table>

Type 2 TN (“atypical TN”) is characterized by a predominance of constant pain, often burning or aching.10 This pain usually exists in addition to the brief, lancinating pain that occurs in type 1 TN. Although not firmly established, some believe that type 2 TN may emerge from long-standing type 1 TN.11

### Anatomy

The trigeminal nerve contains motor and sensory fibers that exit the lateral brainstem at the level of the mid-pons. Just distal to the brainstem root entry zone (REZ), the nerve transitions its myelinating cells from central oligodendrocytes to peripheral Schwann cells. This transition zone, which occurs several millimeters from the REZ at about one-third to one-fourth of the distance to Meckel’s cave, is believed to be particularly sensitive to mechanical irritation.

The cisternal segment of the nerve traverses the subarachnoid space, traveling anterolaterally to pierce the dura near the petrous apex to enter Meckel’s cave, a CSF-filled space between two layers of dura over the
petrous portion of the temporal bone. The nerve then splits into three divisions: (1) ophthalmic (V1; sensory only), which travels through the superior orbital fissure to enter the orbit; (2) maxillary (V2; sensory only), which enters the pterygopalatine fossa via the foramen rotundum; and (3) mandibular (V3; motor and sensory), which exits the skull through the foramen ovale (FO).

**Pathophysiology**

Type 1 TN is classically believed to stem from mechanical irritation of the trigeminal nerve by a blood vessel. Under this model, pulsatile vascular compression causes focal irritation and eventually demyelination. The superior cerebellar artery (SCA) is most commonly implicated (75%), with other offenders being the anterior inferior cerebellar artery (10%), posterior fossa veins (12%), vertebral artery (2%), posterior inferior cerebellar artery (1%), and the basilar artery (1%).

Injured trigeminal axons become hyperexcitable, spilling excitatory neurotransmitters that depolarize neighboring cells via ephaptic conduction (the “ignition hypothesis”) and incite synchronized afterdischarges. Periodic waves of depolarization are experienced as paroxysms of pain in the trigeminal distribution, often corrupting the perception of normal tactile stimuli.

Type 2 TN is posited to result from deafferentation of higher order somatosensory neurons, similar to other types of chronic neuropathic pain. Some have proposed that type 1 and 2 TN sit at opposing ends of a single spectrum. Chronic nerve injury in the setting of type 1 TN may extend proximally to and beyond the REZ, precipitating type 2 TN symptoms.

First-line medical therapy consists of carbamazepine. The mechanism of carbamazepine’s efficacy is unknown, although it is speculated that blockade of voltage-sensitive sodium channels may stabilize hyperexcitable cell membranes, reducing aberrant action potential propagation.

MVD, described in the following text, yields immediate cessation of pain in many patients suffering from TN. The mechanism remains a
subject of debate, but several hypotheses have been put forward. First, mechanical compression generates ectopic action potentials that may be alleviated by decompression.\textsuperscript{20,21} Second, ephaptic conduction may be less effective when a compressive force is removed because there is more relative distance between demyelinated axons. Finally, there may be a pressure-dependent mechanical conduction block on subpopulations of fibers that is dissolved upon decompression.\textsuperscript{2}

**Evaluation for Surgery**

Surgery should be considered for patients with persistent, severe symptoms despite adequate drug therapy or those with intolerable medication side effects. Medication trials at a minimum should include carbamazepine or oxcarbazepine.

An evaluation for surgery should prompt scrutiny of the patient’s diagnosis. There exists a cornucopia of facial pain disorders. TN is a clinical diagnosis, and certain red flags should give the clinician pause: pain that does not respect the midline, age <40 years, absence of any initial response to carbamazepine, and facial numbness, among others.

Surgical options for TN can be divided into two categories: palliative ablative procedures (e.g., percutaneous rhizotomy, stereotactic radiosurgery) and nondestructive MVD. Neuromodulatory techniques are growing in popularity for a select set of facial pain disorders, but there is insufficient evidence or experience to support their use as a first-line surgical option for type 1 or 2 TN.

Regarding procedure selection, Slavin and colleagues\textsuperscript{22} developed a facial pain surgical algorithm that is concordant with our own experience (Fig. 104.1). MVD is best reserved for those patients with type 1 TN, although some data suggest it may alleviate episodic pain in type 2 TN patients as well.\textsuperscript{23} Radiofrequency rhizotomy and other percutaneous variants (glycerol, balloon compression) may be used for both type 2 TN patients and those type 1 TN patients in whom medical comorbidities or personal preferences preclude a retrosigmoid craniotomy or those who have already failed an MVD. Radiosurgery is an option for those patients seeking to avoid an invasive procedure.

Imaging is mandatory in the presurgical evaluation, primarily to rule out pathologies that would be symptomatic of TN yet mandate different treatment, namely, posterior fossa tumors or vascular malformations, multiple sclerosis (MS), and brainstem or thalamic infarctions. The preferred imaging study is a magnetic resonance scan with a thin-cut axial T2-weighted 3D sequence (e.g., constructive interference in steady state [CISS], fast imaging employing steady-state acquisition [FIESTA], or similar) through the brainstem. Such sequences delineate the trigeminal nerve in high resolution. Of particular interest is contact or compression of the cisternal component of the trigeminal nerve by a blood vessel (Fig. 104.2).
FIGURE 104.2 Axial (left) and sagittal (right) fast imaging employing steady-state acquisition magnetic resonance imaging sequences demonstrating neurovascular compression of the superior aspect of the left trigeminal nerve (yellow asterisks) by a loop of the superior cerebellar artery (SCA; red arrowheads). Note the displacement and atrophy of the proximal nerve segment on the axial image. On the sagittal image, only a narrow cross-section of the nerve is captured, but the looping course of the SCA is apparent.

Importantly, the presence of a vessel compressing the trigeminal nerve is not an obligate criterion for MVD candidacy, as some TN patients without radiographic neurovascular compression (NVC) are indeed found to have NVC at surgery, and asymptomatic NVC is frequently observed both in healthy controls and on the contralateral (unaffected) side in patients with TN.\textsuperscript{24,25} It does appear, however, that imaging features such as nerve displacement and atrophy may be more specific, although less sensitive, for predicting whether radiographic NVC is symptomatic.\textsuperscript{26,27}

**Microvascular Decompression**

MVD remains the preferred surgical treatment for medically suitable patients with type 1 TN. MVD offers a high success rate, the longest duration of pain relief, and is nondestructive, thus avoiding complications associated with deafferentation. The surgical goal is to identify and mechanically isolate an irritating vessel from the cisternal segment of the trigeminal nerve.

After the induction of general anesthesia, the patient is positioned supine with the head turned away from the affected side and secured in pin fixation, with the neck slightly flexed and elevated. The approximate courses of the transverse and sigmoid sinuses are outlined on the scalp
We place electrodes for auditory brainstem responses to monitor for traction on the eighth cranial nerve. We have found facial nerve monitoring unnecessary.

**FIGURE 104.3** External landmarks for a left-sided microvascular decompression. The skin incision (red line) is vertically oriented, passing from the top of the pinna down and behind the mastoid tip. The transverse sinus can be approximated by a line connecting the zygoma to the inion. A retrosigmoid craniotomy (black hashed line) is performed just below the junction of the transverse and sigmoid sinuses.

The surgical field is shaved, prepped, and draped. We open a linear incision two fingerbreadths behind the base of the pinna and extending from the top of the pinna, over the digastric notch, and to the level of the mastoid, pointing toward the ipsilateral foot (see **Fig. 104.3**). A pericranial graft is harvested from above the nuchal line for later use in the dural closure. The suboccipital musculature is dissected away, and a burr hole is placed near the junction of the venous sinuses. We use a combination of high-speed drilling and rongeur instruments to create an approximately 3-cm craniotomy, exposing the edges of the transverse and sigmoid sinuses superiorly and laterally, respectively. Mastoid air cells are waxed.

The dura is opened in a stellate manner. A handheld brain retractor is used to depress the cerebellum, and CSF is aspirated from the cisterna magna, slackening the hemisphere. Some surgeons place a lumbar drain at the start of the case or perform a lumbar puncture intraoperatively.

The operating microscope is brought in, and under constant monitoring of the auditory brainstem responses, a fixed retractor is used to displace...
the cerebellum from the lateral skull base (Fig. 104.4). We identify the complex of the seventh and eighth nerves coursing out to the internal auditory canal. A petrosal vein or venous complex usually obscures the view of the (deeper) trigeminal nerve; this can be coagulated and divided safely.

**FIGURE 104.4** Intraoperative photographs from a left-sided microvascular decompression. Left panel: Relevant anatomic structures visualized after dural opening and placement of a retractor on the lateral cerebellum (C). From inferior to superior (left to right on the image): arachnoid membranes overlying the complex of cranial nerves VII and VIII (white arrowhead), trigeminal nerve (yellow asterisk), petrosal venous complex (blue triangle), and tentorium (T). Middle panel: View of compression of the superior surface of the trigeminal nerve (yellow asterisk) by a loop of the superior cerebellar artery (red arrowhead). Right panel: Teflon pledgets (black arrowheads) are interposed between the trigeminal nerve and the artery.

Arachnoid adhesions are taken down sharply, and the trigeminal nerve is traced to its entry zone in the lateral pons (see Fig. 104.4). The most common offending vessel is the superior cerebellar artery (>80%), which generally contacts the superomedial surface of the nerve. Other vascular offenders may include the anterior inferior cerebellar artery and posterior fossa veins. The segment of the nerve that is most sensitive to mechanical irritation is the transition zone from central to peripheral myelin, which occurs approximately 1 to 3 mm from the brainstem; sometimes an area of demyelination is visually apparent as a discolored patch on the surface of the nerve.

A straight dissector is used to tease any offending vessel away from the nerve. Teflon pledgets are interposed between the vessel and the nerve, with care taken to ensure the vessel is not kinked in the process.

The cerebellar retractor is removed, and the field is irrigated. We close the dura watertight using a pericranial graft. The duraplasty is coated with a layer of fibrin glue, and the bony defect is corrected with bone cement or
a titanium mesh. The soft tissue is closed in layers, culminating in an absorbable stitch on the skin. Patients are monitored in the intensive care unit for one night and usually discharge on the second postoperative day. They are initially maintained on their baseline TN medication regimen, which is then weaned later as an outpatient.

OUTCOMES
MVD offers excellent long-term pain control. Eighty percent to 96% of patients experience initial pain relief after MVD. At 5 years, pain control is maintained in 72% to 85%. One study with extended follow-up reported that 73% of patients were pain free 15 years after surgery.

One of the landmark series of MVD for TN reports on the outcomes of 1,185 patients who underwent MVD over a 20-year period with outcomes prospectively evaluated. At 10 years after surgery, 70% of patients were pain free while off of medication. This study found that most recurrences occur during the first 2 years after surgery, with very low recurrence rates later.

MVD has better outcomes in type 1 TN than type 2 TN perhaps because patients with type 2 TN have greater underlying damage to the trigeminal nerve. Presence of arterial compression of the nerve is also associated with better outcomes, with greater degree of compression additionally correlated with positive outcome. Treatment failure is associated with longer symptom duration prior to surgery, presence of venous NVC, and lack of immediate postoperative symptom relief.

Although MVD has a higher complication rate than percutaneous procedures, in experienced hands, the procedure is relatively safe. Mortality is low (0.15% to 0.8%) and related to hospital and surgeon volume. Trigeminal sensory deficit occurs in 1.6% to 22% of cases. The incidence of facial weakness is 1.2% to 6.8%. Hearing loss occurs in 1.2% to 6.8% but may be decreased by the use of brainstem auditory evoked potential monitoring.

Other serious complications include cerebrospinal fluid leak (1.5% to 4%) and cerebellar infarct or hematoma (<1%). Anesthesia dolorosa is very uncommon after MVD, with one large series reporting 0%
incidence,\textsuperscript{16} although the rate may be higher with internal neurolysis, a procedure involving the longitudinal splitting of trigeminal nerve fibers that is sometimes used when NVC is not identified intraoperatively.\textsuperscript{32}

**Percutaneous Rhizotomy**

Radiofrequency rhizotomy is an excellent surgical option for patients with type 2 TN or for patients with type 1 TN who medically are not candidates for MVD or have already failed MVD. The goal of a rhizotomy is to lesion the retrogasserian trigeminal root, which can be accessed percutaneously through the FO. The procedure is effective, can be performed on an outpatient basis without general anesthesia, and can be repeated. Drawbacks include facial numbness and the risk of deafferentation pain.

The patient is positioned supine on the operative table. Midazolam (1 to 2 mg) is administered for anxiolysis as well as meperidine (25 to 50 mg) to blunt bradycardia that can occur with trigeminal stimulation. The head is turned slightly away from the affected side, and submental vertex fluoroscopy is used to identify the FO near the junction of the pterygoid plate and the petrous ridge.

The face is prepped with alcohol and squared off with sterile towels. Local anesthetic is instilled in the soft tissue along the anticipated needle trajectory. The needle entry point is generally 2.5 cm lateral to and at or just below the labial commissure. A 20G spinal needle is advanced toward the FO, using the midpupil as an approximate external landmark. Fluoroscopy is repeated when the needle contacts the skull base, and the trajectory is adjusted until the FO is entered, which is often signified by a jaw jerk and wince.

The fluoroscope is rotated into a lateral view. Under constant fluoroscopy, the needle is advanced toward the clival line (Fig. 104.5). On the lateral view, V2 fibers are encountered approximately at the clival line, with V1 being deeper and V3 more superficial (see Fig. 104.5).

Radiofrequency rhizotomy is best reserved for cases of V2 or V3 TN; V1 fibers can be difficult to reach without a curved needle, and a radiofrequency lesion risks corneal hypesthesia and resulting keratitis; for these reasons, balloon compression is preferred for cases involving V1
pain (see the following text).

**FIGURE 104.5** Percutaneous radiofrequency rhizotomy, lateral view. Left panel: The gasserian ganglion (GG) is located within Meckel’s cave. A spinal needle is used to pierce the foramen ovale, and radiofrequency lesions are created in the retrogasserian fibers. V3 fibers are encountered superficially, with V2 and V1 fibers deeper. Right panel: Lateral fluoroscopy demonstrating a spinal needle passing through the foramen ovale (black arrowhead). The outline of the sella (S) can be seen superiorly. V2 fibers are encountered at the clival line (white arrowheads).

The stylet is withdrawn and replaced with the radiofrequency probe. Low-temperature stimulation (40° to 50° C) is delivered to confirm the correct division has been targeted. Patients describe a burning sensation in the corresponding sensory distribution. Propofol (2 to 4 mL) is administered, and a radiofrequency lesion is delivered (60 seconds; 75° C if at the clivus, 85° C if superficial to the clivus). We then withdraw the needle ~2 to 3 mm and repeat this process iteratively, with the goal of abolishing the patient’s ability to discriminate between pinprick and light touch (usually two or three lesions per sensory division). When this is achieved, the needle is withdrawn, and the patient is taken to the recovery area.

Balloon compression is a percutaneous rhizotomy variant uniquely indicated for V1 pain; the goal is to compress the trigeminal nerve within the porus trigeminus. Surgical technique is similar to the radiofrequency rhizotomy, except that it is typically done under general anesthesia and requires a larger cannula (14G) to accommodate the balloon. A balloon catheter is introduced after the FO has been cannulated, and it is advanced on the lateral fluoroscopy view until the tip is just past the clival line. The balloon is inflated to 1.5 atmospheres for 60 seconds before being withdrawn.
OUTCOMES

Percutaneous Radiofrequency Rhizotomy

Initial response to percutaneous radiofrequency rhizotomy is excellent, with rates of pain relief up to 97.6%, on par with MVD. However, as with other percutaneous procedures, the response to radiofrequency rhizotomy is less durable, and the procedure may need to be repeated. One of the largest series of radiofrequency rhizotomy followed the results of 1,600 patients with TN who underwent 2,138 radiofrequency rhizotomy procedures over 25 years. This study found that 58% of patients who had undergone a single procedure had complete pain relief at 5-year follow-up, whereas 92% of patients achieved pain relief with multiple procedures at 5 years. At 20 years, 41% of patients who had undergone a single procedure had pain relief, and all of the patients who had undergone multiple procedures and were followed were free from pain.

Type 1 TN may be associated with better outcomes following radiofrequency rhizotomy, as is postoperative facial numbness. One of the relative advantages of radiofrequency rhizotomy is that it allows more selective targeting of specific trigeminal nerve distributions than chemical or balloon rhizotomy.

Radiofrequency rhizotomy has a higher rate of decreased corneal sensation than other percutaneous procedures at 5.7% to 17.3%. Anesthesia dolorosa occurs in 0.8%. Higher lesioning temperatures may be associated with higher rates of trigeminal sensory dysfunction. Masseter weakness occurs in 3% to 29% of cases. Some of the adverse effects of radiofrequency rhizotomy are thought to occur via selective damage to small unmyelinated trigeminal pain fibers.

Percutaneous Balloon Compression

Percutaneous balloon compression similarly has a high rate of initial pain control, with up to 94% reporting initial pain relief, with recurrence rates of 20% to 48%. One of the largest published series reported on the outcomes of 901 patients who underwent percutaneous balloon compression at a single institution. This series found a 92.7% rate of significant pain relief at 1 month, with excellent pain relief in 67.1% at 1 year and complete pain relief in 62% at mean 16.5 year follow-up.
The rate of postoperative trigeminal sensory disturbance is high following balloon compression, with initial disturbance in almost all patients, and persistent symptoms in 4.6% to 40% of patients.\textsuperscript{37} Trigeminal dysfunction may be related to the rate and duration of balloon compression.\textsuperscript{48} Balloon compression has a low rate of decreased corneal sensation, perhaps because it damages medium and large myelinated pain fibers, sparing small fibers important in corneal sensation.\textsuperscript{45} As such, it is the percutaneous treatment of choice for V1 distribution TN.

Conversely, the rate of masseter weakness following balloon compression is high at 10% to 50%.\textsuperscript{42} Hearing loss is reported in 2.4% to 6.3%.\textsuperscript{49} And the rate of intraoperative trigeminal reflex bradycardia and hypotension may be higher in balloon compression than other percutaneous procedures, an important consideration for patients with preexisting cardiac comorbidities.\textsuperscript{45}

---

**Radiosurgery**

Radiosurgery uses focused radiation to the trigeminal nerve or ganglion to disrupt pain transmission. Several different radiosurgery systems have been used to treat TN. One of the most commonly used is Gamma Knife, which uses 201 cobalt-60 radiation sources arranged in a hemispheric assembly to target energy to a focal point. Linear accelerator–based therapies have also been used in TN and generate high-energy particles that are delivered through a single source that moves relative to the patient around the planned focal point. One such system is CyberKnife, which uses a linear accelerator mounted on a robotic arm, with two orthogonally positioned x-ray detectors that provide movement correction by imaging the patient’s bony anatomy.\textsuperscript{50} This system has also been used for TN with success.\textsuperscript{50} All systems seem to have similar efficacy in TN.

During radiosurgery, the patient’s head is fixed using a head frame or facemask, depending on the system being used. The patient’s MRI or CT is used in conjunction with planning software to identify the target. Several targeting strategies have been used, including a single isocenter in the REZ,\textsuperscript{51} the cisternal portion of the trigeminal nerve,\textsuperscript{50,52} a retrogasserian target in the anterior cisternal portion of the trigeminal nerve anterior to
the emergence of the nerve,\textsuperscript{53,54} or two isocenters in the gasserian ganglion and the REZ.\textsuperscript{55} One trial randomized patients to one versus two retrogasserian isocenters and found that two isocenters did not improve pain outcomes but resulted in a higher rate of sensory disturbances.\textsuperscript{56} Shorter distance between the target and brainstem may be associated with better pain outcomes.\textsuperscript{57} Median doses of 70 to 90 Gy are generally used.\textsuperscript{58,59} Higher dose rate may not only be associated with better initial pain relief and lower recurrence rates\textsuperscript{59,60} but also be associated with higher rates of trigeminal sensory dysfunction.\textsuperscript{60}

One of the disadvantages of radiosurgery is that it has a delayed onset of pain relief, with a median latency of 1 to 2 months,\textsuperscript{61} making it less suitable for patients in acute pain crisis. A shorter latency to response may predict longer durability of pain relief.\textsuperscript{62} Patients who undergo radiosurgery early in their disease course have decreased latency to response and longer durability of symptom relief.\textsuperscript{62}

**OUTCOMES**

A high proportion of patients have at least some improvement in pain after radiosurgery, with 79% to 92% reporting initial pain improvement.\textsuperscript{37} Unfortunately, durability and extent of pain relief are limited. Patients who have not had previous surgery have better pain outcomes.\textsuperscript{54,63} Better outcomes are also associated with type 1 TN, previous percutaneous procedures, and older age.\textsuperscript{61,64} Interestingly, radiosurgery may also be effective for MS-related TN.\textsuperscript{61}

A large study reported on the outcomes of a series of 503 TN patients treated with Gamma Knife. This study found that 89% of patients achieved an initial Barrow Neurological Institute (BNI) pain score of I to IIib (pain adequately controlled with medication); this rate was 80% at 1 year, 46% at 5 years, and 30% at 10 years.\textsuperscript{63} There was a 10.5% rate of new trigeminal sensory disturbance.\textsuperscript{63} Another large study reported on 497 patients with type 1 TN not previously treated with radiosurgery and followed for at least 1 year. This study reported that 92% had initial freedom from pain, whereas at 5 and 10 years follow-up, 65% and 45% of patients were pain free off medication, respectively.\textsuperscript{54}

The most common side effect after radiosurgery is trigeminal sensory
disturbance, with decreasing rates with increasing time after the procedure. Higher radiation dose may be associated with greater rates of sensory disturbance, ranging from 6% to 42%. Importantly, postprocedure facial numbness is a predictor of treatment durability. The rate of anesthesia dolorosa is very low (0.2%). Repeat radiosurgery is associated with a higher rate of sensory dysfunction. Other, rarer complications include masticator weakness and hearing loss.

In patients who have recurrence of symptoms after initial radiosurgery, repeat radiosurgery can provide symptom relief. One study found that 63% of patients were pain free off medication at 1 year after repeat Gamma Knife, whereas at 5 years, the rate had fallen to 37%. Response to initial Gamma Knife and facial numbness after initial Gamma Knife were predictors of response to repeat radiosurgery. Third Gamma Knife procedure has also been reported in a small series, with 47% reporting initial complete pain relief, and 35% maintaining this at mean 22.9 months follow-up. There were no new sensory deficits after third Gamma Knife.

Conclusions

TN is a chronic facial pain disorder thought to stem from NVC of the cisternal segment of the trigeminal nerve. There are two clinical variants: type 1, consisting predominantly of brief, lancinating, or electrical pain, and type 2, chiefly with constant burning or aching pain. Surgery should be considered in patients’ refractory to carbamazepine or oxcarbazepine. MVD remains the treatment of choice for type 1 TN, with excellent long-term pain control—even in patients without radiographic NVC. Radiofrequency rhizotomy is suitable for type 2 TN or patients with type 1 TN refractory to MVD or who are not suitable for a craniotomy. Stereotactic radiosurgery offers more modest pain relief rates and effective duration but is an excellent option for patients seeking to avoid an invasive procedure.

Consideration of an ablative procedure for chronic pain typically follows numerous evaluations for other therapeutic options that have either failed or were deemed not suitable for the patient. The decision tree for deciding a patient’s candidacy for surgical ablation hinges on careful consideration of the type of pain present, its mechanism, the anatomic distribution, the desired durability of a cure, and the overall state of health and life expectancy of the patient. This clinical information is then merged with our current framework and understanding of pain signaling pathways to develop a treatment plan with the highest probability of achieving the patient-specific metric for success. The efficacy of ablative procedures depends heavily on our understanding of the physiology of the human pain experience incorporating all elements beginning with the nature of the peripheral stimulus and ending with behavioral and emotional perception of pain. Current theory has evolved from concepts of serial processing defining the “labelled line” theory of pain transmission to more sophisticated, distributed models of a “pain matrix,” in which peripheral nociception feeds into multilayered central circuitry that not only localizes painful stimuli but also incorporates emotional and temporal contexts, elicits top–down control, and changes the way future stimuli are perceived.\(^1\) Ablative procedures seek to alter pain processing by removing part of this complex circuitry (Fig. 105.1). In doing so, it is possible to disrupt pain transmission but also to change how it is processed—sometimes leading to initial pain relief followed by recurrence. Because neuroaugmentative procedures incorporating high-frequency stimulation and local analgesic administration have become routine parts of clinical
practice, use of neuroablative techniques has decreased. However, several procedures still provide significant value in certain clinical scenarios. In this chapter, we review the indications, anatomy, techniques, and outcomes in dorsal root entry zone lesioning, cordotomy, stereotactic cingulotomy, thalamotomy, and tractotomies within the brainstem.

FIGURE 105.1 Specific ablative lesions and their locations relative to the nociceptive pathways.

**Dorsal Root Entry Zone Lesioning**

**INDICATIONS**

Lesioning of the dorsal root entry zone of the spinal cord (DREZ procedure) is performed in patients with refractory neuropathic pain of peripheral origin, most commonly resulting from nerve root avulsion or injury within the brachial plexus. The procedure has also been performed in neuropathic pain resulting from spinal cord injury (SCI), spasticity, and postherpetic neuralgia. Although less typical, it has also been performed in patients suffering cancer-related pain. Because the DREZ procedure disrupts afferent pain signaling at a specific level, patients with pain distributions that are focal, only spanning a few dermatomal levels, are considered better candidates for this procedure compared to individuals with more diffuse pain syndromes.
ANATOMY AND PHYSIOLOGY
The DREZ procedure is built on the hypothesis that following injury of primary peripheral neurons and subsequent deafferentation, central second-order neurons in the spinal cord become hypersensitive and produce aberrant afferent pain signals. This occurs in the absence of a real painful stimulus and is therefore neuropathic in nature. The cell bodies of the second-order sensory neurons carrying afferent pain information reside in the substantia gelatinosa (Rexed layers 1 and 2) of the dorsal horn throughout the spinal cord.\(^3\) Primary neurons, whose cell bodies reside in the dorsal root ganglion, enter the spinal cord via the DREZ and either immediately synapse in the substantia gelatinosa or travel within Lissauer’s tract 1 to 2 levels above or below the level of entry prior to synapsing.\(^5\) The area of synapse lies immediately deep and medial to the entry zone where nerve rootlets enter the spinal cord (Fig. 105.2). Lesioning this area disrupts the abnormal pain signaling of second-order neurons at the associated dermatomal level but does not affect transmission of painful stimuli arising from levels below the lesion that travel within the spinothalamic tract. This is in contrast to cordotomy which specifically targets the ascending spinothalamic tract, thus severing pain transmission of all dermatomal levels whose second-order neurons have already entered and are traveling in the spinothalamic tract. It is important to recognize that the corticospinal tract lies lateral to the dorsal horn and ablations targeted too laterally can result in ipsilateral hemiparesis. Additionally, in cervical levels of the spinal cord, proprioceptive information from the ipsilateral arm runs in the dorsal column just medial to the dorsal horn. Therefore, lesioning aimed too far medially may result in loss of ipsilateral upper extremity proprioception.\(^5,6\)

TECHNIQUE
Under general anesthesia, the patient is placed in the prone position with rigid head fixation. Multiple laminotomies are made to provide adequate access to the spinal cord level of interest and one to two spinal cord levels above and below. A midline durotomy is performed, and the posterolateral sulcus on the affected side is identified. In instances of nerve root or brachial plexus injury, nerve root atrophy can often be observed and used
to identify the appropriate level for lesioning. This can be confirmed after placing the radiofrequency ablation (RFA) probe (e.g., Nashold electrode) in the DREZ and measuring an impedance value between the DREZ of the spinal cord and a peripherally placed grounding electrode. Injured areas have markedly decreased impedance values. This measurement will also serve as a preablation baseline (typically 900 to 1,200 ohms) because the impedance will also decrease after lesioning is performed. To perform the ablation, the Nashold electrode is placed 1 to 2 mm into the area of the entry zone at an angle 20 to 30 degrees medial to lateral relative to the plane perpendicular to the spinal cord surface. Each RFA is then carried out by powering to a temperature of 75°C for 15 to 20 seconds. A total of 40 to 60 lesions centered around the level of interest are performed. Microsurgical technique as well as laser ablation serve as alternatives to RFA.

**OUTCOMES**

Patients experiencing the most favorable outcomes following the DREZ procedure are those suffering from neuropathic pain related to brachial plexus avulsion injury. A review of the published clinical studies that reported greater than 20 patients identified 62% to 91% patients suffering from brachial plexus avulsion pain to have “good improvement” in symptoms after the surgery, where “good improvement” was defined as the need for only minimal ongoing medical management to maintain satisfactory pain relief. The knowledge surrounding the durability of pain control is limited by the length of follow-up in the published studies but has been confirmed to last, in some instances, up to 3 to 5 years. One particular study performed a subgroup analysis to evaluate the effect of intraoperative electrophysiology mapping of the DREZ on outcome and found improved pain control in the group that received intraoperative mapping. Patients undergoing DREZ for SCI-related pain can expect pain relief of localized, end-zone pain occurring just at or above the level of sensory loss. More diffuse and distal pain phenomenon below the level of injury, however, is not as well managed, with efficacy rates falling to 20% or lower. To improve efficacy of the DREZ procedure in SCI patients, Falci et al. have suggested using intramedullary
electrophysiologic guidance to identify regions of spontaneous DREZ hyperactivity to identify optimal lesion placement. In a group of 32 patients who underwent this approach, 84% achieved 100% pain reduction. Pain control following the DREZ procedure in patients suffering from postherpetic neuralgia is felt to be only transient, with only approximately 25% of patients experiencing relief at 1 year.\(^2\) Outcomes are largely comparable for RFA versus laser or microsurgical technique.\(^{15}\) However, many surgeons utilize the RFA technique because of the reproducible lesions provided by the Nashold electrode.\(^5\)

The most common adverse effect of the DREZ procedure is paresthesia, which is usually transient but can be permanent in a minority of cases. This is estimated to incidence of transient or permanent paresthesias, that is, 15% to 30%.\(^4\) Transient or temporary motor weakness is also a known risk of the procedure which results from an ablation field that extends laterally beyond the DREZ to involve the corticospinal tract. Incidence rates of permanent weakness vary widely, with the majority of studies citing less than 10% risk, with some studies citing up to 40% to 60% according to a review by Konrad.\(^5\)

**Cordotomy**

**INDICATIONS**

Destruction of the anterolateral column, or spinothalamic tract, for treatment of chronic pain, was first reported in 1912 by Spiller and Martin.\(^{16}\) The procedure, referred to as cordotomy, has evolved since that time but exists today in its same conceptual form, with the goal of eliminating the transmission of afferent pain signal by ablating the spinothalamic tract. The most appropriate candidates are those who have localized, unilateral pain that is nociceptive in origin.\(^{17}\) The most typical, current-day indication would be in the setting of intractable unilateral pelvic, flank, or chest wall pain from metastatic cancer. Cordotomy has become less commonly performed due to the rise of opioid therapies and intrathecal pain pumps for palliation but should continue to be considered in situations in which these initial therapies are ineffective or inappropriate in the setting of the patient’s wishes or life expectancy. Additionally, it is
important to note that chronic cancer-related pain can develop a neuropathic component due to actual injury to nerve fibers, and it is important to counsel patients regarding the likely persistence of the neuropathic component after cordotomy. The surgery is either performed percutaneously at the C1/2 level with the patient awake to provide sensory feedback or via an open surgical approach at an upper thoracic level with the patient under general anesthesia in the prone position. For percutaneous cervical technique, the patient must be able to tolerate lying flat and still for approximately 45 minutes. For thoracic open cordotomy, the patient must not have other active cardiac, pulmonary, or hematologic medical problems that would contraindicate an open surgery in the prone position.

ANATOMY AND PHYSIOLOGY
The anatomic target of the cordotomy is the spinothalamic tract within the anterolateral quadrant of spinal cord at the high cervical level (C1/2) or mid-to-upper thoracic level (T4) on the side contralateral to the patient’s pain. Pain-mediating afferent fibers enter the spinal cord through the DREZ on the side of the painful stimulus before synapsing in the substantia gelatinosa of the dorsal horn and decussating via the anterior commissure and joining the ascending fibers of the spinothalamic tract contralateral to the side of pain. The decussation of fibers for a given nerve root entry level can occur over 2 to 5 spinal levels. Therefore, the cordotomy lesion ought to be sufficiently rostral relative to the level of pain in order to fully disrupt nociceptive transmission. As general rule of thumb, allowing for per-patient variation, a C1/2 cordotomy tends to result in analgesia at C5 and below, whereas a T4 cordotomy will achieve analgesia at T10 and below. The somatotopic arrangement of the spinothalamic tract lends itself to targeted lesioning when percutaneous RFA is performed. The ascending spinothalamic tract accrues fibers decussating from their contralateral entry at its medial-most aspect. This leads to the sacral representation being most dorsal, and lateral and the cervical representation being most ventral and medial, with lumbar and thoracic information arranged accordingly in between. This somatotopy is demonstrated in Figure 105.2.
As a result, in patients with predominant hemipelvis or unilateral lower extremity pain, it is possible to selectively lesion sacral and lumbar fibers while preserving the cervical and thoracic domains of the spinothalamic tract.\(^{17}\)

The operating surgeon must be keenly aware of critical structures in near proximity to the lesion target. Anterior horn cells controlling level-specific motor function lie deep and medial to the spinothalamic tract throughout the spinal cord and are at risk of being involved in the field of ablation. Therefore, C1/2 and midthoracic levels are preferred because loss of anterior horn cells at these levels is not associated with significant morbidity. However, high cervical lesions near the cervicomedullary junction can involve decussating fibers of the cortical spinal tract and pose the risk of causing contralateral weakness of the lower extremity. Importantly, interneurons involved in respiratory control reside within the
upper cervical levels and are located within the ventromedial cord in near proximity to the spinothalamic tract. Because of this, bilateral cervical cordotomies must be judiciously considered in order to avoid the life-threatening sleep-related apnea phenomenon, commonly referred to as Ondine’s curse.\textsuperscript{17}

TECHNIQUE

Percutaneous cervical cordotomy is performed under either fluoroscopic\textsuperscript{21} or computed tomography (CT)-guidance.\textsuperscript{17} The patient is placed in the supine position with the head maintained in slight flexion either with a fixation band or rigid frame fixation depending on surgeon preference. A combination of local anesthetic and light sedation is provided for anesthesia. The C1/2 interspace is identified using lateral x-ray or CT imaging. In the case of fluoroscopy or x-ray technique, a 20-gauge spinal needle must first be introduced into the subarachnoid space in order to inject contrast to aid in identification of the dentate ligament, which is the critical landmark in the anterior-posterior dimension for safe localization of the spinothalamic tract. CT myelogram with contrast injection through either lumbar or cervical site provides multiplanar acquisition of imaging to more confidently identify the needle or cannula trajectory with respect to the dentate ligament and spinothalamic tract. Once the dentate ligament is identified, the electrode cannula with stylet is introduced into the spinal cord with a goal target of 1 to 2 mm anterior to the dentate ligament for sacral and lumbar fibers and 2 to 3 mm anterior to the ligament for thoracic and cervical fibers. Repeat CT imaging may be obtained to confirm appropriate cannula positioning. The stylet is then removed, and the noninsulated electrode (2.5 mm in length by 0.25 mm in diameter) is introduced into the spinal cord through the cannula. The electrode impedance is tested to confirm intraparenchymal placement (greater than 800 ohms).\textsuperscript{17,21} Stimulation of 0.2 to 1.5 mV can be provided at 100 Hz to obtain neurophysiologic confirmation of electrode placement. The patient will likely experience dysesthesias in the form of inappropriate temperature sensation. Once there is satisfactory confirmation of correct electrode positioning, ablation is performed by heating the tissue to 70° C to 80° C for 60 seconds. Depending on the extent of the patient’s pain

5185
symptoms, multiple lesions may be performed. Postprocedurally, the patient is monitored closely either in perioperative recovery unit or in the intensive care unit for at least 4 to 6 hours prior to less intensive monitoring or discharge.

Open thoracic cordotomy is performed in the operating room with the patient in the prone position. A bilateral or hemilaminectomy is performed and a durotomy is made to provide access and direct visualization of the spinal cord. The dentate ligament is identified and separated from the dura to facilitate gentle upward rotation of the spinal cord to provide the surgeon access to the anterior spinal cord. An angled cordotomy knife is then inserted anterior to the dentate ligament to a depth of 3 to 4 mm and swept anteriorly to ensure complete disruption of the spinothalamic tract. It is essential that the surgeon respect the dentate ligament as the posterior boundary in order to avoid injury to the corticospinal tract. The dura is then closed in a watertight fashion in order to prevent cerebrospinal fluid (CSF) leak. Figures 105.2b and 105.2c demonstrate the differences in approach and the expected lesion size for percutaneous and open cordotomy. Of note, the ventral spinocerebellar tract is more likely to be involved in the open lesion which may contribute to postoperative ataxia.

OUTCOMES
Compared to other ablative procedures for pain, cordotomy is well studied with over 3,600 patients reported in the literature, including one prospective study. In general, as reviewed by Konrad, immediate pain relief following percutaneous cordotomy occurs in approximately 90% of patients with rates of pain relief falling to 50% to 60%, 1 year after procedure. Similarly, open cordotomy provides high rates of immediate pain relief (up to 93% reported by Cowie and Hitchcock) which fall to 54% to 65% after 1 year follow-up. Therefore, cordotomy remains an impactful option for patients with severe pain due to advanced metastatic disease. Its efficacy has also been studied in cases of chronic pain from nonmalignant etiologies. In a study of 122 patients who underwent percutaneous cervical cordotomy, 27 suffered from nonmalignant sources of pain. In this subgroup, only 20% experienced complete pain relief compared to a rate of 66% in cancer patients. Cordotomy, therefore, is felt
to be most effective for cancer-related pain but still remains an option for patients suffering from intractable pain due to SCI or other etiologies, in which all other options have been exhausted.

The most common adverse outcomes reported following cordotomy include spinal headache from dural puncture, short duration of “mirror pain” during which time symptoms similar to preoperative pain are experienced on the contralateral side of the body, dysesthesias, ataxia, temporary leg weakness, and temporary bowel and/or bladder dysfunction. Estimated incidences of these side effects are reported to be in the range of 10% to 34%, with ataxia and bladder dysfunction being most commonly reported. Serious adverse events including respiratory impairment and even associated death have been reported even in unilateral procedures. Ischia et al. cites a 0% to 9% risk of mortality rate in unilateral procedures and 11% risk of death in bilateral cervical cordotomy. It is generally felt that the majority of complications arise from poor electrode placement and that the rise of CT guidance has led to decreased rates of severe complication. Open cordotomy comes with the increased risk of CSF leak due to larger durotomy, but the ablation-related neurologic side effects discussed are largely similar in both percutaneous and open approaches.

Cingulotomy

INDICATIONS

Although cingulotomy was first performed for psychiatric disease by Sir Hugh Cairns in 1948, it was not until over a decade later in that the first series on cingulotomy for intractable pain was reported in 1962 by Foltz and White at the University of Washington. Motivated by significant reduction of intractable pain in patients who had undergone prefrontal lobotomy in combination with animal studies implicating the frontal cingulum fasciculus as the critical white matter tract involved generating the emotional valence of pain, Foltz and White sought to employ stereotactic cingulotomy as a refined ablative approach for pain control. Rather than enrolling patients based on a specific etiology of intractable pain, they worked with psychiatry colleagues to select patients who
showed prominent emotional factors” such that the cingulotomy might “modify the patient’s emotional response . . . so that his expressions of fear and anxiety no longer augmented critically whatever pattern of organic pain was present.” Following their initial success with their report describing 11 of 16 patients experiencing good pain relief, many other groups explored the role of anterior cingulotomy for chronic medically refractory pain, including applications for both neoplastic and nonneoplastic sources of pain. In recent years, however, the rise of implantable intrathecal pain pumps and neuromodulatory devices, anterior cingulotomy has become less popular. However, anterior cingulotomy continues to offer a widely applicable approach for severe, intractable pain, especially in patients predominantly featuring an affective component to their pain. It may also be most appropriate in patients who are not candidates for implantable devices due to barriers to frequent follow-up care or due to short life expectancy in the setting of end-stage malignancy.

**ANATOMY AND PHYSIOLOGY**

General pain perception has been described as being divided into two components: a lateral pain system involved in spatial discrimination of pain and a medial pain system involved in the affective and autonomic response to pain. The anterior cingulate is a main component of the medial system. It is located mesial, ventral, rostral, and dorsal relative to the genu of the corpus callosum and has broad connections to many different sites involved in pain processing. These include the medial frontal cortex, thalamic nuclei (anterior, midline, interlaminar, and others), septum, amygdala, basal ganglia, nucleus accumbens, and brain stem sites such as the periaqueductal gray. The anterior cingulate receives nociceptive input and has connections with several sites involved in the affective and attentional component of pain which is supported by a broad range of data. Foltz and White, for example, noted changes in comfort and affect in several patients immediately following lesioning in the operating room. Additionally, functional imaging studies have shown bilateral response within the anterior cingulate in response to pain. Furthermore, intraoperative single neuron recordings in humans
undergoing anterior cingulotomy for psychiatric disease have demonstrated modulated activity in response to thermal and mechanical noxious stimuli. Those same neurons did not respond to nonnoxious stimuli. Furthermore, stimulation studies in monkeys and humans have been able to induce responses of fear or happiness in response to anterior cingulate stimulation.

**TECHNIQUE**

When the procedure was first developed in the 1950s prior to CT and magnetic resonance imaging (MRI) availability, ventriculography was used for anterior cingulate localization relative to the frontal horn of the lateral ventricle. The lesion was frequently performed with the patient awake to allow for continuous assessment of the patient’s emotional, affective, and motor function. In current practice, the procedure is performed with either under CT- or MRI-based stereotactic guidance, with MRI becoming progressively more popular. The bilateral anterior cingulate targets are mapped preoperatively with standard coordinates being 20 to 25 mm posterior to tip of frontal horn, 7 mm lateral from midline, and 2 to 3 mm superior to the corpus callosum. Importantly, two retrospective analyses of patients with lesions ranging from 17.5 mm to 37.5 mm posterior from the tip of the frontal horn showed that patients with more posterior lesions had less effective pain relief. In the operating room, the target is accessed through the placement of two burr holes, each approximately 20 to 30 mm from midline just anterior to the coronal suture. Correct stereotactic placement can be confirmed by the use of microelectrode recording. An uninsulated 10-mm radiofrequency thermocoagulation electrode is placed in the target tissue which is then heated to 85°C for 90 seconds. Typically, the electrode is then pulled back 5 mm, and a second lesion is made. Multiple lesions along the cingulate cortex in the anterior-posterior direction can be performed. Figure 105.3 provides postoperative MRI demonstrating ablation of the bilateral anterior cingulate cortex with three lesions on each side. Alternative methods for creating the lesion include radiofrequency thermal ablation and laser interstitial thermal therapy.
FIGURE 105.3 Postoperative magnetic resonance imaging following stereotactic anterior cingulotomy. A: Sagittal T1 sequence reveals three lesions (white arrow) within the anterior cingulate gyrus. B: Coronal postcontrast T1 sequence shows bilateral lesions within the anterior cingulate gyrus with postsurgical changes along the stereotactic probe trajectories through the bilateral frontal calvarium and frontal lobes.

OUTCOMES
Anterior cingulotomy has generally been referred to as an option most appropriate for patients suffering from cancer-related nociceptive pain. However, a recent review and meta-analysis by Sharim and Pouratian\textsuperscript{32} showed equivalent outcomes in both neoplastic and nonneoplastic populations. In a total of 224 patients (97 with cancer-related pain and 127 with noncancer pain) across 11 studies, 66.5% reported pain relief after the procedure. This rate was comparable in both cancer patients (65.3%) and noncancer patients (68.0%). Table 105.1, adapted from their review, contains the breakdown of the outcomes on a per study basis. Types of noncancer pain varied widely including neurofibromatosis, thalamic stroke, trauma, failed back syndrome, phantom limb pain, atypical facial pain, and peripheral neuropathy.\textsuperscript{32}

Although up to two-thirds of patients will report pain relief at some point postoperatively, the durability of the relief has been shown to diminish with time. In some instances of persistent pain in the immediate postoperative period, repeat cingulotomy is offered in order to expand the extent of the lesion. The incidence of repeat cingulotomy has been estimated at 7.6% across all published cases; however, the current routine addition of a second ablative site after withdrawing the ablative catheter 5 mm is thought to mitigate this risk.

Temporary postoperative adverse symptoms associated with cingulotomy include urinary incontinence, confusion, and disorientation. More serious reported events include a less than 5% incidence seizure and less than 1% incidence of hemiparesis or personality change. Longer term assessment of effect on cognition have revealed decrements in executive function that peaks in severity at approximately 3 months postoperatively but tends to resolve by 1 year postprocedure. Persistent impairment in spontaneous word production and speech fluency have also been reported.

### Thalamotomy

**INDICATIONS**

The thalamus is a collection of nuclei through which nearly all sensory
input passes in order to reach the cortex and conscious perception. As such, the thalamus was recognized early as a logical target for disrupting nociceptive transmission through anatomically precise ablative procedures.\(^{41,42}\) However, early experience with thalamic lesioning for chronic pain forced a reconsideration of the thalamus as a simple relay station because therapeutic pain relief achieved by thalamotomy frequently waned within 3 to 6 months of the procedure.\(^{43}\) These observations, combined with other unwanted sensory and psychiatric side effects, and the advent of more sophisticated pharmacologic and deep brain stimulation procedures for chronic pain control have led to a general paucity of rigorous clinical data assessing the efficacy of thalamotomy. It is currently a relatively rare procedure used for chronic, nonmalignant pain and is considered a last-line approach for malignant neuropathic pain.\(^{22}\) Most typically, it is used in scenarios of limited life expectancy where direct tumor invasion is causing intractable face and/or head pain that is not alleviated by pharmacologic therapy and is not anticipated to be adequately managed by an ablative lesion at the spinal cord or peripheral level. Thalamic targets have evolved from lateral to medial with the observation that ventrocaudal thalamic nucleus lesions tend to produce more unwanted side effects.\(^{44,45}\) Currently, medial targets including centromedian (CM), parafascicular (PF), and centrolateral (CL) are most common, with the pulvinar nucleus also being targeted.\(^{46}\) Recently, with the emergence of focused ultrasound (FUS) as a technique for achieving precise ablation, thalamotomy is being revisited as a method for treatment of nonmalignant chronic neuropathic pain.\(^{47}\) As results using this method become more established and as refinement of FUS technique occurs, reconsideration of thalamic targets for ablation in specific clinical scenarios may be warranted.

**ANATOMY AND PHYSIOLOGY**

Thalamic nuclei are anatomically organized into medial, lateral, and anterior groups separated internally by the internal medullary lamina (which houses intralaminar nuclei) and contained laterally by the thalamic reticular nucleus.\(^{48}\) Additional functional characterization of nuclei exists based on the origin of their inputs as well as the specificity of their
projections. Medial nuclei receiving peripheral nociceptive inputs include the dorsomedial nucleus (DM), which primarily receives inputs from the amygdala, olfactory cortex, and limbic basal ganglia. The DM also projects to frontal cortex in a diffuse manner. Lateral nuclei receiving nociceptive inputs include the ventral posterolateral nucleus (VPL), the ventral posterior medial nucleus (VPM), and the pulvinar nucleus (PVN). VPL receives inputs from the spinothalamic tract and projects in a precise manner to somatosensory cortex, relaying peripheral nociceptive signals from the body. The VPM analogously receives inputs from the trigeminothalamic tract projecting in an anatomically precise manner to the somatosensory cortex and relaying nociceptive signals originating from the face. The specificity of inputs and projections associated with lateral nuclei may underlie why targeted ablation of these nuclei produce sensory deficits, whereas medial targets with broader inputs and outputs can be ablated without as many obvious side effects. Anterior targets include the anterior nucleus of the thalamus (AT). AT receives inputs from the hippocampus and amygdala and projects to the cingulate cortex. Intralaminar nuclei receiving peripheral nociceptive inputs include the CL which is part of the rostral intralaminar nuclei as well as the CM and PF which are subsets of the caudal group of intralaminar nuclei.

**TECHNIQUES**

**Stereotactic open approach:** The general surgical method for stereotactic ablation of thalamic targets involves awake surgery to simultaneously record from and identify the nucleus of choice and then ablate it using thermal energy. The procedure starts by placing the patient’s head in a rigid stereotactic frame. The frame is then fixed to the operating table in final position. A pilot CT scan is obtained via portable or intraoperative CT. This CT image is merged with a previously obtained MRI in order to determine stereotactic coordinates of the target in relation to the line defined by connecting the anterior and posterior commissure (AC-PC coordinates). Coordinates from 6 to 10 mm lateral to the AC-PC line, 7 to 11 mm posterior to the AC-PC midpoint, and from 1 mm below to 2 mm above the AC-PC line have been used to target DM and CM. An entry point is typically chosen near the coronal suture 3 cm from midline. A
curvilinear incision is made and a burr hole drilled and then dura opened in
standard fashion to give access to the brain. Depending on the target and
surgeon preference, microelectrode recordings can be used for localization.
Although there is not always a clear electrographic correlate to localize the
nucleus, in certain cases, neuronal bursting patterns may indicate
deafferentation pain.\textsuperscript{51} Medial nuclei, in general, provide a large target
with no somatotopic projection pattern. Therefore, electrical recording
may be of little utility; nonetheless, test stimulation for motor and sensory
phenomena can always be conducted as a safety measure prior to
 lesioning.\textsuperscript{46} Using a thermocouple probe, a test lesion is made at a lower
temperature (40° C for 25 seconds), and if the patient shows no adverse
effects, an ablative lesion is made (70° C for 70 seconds).\textsuperscript{46}

**Noninvasive radiosurgery and focused ultrasound:** Radiosurgery
techniques used for thalamotomy include both Gamma Knife and linear
accelerator methods. FUS is beginning to emerge as an alternate energy
source for creating precise lesions. As imaging technology for lesion
localization becomes more accurate, clinical results of noninvasive
ablative approaches may near those of stereotactic open approaches.\textsuperscript{52} One
key difference with respect to radiosurgery approaches is the time needed
for lesions to mature following radiation treatment. Young et al.\textsuperscript{49}
describes a case series in which 24 medial thalamic lesions were created
via Gamma Knife using 140 to 180 Gy. The emergence of distinct lesions
via MRI occurred 3 to 6 weeks after the initial procedure and did not fully
mature until 8 to 12 weeks. Ultimately, 9 out of 15 total patients achieved
a greater than 50% pain reduction at 3-month follow-up, which is
comparable to the results of stereotactic ablation. However, if shorter term
pain relief is needed, such as in the context of severe pain and limited life
expectancy, then stereotactic alternatives will need to be considered to
provide prompt palliation to the patient. Moreover, recent results of
noninvasive thermoablation by FUS suggest that it may represent a
tractable alternative. In a case series by Jeanmonod et al.,\textsuperscript{47} transcranial
MR-guided FUS (tcMRgFUS) was used to perform CL thalamotomies on
12 patients suffering from chronic neuropathic pain. Lesions 3 to 4 mm in
size were made using tcMRgFUS to heat the tissue to 51° C to 64° C as
monitored by MR thermometry. Six patients experienced some degree of
immediate pain relief, whereas a mean pain reduction of 49% was experienced by nine patients at 3-month follow-up. A randomized sham-controlled clinical trial is currently underway to assess the efficacy of ExAblate FUS technology in treatment of refractory chronic trigeminal neuropathic pain of nonmalignant origin (NCT03309813). The key technical barrier to improvement in precision and accuracy of both radiosurgery and FUS techniques is improvement in MR technology for target localization. Real-time continuous MR imaging and MR thermometry monitoring dictate both lesion accuracy as well as accuracy of thermal effects during FUS ablation. As this technology improves, the noninvasive nature of approach will likely make it a more favorable alternative to stereotactic thermoablation.

OUTCOMES

Although efficacy of medial thalamotomy has been shown in multiple case series and case reports, systematic studies of methods, targets, lesion sizes, and indications have not been conducted. Raslan et al.\(^{22}\) conducted a systematic review of ablative pain procedure studies including thalamotomy for malignant pain and found only a handful of reports, all case series level evidence. The results of the systematic review for thalamotomy are summarized in Table 105.2, which is adapted from Raslan et al.\(^{22}\) It is therefore not surprising that there is no consensus as to a specific nucleus to optimally target for ablation. As mentioned, medial targets with less somatotopic mapping seem to produce fewer side effects. In addition, it seems that pain caused by direct tissue damage (nociceptive, for example from malignant invasion) responds more favorably than neuropathic pain, although individual reports vary. Sugita et al.\(^{55}\) found 85% had excellent or satisfactory pain relief initially, whereas Richardson\(^{53,54}\) found mixed results with return of chronic pain occurring in all patients. The aforementioned noninvasive techniques seem to produce approximately 50% pain reduction at 3 months postprocedure.\(^{52}\) As with all ablative procedures, the outcome depends in large part on the circuit pathophysiology prior to intervention and the reaction of the remaining circuit or network after ablation. As our understanding of pain physiology advances; as the technology to interrogate the circuitry prior,
during, and after ablation improves; and as our methods of ablation become more precise, it is possible that the seemingly heterogeneous outcomes of thalamotomy will become better understood.

### Ablative Procedures of the Brainstem

5196
INDICATIONS
Because the anatomical basis of pain transmission was established throughout the 19th century, surgical procedures for treatment of pain advanced, leading to cordotomy in 1911 as well as spinothalamic tractotomy. However, throughout the first half of the 20th century, it became apparent that existing procedures did not provide long-term relief of neck, shoulder, and face pain. This led Spiegel and Wycis to pioneer stereotactic lesioning of the mesencephalon in 1953 and later Hitchcock to use stereotaxis for lesioning of the pons and trigeminothalamic pathways in the brainstem. Here, we discuss mesencephalic tractotomy (lesioning of the spinothalamic tract in the midbrain) and ablation of the trigeminothalamic tract and nucleus caudalis (the caudalmost subdivision of the spinal trigeminal nucleus). These procedures are indicated in cases of facial, head, neck, or shoulder pain which are unresponsive to pharmacologic therapy and more conservative measures. Furthermore, for pain rostral to C5, cordotomy may be limited, in which case mesencephalic tractotomy serves as an alternative. Typically, underlying disorders in which the aforementioned procedures are considered include geniculate or glossopharyngeal neuralgia, failed trigeminal surgery or anesthesia dolorosa, posttraumatic neuropathy, postherpetic dysesthesia, atypical facial pain, and cancer-related pain.

ANATOMY AND PHYSIOLOGY
The trigeminal sensory nuclei not only receive somatic sensory input in large part from the trigeminal nerve but also receive input from the facial nerve (sensation near outer ear), glossopharyngeal nerve (sensation for middle ear, external auditory meatus, pharynx, posterior third of tongue), and vagus nerve (sensation for pharynx, outer ear, infratentorial meninges). The trigeminal nuclear complex extends from the rostral cervical spinal cord to the midbrain and is made up of the mesencephalic, chief sensory, and spinal trigeminal nuclei. These nuclei transmit fine touch, pressure, temperature, and pain sensations from the face to the brain in an analogous manner to posterior columns and anterolateral systems of the spinal cord. Namely, the chief sensory nucleus (located dorsolaterally in the rostral pons) receives synaptic input from large diameter sensory
fibers carrying fine touch and pressure transmission. Cell bodies in the nucleus give rise to the trigeminal lemniscus in the rostral aspect of the pons which decussates and travels to the VPM adjacent to the medial lemniscus in the dorsal brainstem. Fibers carrying crude touch, pain, and temperature enter the pons and immediately descend via the spinal trigeminal tract (an analogue of Lissauer’s tract) to synapse on the spinal trigeminal nucleus in the dorsolateral brainstem starting at the cervicomedullary junction (the rostral extent of the dorsal horn). The spinal trigeminal nucleus is subdivided from rostral to caudal into the nucleus oralis, nucleus interpolaris, and nucleus caudalis (extending caudally to the C2 segment of spinal cord and substantially overlapping with substantia gelatinosa containing cervical inputs). The spinal trigeminal nucleus gives rise to the trigeminothalamic tract which decussates and ascends to the VPM alongside the spinothalamic tract (in the dorsal pons at the level of the middle cerebral peduncle). Of note, there is somatotopic organization of the trigeminothalamic tract and spinal trigeminal nucleus as described by various authors\textsuperscript{1,48,57} with an “onion skin” topology in which the central face is represented rostrally, and the peripheral face is caudal with V1 to V3 organization assuming a ventral to dorsal pattern. The mesencephalic trigeminal nucleus and tract together mediate facial proprioception and are located adjacent to the periaqueductal gray matter in the dorsal pons. The nucleus houses cell bodies of proprioceptive neurons, whereas the tract houses axons of these neurons. Of particular clinical significance is the anatomic relationship of the nucleus caudalis and spinal trigeminal tract to the dorsal spinocerebellar tract which is located just lateral on the dorsal surface of the spinal cord and brainstem as well as the lateral spinothalamic tract, located ventrally. Extensive lesioning at this level can cause an ipsilateral ataxia from damage to the spinocerebellar tract or contralateral anesthesia from spinothalamic tract damage. Similarly, damage to the nucleus cuneatus which receives dorsal column input and is located in a caudal and medial direction would cause ipsilateral proprioceptive and fine touch deficits.\textsuperscript{1,57} Finally, extensive lesioning of the spinothalamic tract in the midbrain is known to cause oculomotor deficits as well as ptosis due to proximity to the oculomotor nucleus and Edinger-Westphal nucleus.\textsuperscript{58}
TECHNIQUES

Mesencephalic tractotomy is performed using stereotactic lesioning via a radiofrequency probe as previously described. Of note, the procedure is performed under local anesthesia which facilitates intraoperative stimulation prior to lesioning to ensure that the target has been identified. Namely, as described by Frank et al., prior to lesioning, an evoked feeling of thermal sensation should be obtained to ensure the stimulator is in the spinothalamic tract. Also, while lesioning, sensation and proprioception should be assessed systematically to ensure the medial lemniscus is not inadvertently targeted (which could lead to painful anesthesia following the procedure as observed by Spiegel and Wycis). The spinothalamic tract can be localized using various imaging protocols including CT with ventricular contrast or MRI. Integrated data suggest that most lesions are 5-mm behind the posterior commissure, 5 to 10 mm lateral, and 5 mm below the AC-PC plane. Of note, although the original procedure was designed to target the lateral spinothalamic (and also the trigeminothalamic) tracts, evolution of the procedure has included simultaneous lesioning of the DM of the thalamus in order to disrupt its prefrontal connections thought to carry the affective “suffering” component of pain. Similarly, Spiegel et al. have advocated a more medial target to include spinoreticular pathways, also thought to project an affective component of pain processing to limbic structures.

After satisfactory localization of the spinothalamic tract, a radiofrequency lesion can be created in stepwise manner. It is also crucial to assess eye movements and eyelid function throughout this process because the surrounding oculomotor, abducens, and Edinger-Westphal nuclei can be damaged causing gaze palsies (see in the following discussion).

Kanpolat has developed a technique for a CT-guided percutaneous trigeminal tractotomy and nucleotomy. Contrast is injected into the subarachnoid space via lumbar puncture prior to the procedure, and a CT is then obtained with careful measurements taken of the depth from skin to dura. The patient is positioned prone, and local anesthetic is given. The procedure is done percutaneously using the electrode system developed by Kanpolat. Impedance measurements are initially used to guide electrode
placement. Stimulation is performed with low and high frequencies, and the patient is monitored for paresthesias of the face indicating the electrode is in projecting trigeminal nerve axons. Once positioning of the electrode is acceptable and confirmed by CT, the patient is given additional anesthesia prior to lesioning, which can be painful. One to three lesions are made in a stepwise manner starting with a temperature of 50° to 60° C and then 60° to 80° C for 60 seconds.

**OUTCOMES**

In a systematic review of ablative procedures for malignant pain control, Raslan et al.\(^{22}\) reviewed data for both trigeminal tractotomy and nucleotomy as well as mesencephalotomy (see adapted Table 105.3). Mesencephalotomy and pontine tractotomy (combined) are rarely performed (a total of seven studies were cited up until 2011), but effective pain relief generally achieved in a population of patients with very limited life expectancy. Trigeminal tractotomy for cancer-related pain, similarly, was found to have only a small number of studies qualifying for systematic review with the one noncase series piece of evidence being an open-label prospective study.\(^{62}\) This study employed standardized outcome measures of pain and reported sustained pain relief in 80% of subjects at 6 months.

More recently, in his case series, Kanoplat\(^{57}\) described 81 patients who underwent 96 CT-guided trigeminal tractotomy and nucleotomy. Sixty-six
(85.7%) patients achieved complete or partial satisfactory pain control, whereas 15 patients (14.3%) responded poorly to the procedure. The largest fraction of patients in this series had glossopharyngeal neuralgia. Of note, at the conclusion of the follow-up period (maximum 216 months), 55 patients (71.4%) achieved sustained pain relief, 13 (16.9%) reported partial pain control, and 9 (11.7%) reported failure of pain control.

Frank et al.\textsuperscript{58} describe 14 patients treated with stereotaxic rostral mesencephalotomy (a total of 19 procedures) for unilateral thoracobrachial cancer-related pain with frequent neck and/or face involvement. The mean follow-up time was 4.9 months with 14 procedures leading to good or excellent pain relief, whereas 4 led to only fair or no pain relief. The reported complications include two cases with persistent Parinaud syndrome; one case of bilateral ptosis; and single reports of dysesthesias, painful anesthesia, and mental changes.\textsuperscript{58} Kim et al.\textsuperscript{60} more recently reported a case of MRI-guided stereotactic mesencephalotomy in which initial pain control was achieved with a subsequent increase in pain at the 2-month mark. From this and preceding evidence, the authors argue that mesencephalotomy is rarely indicated for pain other than cancer pain and thalamic syndrome due to probability of pain recurrence at long-term follow-up.\textsuperscript{63}

**Conclusion**

With the development of improved pharmacotherapy, intrathecal delivery systems, and high-frequency stimulation, ablative procedures for pain have become less commonly utilized treatment options. Like all functional procedures, their utility is limited by current knowledge of the underlying circuitry. Indeed, with the elucidation of nearly every major element of the pain transmission pathway, there has come a corresponding ablative procedure. Here, we discussed indications, anatomy, techniques, and outcomes regarding the DREZ procedure, cordotomy, cingulotomy, thalamotomy, and tractotomies within the brainstem. Unfortunately, the complexity, inherent feedback, and nonlinearity of the pain transmission circuitry has made durable solutions to chronic pain more difficult than simply ablating component parts of the pain pathway. Systematic study of
ablative procedures is still lacking, but the literature, as we discussed here, contains many instances of ablative procedures effectively providing relief to patients with severely intractable pain. As neurosurgical procedures for pain become less invasive, including techniques that allow one to lesion without even entering the skull, the need for a thorough understanding and optimization of ablative approaches is crucial. We anticipate that as technology and understanding of functional anatomy advances, we will have the opportunity to readdress ablative approaches and consider more precise or combination therapies to provide satisfactory pain relief to patients with no reasonable alternative.

History of Interdisciplinary Chronic Pain Management

In the 1940s, John J. Bonica became the first physician to publicly recognize the complexity of chronic pain syndromes, understanding that they affect patients not only physically but also across myriad dimensions of their lives. Chronic pain of nonmalignant origin (i.e., noncancer pain) has been noted to be the most unpredictable type when compared to acute and chronic pain due to malignancy, which also makes it the most challenging to address. Bonica found himself frustrated by his inability to effectively treat those with chronic pain and found that consultation with his colleagues seemed to benefit all who were involved. Because of this, Bonica developed the first formal multidisciplinary pain management team at MultiCare Tacoma General Hospital, with members including an anesthesiologist, orthopedist, neurosurgeon, internist, psychiatrist, and radiation therapist. However, the model used was multidisciplinary triage in order to determine which team member would provide treatment and included only physicians with differing specialties versus professionals.
from entirely different fields.

Concurrently, unbeknownst to Bonica, others were simultaneously developing similar programs in Texas, Oregon, Canada, and Europe. Although some of these programs were successful, Bonica’s efforts to change the overall approach to chronic pain management were not so, and he wrote accordingly, “Despite my persistent drum beating, consisting of several hundred lectures and the publication of numerous articles in various parts of the world, the multidisciplinary concept was ignored by the medical profession for two decades.” Fortunately, the integration by clinical psychologist Wilbert Fordyce of a strong behavioral medicine into Bonica’s team in the late 1960s was instrumental in the development of the first multidisciplinary pain evaluation and triage team, which included disciplines outside of medicine. With the availability of behavioral approaches to assessment and treatment, the focus of pain clinics shifted from the eradication of pain to teaching patients how to manage their symptoms and restore a positive quality of life. Behavioral approaches were soon replaced by cognitive-behavioral approaches, which noted only were less time-consuming and costly but also emphasized the patient as an active participant in his or her rehabilitation who is able to develop the coping skills necessary to restore independence.

Multidisciplinary chronic pain management programs proliferated in the 1970s and 1980s, described as “medicine’s new growth industry.” Among the most active and prestigious of these facilities was that developed by Bonica at the University of Washington where he was succeeded in directorship by the neurosurgeon, John Loeser. According to Loeser, the great success of the program was due to the interaction between the various disciplines of the team members rather than to any specific intervention that was applied. This encapsulates the magic of interdisciplinary treatment which is often difficult to explain to outsiders but easily understood by those who have worked in the milieu. By the early 1980s, approximately 1,000 multidisciplinary evaluation and treatment centers were in operation in the United States and were becoming more numerous in other parts of the world as well. However, these programs were multidisciplinary rather than interdisciplinary. Contrary to common belief, the first truly interdisciplinary treatment
program was not developed until the early 1980s, when Wilbert Fordyce and John Loeser opened the facility at the University of Washington that resembled the modern concept of the interdisciplinary chronic pain management (ICPM) program (J. Loeser, personal communication, December 2, 2017).

Although third-party payers were initially enthusiastic regarding these programs, they soon became less supportive. It is difficult to specifically determine the point at which the number of interdisciplinary treatment programs and the availability of this type of pain management began to decline; however, Schatman\textsuperscript{9,10} has noted that the number of programs in the United States accredited by the Commission on Accreditation of Rehabilitation Facilities (CARF) declined from 210 in 1998 to 84 in 2005; in 2017, the total number of CARF-accredited pain rehabilitation programs has dwindled to 67. The availability of ICPM programs in the United States has flourished only in the Department of Veterans Affairs (VA) with the Department of Defense following step, a phenomenon which will be explored in greater depth later in this chapter.

**EMPIRICAL SUPPORT FOR INTERDISCIPLINARY CHRONIC PAIN MANAGEMENT**

The evidence to support the clinical efficacy and cost-effectiveness of ICPM is robust, and the studies are numerous; therefore, it is most efficient to focus on meta-analyses and systematic reviews that provide the approach with unequivocal empirical support. These studies will be reviewed briefly, and several prominent and more recent studies will be highlighted. Flor and colleagues\textsuperscript{11} performed the earliest meta-analysis of ICPM in 1992. The review of 65 studies identified numerous benefits for participants: reducing medication use, reducing emotional distress, reducing health care utilization, reducing iatrogenic consequences, increasing return to work and physical activity levels, closing disability claims, and an average pain reduction of 20%. Although the figure for pain reduction may not seem impressive, patients in these programs are generally told that pain relief is not the goal of treatment and are taught to focus on functional and emotional benefits. Not surprisingly, ICPM programs were determined to be superior to unimodal treatments as well as
to no treatment and waiting list controls. The beneficial effects of the programs appeared to be stable over time. As with most large-scale reviews, it was recommended that results be interpreted with some caution due to inconsistencies in methodologies and quality of research designs and descriptions.

The area of cost-effectiveness for ICPM deserves attention because it is typically regarded as an intensive and concomitantly expensive option for chronic pain management; however, a review of the literature does not support this widely held belief. In 1998, Turk and Okifuji\textsuperscript{12} performed a comparative analysis of ICPM programs in order to assess their cost-effectiveness as compared to surgery, chronic opioid therapy, and implantable devices. Most striking was the finding that ICPM programs were up to 21 times more cost-effective than alternative treatments for chronic pain such as surgery.\textsuperscript{12} Okifuji and colleagues\textsuperscript{13} performed a review of the literature on various treatment approaches to chronic pain, analyzing the cost-effectiveness of ICPM in comparison to surgery or conventional medical treatment. ICPM compared favorably to other treatments in terms of pain reduction, management of opioid analgesics, restoration of function as measured by activity levels and return to work, health care utilization, and closure of disability claims. Additionally, the authors dispelled the myth of ICPM representing an expensive approach to pain management, calculating that its use in lieu of the other typical approaches could result in a cost savings of $5 billion per year in the United States. Turk\textsuperscript{14} obtained similar findings in a 2002 review, noting not only that ICPM is comparable to oral medications, surgery, spinal cord stimulation (SCS), and intrathecal drug delivery in terms of pain relief but also that interdisciplinary treatment can provide considerable savings in costs for medications and additional health care utilization. Turk’s\textsuperscript{14} data on cost-effectiveness are dramatic, as he determined that interdisciplinary care is 6.29 times more cost-effective than surgery, 15 times more so than conventional care, and 25 times more cost-effective than SCS. This opens up the question regarding why insurance would reimburse procedures such as SCS but deny any coverage for ICPM programs when the evidence suggests that this is misguided.

Turk and Swanson\textsuperscript{15} performed an “analysis and evidence-based
synthesis” of the efficacy and cost-effectiveness of medications, surgery, SCS, intrathecal drug delivery systems, and ICPM in the treatment of chronic pain. The authors found that all of these approaches resulted in roughly the same amount of pain relief, with only ICPM determined to be essentially free of iatrogenic complications and adverse events as well as being numerous times more cost-effective than the other treatments considered in achieving therapeutic goals. Perhaps the most compelling empirical support for ICPM is provided by the 2001 and 2002 systematic\textsuperscript{16} and Cochrane\textsuperscript{17} reviews by Guzmán and colleagues and the 2003 Cochrane review by Schonstein et al.,\textsuperscript{18} as these studies involved careful analyses of trial quality. In each of these reviews, the authors determined that ICPM improves pain and function, which was not determined to be the case for less intensive treatments.

In an ICPM context and beyond, increasing functioning and optimizing quality of life often requires the reevaluation of pharmaceuticals. With a recent emphasis on reducing the use of analgesics that are not always helpful and potentially harmful, including opioids, it is worthwhile to include several studies demonstrating the role of ICPM programs in this effort. A 2013 study by Murphy et al.\textsuperscript{19} examined the outcomes of more than 700 participants who completed the inpatient ICPM program at the VA in Tampa, Florida. Since the program’s advent in 1988, veterans who enter the program taking opioids are tapered off during the course of their 3-week participation. The study compared how those who were on opioid medications at program admission fared against those who were not on opioids.\textsuperscript{19} There were no significant differences between groups at admission and all participants improved, but those on opioid analgesics at program initiation benefitted even more on several domains including catastrophizing and activities of daily living. A study and 6-month follow-up conducted by the ICPM program at Mayo Clinic in Minnesota examined treatment outcomes following opioid analgesic cessation\textsuperscript{20,21} and found that although patients on opioid analgesics at admission reported higher levels of pain and depression relative to those not taking opioids, there were no differences in outcomes at discharge or 6-month follow-up. Clearly, further research on the effects of opioid tapering on ICPM outcomes is warranted because the Tampa and Mayo studies.
suggest a significant and sustained improvement in pain severity and functioning following interdisciplinary treatment regardless of previous opioid status.

Evaluating medications not only is important to patient long-term well-being but also has financial implications. A novel economic analysis was conducted in 2015 by Mayo Clinic’s Florida ICPM program in collaboration with Florida Blue, the state branch of Blue Cross Blue Shield. Sletten et al. collaboratively examined the economic impact of participation in an ICPM on health care utilization and expenditures. Results indicated decreases in overall medical costs for up to 18 months including the use of specialty care, tests, and procedures. Of note, unlike many other cost-effectiveness studies that focus on low back pain, this ICPM sample included a broad range of chronic pain conditions with an average pain duration of 8 years. The involvement of a third-party payer in this analysis represents an important model for future studies because this may be the most convincing way to garner the support of insurance companies. This is consistent with Schatman’s work on the demise of interdisciplinary pain management in the United States, in which he posited that insurers’ exclusive focus on cost-containment and profitability trumps pain patient well-being. In the future, it would be ideal for ICPM programs to partner together and enlist the collaboration of multiple health care plans and payer types to once again demonstrate the economic benefit of interdisciplinary care.

Given these data, the process by which third-party payers determine what is worthy of a cost investment can be puzzling. Procedures such as back surgery, which is costly and risky and yields very mixed empirical outcomes, are typically covered, yet payers are unlikely to reimburse evidence-based and lower risk ICPM programs. This in part speaks to the antiquated yet ongoing biomedical approach that much of the public, providers, and payers apply to chronic pain treatment. Although it is clearly a complex biopsychosocial experience that persists across time, chronic pain continues to be approached in the same manner as acute pain. This error is a significant reason why individuals and systems seek and support medical solutions that “cure” pain rather than understanding that pain can be best minimized and quality of life improved with a whole-
THEORETICAL BASIS OF THE INTERDISCIPLINARY APPROACH

Before proceeding, it is important to clarify the distinction between multidisciplinary and interdisciplinary. Although the terms are often used interchangeably, they are not synonymous. Multidisciplinary treatment suggests that there are providers from multiple disciplines treating a patient in parallel. Communication may exist, but is not required, and varies widely. Coordination of care and treatment planning is atypical and is unfortunately often fragmented. This is a common approach in primary and secondary care, in which specialists are consulted as needed and work in silos. On the other hand, interdisciplinary care is best reflected in a cohesive team composed of experts from various disciplines who share a philosophy of care and communicate routinely regarding patient treatment. They are ideally colocated, although if not, may use technology for information sharing (e.g., phone calls, e-mails, electronic medical records) as well as holding scheduled and unscheduled in-person meetings. The importance of regular communication among team members cannot be overstated, and consistency in the philosophy of patient care is critical for program success.

All ICPM is based on the biopsychosocial approach that emphasizes the complex and dynamic interaction between physiologic, psychological, and social factors. These variables and how patients respond to them can exacerbate or ameliorate the patient’s pain experience. For Bonica, the addition Fordyce contributed to the evolution of the approach by considering the emotional and behavioral sequelae of chronic pain as well as nociceptive experience was invaluable. Chronic pain is a disease of the person, and the person is often obscured by using the traditional biomedical approach without the integration of other critically relevant factors. Therefore, to effectively treat chronic pain, the motivational-affective and cognitive-evaluative contributions must be weighed in addition to the nociceptive. ICPM recognizes the bidirectionality of pain and psychosocial factors, considering that emotions and maladaptive behavioral patterns can perpetuate as well as result from persistent
physical discomfort. Regardless of the etiology of pain and even its comorbidities, patients who have functional impairments can improve on multiple dimensions if they are provided with appropriate guidance and are motivated by the staff to exert maximal effort. The goal is for participants to achieve management of their pain, with an emphasis on increasing self-efficacy and restoring independence and overall quality of life.

**COMPOSITION OF THE INTERDISCIPLINARY TEAM AND ROLES OF MEMBERS**
ICPM is based on the premise that no individual or discipline can “cure” the patient of all of the ills associated with his or her pain condition. Although specialization serves to enhance expertise, specialization without diversification results in limitations to what health care can offer patients whose conditions are as complex as chronic pain. This, perhaps, was the greatest wisdom that Bonica contributed to the pain treatment community. Although the specific construction of ICPM programs vary depending on factors such as available resources, the typical treatment provided includes three common elements: (1) medication management, (2) graded physical exercise, and (3) cognitive and behavioral techniques for pain and stress management.\(^{13}\) The CARF standards\(^ {24}\) identify only two defined disciplines as essential for ICPM rehabilitation programs: the pain team physician and pain team psychologist; additional health care professionals are based on the needs of the persons served. The roles of ICPM team members that are generally identified as constituting the core as well as other members that expand and enrich services provided are reviewed in the following discussion.

Core Team Members
- Physician/medical director: The ICPM program medical director provides medical leadership and accepts responsibility for the physical well-being of the patients treated. Although it is important that the physician possesses expertise in the rehabilitation of pain disorders, a survey of programs yields wide variance in the training experience and practice specialties of their medical directors. These specialties range from physical medicine and rehabilitation to psychiatry, rheumatology to internal medicine. Of note, the CARF
standards require that a medical director be a physician who is certified in their recognized board, has met established interdisciplinary training requirements, and is involved in the field of pain and in the ICPM program. The precise duties of the medical director vary depending on his or her engagement in patient care versus nurse practitioners or physicians’ assistants, which is discussed in the following text. If involved in a more hands-on role, the physician may take a medical history, evaluate the patient for purposes of providing or confirming a diagnosis, analyze test results, manage medications, and in some cases provide interventions such as trigger point injections. If nurse practitioners or physicians’ assistants provide much of the direct clinical contact, the medical director may be called on to see patients who are most complex or may value from the input of a physician. The medical director also may represent the program to hospital or academic leadership. In general, the physician who is seen as warmer and less directive is likely to foster greater team cohesiveness. Similarly, Spoonhour and Schatman have suggested that selflessness is ideal because the most effective medical directors are those who are willing to allow the team member with certain expertise to function in a manner maximizing the benefit of that expertise.

- Advanced practice nurses and physicians’ assistants: As mentioned, the day-to-day duties involved in an ICPM may be carried out by a nurse practitioner or physician’s assistant. This is done typically to conserve fiscal resources, although nurse practitioners and physicians’ assistants often have high levels of pain expertise and need limited input from a physician. They perform duties such as evaluating individuals for program appropriateness, completing histories and physicals, managing medication regimens, evaluating patients during crises, participating in team meetings, and offering input on various impacts of biomedical information regarding the treatment plan. They may communicate with the medical director or other physicians often or seldom, depending on the structure and needs of the specific program.
- Psychologist: Pain psychologists on interdisciplinary treatment teams
are primarily responsible for the psychosocial aspects and status of patients’ care. As patients’ pain becomes more chronic, their development of maladaptive emotional and behavioral patterns increases, necessitating expert psychological care if they are to become more functional in their lifestyles. In addition to a medical director, CARF requires a pain psychologist on the team whose qualifications include licensure, completion of established interdisciplinary training requirements, and routine involvement in the ICPM program.\textsuperscript{24} Although CARF does not specify the discipline of the pain program director, this is often fulfilled by the psychologist.

The duties of psychologists in ICPM are vast. Initially, they assist in determining whether a patient is appropriate for program participation by evaluating pain-related functional status and psychological stability. Often, they communicate information regarding program benefits and expectations. During the program, the pain psychologist will work with patients on both an individual and group basis, with an emphasis on identifying more adaptive ways to respond to pain, acquiring problem-solving and stress management techniques, decreasing catastrophization, and enhancing self-efficacy. Through these approaches, reductions in depression and anxiety along with more adaptive behavioral responses to pain are typically evidenced.

Although not always the case, psychologists also may serve as the biofeedback therapist on the ICPM team to facilitate reducing patients’ psychophysiological reactivity to stress. Effective use of relaxation techniques (e.g., progressive muscle relaxation, imagery, diaphragmatic breathing) are a cornerstone of pain management and help shift a patient toward internal locus of control\textsuperscript{27} as well as reduce tension and pain. In some cases, the biofeedback therapist works in tandem with the physical therapist, using biofeedback technology to help patients improve patterns of muscle activation during physical activities. The ICPM psychologist will also often work with a patient’s family during the course of a program because the family may unwittingly be reinforcing the “patient role,” thereby enabling the patient. Finally, as psychologists are trained as scientist
practitioners, they are likely to coordinate outcomes information and performance improvement projects for the ICPM team.

- **Nurse:** Nurses on ICPM treatment teams often assume diverse responsibilities and are accordingly invaluable. Because of their medical backgrounds, they can potentially serve in a variety of roles. They support other medical staff and often provide education to patients and their families. In a role delineation study, Pellino and colleagues determined that assessing, evaluating, and monitoring pain were nurses’ most common activities. Nurses are also the multidisciplinary team members that spend the greatest amount of time with patients. Additionally, as many nurses are trained and experienced in case management, a nurse is often the team member responsible for the day-to-day management of the program.

- **Physical therapist:** Movement-based therapies are an essential element of physical activation that is key for effective pain rehabilitation. The physical therapist on a pain treatment team is responsible for assessing patients’ levels of functioning and then designing and monitoring programs of graded therapeutic exercise that will safely increase these levels. Areas of focus may include increasing flexibility and range of motion, restoring appropriate posture and body mechanics, ambulation and gait training, development of core and limb strength and stability, and decreasing pain-related fear of movement. Treatment is typically provided on both an individual and group basis. Modalities such as ultrasound and massage are generally avoided, as the focus of ICPM is on teaching patients independent active management of their pain. Stretching and strengthening are emphasized because these exercises have been empirically supported through systematic reviews as being among the most effective treatments for a number of types of chronic pain. It is critical that the ICPM physical therapist has received specialized training in chronic pain management emphasizing a behavioral approach, which is not the norm; however, for those who value working on a team and the reward of success with patients with longer standing issues, it can be an excellent fit.

- **Case manager/coordinator:** This is a role versus a discipline and can
be performed by those in various areas but is most commonly fulfilled by a nurse. Duties are critical for smooth maintenance of the program and may include triaging referred patients; confirming insurance sponsorship; development of policies and procedures; quality assurance; collection and maintenance of patient data; and correspondence with referral sources, employers, attorneys, health insurance providers, and other health care professionals treating a patient.

Other Team Members

- **Vocational counselor**: The vocational counselor on the treatment team is responsible for evaluating the capacity, goals, and needs of patients in the area of return to work, school, or other meaningful activity. A common aspect of this interaction is helping the patient understand the benefits of returning to the work force because participating in gainful employment is considered a primary goal of many ICPM programs, particularly those that emphasize a functional restoration approach. Vocational counselors may serve as case managers who contact employers, obtain and analyze job descriptions, and facilitate return to previous employment. They may also provide testing and counseling in order to prepare patients for vocational retraining. Perhaps even more than other team members, it is important for vocational counselors to understand issues such as primary and secondary gain as well as the role of psychological factors in perpetuating perceived disability.

- **Occupational therapist**: Areas that are considered primarily within the domain of occupational therapists include ergonomic training, upper extremity activities of daily living, work activities, leisure activities, and any other activities that are meaningful and purposeful to the individual patient. Some occupational therapists perform work-site analyses, visiting the work place to which the patient intends to return, observing the specific job-related tasks that he or she will need to perform, and then developing a work simulation component of the ICPM program. If a patient has a specific job to which he or she intends to return, a workplace analysis may be conducted by an occupational therapist and vocational counselor in order to assess the
physical and emotional safety of returning to that position.

• Aquatic therapist: When available, the use of supervised exercises in a heated therapeutic aquatic environment can be a helpful element of physical rehabilitation and one of those most enjoyed by the patients. It can be conducted by those in various disciplines but is most commonly a physical therapist or kinesiotherapist who is interested and has additional competency in the area. Water-based treatments are complementary to land-based exercises and have various therapeutic benefits that are especially helpful for those with chronic pain, such as buoyancy that reduces the effects of gravity and hydrostatic pressure that offers stability and support.

• Recreational therapist: Those programs fortunate enough to have the influence of a recreational therapist reap various patient benefits. Due to the social isolation that many with chronic pain experience, recreational therapy typically offers an opportunity to be around others and practice potentially rusty social skills. Recreational therapists also evaluate pleasurable activities in which patients wish to engage (either through initiation or rekindling) and determine how to help individuals move toward their goals. They often offer options such as crafts and art work as a means to stimulate creativity, improve focus, and distract from pain.

• Clinical pain pharmacist: Particularly with the emphasis on analgesics, the presence of a pain pharmacist can be very helpful in providing support to medical and other staff as well as to patients regarding medications. Within the context of ICPM programs, pain pharmacists typically advise on medication choices, provide educational classes, and meet with patients as needed to answer in-depth questions about pharmaceuticals, including addressing issues regarding polypharmacy, adverse events, and side effect profiles.

• Social worker: Social workers may play a variety of roles in ICPM programs. They can function in a case manager and coordinator role, tracking patient participation and addressing issues that arise. If participation in the program involves travel, social workers often play an important role in making sure that transportation is arranged and patients are able to access what is needed at the facility. They also
provide more traditional guidance on introducing various administrative forms and can teach classes on how to access opportunities in the community. Those who are licensed clinical social workers may have more direct contact to address clinical needs.

In addition to those specialties listed here, many ICPM programs include other professionals, including a dietician who reviews the important role of nutrition and weight in pain management, a chaplain who addresses spiritual needs, a yoga or tai chi instructor who provides guided direction on these active and beneficial treatments, as well as options such as an art therapist, music teacher, and other disciplines that encourage the development of activities that are enjoyable and assist with fostering positive self-esteem and sense of purpose.

The Process of Interdisciplinary Chronic Pain Management

Despite the long history and strong empirical support for ICPM, this form of treatment is often seen as a “last resort” by referral sources, many of whom have a limited understanding of the complexities of and best treatments for chronic pain. This is a reflection of a biomedically based health care system and society that tends to seek passive/receptive interventions for the management of pain rather than approaching it as a chronic condition that requires active self-care by the patient as a foundation for the potential success of other treatment options. ICPM programs are viewed as tertiary, which too often subsumes that all other treatments have “failed”; however, it is a treatment best correlated with complexity and pain-related functional impairment and should be considered as soon as possible when these conditions are met. If individuals had access to ICPM programs earlier in their pain journeys, it is likely that our system could be spared billions of dollars because the chronification and negative impacts for many would be minimized.

Referrals may come from a wide variety of sources, including other physicians and health care providers, attorneys, employers, and insurance carriers. Some ICPM programs are a part of a broader pain management system, in which case triage may be necessary. Due to economic realities,
insurance coverage is generally confirmed prior to proceeding. Once this is accomplished, medical records are requested and reviewed to ascertain the patient’s appropriateness for evaluation. In systems such as the VA, referrals for evaluation can be made more easily because third-party payer obstacles are removed and shared medical records facilitate screening evaluation processes.

The initial evaluation of a candidate for ICPM may occur in a variety of ways, but the goal is to determine if the individual is appropriate for the treatment, provide education on the treatment approach, and determine collaboratively a plan of care. Typically, providers from more than one discipline are involved in this process so that information regarding all relevant biopsychosocial factors can be assessed. For example, a medical professional gathers information regarding medication use and comorbidities as well as physical fitness and ability, whereas a mental health professional ascertains details regarding pain-related functional impacts and emotional and social factors and shares the program’s philosophy, expectations, and potential benefits from participation. Physical therapists or others may also be involved in this evaluation in order to obtain objective measurement of functional capacities. At times, the patient is deemed to be not currently ready for ICPM due to various factors including psychiatric or medical instability (e.g., active suicidal ideation and intention, unmanaged psychosis, cardiac issues). If the ICPM team believes that these factors can be addressed, delaying admission until the patient has received appropriate treatment may be in the best interest of the patient and the program. If the option for reconsideration is not viable, the program should provide treatment recommendations to the patient and the referral source.

ICPM programs tend to be intensive, often requiring patients to participate from 20 to 40 hours per week. Although patients may find the prospect of such a commitment daunting, they will not be asked to perform physical tasks that are beyond their functional capacities. Distinguishing between “hurt” and “harm” and assuring patients that the treatment team considers their physical and emotional safety to be of the greatest importance helps build therapeutic trust, thereby enhancing adherence. The specific “mix of services” that patients receive between and within
programs will vary. Typically, patients spend significant time engaging in physical activities that will increase their flexibility, strength, and functional capacities. Patients whose emotional status and behavioral responses to their pain are less unhelpful will likely require less time with the psychologist than will those patients who are struggling psychosocially. Similarly, patients demonstrating limited psychophysilogic reactivity to stress will require less intensive biofeedback training, and those whose vocational issues are more straightforward will require less concentrated vocational counseling services. The frequency with which a patient sees the physician and/or nurse practitioner or physicians’ assistant on an individual basis will vary depending on the specific program. Frequent individual physician appointments are generally discouraged because the goal of ICPM is typically reduction of medical services in lieu of enhanced independent self-management of pain.

The patient-centered nature of ICPM requires regular team conferences in which the entire treatment team meets to discuss patient progress, which includes any issues that are potentially limiting gains and therapeutic goals. This may happen with the patient, without the patient, or both. Regardless, feedback to patients should be immediate, consistent, and coherent. In situations in which patients’ adherence is considered good and they are making progress, team conference provides a forum in which they are able to receive much-needed positive reinforcement regarding their attitude and effort. Patients with chronic pain are often unjustifiably blamed for the failures of the primary and secondary care systems to help them recover, making appropriate positive reinforcement even more important. Conversely, in cases in which adherence and progress are considered by the team to be inadequate, the conference provides an opportunity for the treatment team to develop an approach for patient feedback and/or to present a united front in addressing the relevant issues and work with patients to remedy any problematic aspects of their programs. Because the literature confirms that individuals with personality disorders are prevalent in ICPM programs, it is not unusual to encounter attempts to “split” treatment team members. Because of this, it is particularly important for the program team to develop a coherent plan
together and enforce it consistently so that patients receive a unified message throughout their participation. Unfortunately, although ICPM programs work to facilitate success for all patients, some circumstances necessitate early discharge. Stanos\textsuperscript{40} has recently suggested that such premature discharge can potentially encourage enhanced compliance or efforts among other patients in the group.

Once a patient has completed an ICPM program, he or she can be neither forgotten nor abandoned. Although programs are typically close-ended, some form of follow-up to determine implementation of what has been learned in the program is important. Additionally, if the program is involved in outcomes research, follow-up provides a source for collection of more data. For the sake of cost-efficiency, selected measures of patients’ emotional and behavioral responses to their pain that are administered can be sent to them to determine longer term outcomes and identify any clinical needs. Positive outcomes data should serve as a powerful tool for demonstrating the program’s effectiveness to patients and providers which can assist with marketing. Potential referring physicians may be uninformed regarding the wide range of benefits of interdisciplinary treatment for their patients, and well-organized data may help them understand how a program can make their own lives easier as well as helping their more challenging patients. Additionally, although some health insurance programs may argue against the efficacy of ICPM, data that invalidates their arguments will ideally help convince them of the legitimacy of this treatment approach.

Interdisciplinary Chronic Pain Management in Veterans Healthcare Administration: Overview of a Model System

Although ICPM programs have greatly diminished in the United States in the last 20 years, there is one place where they have flourished: the VA health care system.\textsuperscript{41} The VA undertook specific efforts to highlight the need for improved pain care in 1998. At that time, leaders in the VA acknowledged that pain was an underrecognized and undertreated issue that impacted veterans across the continuum of care. This led to a series of
successful initiatives and collaborations that increased the measurement, tracking, treatment, and overall quality of services available to veterans with pain. One of the most important was a 2003 pain management policy, the first of its kind and an important step toward establishing pain as a high priority for the Veterans Healthcare Administration (VHA).\textsuperscript{42} In 2004, pain management was established as a separate organizational entity within VA Central Office under the direction of clinical psychologist, Robert D. Kerns. Among many identified areas of focus was an emphasis on multidisciplinary and interdisciplinary pain care, the least common models previously found in the community.

In 2009, a revised VHA pain directive was established which introduced a stepped care approach to pain management as the standard for the VA.\textsuperscript{43} It not only reasserted VHA’s commitment to an approach that is informed by a biopsychosocial model of pain and an interdisciplinary, multidimensional, and multimodal approach to pain management but also asserted that improved quality of life, rather than pain relief per se, is the accepted standard outcome measure of effectiveness. In addition to many other recommendations such as establishing facility multidisciplinary pain committees and specific research efforts, the stepped care model delineated the primary level Patient Aligned Care Team (PACT) and reinforced secondary level specialty pain care (e.g., pain medicine, behavioral health). The tertiary level was defined as interdisciplinary care for the most complex, treatment refractory, and at-risk patients. Along with the availability of advanced pain diagnostics, VHA made a commitment to developing at least one interdisciplinary pain rehabilitation program in each Veterans Integrated Service Network (VISN) by the end of September 2014. These programs were to be accredited by CARF, ensuring the highest level of quality for care.

At the time the directive was published,\textsuperscript{43} there were only two CARF-accredited programs in the VA system, located in Tampa, Florida, and San Juan, Puerto Rico, both in VISN 8; therefore, developing and implementing programs for the other 20 VISNs was an ambitious mandate. Five years were allotted to accomplish the goal, with no particular pathway defined for how each different region or facility would meet it. Furthermore, no resources were provided by VA Central Office, and the
details and timeline of implementation were left to the VISNs. The VA pain team training program was established under the leadership of clinical psychologist, Michael Clark at the James A. Haley Veterans’ Hospital in Tampa, Florida, site of the longest standing CARF-accredited pain rehabilitation program in the VA. Over the next 5 years, the program directly assisted facilities with training visits, providing models and advisement in their fulfillment of the directive as well as ongoing consultation as needed. Tampa trained over 30 VA teams in the philosophical and practical foundations of an interdisciplinary pain rehabilitation program, many of whom went on to implement their own versions at local facilities.

In 2017, the VA’s 20 programs represent almost a third of the 67 CARF-accredited pain programs that are available in the United States, even though veterans served by the VA represent only a fraction of the nation’s population. Although the overall presence of programs has steadily decreased in the United States, the VA has maintained an upward trend and taken steps to coordinate these centers across the country. The first author of this chapter (JLM), the VA’s liaison for the development and maintenance of CARF programs, formed a national CARF Pain Programs Leadership Committee in late 2015 which serves as a community of practice and forum for collaboration across CARF sites. Through regularly scheduled calls, members share questions and updates and consult with each other in order to maintain the CARF standards. As an example of collaboration across sites, a group of VA programs established mutually agreeable core outcome measures to foster a means for comparison of program outcomes. Although not required, this effort serves as a model for the level of coordination that may one day become standard across the system as a means for continual program improvement.

The current state of affairs begs the question, “Why is the VA committed to ICPM programs more than the private sector?” There are several explanations which have been reviewed by LaChappelle et al.42 First, the VHA emphasizes those treatment options such as ICPM, which have the greatest evidence base. This is supported in the mission statement of the VA as well as in the policies for interventions and pharmaceuticals. Undoubtedly, another factor is the cost–benefit analysis of lifelong patient
care that takes into account and often prioritizes long-term outcomes over short-term outcomes. Outside the VA, third-party payer health insurance plans will often fund and reimburse care that may be less expensive in the short term but may be more expensive in the long term, since changes in insurance coverage occur routinely. However, a system that treats patients for the span of their lives is more likely to value an initial higher financial cost of multidisciplinary treatment. This investment in the interdisciplinary approach achieves greater health and well-being in the long term rather than lower cost financial investment in the short term, with poorer health outcomes in the long term.44,45 Although a number of factors contribute to frequently switching health insurance carriers in the private sector, the behavior results in a disincentive for insurers’ coverage of ICPM programs. Despite the literature supporting their cost-efficiency, they are considered a formidable expense in the short term, and accordingly, insurance payers are more likely to cover inferior (and often more dangerous) but less expensive treatment options. Sadly, if insurance companies would recognize that the investment in ICPM care is well worth the cost, these programs would flourish outside of the VA system and all would benefit as demonstrated by the 2015 Mayo Clinic study.22

There are numerous lessons to be learned from the growth of ICPM programs in the VA. First, although many in the private sector perceive the VA system to be flushed with endless resources, the limitations of space and personnel are familiar barriers across the system. Because of this, programs have taken a variety of forms, tailored and built to fit the unique picture of each particular facility. For instance, a program that is 2 to 3 days per week may require 25% of a full-time physical therapist who also works in other settings. Others in less routinely incorporated specialties such as a chaplain, dietician, pharmacist, or addictions counselor may be able to provide a group once during the course of a program, something that adds greatly to the richness of program content while not taxing human resources. Although these creative strategies could theoretically be helpful in convincing insurers to reconsider coverage of ICPM programs, “carving out” essential aspects of them has been empirically established as resulting in far less favorable outcomes.46,47

In addition, VA’s model of setting an administrative mandate for one
CARF ICPM program per region was an ambitious goal, yet it has served several purposes. First, it represented formal recognition by leadership of the importance of interdisciplinary care. Second, although the number was insufficient to serve the entire veteran population, the emergence of ICPM programs throughout the country introduced the treatment approach to providers and patients who were previously unfamiliar. This has served to reinforce the need for a biopsychosocial model and increase access to additional pain care options that are not strictly medical or pharmacologic. Because insurance companies appear unlikely to return to coverage of ICPM programs, a legislative mandate supporting ICPM programs is necessary to effect a restoration of reimbursement for this effective mode of chronic pain treatment. As in the VA, it took a national pain directive recognizing a public health need to spur the development of this valued treatment option and a similar call from on high is needed in the private sector.

Future Considerations for Interdisciplinary Chronic Pain Management

Chronic pain is and has been underrecognized and undertreated as a health care need. Although the biopsychosocial model is recognized as the gold standard for pain care, in reality, the biomedical model continues to reign supreme. This means that despite the overall clinical efficacy and cost-effectiveness of ICPM programs, the number in the United States has decreased precipitously since 1999 (A. Whitney, personal communication, July 16, 2007), thereby severely limiting the availability of a treatment approach that has been the most rigorously validated. The demise of these programs is a disturbing phenomenon particularly given the cost of chronic pain and the drastic increase in opioid use disorder and opioid-related overdose deaths. As Chapman states, “Concurrent with the decline of intensive programs is the rise of procedural interventions and medication, which receives a great deal of support from medical technology and pharmaceutical companies.”48 These unfortunate realities only underscore the need for an approach to chronic pain that matches its complexities without defaulting to a unimodal medical attempt to cure something which
requires long-term management.

One potentially positive result of America’s prescription opioid crisis has been a shift in focus to treatments that are nonpharmacologic. This has significantly increased the interest of some in options such as pain psychology, complementary integrative health (e.g., acupuncture, yoga), and ICPM programs which provide comprehensive care with a decreased focus on medical modalities and an increased emphasis on self-management strategies. It is unfortunate that it took the drastic increase in opioid prescribing and related negative events to propel health care professionals, systems, and even lawmakers toward considering treatment options that capture the biopsychosocial approach, but the momentum is welcome. Additional funding for treatment options as well as research that considers physiologic as well as other highly relevant factors in the chronic pain experience may lead to improvement in the availability of ICPM options. The growth of interdisciplinary pain rehabilitation programs within the VA demonstrates a cultural transformation within the largest single health care system in the United States, one that should be used as a model for how to walk the walk of whole person pain care across the country.

Conclusion

Seventy years after Bonica introduced the concept of interdisciplinary pain management, those who work in the field sadly continue to encounter similar challenges to those that he faced. The lack of acceptance by the medical community of the interdisciplinary approach that left Bonica ready “to give up” still challenges those that rightly acknowledge the necessity of an interdisciplinary treatment model for optimal patient outcomes. Despite substantial and unequivocal empirical support for its clinical utility and cost-efficiency, in every setting but the VA, the number of programs in the United States has dwindled. Patients have been forced to resort to less effective, more expensive, and often more dangerous treatment options which tend to focus on body parts as opposed to the person in need.

Although third-party payers and some in the field suggest that the ICPM
model should be pared down to deintensify the commitment by providers and patients, the evidence suggests the opposite: Providers, payers, and patients should instead embrace the intervention which best matches the treatment needs of those with complex chronic pain. The evidence indicates that the model is not broken—the system is. As one of the most pervasive and costliest health care issues, chronic pain and the ICPM approach deserves the attention and support of legislators, insurance companies, and the health care industry at large. Those who have the privilege of working in a true interdisciplinary framework must be the leaders in this mission: to advocate, to educate, to model, and to celebrate the patients with whom they have the ability to effect change. The noble practitioners of the interdisciplinary approach need to become ICPM “champions” to defend the life of that which science and clinical experience tells us is the closest thing we have to a “cure” for our patients.

Back pain is one of the most common chief complaints in the emergency room and primary care clinic. It is composed of a wide range of symptoms with varying characteristics. Patients may present with or without associated neurologic signs or symptoms. Adding to this complexity is the multiple potential pain generators that exist in the spine, which include disks, facets, bones, muscles, ligaments, and nerves. For these reasons, back pain presents a great challenge to health care providers, one where it is difficult to correctly identify an underlying cause and develop an efficacious treatment.

Anatomically, the human spine is a structure of tremendous intricacy. Consider, for example, the primary roles of the spine—support and flexibility. On one hand, it must be strong enough to maintain an upright posture. On the other, its elastic properties should permit broad motion through flexion, extension, lateral bending, and rotation. The spinal column also has a protective function to surround and cushion the delicate structures of the spinal cord and nerve roots. It is capable of accomplishing these tasks through a conglomeration of bones, joints, ligaments, disks, and neural elements. Spinal anatomy is further complicated by the number of mobile segments, the proximity of the spinal cord and nerve roots, the intricate motions of multiple small joints, and the natural changes that occur with aging.

Knowledge of the intricate biochemistry of the intervertebral disk and the role of inflammatory mediators in back pain continues to expand. There is also a significant psychological component that impacts the behaviors of patients with back pain and their recovery from injury. Considering the complexity of the spine, it is understandable that definitively diagnosing the exact source(s) of symptoms is often difficult and sometimes impossible.\(^1\) This task is made even more difficult by the
strong impact of personality in reporting and dealing with pain, particularly work-related low back pain.\textsuperscript{2}

The spine is continually beset by physical stresses, and once an individual reaches adulthood, it is in a constant state of degeneration. The very complexity of the human spine creates the conditions that make it so difficult to resolve back pain. With so many complex and interacting structures, pain can arise from individual structures, multiple structures, or their dynamic interaction. As noted by Jerome Groopman\textsuperscript{3} in his best-selling text, How Doctors Think, “given all of these structures, the source of the chronic . . . back pain is often a mystery. Doctors can be hard-pressed to identify why a patient is uncomfortable.”

Despite its complexity, back pain is nearly universal in the general population with a lifetime prevalence of 65\% to 80\% in the United States and an annual economic impact that ranges from $84.1 to $624.8 billion.\textsuperscript{4} Using data from the 2002 National Health Interview Survey, Strine and Hootman\textsuperscript{5} reported that the 3-month prevalence of back and/or neck pain among adults in the United States was 31\%. Understandably, these subjects generally had more comorbid conditions and greater psychological distress than did subjects without back or neck pain. Supportively, some studies have indicated that psychosocial factors have an even more influential contribution than mechanical factors toward back pain.\textsuperscript{6} In addition, Fanuele et al.\textsuperscript{7} using the Short Form Health Survey (SF-36) general health status questionnaire reported back pain patients were significantly impaired, even when compared to a variety of other health conditions. In order to effectively treat such patients, one must understand the severity of the problems and appreciate that back pain may often be accompanied by a variety of comorbidities.

The patient with chronic back pain is often passed from practitioner to practitioner, at times of widely varying expertise, training, and experience, and each subjecting the patient to his or her own preferred techniques for palliation. As the patient drifts further into disability, pain, and medication use, desperation and the cost of single-modality treatments increase in parallel, whereas the probabilities of overcoming the pain and of improving function diminish. It is, according to Groopman,\textsuperscript{3} “as though each approach to diagnosis and treatment is essentially a ‘franchise’ and
that too many franchises are battling for control.” Such a state of affairs leads to treatments that are increasingly expensive, unfocused, unsubstantiated, and ineffective.

Thus is the complexity of chronic back pain and the costly, untenable nature of many treatments. All point to the need for a different approach to manage back pain where improvement in value depends on improved performances and accountability among individuals who have a shared goal that unites the interests and activities of all stakeholders. The desired approach is no different now from that developed for general chronic pain by Dr. Bonica, and aptly described by Loeser et al. in the third edition of Bonica’s Management of Pain. They state that Dr. Bonica

... brought clinical psychologists, pharmacists and other non-physician providers to the conference table with anesthesiologists, neurologists, physiatrists, neurosurgeons, orthopedic surgeons, psychiatrists and others. This blend of perspectives kept each specialist from exercising specialty-specific tunnel vision, and in conferences a group understanding often emerged that greatly exceeded the understanding that the record would yield after a series of serial consultations.

This is an apt description of the multidisciplinary approach to care. Of course, a multidisciplinary approach alone does not guarantee either efficiency or effectiveness. In order to provide maximally effective and efficient treatment, and to limit treatment costs, a spine treatment facility must include practitioners with the highest levels of training and experience, who follow treatment guidelines that are scientifically validated yet flexible enough to address the idiosyncrasies of individual patient problems. The care needs to be carefully coordinated to avoid duplication, unnecessary expense, and use of treatments with limited possibility of success. A number of specific principles should guide the multidisciplinary spine facility:

1. Specific algorithms for evaluation and treatment
2. Ongoing multidisciplinary case management and case discussion
3. Active process of continuous quality improvement including outcome measurement, assessment of patient satisfaction, and use of results to improve treatment algorithms
4. Professional education of treatment team members
5. Participation in active research programs

In this chapter, we discuss the key elements needed to establish and maintain an effective multidisciplinary spine facility.

**Treatment Components**

The three major components that comprise the clinical aspects of a multidisciplinary spine center are (1) a group of dedicated, highly trained physicians and allied health providers with expertise in spine care, (2) a set of treatment algorithms guiding assessment and intervention, and (3) active and aggressive case management, especially when patients fall outside of established treatment algorithms. One of the keys of a successful center is building a multidisciplinary team that understands and respects the roles and skills of individual team members. In caring for patients with acute or chronic back pain, we emphasize the importance of interprofessional communication and teamwork among all care providers (Fig. 107.1).

![Illustrative diagram demonstrating the intricate relationships between care providers and the patient at a comprehensive spine center. Close communication among the various providers and the patient is required to provide the highest level of clinical care.](image-url)
CONSERVATIVE CARE GATEKEEPERS

Of the many individuals who experience back pain, only about 10% ever undergo spine surgery. It is therefore logical that the initial evaluation of patients presenting to a comprehensive spine center should be conducted by a “conservative care” physician—one who is specially trained in the assessment and treatment of spinal disorders. These physicians should be competent in triaging patients and placing them into appropriate assessment and treatment algorithms. Complicated cases and those requiring urgent or emergent intervention can be promptly identified and referred for appropriate diagnostic workup and intervention. However, the majority of cases will be best handled using standard treatment algorithms in which resolution of the back pain is expected with minimal intervention. Such physicians may include primary care doctors or specialists in anesthesiology, physical medicine and rehabilitation (PM&R), or occupational medicine. All of these providers must be able to recognize the “red flags” of back pain, which warrant further lab or imaging studies and timely intervention.

PAIN MANAGEMENT

The most ubiquitous and bothersome indication of spine injury is back pain. Unremitting pain, often fluctuating randomly, can decimate both emotional stability and physical capability. Physicians now have a diverse armamentarium of oral, topical, and injectable medications that may provide immediate, and at times prolonged, relief. The mainstay nonprescription medications for the treatment of back pain are acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs). Prescription oral medications include muscle relaxants, opioids, corticosteroids, and certain antidepressants and antiseizure medications. The opioid analgesics, even in recently developed time-release preparations, carry with them both the potential for physical dependence and addiction in up to 40% of chronic pain patients which have been reported to cost upward of $53 billion to treat. Therefore, it is imperative that only one provider in a multidisciplinary team is prescribing and
managing the medications. A pain treatment agreement should be implemented early on. Targeted injections are of some value in specific conditions (see Chapters 99 and 100 for a detailed discussion), but their use requires sophisticated equipment and advanced training in order to be used safely and effectively. Physicians with subspecialty training in pain medicine, often specially trained anesthesiologists or PM&R specialists, can effectively use injection therapy, but these treatments must be used in coordination with the other evaluation and treatment efforts, including physical therapy (PT).

PSYCHOLOGY
Patients suffering with spinal injuries and back pain experience dramatic emotional and social changes. Up to 80% of patients with persistent back pain are diagnosable with clinical depression,\textsuperscript{12} and many will express anger as the most common emotion they experience.\textsuperscript{13} Fear and avoidance of pain often drive patients into unnecessary functional decline. Marriages and relationships can shatter, and spine injuries often leave economic devastation in their wake. For these reasons, specifically trained psychologists often play a pivotal role within the spine center. Numerous studies have shown that psychosocial factors can complicate recovery from spine surgery (see Chapter 76 and Block et al.\textsuperscript{14} for a review). Thus, one of the major functions played by psychologists is to perform presurgical psychological screening, providing information to surgeons about the level of psychosocial risk found in patients who are being considered for spine surgery. Such a process allows the surgeon to individualize treatment protocols. In patients who have a high level of identified psychosocial risk, alternatives to spine surgery can be considered. Psychologists often see nonsurgical patients as well, helping them cope with the emotional sequelae of spinal injury and to help them learn new means of coping with pain and its limitations. Social workers can also play a pivotal role in counseling these patients while establishing support network to help them recover.

PHYSICAL THERAPY
Many patients with back pain require little intervention from a physician.
Their problems are related to body mechanics and deconditioning. For this reason, a conservative approach to the treatment of back pain incorporates PT as a first-line treatment. Frequently, therapists provide a combination of strengthening, stretching, palliative modalities (such as heat or electrical stimulation), and hands-on muscle activation that offer good pain relief. Fritz et al. found that patients with acute spine pain who have high adherence rates to active PT-based exercise programs achieve excellent reductions in disability and pain. Symptomatic management with structured PT may delay or avoid more invasive interventions altogether.

Another benefit of PT is that patients often continue the activities they learned during therapy well beyond their treatment course. Many rehabilitation centers provide patients a home exercise program as their formal treatment period ends. Additionally, getting into the habit of exercise during PT may encourage patients to continue a more active lifestyle, improving their general health as well as potentially decreasing their back pain.

**OCCUPATIONAL THERAPY**

One of the most challenging and costly aspects of back pain is effectively managing patients who suffer workplace-related back pain. Patients with pain that is inadequately treated may function poorly at work, which can lead to termination of current employment, unemployment, and disability. Occupational therapists play a central role in conducting structured functional evaluations to determine the patient’s current level of performance compared to their job demands. Their primary goal is to help restore patients to their baseline functional status so they can lead a productive lifestyle at home and at work. Of note, in many settings, physical therapists take on part of the role of occupational therapists.

It is important to remember that the response to physical and occupational therapy may vary among patients, as is the duration of therapy required before a response is observed. Therefore, therapy is generally recommended for at least 6 weeks. With regard to conservative management of back pain, if standard treatment modalities are ineffective, patients may be encouraged to explore alternative options such as chiropractic and acupuncture.
SPINE SURGERY

Spine surgery is the topic of much discussion as many surgeons are devoted to developing novel implant designs and operative techniques. As previously noted, only about 10% of patients seeking care for back pain go on to have surgery. The most important, and arguably the most difficult, aspect of spine surgery is choosing the appropriate indications for surgery. Although the outcomes for surgery for radicular leg pain and neurogenic claudication are more predictable and favorable, surgery for back pain without any clear underlying etiology is less so. When patients have exhausted nonoperative treatment options for back pain, the default unfortunately is to resort to surgery. However, operative intervention is generally not recommended for pure mechanical back pain, as surgery can lead to more pain and disability. This dilemma highlights the importance of having an interdisciplinary spine care team that upholds high standards and expectations while holding each member accountable for high-quality patient care. Even when the indications are appropriate to proceed with surgery, the risks involved, as well as the costs, mandate that surgery is used sparingly and only when nonoperative options have failed to provide adequate symptomatic relief.

A spine center of excellence certainly needs a group of well-trained spine surgeons. Although not frequently addressed in the literature, there has been some investigation into the relationship of surgeon experience and complications associated with spine surgery. Wiese et al.\textsuperscript{16} found that the complication rate following lumbar microdiscectomy was significantly less among surgeons with a greater level of experience (2.2\% vs. 10.7\%).

In results from a multicenter total disk replacement study, it was reported that among the high-enrolling surgeons and/or centers, the length of hospital stay, operating time, and complication rates were significantly less than among low-enrolling sites.\textsuperscript{17} Results of the studies suggest that established spine centers that make use of a team of specialists with varying expertise have an advantage over individual physicians with respect to complication rates.

Although surgery is sometimes viewed as the “end of the road” in treatment, this should not be the case. Although surgery is a dramatic event, it is only one step in a continuum of care. Treatment does not end
with surgery. Most patients who undergo spinal surgery will not have been engaging in typical activities due to pain. Although the surgery may address the structural component of their problem, it cannot address the deconditioning that has occurred. In a spine clinic, there are postoperative rehabilitation protocols for the various types of surgery performed. In this day of escalating surgical options and approaches, physical therapists must gain a clear understanding of each operative intervention and lend their expertise to developing safe and effective rehabilitation protocols that will maximize functional recovery after surgery. For example, a therapist not working closely with spine surgeons may have a difficult time devising the most appropriate and safe program for a patient who has undergone surgery using a nontraditional approach such as the trans-sacral approach to the L5–S1 disk space or extreme lateral interbody fusion for other lumbar disks. Some new procedures require avoidance of specific motions early after surgery with guided progression back to full activity. Without an understanding of the goals and functions of new implants, it is unlikely that a physical therapist working in isolation will be able to design an optimally safe and effective rehabilitation regimen.

Surgeons at a specialty spine center should be slow to adapt new technologies and techniques, and the group’s practice should be standardized and evidence-based. One of the advantages of a spine specialty center is the enhanced opportunity for surgeons to participate in clinical trials evaluating new technologies. These centers are often preferred sites due to the expertise of the surgeons and the ability to have a large enough patient population to meet enrollment needs. The benefit to the surgeons is that they can offer patients interventions that would otherwise be unavailable outside of an investigational setting for many years to come. Patients have the benefit of participating in clinical trials if they meet the selection criteria and elect to participate. The multidisciplinary nature of an established spine center offers the optimal atmosphere for testing new and emerging technologies for treating spinal disorders.

**CHRONIC PAIN MANAGEMENT PROGRAM**
The multifaceted nature of spine injuries points to the importance of
approaching spine treatment in a multidisciplinary fashion. After treatment, patients must often resume a life where the very assumptions and boundaries have been greatly distorted, all too often by ongoing pain or marked functional limitations that were not present before illness or injury. With or without surgery for spinal disorders, pain and concomitant limitations often linger and, without proper treatment and planning, these can magnify. The chronic pain management program (CPMP) thus becomes a truly integral component of treatment in most spine centers. Such programs, involving many disciplines (most often pain medicine, PM&R, PT and occupational therapy, and psychology), rely on therapeutic group milieu to assist patients in learning (and helping each other to learn) new ways to deal with pain, minimize its impact on their lives, and overcome psychosocial barriers. Research on the CPMP approach indicates that patients achieve an average pain reduction of approximately 50%, about 75% are able to get off narcotic medications, and the return to work rate from such programs is approximately 67%. Of course, CPMPs vary widely in terms of their composition and effectiveness. The spine center should, at a minimum, be certified by and adhere to the standards set by the Commission on Accreditation of Rehabilitation Facilities (CARF) or a similar international organization.

**POTENTIAL BENEFITS OF A SPINE SPECIALTY CLINIC**

Many components of treating chronic pain of other origins and back pain are similar. What, then, is the advantage of having a spine specialty clinic? Focusing solely on back pain has several potential advantages.

Although in the past, there may have been more separation between nonsurgical care providers and surgeons, the two can be blended into a comprehensive system. As reported by Rasmussen et al., the initiation of multidisciplinary “nonsurgical” spine clinics significantly reduced the number of lumbar discectomy surgeries performed. One of the factors that was felt most likely to account for this decline was an improved diagnostic evaluation process.

Considering the wide range of potential pain origins as well as the potential and varying roles of psychosocial factors related to back pain, it
is not surprising that patients cover a very broad spectrum of problems and needs. This gives rise to the need for true multidisciplinary care. It is imperative that the care providers have, and maintain, a strong and specific knowledge base regarding spinal disorders. Such skills can only be developed and continually honed by ongoing interaction with patients, continuing professional education, and the cross-training provided by the frequent interaction of professionals from various disciplines caring for similar patients. This is true not only for the physicians involved in the clinic but also for the physical therapists and other members of the treatment team. By building a strong knowledge base in one area, providers can equip patients with a greater level of education in discussing their spinal problems and working together toward effective solutions.

Specialized spine centers require a large patient population to support all the facets required for the multidisciplinary approach to care. Although some painful conditions are relatively rare, back pain is a very common problem. Considering that 80% of people have back pain at some point during their lives and that about 10% go on to develop chronic pain, there are likely to be large enough patient populations in most communities to make a spine center a viable undertaking.

The term center of excellence is a determination used in several specialties to provide quality assurance for new procedures or technologies or for those surgeries not widely performed, such as video-assisted thoracic surgery.\textsuperscript{21} A number of centers of excellence in spine care have emerged in recent years, but there is no uniform set of criteria used to define a spine center of excellence. Such centers have a multidisciplinary treatment philosophy and are committed to providing the highest quality of care. It is these centers of excellence that should be the lead sites in developing treatment guidelines, participating in registries, performing research, and providing education. Implementation of a structured quality assurance program is a critical element of developing a spine center of excellence. Designing and implementing guidelines, assessing outcomes, and implementing changes for improvement may be more manageable in a spine clinic. This type of program is becoming increasingly needed in this age of increasing demands for ongoing quality assessment and reimbursement initiatives such as pay for performance.
Within the spine clinic, subspecialization will naturally take place. Based on the interests and skills of the professionals involved with patient care, various physicians will gravitate toward treatment of specific spinal disorders. For example, one may take the majority of patients with unusually challenging cervical spine problems, another may be a leader in one or more areas of spine arthroplasty, and there should be at least one surgeon adept at diagnosing the multiply operated failed back patient who eventually arrives at a spine specialty facility. Some physicians may elect to perform injections, whereas others do not. There is a need for advanced interventions such as spinal cord stimulation for pain management. This type of subspecialization within a spine clinic further provides the care provider the opportunity to hone highly specialized skills as well as allowing them to pursue the interventions they are most interested in providing.

The presence of professionals from multiple disciplines in a spine clinic will also increase awareness about alternate pain mechanisms and approaches to treatment. For example, the addition of chiropractic care providers will increase the awareness of all the care providers of problems arising from the sacroiliac joint and the role of manipulative therapy in treating this group of patients with low back pain.

**COORDINATION OF CARE**

Working one’s way through most health care systems can be daunting for patients. A comprehensive spine clinic can reduce confusion and anxiety. Patients can receive a wide variety of services as needed within a single facility. Patients receiving treatment in a single center will become familiar with employees, and they will find less redundant paperwork required for insurance and providing basic history and health data. The best spine centers provide close coordination of care from one provider to another through close communication.

**RESEARCH AND EDUCATION**

If practicing in a university setting, education and research are built into the framework and environment of patient care. However, the success of programs still depends strongly on the commitment made by the
individuals involved. Although this is also true in private practice, the challenges are greater. There is no institutional framework or incentive built into the practice that promotes involvement in either research or education. To create a research environment outside the university setting requires a commitment of time and financial resources. However, a practice cannot hope to become a spine care center of excellence without incorporating research and education. The implementation of a research program is becoming easier with the growing use of electronic medical records and registry systems in spine care facilities. Establishing an infrastructure for data collection complements the current demands for evidence-based medicine and cost-effectiveness information for back pain interventions. Considering the societal costs associated with back pain, these demands may be even greater for spine care specialists than for other disciplines. Although in the past, care providers may have been able to be successful without engaging in organized data collection, this is likely to change. Research also provides a venue to gain recognition in the peer group. This is more easily accomplished in a specialty clinic than in one spread across multiple specialties, unless focused efforts can be made in multiple areas.

The increasing use of electronic medical records and national study registries in spine has greatly facilitated tracking treatment outcomes. Although these mechanisms are far superior to traditional paper data collection, they still require time to harvest the data, address unanticipated scenarios, download, analyze, and prepare reports of the data and write abstracts and manuscripts. One of the greatest advantages of the registries is that some are programmed to contact patients by e-mail up to 24 months after treatment and have patients complete self-assessment forms online without returning to the clinic. Although radiographic follow-up cannot be achieved, the patient’s clinical condition can be evaluated.

Another opportunity to become active in spine research is through participation in clinical trials. To do so is a great responsibility for the investigator to ensure that the trials are being conducted in accordance to federal regulations and study protocols. Staff should be hired with experience in conducting clinical trials, regulatory requirements, and experience interacting with institutional review boards or human
experimentation ethics committees. Many such trials are financially self-sustaining, as industry sponsors will provide the funding to cover the cost of conducting the trial. Participation in such studies provides the framework for rigorous data collection.

Research is a vital part of quality patient care. Although all care providers want to take the best care of their patients, without measuring and being willing to critically appraise their own outcomes, it is impossible for the individual practitioner to assess and improve the quality of care he or she is delivering. Through the collection of data and ongoing assessment of results, problems, such as spikes in particular complication rates, can be identified and addressed. This is particularly important in a multiple-physician group to assess the complications and clinical outcomes of all the care providers in the practice and to ensure that problems are addressed as soon as they are identified. The emergence of Patient-Reported Outcome Measurement Instrument System (PROMIS) and its associated computer-adaptive test (CAT), which strongly correlates with other “gold standard” spinal outcomes measurement instruments but has a significantly lower completion time, shows immense promise toward making this process more seamless.22

Accepting the role of serving as faculty for a residency program or establishing a fellowship program can also enhance the intellectual environment of a spine clinic. Such programs often lead to creating lecture series such as grand rounds and journal clubs, which are relatively inexpensive. Creating forums for discussion among all care providers in the group can strengthen the bonds of the practice, allow more insight into what the other team members’ discipline offer to overall care, and enhance care by getting the right patient to the right provider more quickly.

Spine specialty centers have the potential to step to the forefront in shaping the future of spine care on a large-scale basis. Being specialized and focused in one area makes it easier to participate in registry networks and other quality improvement initiatives.

Conclusion

The spine is a complex structure that often presents diagnostic dilemmas
and treatment challenges to health care providers. The complexity is compounded by the frequent and profound psychosocial impact of chronic spinal disorders. A spine center of excellence must be designed to address the complexity of these challenges. One of the primary needs is an organized, deliberately planned approach to the evaluation and treatment of the broad spectrum of back pain patients. Members of the multidisciplinary team must be trained and focused on quality spine care. The use of electronic medical records greatly enhances the ability to track patients and events related to their care. The team of providers must understand the role of the other team members and respect what each has to offer in providing quality care to patients. There must be strong leadership to keep the team focused, efficient, and effective.

Part of developing a center of excellence is incorporating research and education. Research efforts can provide patients and practitioners with the opportunity to participate in clinical trials which can enhance the reputation of the center in the community while at the same time providing a means to assess outcomes of various treatments provided in the clinic. Only through incorporating research can providers have access to the latest technology and be involved in continually improving the delivery of patient care. Everyone benefits from education, which can take on many forms including lectures, journal clubs, conferences, fellowship programs, and research.

Introduction

PREVALENCE OF PAIN IN THE UNITED STATES
Pain is the most common reason cited for patients seeking medical care, and pain accounts for up to 80% of total visits to physicians’ offices.\(^1,2\) Although it is difficult to determine the prevalence of pain precisely, recent surveys suggest that 75 to 105 million Americans experience pain daily or intermittently.\(^3-5\) Given this widespread prevalence, the Institute of Medicine (now the National Academy of Medicine)\(^6\) and the U.S. Department of Health and Human Services,\(^7\) among other important stakeholder groups, have called primary care the foundation of pain treatment in the United States, a foundation that should be adequately trained to meet the challenge of delivering high-quality pain care.

ECONOMIC IMPLICATIONS OF CHRONIC PAIN
The National Academy of Medicine estimated the cost of pain to be approximately $565 billion dollars, making it one of the costliest conditions in the United States. Although the precise figure has been debated, there is little argument that the costs associated with pain treatment and the economic impact of missed days of work and unemployment and other societal costs are high and increasing.

Care management plans and disease management programs are abundant for other chronic conditions, such as asthma, hypertension, hyperlipidemia, and diabetes mellitus. Treatment strategies include case management, treatment algorithms, provider education, and patient support groups. In contrast, very little emphasis has been placed on studying and developing such initiatives for chronic pain conditions. Given the large allocation of United States health care dollars for treating patients with
these conditions, it is time for the provider, payer, and policymaker communities to take notice; emerging models discussed at the end of this chapter may signal the beginning of a promising trend.

**CHRONIC PAIN MANAGEMENT: THE STATUS QUO**

With the onset of pain, most patients attempt self-care with over-the-counter products and/or self-help techniques (e.g., distracting activities, rest). When these methods fail to provide adequate relief, the patient generally seeks help from a medical professional. In many cases and particularly in health care systems with limited access to specialty care, the gatekeeping primary care provider is the first medical contact. The primary care provider recommends treatment and refers the patient for appropriate specialty care, such as a physical medicine assessment for low back pain.

When pain becomes chronic and specialty care is ineffective in improving the underlying condition, care management becomes more difficult. In a recent survey, only 34% of internists reported that they felt comfortable with their abilities to manage patients with chronic pain.² In a related article, Ballantyne and Mao⁸ wrote that the most difficult issue now facing physicians is “whether and how to prescribe opioid therapy for chronic pain that is not associated with terminal disease, including pain experienced by the increasing number of patients with cancer in remission.” In part, physicians are hesitant to prescribe opioids because they lack both the understanding of how to comprehensively assess pain and its common comorbidities and the knowledge of available pain therapies.

The varied presentations and manifestations of chronic pain may at times confound primary care providers. Physical exam and radiographic abnormalities are not predictive of pain severity or dysfunction.⁹ Many patients experience pain that may be constant and occurs for several years, and yet their life functioning is not changed in major ways. Conversely, there are other patients with similar structural abnormalities who suffer substantially more and cannot maintain their usual levels of activity.¹⁰ Patients whose lives are significantly disrupted by pain engage in behaviors that are maladaptive, anticipate more distress, amplify sensations associated with pain, spend more time resting, and complain of
less ability to control pain. It may be reassuring to providers to recognize that this same degree of variability is seen in virtually all chronic conditions as a manifestation of the complex interplay of biologic, psychological, and social factors.

At the same time, surveys evaluating the adequacy of pain treatment demonstrate that the current system is dysfunctional. Patients report that they are not asked about pain, that they are afraid to report pain to their primary care providers, and that they are often not offered treatment. In one survey, 22% of patients with pain reported being uncomfortable discussing pain with their personal physicians, 13% said they were denied pain medication or referrals to pain specialists, and 70% reported experiencing continued pain despite treatment. Much of these system problems can be attributed to the treatment of pain at the primary care level.

SEARCHING FOR SOLUTIONS
There have been tremendous advances in the knowledge of pain pathophysiology, the understanding of treatments for pain, and recognition of the value of an interdisciplinary approach to pain management. On the scientific front, there has been an explosion in pain research, and new pharmaceutical agents have become available for treating different types of pain. Complementary and integrative health therapies for pain management have gained recognition and an increasingly robust evidence base. Novel interventional techniques and surgeries have been introduced. Professional pain societies have sprung up, and training is now available to provide physicians and other health care professionals with expertise in pain management. Despite this unprecedented progress, pain care remains inadequate, and undertreatment of pain is still considered pandemic. The reasons for these continuing inadequacies are varied, but it is clear that new solutions must focus on primary care.

A New Approach to Chronic Pain Management
There are many different types of pain that it is difficult for a nonexpert provider to become familiar with and comfortable treating all pain
conditions. Current categories for classifying pain include nociceptive versus neuropathic, acute versus persistent, cancer versus noncancer, and area of the body (headache, abdominal pain, chest pain). These categories are simplistic and helpful only in a general way.

We are accustomed to accepted, well-defined, objective measurements to assess the quality of care. For many other chronic conditions, there are standardized outcome measures. In patients with diabetes, we can measure hemoglobin A1C levels. In patients with asthma, peak flow and the use of inhaled β agonists guide care. Treatment outcomes for pain are often subjective, confusing, and controversial. If a patient’s pain severity is better but function is not improved, is this outcome adequate? If the patient is satisfied with treatment but pain intensity levels remain high (e.g., an 8 on the 0 to 10 pain numerical rating scale), is this treatment sufficient? If the patient returns to work but is on high doses of opioids, is this acceptable? All of these questions frequently arise in the primary care and complicate treatment.

**WHO TREATS CHRONIC ILLNESS?**

When pain becomes chronic, a behavioral syndrome and comorbidities may emerge including depression, anxiety, helplessness, insomnia, deconditioning, and increased reliance on the health care system, what has been called “high-impact” chronic pain. At this point, chronic pain becomes a disease process that needs chronic disease management.\(^{15}\) Chronic back pain is not a diagnosis but rather a description of duration and location. In many cases, it is not possible to be more precise in the diagnosis of, for example, low back pain because even experts disagree on the underlying etiology.\(^{16}\) Neuroscience increasingly points to dysregulated neuroplasticity and central sensitization as common pathways to chronic pain,\(^{17}\) further underscoring the futility of “imaging” chronic pain in most cases. Providers would do well to learn to message to patients that a lack of imaging findings is important for ruling out sinister causes of pain (e.g., cancer) but does not mean the pain is not real.

Failure to be more precise in the diagnosis should not delay treatment or impede medical management. Treatment in primary care often involves uncertainty, as most of the conditions encountered cannot be diagnosed.
precisely: Viral illness, rash, or headaches are common, and the etiology unexplained. Chronic pain falls into the group of conditions that often defies definitive diagnosis and is suited to the primary care practice. A patient’s suffering can be ameliorated by nonpharmacologic interventions including patient education and self-management skills that may be combined with analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs).

All primary care physicians must treat patients with a variety of chronic diseases. In fact, most chronic illness is principally managed at the primary care level. Improvements in the medical management of asthma, hypertension, and diabetes have arisen from interventions implemented in primary care. Despite the lack of specialty training and through the use of practice guidelines, following treatment recommendations, conducting chart reviews, discussing shared experience, and providing expert assistance, primary care delivers excellent medical care. Management of persistent pain lends itself to the same paradigm.

WHY PRIMARY CARE IS INVOLVED?
Primary care is based on the elements of trust, therapeutic alliance, advocacy, continuity, care coordination, preventive care, and careful attention to quality of life/lifestyle issues. Motivating patients to strive for better health through exercise, diet, stress management, medication adherence, and disease monitoring is a common role played by the primary care provider—a role that requires the provider to adopt and maintain a nonjudgmental attitude.

Primary care is uniquely positioned to provide care for patients with chronic pain. Of all specialties, primary care providers have the largest geographic distribution. Rather than clustering around medical centers in the largest cities, they are broadly distributed over diverse communities—from urban clinics to suburban medical centers to private practices in small towns and rural areas. Furthermore, primary care providers are trained in patient-centered communication, biopsychosocial assessment, and multimodal treatment planning, all core features of a high-quality approach to chronic pain.

By its very nature, primary care entails continuity by developing a
longitudinal experience with patients. Each office visit enables the provider to achieve greater understanding of how individual patients are dealing with their persistent pain. Primary care providers are experienced in providing comfort and disease management for chronic conditions. When clinicians are challenged to broaden their definition of pain as a symptom and begin to view it as a chronic illness, primary care is well equipped to deal with chronic pain.

When a patient’s pain becomes persistent and specialty care is either unavailable or ineffective as a treatment option, the providers can continue to play a key role by coordinating care, intervening when symptoms change, and constantly encouraging patients to make lifestyle choices as they do in all other chronic diseases: weight loss, sleep hygiene, anxiety/depression/mood management, physical activity, education, and judicious use of medications.

From a cost and utilization perspective, primary care is the most appropriate setting for chronic pain management. Most types of health insurance, as well as Medicare and Medicaid, cover primary care visits yet may not cover long-term psychosocial treatment or interventional procedures. A classic 1995 study of low back pain examined 1,555 patients cared for by chiropractors, orthopedic surgeons, or primary care providers. Cost, work status, and time to restoration of baseline status were monitored. All groups achieved similar outcomes yet primary care was the least costly. Risks of polypharmacy are better managed within the primary care structure because it is accustomed to dealing with multiple diseases and their treatments in a single patient.

TREATING CHRONIC PAIN IN THE PRIMARY CARE SETTING—WHY A CHALLENGE?

Training in Pain

Much of formal medical training occurs in hospitals where acute symptoms and life-threatening conditions are studied. Historically, very little practice has been offered in the management of chronic pain in the outpatient setting. Training in pain management may be limited to a brief session in a pharmacology or neuroanatomy course during medical school. As a consequence of this limited training, many residency-trained primary
care providers are ill equipped and therefore uncomfortable treating patients with persistent pain.\textsuperscript{21} This may lead to inadequate assessment, substandard treatment planning, poor follow-up and monitoring, and generally poor quality of care.

However, the opioid crisis has prompted medical schools to re-examine pain management curricula and has spurred widespread calls for medical student and provider education to be cornerstones in addressing the crisis.

\textbf{Disagreement among Experts—To Treat and Not to Treat}

In recognition of the need to improve pain management, the Federation of State Medical Boards issued guidelines on the appropriate workup and treatment of persistent pain.\textsuperscript{22} Most states have adopted the Federation’s recommendations in the form of Intractable Pain Treatment Acts. The safe and proper use of opioids is the cornerstone of these acts, encouraging providers to assess patients’ pain and use medication when necessary. Increasingly, adequate pain relief is being viewed as a patient’s right—and a clinician’s obligation—sometimes to the point of allowing the patient or family to take legal action against doctors for the undertreatment of pain. On the other hand, the opioid crisis has ushered in a new era of caution in treating pain.

The Centers for Disease Control and Prevention (CDC) released the Guideline for Prescribing Opioids for Chronic Pain in March 2016,\textsuperscript{23} a landmark effort that garnered widespread publicity and spurned heated discussions of controversies related to guideline recommendations. For example, the CDC guideline contrasted significantly to the 2009 American Pain Society/American Academy of Pain Management’s Clinical Guidelines for the Use of Chronic Opioid Therapy in Chronic Noncancer Pain\textsuperscript{24} as decidedly “opioid avoidant.” The CDC guideline promoted nonopioid analgesics and nonpharmacologic treatment options as preferred in the treatment of chronic pain, identified recommended limits in opioid doses prescribed, and advocated for heightened vigilance and monitoring for indications to taper down or discontinue opioids especially among patients already on long-term opioid therapy when benefits no longer outweigh harms. The CDC guideline also emphasized the lack of evidence demonstrating long-term efficacy of long-term opioid therapy in contrast
to other treatments for chronic pain\textsuperscript{25} and the growing evidence of potential harms, especially at higher doses.

It is too early to tell the full impact of the CDC guideline. However, the CDC guideline has already changed many providers’ approach to opioid therapy specifically and chronic pain care generally. More providers appreciate that high-quality pain care involves a combination of nonpharmacologic and pharmacologic options. Treatments where patients take an active role (e.g., yoga) are viewed as particularly valuable. Pain self-management skill building is considered low cost and effective and promotes less reliance on the health care system and that it may be in patients’ best interests to reduce or avoid taking opioids, especially long term. Avoiding long-term opioid therapy has been informed by consistent observational data and emerging randomized controlled trial (RCT) data that patients may experience accelerated decline in well-being and accrue a variety of bothersome and sometimes serious harms on long-term, and especially high-dose, opioids. That said, for individuals already on long-term opioid therapy for whom benefit is outweighing harm, the therapy (and ongoing close monitoring of it) should be continued. Involuntary tapering of patients not experiencing harm is not evidence based, not patient centered, and may have its own set of serious risks and unintended consequences.\textsuperscript{26}

**Barriers to Treating Pain**

Many barriers to the management of pain have been welldocumented in this text and others.\textsuperscript{27} These obstacles relate to the medical system, providers, patients, and regulatory and governmental agencies, all of which are operant in primary care practices. At the same time, other obstacles are unique to primary care, making pain management more difficult even for the well-trained, conscientious provider.

**Time Constraints**

Primary care providers often perceive pressure to do more in less time, especially in light of cuts in reimbursement (Medicare, Medicaid, and other types of commercial insurance). Furthermore, the typical 15-minute office visits are crowded by other activities: telephone calls, add-on
appointments, emergencies, hospital admissions, serving as preceptor for
students or midlevel providers (i.e., interns, residents, nurse practitioners),
and reviewing laboratory and x-ray reports.

Patient complexity is also a major contributor to time constraints.
Patients may present with multiple medical issues at each visit—ranging
from chronic conditions (diabetes, hypertension, and
hypercholesterolemia), situational issues (insomnia, stress at work,
menopausal symptoms), preventive care needs (immunizations, cancer
screening), procedural needs (skin tag removal, knee injections), and other
issues (medication refills, disability forms, jury excuses).

Comprehensive assessment and documentation of pain would be
difficult in this setting even if the entire 15 minutes were available to
address pain during the visit. To address these issues but still harness the
wealth of resources that make primary care such a compelling foundational
treatment setting, promising new care models described in the following
discussion have emerged.

Lack of Guidelines Specific to Primary Care
A variety of well-recognized treatment algorithms and evidencebased
guidelines exist for treating other chronic conditions encountered by
primary care physicians (e.g., cancer, neuropathy, fibromyalgia
syndrome). Although guidelines have been developed for some pain
problems, there are relatively few specific recommendations for the
treatment of persistent pain and rarely address the practical challenges to
managing chronic pain in primary care.

Even when guidelines are available, studies show that often they are not
followed by clinicians. This can be explained in part by the nature of
chronic pain. When a patient’s chronic pain worsens, the cause is
frequently undiscoverable, making it difficult to apply a guideline or to
decide on a different treatment when so many therapeutic options have
been ineffective.

Patient Nonadherence to Treatment
In other diseases, the consequences of nonadherence are not apparent to
the patient. Patients with worsening atherosclerosis, hypertension, or
diabetes are often asymptomatic. In contrast, nonadherence to medical
management has serious implications for patients with persistent pain and their physicians. Detriments to patients’ pain intensity, functional status, quality of life, and mental health conditions may occur as a result to nonadherence.

Specialty Referrals
Referrals for patients with persistent pain may differ for other conditions in primary care practice. After referrals to specialists in other conditions, patients may return to the primary care provider after the medical issue has resolved or the chronic illness has an expected treatment course. Some examples include dysfunctional uterine bleeding is diagnosed and treated before referral back to primary care. The fractured bone is set and stabilized, rehabilitation is arranged, and the patient presents back to primary care with restored function. The patient with congestive heart failure has further diagnostic testing, medication adjustments, and returns to primary care when symptoms have improved and the patient is stable.

The workup and treatment of the patient with persistent pain, on the other hand, may be less amenable to these clear benefits and resolution of symptoms. The acupuncturist diagnoses an imbalance of energy or “chi” and treats with needles and herbs. The physiatrist may focus on muscle tightness and nerve injury and offers rehabilitative therapies. The interventionalist uses injections to alleviate radicular pain. The chiropractor focuses on structural imbalance of the skeleton and offers manipulation therapy.

Often, the diagnoses and procedures for chronic pain are less familiar to the primary care provider (e.g., disk disruption, discogram, vertebroplasty, facet arthritis, radiofrequency ablation). Unfamiliar drugs and drug combinations are uncomfortable for physicians to prescribe and monitor. These may include polypharmacy with four or five drugs, such as combinations of multiple anticonvulsants (gabapentinoids), serotonin norepinephrine reuptake inhibitors, multiple opioids, and/or other analgesics; drugs rarely prescribed (e.g., methadone); and doses not used (e.g., high-dose opioids or gabapentin). After referral, patients may return to primary care with unclear parameters on what constitutes treatment “success.” Too often, the patient’s pain level is as high as when first referred for specialty care, and psychosocial issues such as depression and...
anxiety may not have been addressed.

Comorbid Conditions
The most commonly occurring comorbid conditions in patients with persistent pain are depression, anxiety, insomnia, and substance misuse or substance use disorders. These comorbidities complicate care. Patients may resist psychiatric care for many reasons including the perceived stigma, the additional cost, or the belief that their pain is unrelated to their mental health comorbidities.

Pain can make depression worse, and depression can make pain worse, both independently. Patients seeking relief from their pain and comorbid conditions may self-medicate with alcohol and other substances such as marijuana, which can further complicate the problem. They may take prescribed pain medications to treat the comorbid condition and temporarily relieve their symptoms but can make them feel worse long term.

Failure to address underlying anxiety, depression, insomnia, and substance use disorders makes pain treatment more difficult. These comorbid conditions are difficult to treat in stable patients. When persistent pain or a chronic illness is also present, the treatment is even more complicated because the pain experience is more severe and less amenable to treatment. It is unlikely that a simple, single-drug regimen or series of epidural steroid injections will be the long-term solution for chronic pain and comorbid conditions.

Adversarial Relationship
Medical practice in primary care is built on trust, respect, and advocacy for the patient. The doctor–patient relationship is fundamental and develops over years of providing preventive care, treating acute conditions, and supporting the patient through life transitions such as the birth of a child, unemployment, and the death of a close family member. This long-term relationship enables the primary care provider to better understand the patient as an individual and allows the provider to more effectively share medical advice and decisions with their patients.

Persistent pain may disrupt this stable pattern and create an unusual relationship that may not emerge in the management of other chronic
diseases. The primary care provider may, at times, feel forced into an uncomfortable adversarial position that he or she is not well trained to manage. Patients with chronic pain ask for many things that are not guideline concordant at times the physician must argue against or deny certain diagnostic tests or treatments. For example, the patient wants the doctor to order additional or repeated expensive procedures (e.g., magnetic resonance imaging [MRI]) when his or her pain worsens. The doctor refuses because it is not consistent with guidelines, will not change the treatment plan or lead to a cure for the persistent pain, or is not approved by the patient’s health insurance plan.

In this scenario, the provider may find themselves in the difficult role of contradicting the patient’s wishes. When the doctor is unable to be supportive, the patient begins to question whether his or her “advocate” still wants to help. The patient–provider relationship may become strained, and the patient may resist potentially beneficial treatment options recommended.

**Addressing Barriers to Care**

As mentioned earlier in this chapter, primary care providers may lack comfort and confidence in managing chronic pain. In addition to limited training, there are a number of other underlying reasons for this.

**MYTHS AND BIASES**

Patients—Without conscious intention, people attach meaning to all sensory experiences. The smell of a rose may hold a special meaning to someone who received her first bouquet for the high school prom. The sound of the musical tune “Jingle Bells” may signify happiness, family gatherings, and holiday gifts. Pain, especially when it is persistent, often conveys a sense that the person is being punished for some real or perceived infraction.

Too often, patients with chronic pain believe that they suffer because of some mistake they made or that pain is to be expected as a part of aging. At times, there is so much salience attached to pain that it is difficult to convince the patient otherwise. These beliefs about “needing pain” or “deserving pain” complicate treatment.
Providers—Primary care providers may be suspicious of patients who complain of pain. Physicians understand certain types of pain—cancer pain, end-of-life pain, or acute trauma/illness pain—but are less accepting of the persistent pain that has few objective signs of defined conditions. We ask, “Why do some patients complain while others, with the same pathology or anatomy, do not complain?” “What is the secondary gain?” “Is this pain real?”

Some providers still cling to the outdated notion that most causes of chronic pain should clearly be identifiable on imaging studies. When pain is not easily explained in this paradigm, bias may lead the primary care provider to suspect mental health causes. In addition, mental health comorbidities are common with persistent pain. The primary care provider may believe that the persistence of the pain relates directly to the patient’s depression or anxiety, thereby depreciating the pain complaint. Patients perceive this attitude as devaluing their experience.

**PATIENT RESISTANCE**

The false dichotomy of physical pain versus emotional pain, still often perpetuated by health care providers, affects patients’ experiences as well. The patient reasons, “If my doctor cannot find anything wrong with me and if there is no fix for my situation, he or she will assume that I must be crazy.” For this reason, feelings such as “you think this is all in my head” are often expressed in patient encounters.

In fact, physical and emotional pain cannot be separated. They coexist and feed on each other. For instance, the most balanced, rational, and accepting patients can still experience high pain levels from fibromyalgia syndrome even when anatomic pathology is lacking on physical exam or diagnostic studies. As noted earlier, advances in neuroscience have elucidated pathways that explain this phenomenon.

Despite wide recognition that mental health comorbidities frequently coexist, patients often resist the suggestion that anxiety and depression may be exacerbating their pain. They equate these diagnoses with hysteria or hypochondria and feel that the physician is depreciating their pain experience. Treating comorbidities is difficult in this setting, especially for providers with inadequate training.
REGULATORY SCRUTINY
Fear of regulatory scrutiny is common in primary care settings, although in reality, very few primary care physician practices are ever investigated by regulatory bodies. Even fewer practices have had their licensure suspended. These few cases and those covered in the media often involve high-profile providers or illegal and unethical activities. Despite this fact, reality sometimes does not mitigate perception, and regulatory scrutiny, as noted in a previous chapter by Gilson in this text, continues to impede more aggressive pain management in many primary care practices.

PATIENT EXPECTATIONS
The paternalistic relationship commonly seen in medical practice is being challenged by consumer activism. Patients have more access to health information than ever before. They have more time and motivation to research their conditions on the Internet and may sometimes know (or believe they know) more about treatment options and a particular disease process than their primary care physician. As is often the case, this is a mixed blessing. On the one hand, an informed patient may be much more amenable to self-management. In some cases, however, an informed patient may have misguided beliefs based on less reputable information sources.

Most patients with persistent pain do best after learning and adopting self-management skills. Acceptance of their chronic condition, developing strategies including conditioning exercises, and making changes in work or hobbies lead to the best results. However, when information-seeking patients are confronted with “miraculous cures” and daily news articles touting advancements in pain treatment, adapting to pain is difficult for the provider to sell. Too often, patients find themselves on a constant search for the next cure or “fix” only to be disappointed when it fails and then moving on to the next “harmless, 100% effective” treatment. As this pattern repeats over and over, the best treatment—acceptance, adaptation, and conditioning—is delayed. The expectations of desperate patients seeking miracle cures create significant barriers to optimal care.

Pain Practitioner: A Primary Care Model
TRAINING
As in other disciplines, training received by primary care providers may become outdated as new knowledge is accumulated and scientific advancements are achieved. Education in all areas of medicine must be lifelong and constantly updated. Medical training provides a knowledge base with courses in neuroanatomy, pathophysiology, and pharmacokinetics. This training serves primarily as a foundation and a method for learning and applying new knowledge.

The process of learning and reapplying new knowledge is well accepted in medicine. Despite all the practice management issues and the multilevel barriers to pain care, primary care providers continue to learn and apply new information in their daily clinical practice.

COLLABORATION WITH PAIN SPECIALISTS
Complex conditions are always better managed when primary care providers and specialists have open lines of communication and clearly delineated systems for coordinating care; pain care is of course no different. For their part, informed and collaborative pain specialists trained in the biopsychosocial approach to pain can be a great asset to primary care by guiding primary care physicians through learning new skills and providing direction regarding when to refer patients back for further specialty care. Such constructive communication can lead to greater self-assurance and competence among primary care physicians as they manage complex pain patients in their practices.

NEW FOCUS
Patients with persistent pain have similarities and differences from patients with other chronic illnesses. They both have chronic conditions where cure is unlikely. Self-management is the key to reaching treatment goals. Denial about the disease and nonadherence to treatment recommendations are common and expected challenges for the provider.

On the other hand, mental health issues are more common in persistent pain and interfere with treatment. Patients may resist psychosocial diagnosis and interventions. Long-term opioid management can be challenging for the patient and the provider. Nonadherence to treatment
recommendations increases morbidity and mortality in diabetes, hypertension, and congestive heart failure. In chronic pain, nonadherence increases the clinicians’ work stress, by requiring more office visits, documentation, and medication surveillance. Although regulatory scrutiny does not occur often, the perception of legal difficulties increases practice discomfort.

In managing pain, it is important for the physician to understand that pain scores are subjective and that a stronger focus should be placed on function. Although measuring pain is important and mandated in a variety of settings, the physician must not lose sight of the agreed on goals of treatment. A new pain complaint or worsening symptoms do not necessarily mandate more medication. In treating diabetes, a worsening glycated hemoglobin (HgBA$_1$C) leads the physician to recommend adjustments in diet, exercise, and medication. Similarly, in treating chronic pain, recommendations should take into consideration life stressors, pacing daily activities, depression, anxiety, and worsening of underlying pathology as well as medication. When the primary care provider understands that an increase in pain does not necessarily mean increasing the patient’s medications, treatment issues may become easier.

**ASSESSMENT AND EVALUATION DURING SHORT VISITS**

Given the typically short office visit and the many pressures on the physician’s time, chronic illness management is becoming more difficult. In the typical 15-minute appointment, the patient with low back pain must be evaluated, but he or she may have other conditions requiring assessment, such as hypertension, diabetes, a sleep disorder, and fatigue that are also bothersome to the patient and they want addressed. Given an hour for the evaluation and adequate support staff, primary care physicians would all be better pain managers. But given a short time, stressed, and overworked support staff and patients with sometimes myriad complex conditions to be addressed, this is not the case.

Despite the reality of a busy office schedule, primary care is uniquely positioned to take care of the patients with chronic pain. We know our
patients through associations developed over years of repeated exposure at routine medical care. We understand our patient’s coping strategies, family dynamics, and work stresses. The solution to the dilemma lies in making the typical short office visit more effective for patients needing chronic pain management.

THE 15-MINUTE OFFICE VISIT

Validating the Patient

Validation is straightforward when a patient presents with an ankle sprain or a sore back. The injury is easily identified by the history, and the diagnosis is easily confirmed by physical examination. Diagnostic imaging and/or laboratory reports further support the physician’s initial impression, and the patient’s chief complaint and the associated pain improve steadily with a short course of uncomplicated therapies—an NSAID, muscle relaxant, application of cold or heat, and rest.

Validation poses problems for primary care when the patient suffers from chronic pain. We are concerned that the patient will request something we cannot deliver, such as total pain relief, additional MRI studies, or unsafe doses of medication. The evidence shows that, in fact, clear, nonjargon-laden, nonjudgmental education makes pain care planning easier. In a study of patients with fibromyalgia syndrome, providing the patient with a diagnosis resulted in the patient making fewer visits to the physician’s office and becoming more empowered and proactive.35

Once the patient understands that we believe the pain is real, more time can be spent dealing with symptom control, exercise, and other important management issues. At each office visit, make sure that the following steps have been taken:

- Ask about pain intensity but more importantly, pain-related functional interference.
- Determine the functional status of the patient and whether the treatment is improving function.
- Modify the treatment according to the patient’s response.
- Use a combination of nonpharmacologic and pharmacologic methods for pain control.
- Explain the available options and foster a positive attitude in the
patient toward dealing with the pain.

- Normalize the interrelationship between mood and pain and help the patient understand that managing mood disorders and other comorbid conditions will also help the experience of pain and thereby improve quality of life.

Having a set routine with these key goals in mind sets the agenda and can streamline even a difficult, complex visit.

Assessment Tools

Chronic pain usually starts as an acute pain episode. In most cases, the acute episode resolves and the patient returns to normal function. Even fibromyalgia syndrome, defined as widespread pain for months to years, has a beginning. The workup and treatment can take months before the correct diagnosis is discovered, and the physician becomes aware that the problem is long term and likely to present problems in management.

At this point, the physician’s attention should focus on chronic disease management (i.e., symptom improvement rather than multiple interventions and cure). How can the physician best do this evaluation in a short office visit? Referral may or may not be an option as specialty referral may not be available, too expensive, and time-consuming for many patients. Evaluation needs to be focused on the desired outcome of pain reduction, functional improvement, and identification and management of comorbidities. Because such an evaluation can easily take up several visits, handouts and questionnaires can be very useful (i.e., The Initial Pain Assessment Tool, Pain Disability Index, Quality of Life Scale, Patient Health Questionnaire-9, Generalized Anxiety Disorder 7 [GAD-7], Zung Self-Rating Depression Scale, and Function and Goal Setting).

Try giving the patient self-assessment forms that measure pain, function, depression, and anxiety and allow the patient to complete the assignment at home. Patients tend to like these questionnaires because they permit patients to describe in detail issues that the physician may not have the time to elicit during the office visit.

A follow-up visit is designed to review the results with the patient. The handouts direct the follow-up visit to the important outcome variables: pain and function. They are helpful in that they let the patient know which
outcomes are most important and what each subsequent office visit will address. The patient who demonstrates anxiety or depression on the self-reported questionnaire is more likely to accept treatment, making discussion and treatment of such comorbidities less time-consuming. Assessment is covered in detail elsewhere in this text.

**Substance Misuse Screening**

Primary care physicians are often hesitant to prescribe opioids. When treating patients with chronic pain, such caution is justified as long-term opioid therapy often offers modest or no benefit, usually involves bothersome side effects, and may lead to serious adverse effects. Substance misuse, particularly involving opioids, is an important comorbidity in chronic pain management. Fortunately, there are multiple questionnaires available to help assess this risk. Commonly used screening tools practical in primary care include The Screener and Opioid Assessment for Patients with Pain,36 Opioid Risk Tool,37 and Drug Abuse Screening Test.38 Patients who score high on any of these scales are more likely to misuse opioids. If referral to a pain management specialist is an option, the primary care physician might consider this. Such screening is also covered fully elsewhere in this text.

**Goal Setting and Plan of Action**

Like other chronic illnesses, patient participation and adherence to treatment recommendations predict better outcomes. Chronic pain affects many life activities and, in turn, quality of life. Goal-setting discussions direct the patient to improved activity and a targeted outcome. For example, if the patient wants and agrees to spend more time out of bed, walk 10 minutes a day, or work in the garden, any of these might serve as a goal that can be tracked with each visit. As patients begin to anticipate the questions the physician will ask about their goals, visits become more streamlined and focused on a functional outcome.

After the patient has been evaluated and treatment has been initiated, adequate follow-up of a patient with chronic pain can be difficult to accomplish in a 15-minute visit. Follow-up does not take as much time when the physician stays focused on the desired functional outcome.
Consider a routine follow-up for a patient with diabetes. We begin by asking about diet, exercise, foot numbness, vision, and home glucose monitoring. We review the self-monitoring results and then perform a physical exam focused on the blood pressure, eyes, heart, and monofilament exam of the feet. We review the HgBA$_1$C, microalbumin, and low-density lipoprotein. We ensure that the patient is taking recommended medications. We change treatment based on all the information received. All of this is done every day with our patients with diabetes and at each visit; all of this can be accomplished in 15 minutes.

The difference in managing chronic pain, and the reason that visits consume more time, is that often it is unclear what to follow, what to ask, and what outcomes to track at each visit. It is vital that each follow-up session remains focused on symptom management and functional improvement. A patient’s pain diary or journal can be helpful in focusing follow-up visits. Pain diaries, available in paper and electronic form, are similar to regular diaries except that the entries focus on pain. Patients record pain-related elements such as the time pain was experienced, pain characteristics (e.g., burning, stabbing, aching), the location of the pain, what he or she did to alleviate the pain, and whether what they did helped. The patient brings the pain diary to each follow-up session, focusing the visit on a particular pain score and whether the recommended treatment was effective.

Activity and sleep questionnaires are also helpful in concentrating the appointment on these quality of life issues. In a mutual goal-setting discussion with the patient, the questions can revolve around previously agreed on and previously documented functional outcomes such as the amount of time spent out of bed, the 10-minute walk, or the time spent working in the garden.

Charts reviewed of primary care visits in patients with pain frequently demonstrate a failure of adequate documentation. Given the time pressures, it is no wonder that documentation often is low on our list of priorities. Handouts and questionnaires filed in the patient’s chart enhance this record keeping and save time.
There are many pharmacologic treatment options for persistent pain. Pharmacology in primary care is difficult because of the many treatment choices, the lack of agreement among experts, and the nearly complete absence of data from pragmatic studies where patients have multiple comorbidities and are on multiple medications for other conditions. How and why a particular medication is used in a patient with pain varies based on pain severity, diagnosis, and many other factors. U.S. Food and Drug Administration-approved drugs or randomized trial results could guide prescribing. Primary care often uses past experience even when this experience is inaccurate or inappropriate. An example of this is the common use of ineffective nonsteroidal anti-inflammatory medications in neuropathic pain treatment in the primary care office.40

Access to medication is also a major force in pharmacologic options in the primary care setting. Nonformulary drugs or third-tier medications requiring high patient copays are a significant factor in prescribing. If the primary care provider has to obtain a preauthorization or justify a prescription, the medication may not be prescribed because this extra step requires excessive time.

As the Ballantyne and Mao article points out, opioid prescribing is one of the most difficult decisions facing primary care in managing persistent pain. When prescribing opioids for pain management, physicians are often faced with scenarios that mirror those we associate with addiction: early refills, lost or stolen medication, borrowed medication, and urine drug tests that are inconsistent with current therapy. In these cases, documentation is critical. Strategies such as the five As of treatment success enable the primary care physician to concentrate on the outcomes that are essential to the patient’s overall quality of life (Table 108.1).41

<table>

<td>At the initial and subsequent visits, work activities, household duties, social activities, hobbies, and physical exercise target are recorded and goal setting is discussed. When treating any chronic condition, follow-up visits are necessary to evaluate the effectiveness of the treatment.</td>
</tr>
<tr>
<td><strong>A-3 = Adverse events</strong></td>
</tr>
</tbody>
</table>
Anticipating and soliciting feedback from the patient regarding side effects from treatment allows the physician to proactively manage adverse events rather.

**A-4 = Aberrant behavior**

Patients on long-term opioid therapy may display behaviors that raise concerns, including early refill requests or using analgesic medication with unprescribed controlled substances or illicit substances. When such patient behavior occurs, careful interpretation is needed. Document the behavior in the patient’s chart, discuss it with the patient, and come to a mutual understanding of what action will be taken if the behavior occurs again.

**A-5 = Adherence to the treatment plan**

Providers should engage patients in a shared decision-making process to arrive at a feasible, acceptable multimodal pain care plan that has at its foundation active pain self-management. Providers should follow-up with patients about adherence to that plan to troubleshoot barriers and coach and motivate patients to greater adherence to the agreed-on plan.

**REFERRAL TO AN ADDICTION SPECIALIST**

When to refer a patient to specialty care may be a difficult question and is highly variable among different practitioners. Some providers refer whenever long-term opioid management begins. Others refer only when intervention or surgery is needed. When behavior around the use of an opioid becomes problematic, referral is often prudent. At a minimum, documentation of the behaviors and an understanding between patient and provider is necessary. The five As allow the physician to address the issue and develop a treatment strategy. It is important for the physician to recognize the risk and recommend a corrective action (i.e., an abnormal urine drug test may trigger a referral to an addiction medicine provider). The patient with a substance use disorder may argue and dismiss the risk.

**MOTIVATING BEHAVIOR CHANGE IN PATIENTS WITH CHRONIC PAIN**

The key message in managing chronic pain is that the way to improve is through changes in lifestyle rather than solely through medication or surgical procedures. This may not always be an easy message for primary care to deliver because patients may expect their physician to give them something to cure their problem. Lifestyle and behavior changes are never easy.

Successful management of chronic pain is much more dependent on what the patient does than on what the physician does to the patient. The issue becomes one of the patient’s readiness to accept responsibility and to adopt a self-management approach. This represents a role reversal for the
physician whose task is not to treat but to understand and motivate patients for self-management. On occasion, this may include convincing the patient not to look for another doctor or another procedure.

Because of their unique relationships with patients, primary care physicians are well suited in motivating patients to change. We are motivating patients to lose weight, stop smoking, take their medication, and obtain flu shots. A patient-centered approach, emphasizing the importance of considering the patient’s perspective when making treatment recommendations, has been shown to be a valuable technique.\(^{42}\) The goals of a patient-centered approach are to

- Address the patient’s concerns
- Enhance a collaborative relationship
- Provide information that the patient is ready to hear
- Refocus the visit from making treatment recommendations to supporting the patient’s self-care
- Foster increased patient control of decision making and responsibility for self-care

This technique requires a reorientation of the traditional patient–physician relationship. The physician must learn to view the patient as an autonomous and equal member of the health care team, whose self-knowledge is pivotal to the management of his or her condition (persistent pain).

Reflective listening is a technique that involves making statements that demonstrate the physician’s understanding of what the patient has said. There are ways of making reflective statements, including the following:

- Restating what the patient has said
- Paraphrasing what the patient has said
- Anticipating and continuing the patient’s thought (i.e., saying what you believe the patient will say next rather than repeating)
- Reflecting the patient’s feelings

The patient’s readiness to change is the basis of a motivational approach. According to one well-regarded model,\(^ {43}\) patients who strongly believe that their pain only requires a medical or surgical intervention are not ready to accept and adopt self-management. On the other hand, patients who believe that medical and surgical interventions can provide
only limited relief from pain are more likely to perceive benefits from self-management techniques. Readiness to self-manage should be assessed on a continuum, and interventions should be tailored to the particular patient’s level of readiness to change.

The physician can help the patient to understand the importance of behavior change by guiding him or her through a discussion of the pros and cons, including whether a given change is attainable, how much effort it will take, and how much time it will take given the known obstacles. Motivating the patient involves eliciting the patient’s feelings about and reasons for pain self-management and reflecting back statements that support the premise that self-management is possible. Although time-pressed physicians may balk at the prospect of such a dialogue, the consultation time is usually more efficient (e.g., fewer arguments, less resistance) when a patient is encouraged to speak in a focused manner about a specific problem.

Goals for Pain Self-management
In general, primary care physicians are in agreement about health care goals such as encouraging smoking cessation, maintaining blood pressure within normal limits, and controlling blood sugar. Although the goals for pain self-management are not as clear cut, most pain specialists would advise primary care physicians to consider the following as important when motivating a patient:

1. Beginning or maintaining a regular exercise regimen
2. Using medications as prescribed
3. Returning to normal daily activities given the pain condition
4. Practicing appropriate pain and stress-coping strategies (e.g., relaxation techniques, reassuring “self-talk”)
5. Returning to or maintaining normal work activities
6. Pacing activities appropriately
7. Monitoring, managing, and/or reporting symptoms of depression as appropriate
8. Practicing good eating habits (e.g., reducing or maintaining an appropriate weight)
9. Engaging in other healthy lifestyle behaviors as necessary (e.g., reducing alcohol consumption, stopping smoking)
Importance and Confidence Scales
Patients will change behavior only when they are convinced that it is important and when they have confidence that the change is possible. Assessing patient perceptions of importance and confidence can be helpful when evaluating motivation. For example, patients who give a low rating to the importance of exercise but a high rating to the belief that exercise could be done would need help to change their views of the importance of exercise before adherence could be expected. On the other hand, brainstorming for solutions may be helpful for those who rate importance high and confidence low.

Strategies for Helping Patients Understand the Importance of Change
Information and advice presented in a lecturing style often leads to patient responses of “Yes, but . . .” and the already too brief visit is taken up with the patient expressing reasons why a recommended change will not work. Social psychology research has shown that, in general, people are more likely to believe what they have said over what others have said to them. It follows that a didactic approach may undermine the physician’s attempts to motivate the patient.

Primary care providers are invested in behavior change and motivation. Four strategies have been shown to be effective in helping patients understand the importance of change and increase their confidence to make that change. These uncomplicated strategies are effective because they enable patients to talk themselves into using pain self-management techniques.

1. Always elicit positive statements from the patient. Use the “why so high” technique. For example, ask the patient with chronic pain to rate the importance of daily exercise on a scale of 0 (low) to 10 (high). If the patient’s answer is 5, ask “Why so high? Why not a 1?” Most patients understand the importance of conditioning and exercise in pain rehabilitation. By asking “why so high,” the patient provides the evidence for an exercise program. Once you know the patient’s thought process, you can use this to motivate a change of behavior.

“You think it is very important for you to make your muscles stronger to make your pain better” (restating what the patient has expressed).
2. Examine the pros and cons of behavior change. Patients will feel ambivalent about self-management. This allows the patient to explore feelings and think through self-management in a judgment-free environment. Bear in mind that although this technique is easy to understand, it can be difficult for the physician to do. He or she must listen, encourage, and provide a summary at the end of the visit. “What do you think will happen if you continue to stay in bed?” The patient may steer the conversation back to you: “Unless you make me better, I cannot get out of bed” or “Unless you give me more pain medication, I will not be able to get out of bed.” Be persistent and keep to the same question. The patient has stated earlier that conditioning and exercise are important.
“Your mother was sick all the time. How did that affect you?” Patients may have an environmental background for pain in another family member which impacted them when growing up. Patients may also express concern about the impact of their pain on the other members of the family. The desire to have their pain not have an impact may motivate the patient to different behavior.

3. Elicit patient concerns about the status quo. Patients who rate the importance of pain self-management as low may be concerned about their current situation. Ask the patient to talk about the consequences of not making the behavior change. Once the patient has listed as many concerns as he or she can think of, summarize these, using the patient’s words if possible. This may help to increase the patient’s perception of the importance of the change.
“If things do not change, what will happen?” The patient may try to guide the discussion back to you and the medical profession, disability, or legal issues. Be persistent about “What will happen with your spouse or children; how will you pay the bills?”

4. Brainstorm for solutions. Without giving specific advice, remind the patient that there are usually many ways to achieve self-management. Guide the patient in conceptualizing a number of possibilities. Help the patient to decide which possibilities might work best for him or her. Guide the patient to develop plan for achieving his or her goal.
“You spend 16 hours of your day in bed. Any activity makes your
pain worse. The last time you tried to exercise, your pain was at a 9/10 and you wanted to go to the hospital. How are you going to get to exercise?” Keep the focus on what the patient can do, or what solutions the patient has. Add suggestions and advice related to the patient’s solutions.

Once the patient has adopted a self-management plan with specific goals, the physician can use open-ended questions to encourage the patient to talk about his or her progress. The questions should communicate the physician’s interest in the patient’s perspective. For instance, “At your last visit, you were thinking about making some changes in pacing your work. I’d be interested in hearing how this is going and whether you’ve noticed any change in your ability to manage your pain.” Such questions enable the physician to conduct an informal assessment of the patient’s readiness and also enhance rapport with the patient.

Emerging Models of Care
There is increasing recognition that team-based care, where providers from multiple disciplines collaborate in the care of patients with chronic pain, may be the key to optimizing primary care’s foundational role in chronic pain management.45 Collaborative care models, adopting successful approaches from other conditions like depression and diabetes, have demonstrated promise in integrated health systems for treatment of chronic pain. These successful programs, published as clinical trials, usually feature a care manager, such as a pharmacist, nurse, or advanced practice nurse, who collaborates with a physician to provide referral-based care to a population of patients embedded within group practices. Several recent studies have demonstrated success with these models in terms of pain intensity, pain-related functional interference, use of multimodal pain care, and patient satisfaction.46–49 Cost-effectiveness studies and implementation trials—to address issues of more widespread dissemination of these models—are underway. Another example of team-based care involved a study where nurses team with primary care providers in an intervention that improved adherence with opioid therapy for chronic pain guidelines.50 More resource-intensive primary care–based clinics that manage patients with high-risk opioid use and chronic pain
have also demonstrated initial promise.\textsuperscript{51}

### Conclusion

Persistent pain, a highly prevalent condition in the United States, has a significant impact on our health and productivity as a society as well as on our medical and financial resources. Primary care is the most appropriate setting for the management of patients with chronic pain because of the mutual understanding that results from a long-standing physician–patient relationship. The barriers to managing chronic pain are significant but not insurmountable. Persistent pain is similar to other chronic illness but also has many unique differences, making management complicated and difficult in the busy primary care office. A new skill set is required by the provider to help the undertreatment of pain. Available tools (e.g., questionnaires, pain diaries, pain scales) and techniques (e.g., reflective listening, goal setting) make it possible for the primary care physician to provide management for patients with chronic pain in a 15-minute office visit. Diabetes, chronic obstructive pulmonary disease, and other chronic, complicated illnesses require other skills yet have been handled skillfully and competently in the primary care setting.

Some of the most appreciative patients are those who have a sympathetic provider to help them with chronic pain. Yet treating chronic pain patients is rarely met with enthusiasm in primary care. Patients with chronic pain may have complex conditions that are rarely cured. They may have previously made little progress toward normal life functioning and often have complex psychosocial issues that a physician cannot address. There is never sufficient time to adequately follow up patients with pain. The primary care provider is accustomed to dealing with chronic problems through short, focused visits and a longitudinal experience. A treatment plan and mutually agreed on goals allow the physician to conduct a follow-up visit in 15 minutes by focusing discussions on the treatment success that both the physician and patient desire.

Adequate relief of pain at the end of life is an ethical imperative. Studies suggest that although pain may not be the most prevalent symptom during the final days or weeks of life, it is frequently the most distressing.\textsuperscript{1-7} In addition to the negative consequences pain has on the patient, inadequate pain control adversely affects the ongoing emotional well-being of family and friends at the bedside. To witness unrelieved pain during the final hours of life leaves long-lasting negative memories of the dying process that can hamper bereavement. The setting of care can dictate whether patients will receive adequate relief during the dying process, and significant change in our systems of care is needed. The majority of end-of-life care is currently provided in institutions, with more than two-thirds of individuals dying in hospitals or nursing homes. In a large survey of surviving family members, more than 25\% reported that their loved one received inadequate relief of pain in these settings.\textsuperscript{8} The challenge for our health care system is to ensure that regardless of setting, pain management at end of life is provided by skilled professionals who understand the special needs of the dying. These skills include assessment of pain in those who might not be able to verbally describe their pain, awareness of pain syndromes common at end of life, as well as familiarity with the pharmacologic and nonpharmacologic management of pain in the dying. Furthermore, clinicians must be aware of the role of suffering and existential distress as well as management of intractable symptoms.

Introduction

Currently, death in developed countries is more likely to occur after a long
chronic illness. This is in contrast to a century ago when people died a more rapid death, often due to infection. Currently, the most common causes of death in high-income countries include ischemic cardiac disease, cerebrovascular disease, and cancer.\textsuperscript{9} Globally, more than 70\% of deaths are due to chronic, noncommunicable diseases, principally cardiovascular diseases and diabetes, cancers, and chronic respiratory diseases.\textsuperscript{9} Thus, people are more likely to die after a long, protracted illness, and pain is a common comorbidity of these illnesses. Several care delivery models exist to address the specialized pain and symptom needs of those with life-threatening illnesses, including palliative care and hospice. Both of these care models focus attention on the patient and family, not unlike the structure of care delivered in truly interdisciplinary pain treatment programs.

**PALLIATIVE CARE**

Palliative care strives to relieve suffering and improve the quality of life of those individuals with a life-threatening illness.\textsuperscript{10} The palliative care movement in the United States originated in academic medical centers but has moved into community hospitals, outpatient clinics, and other centers of care. Palliative care programs are rapidly growing within hospitals, existing in 67\% of hospitals in the United States with 50 or more beds and in 90\% of hospitals with 300 or more beds.\textsuperscript{11} Commitment to early identification, thorough assessment, and effective treatment of pain are key components of palliative care, as is attention to other physical, psychosocial, and spiritual concerns.\textsuperscript{12} The goal is to neither hasten nor prolong death but rather affirm life by offering a support system to patients and families. To that end, palliative care is optimally provided by an interdisciplinary group of professionals, including physicians, nurses, social workers, chaplains, and others.

Confusion persists regarding the timing of appropriate referral to palliative care. Previous models of care incorporated palliative care during the final phases of life, once all curative therapy was completed (Fig. 109.1). It is clear that patients and families benefit greatly when palliative care is integrated into the plan of care early during the course of illness (Fig. 109.2). Effective pain management provided during cancer treatment,
for example, can allow patients to complete potentially curative or life-prolonging therapies.\textsuperscript{13} Attention to other symptoms associated with the underlying illness, including distressing complications of treatment, can provide improved quality of life during this time. Research supports the feasibility and benefit of integrating palliative and oncology care in ambulatory patients.\textsuperscript{14–19}

\textbf{FIGURE 109.1} Previous models of palliative care and hospice.

\textbf{FIGURE 109.2} Proposed model for integration of palliative care.\textsuperscript{193}

\textbf{HOSPICE}

The modern concept of hospice care developed from the work of Dame Cicely Saunders and others in the United Kingdom during the 1960s. In this model, freestanding centers of care were developed where patients spent their final days receiving pain and symptom management, along with attention to the emotional and spiritual aspects of the individual’s life. A decade later, hospice began in the United States with the same goals of
care, but a home-based model quickly took root. In 1982, the Medicare Hospice Benefit was passed to provide reimbursement for these services. A Medicare Part A beneficiary is eligible for this benefit if she or he is determined to have a life expectancy of 6 months or less if the life-limiting disease or combination of comorbid conditions runs its normal course. Studies reveal that patients at end of life and their family members prefer care provided in the home with the support of hospice, reporting improved symptom management and significantly greater satisfaction with the overall quality of care. Both of these models, palliative care and hospice, provide support to patients and loved ones. As pain is so prevalent, all health care professionals working with people at this time of life must be exceptionally knowledgeable about common pain syndromes as well as appropriate assessment and management.

**Pain Syndromes Common at the End of Life**

Pain syndromes specific to cancer have been well characterized; yet, much research is needed to describe pain associated with other life-threatening illnesses. Furthermore, greater attention is needed to identify pain syndromes most common at the very end of life along with appropriate treatment strategies (Table 109.1).

Peripheral neuropathy due to cancer chemotherapy or treatment of HIV/AIDS
- Arthralgias and myalgias due to aromatase inhibitors
- Surgically induced phantom pain, chronic neuropathy
- Immunocompromise leading to postherpetic neuropathy
- Radiation-induced plexopathies, osteoradionecrosis, lymphedema
- Graft-versus-host disease after stem cell transplant leading to skin and mucous membrane lesions
- Aseptic necrosis due to prolonged corticosteroid use

### Pain Unrelated to Disease or its Treatment
- Pressure ulcers
- Reduced muscle and fat padding at bony prominences
- Muscle atrophy leading to myalgia
- Immobility leading to joint pain
- Contractures

### CANCER
Prevalence rates of pain in advanced cancer vary based on the settings of care in which the studies were conducted, the instruments used to measure pain and other symptoms as well as the methods employed in data collection. In general, approximately two-thirds of patients with advanced malignant disease experience pain.\(^{22-25}\) Cancer patients referred to palliative care or hospice commonly have a greater prevalence of pain and other symptoms. Regarding the pain trajectory in cancer patients very near the end of life, pain occurred in 54% and 34% at 4 weeks and 1 week prior to death, respectively.\(^{26}\) Children dying of cancer also are at risk for pain and suffering.\(^{27,28}\) The result of unrelieved pain and associated interference may include increased desire for hastened death.\(^{29,30}\)

### NONCANCER DIAGNOSES
Many life-threatening illnesses are known to cause pain, including human immunodeficiency virus,\(^{31}\) multiple sclerosis,\(^{32-35}\) amyotrophic lateral sclerosis,\(^{36}\) other neurologic disorders,\(^{37}\) end-stage renal disease,\(^{38}\) and heart failure.\(^{39,40}\) At the end of life, it is apparent that many of the preexisting pain syndromes associated with these disorders can escalate, particularly pain related to progression of disease, immobility, or comorbid complications. Furthermore, many patients with advanced disease are
elderly and more likely to have existing chronic pain syndromes, such as osteoarthritis or low back pain. Regrettably, there have been few studies characterizing the prevalence of pain or the types of pain experienced by these individuals with noncancer diagnoses. Greater awareness of the risk and types of pain seen will lead to improved detection, assessment, and treatment.

Pain Assessment at the End of Life

CHALLENGES IN PAIN ASSESSMENT

Comprehensive assessment of pain at the end of life is imperative. As with all pain, assessment must be conducted upon initial presentation, regularly throughout the course of care, and during any changes in the patient’s pain state. Documentation of and communication about these findings are crucial. Assessment in patients who are cognitively intact and able to verbalize can incorporate standard intensity tools such as the numeric rating scale (NRS), the verbal descriptor scale (VDS), the visual analogue scale (VAS), or the Brief Pain Inventory (BPI) for more comprehensive evaluation. A panel of international experts in palliative care rated essential components of pain assessment to include intensity, temporal pattern, treatment and exacerbating/relieving factors, location, and interference with health-related quality of life as essential dimensions. In their content evaluation of more than 64 pain assessment tools, none were found to satisfactorily incorporate all of these domains.

Tools exist that measure multiple symptoms seen in lifethreatening illness, and the majority include pain. One study demonstrated that using systematic assessment of symptoms in palliative care yielded a 10-fold greater number than when volunteered by the patient. The investigators conclude that specific detailed symptom investigation is necessary. Examples of tools include the Edmonton Symptom Assessment Scale, the M.D. Anderson Symptom Inventory, the Memorial Symptom Assessment Scale, the Rotterdam Symptom Checklist, the Symptom Distress Scale, and others. One constraint of these scales for clinical care at end of life is the length of most of these tools, leading to respondent fatigue. The Brief Hospice Inventory was developed
specifically to evaluate symptoms, including pain, and satisfaction with hospice care. Initial testing revealed that patients at end of life could complete the instrument.

A wide range of health-related quality-of-life instruments, such as the European Organisation for Research and Treatment of Cancer QLQ-C30 and the Functional Assessment of Cancer Therapy—General, include symptoms such as pain, but the burden to complete these tools preclude their use in those with advanced disease. Several tools target patients at the end of life: the Hospice Quality of Life Index, the McGill Quality of Life Questionnaire, and others. These instruments include symptoms and can be useful in assessing the global needs of dying patients. Although these tools are appropriate for patients who are cognitively intact, many patients at the end of life develop delirium, some have dementia, and others have limited ability to communicate due to intubation or neurologic disorders.

**PAIN ASSESSMENT IN THE COGNITIVELY IMPAIRED**

Several excellent reviews thoroughly describe tools used to assess pain in cognitively impaired older adults, primarily those with dementia (Table 109.2). Although many of these tools may be adapted to assess pain in the dying person with delirium or other disorders, none have undergone extensive testing in these populations.

PAIN ASSESSMENT IN THOSE UNABLE TO COMMUNICATE

One in five people who die in hospitals have used intensive care unit (ICU) services during their final hospitalization.\textsuperscript{61,62} In a large multicenter study of patients with serious illness, half of those who died during hospitalization had received ICU care.\textsuperscript{63} Thus, significant percentages of people with life-threatening illness will be admitted to the ICU prior to death. Yet, one in five patients in ICU lack decision-making capacity and are likely unable to accurately describe their pain.\textsuperscript{64} Furthermore, although a number of these patients may be cognitively intact, the use of mechanical ventilation often complicates pain assessment. Some patients may be able to use an NRS, VDS, or VAS, either by pointing to a chart with numbers or a line representing pain or by nodding “yes” when asked sequentially if pain is “mild,” “moderate,” or “severe.” For those patients who cannot use these techniques, several pain assessment tools have been developed to assess pain in the ICU, including the Behavioral Pain Scale\textsuperscript{65} and the Critical-Care Pain Observation Tool.\textsuperscript{66,67} For children, several tools exist, including the Faces, Legs, Activity, Cry, Consolability Observational Tool (validated in children 2 months to 7 years and tested in the ICU),\textsuperscript{68} Distress Scale for Ventilated Newborn Infants (tested in ventilated newborns), and the COMFORT Behavior Scale (tested in neonates to 3 years of age in ICU).\textsuperscript{69}

Although standardized instruments to measure pain at the end of life are needed, several principles can guide clinicians when patients are cognitively impaired and unable to report pain.\textsuperscript{58} Behaviors suggestive of pain should be evaluated, including the furrowed brow, guarding, or vocalizing on movement. Consider causes of pain, including the underlying disease and treatments, as well as new complications such as pressure ulcers, constipation, urinary retention, or infection. Ask family members or others who have known the patient if they observe changes in behaviors that might imply discomfort. If any of these indicators suggest that the patient may be in pain, initiate an analgesic trial and reassess. Resolution of the behaviors provides suggestive evidence that pain exists. Regular administration of the analgesic should then be included in the treatment plan.
PAIN MEASUREMENT IN RESEARCH CONDUCTED AT END OF LIFE

Research in pain at the end of life is hampered by lack of consistency in the use of valid and reliable pain measurement tools. An expert working group convened by the European Association of Palliative Care recommended standardized methods be applied in clinical trials and other pain studies in those with life-threatening illnesses. They recommended unidimensional tools such as the NRS, VAS or verbal rating scales, or, when indicated, multidimensional tools such as the BPI-Short Form or the McGill Pain Questionnaire.\textsuperscript{70}

Pain Management Strategies at End of Life

The principles employed in treating other patients in pain should be applied to the dying. These include the use of multimodal therapies based on the underlying pain mechanisms as determined by comprehensive assessment. Of particular challenge at the end of life is the need for alternate routes of administration and a plan of care when pain becomes intractable to standard therapies or adverse effects to the treatment become unmanageable.

ROUTES OF DRUG DELIVERY

Many patients can use the oral route until death. In one study, 43\% and 20\% of cancer patients were able to take oral opioids at 1 week and 24 hours before death, respectively.\textsuperscript{26} When oral delivery is no longer feasible, alternate routes of administration are available. Oral routes, including sublingual, transmucosal, and buccal delivery, as well as enteral, rectal, nasal, parenteral, spinal, topical, and transdermal routes, have all been employed.

Oral, Sublingual, Transmucosal, and Buccal Routes

When patients have difficulty swallowing pills but can take soft food, microsphere formulations of long-acting morphine or oxycodone provide sustained release when the capsule is broken open and the “sprinkles” are placed in applesauce or other soft food. Oral opioid solutions (e.g.,
morphine, oxycodone, hydromorphone, or methadone) can be swallowed or small volumes (0.5 to 1 mL) of a concentrated solution can be placed sublingually or buccally in patients whose swallowing abilities are limited. Nevertheless, buccal and sublingual uptake of these opioids is slow and not very predictable, particularly with more hydrophilic compounds such as morphine. Small studies suggest that most of the analgesic effect of morphine administered in this manner is due to drug dripping down the oropharynx and into the gastrointestinal tract. Conversely, absorption with the use of more lipophilic drugs, such as methadone and fentanyl, is relatively high. Immediate-release fentanyl products will be described in the following text. Topical morphine and methadone mouthwashes have been reported to treat chemotherapy-induced oral mucositis and might be useful for other pain syndromes associated with oral lesions.

**Transmucosal Immediate-Release Fentanyl Products**

Immediate-release fentanyl products are available as lozenges, sublingual tablets and sprays, and buccal tablets and film as well as nasal delivery. The lipid solubility of fentanyl allows more rapid onset when compared with hydrophilic compounds, making these products useful for breakthrough pain. All of these products are approved for patients who are already tolerant to opioids, and in general, the dose of the long-acting opioid does not predict the effective dose of the transmucosal agent. One major obstacle to the use of these products is their cost, limiting use in hospice or other capitated healthcare delivery systems.

In the United States, the U.S. Food and Drug Administration has instituted a Risk Evaluation and Mitigation Strategy (REMS) for transmucosal immediate-release fentanyl (TIRF) products. This program requires prescribers to enroll in the TIRF REMS Access Program after reading educational materials and completing a test knowledge focusing on safe use of these products. This program applies to transmucosal (buccal and sublingual) and nasal fentanyl products.

**Oral transmucosal, sublingual, and buccal fentanyl:** Oral transmucosal fentanyl citrate (OTFC) is a lipid-soluble (lipophilic) synthetic opioid formulation that consists of a lozenge on a stick. Patients must actively rub the fentanyl-containing lozenge against the oral mucosa.
to provide rapid absorption of the drug, usually experiencing some relief in 5 to 15 minutes, with a peak effect of 30 minutes.\textsuperscript{77,79,80} Too rapid application, usually less than 15 minutes, will result in more of the agent being swallowed rather than being absorbed transmucosally. Some patients develop oral candida due to the high sugar content of the compound, and others complain of the sweet taste and lack of variety in flavor, particularly with prolonged use. Xerostomia can reduce bioavailability of the agent and altered dexterity may complicate use.

Other transmucosal fentanyl products include fentanyl sublingual tablet (FST)\textsuperscript{81} and fentanyl sublingual spray (FSS)\textsuperscript{82} as well as fentanyl buccal tablet (FBT)\textsuperscript{83} and fentanyl buccal soluble film (FBSF).\textsuperscript{84}

These products are generally well tolerated and produce more rapid onset of analgesia when compared with immediate-release oral morphine. A randomized study compared FSTs with subcutaneous morphine in people with severe cancer breakthrough pain and found that more than 90\% of patients preferred the tablets.\textsuperscript{81} Few trials compare these fentanyl products for superiority. In one study, the rate and extent of fentanyl absorption were greater following FBT compared to OTFC, such that approximately 30\% less drug was required when administering FBT to achieve similar OTFC systemic drug levels.\textsuperscript{80}

**Nasal fentanyl:** Two nasal fentanyl preparations are accessible globally for breakthrough pain, intranasal fentanyl spray (INFS) and fentanyl pectin nasal spray (FPNS), although in the United States, only FPNS is available. Both of these delivery systems provide significant analgesia within 10 minutes.\textsuperscript{85,86}

**Enteral and Rectal**

Preexisting enteral feeding tubes can be used to deliver medications when patients cannot swallow at the end of life. It is rare that circumstances would require placement of a tube at this time, and doing so may send a contradictory message about the need for enteral nutrition and hydration. The size of the tube and volume of fluid used to mix the “sprinkles” formulation of morphine or oxycodone must be considered when delivering this form of long-acting opioid to avoid obstruction of the tube.\textsuperscript{87}
Opioids can be delivered via the rectal route using commercially prepared suppositories, compounded suppositories, or microenemas. Studies suggest a larger area under the curve when morphine suppositories are used when compared with oral sustained-release morphine. Sustained-release morphine tablets have also been used rectally, with resultant delayed time to peak plasma level and approximately 90% of the bioavailability achieved by oral administration. Rectal methadone can be used safely and has bioavailability approximately equal to oral methadone. Neutropenia and thrombocytopenia are generally considered contraindications to rectal drug administration, but clinicians must consider the goals of care for delivering these drugs as well as the risks and benefits at this time of life. Painful rectal lesions, such as hemorrhoids or fissures, preclude the use of these routes. Attempting to place agents rectally at home may be difficult for family members when caring for loved ones who cannot move or reposition without significant assistance.

**Parenteral**

Parenteral administration includes intravenous and subcutaneous delivery of drug. Intramuscular opioid delivery is inappropriate in the palliative care setting due to the pain associated with this route and the variability in systemic uptake of the drug. Intravenous administration of drugs is often used when patients are hospitalized at end of life, as this route provides rapid and predictable drug delivery. For patients being cared for at home, the need for vascular access may be cumbersome. Subcutaneous infusions, including morphine, hydromorphone, and fentanyl, provide an effective and safe alternative. Methadone has been reported to cause local site irritation, although small case reports suggest that lower doses given intermittently are less likely to cause pain. Subcutaneous boluses of morphine have a slower onset and lower peak effect when compared with intravenous boluses, although with continuous infusions they provide similar blood levels and resultant pain relief. Subcutaneous infusions may include up to 10 mL per hour, although most patients absorb 2 to 3 mL per hour with the least difficulty. Volumes greater than 10 mL per hour are often poorly absorbed and can lead to pain or leakage of fluid.
Hyaluronidase has been reported to speed absorption of subcutaneously administered fluids, although a randomized trial yielded no difference in pain or edema between treatment and placebo groups.\textsuperscript{95} Despite these findings, these investigators and others suggest that hyaluronidase may have utility when subcutaneous absorption is not well tolerated.

**Spinal (Epidural/Intrathecal)**

Intraspinal routes, including epidural or intrathecal delivery, allow administration of drugs such as opioids, local anesthetics, and/or \( \alpha \)-adrenergic agonists more proximate to their respective effector sites.\textsuperscript{96,97} A randomized controlled trial demonstrated benefit for ambulatory cancer patients with a life expectancy of at least 3 to 6 months experiencing pain.\textsuperscript{98} However, initiating this therapy during the final hours of life requires the availability of experts to place an external catheter as well as caregivers with specialized knowledge to safely and effectively provide care. As with all therapies, the potential risks, including greater caregiver burden, need to be weighed against the benefits. Intraspinal delivery may be considered when patients do not obtain adequate relief from aggressive titration of systemic opioids and other analgesics or they experience intolerable adverse effects. A systematic review of spinal opioids in cancer pain found only weak evidence to recommend this therapy.\textsuperscript{99} More information regarding the use of intraspinal drug delivery is available in Chapter 100.

**Topical**

Topical morphine administration to open areas, such as pressure ulcers, burns, malignant skin lesions, and ulcers associated with venous stasis or sickle cell disease, has been reported to be effective in case reports and open-label trials.\textsuperscript{100–102} However, a randomized controlled trial of topical morphine used to treat painful skin ulcers found no benefit when compared with placebo.\textsuperscript{103} An analysis of the bioavailability of morphine when delivered to open ulcers found little systemic uptake, a possible explanation for the lack of efficacy.\textsuperscript{104} Topical morphine applied to the wrist in a pluronic lecithin organogel (PLO) base for systemic delivery is being used in some settings; yet, evidence of its efficacy is lacking. A
bioavailability study of topical morphine in healthy volunteers revealed that morphine was seldom detected in plasma samples after topical administration, and when values were detected, they were below the level of quantification.\textsuperscript{105} These results suggest that topical administration of morphine compounded in a PLO base for topical drug delivery is unlikely to provide relief of pain.

**Transdermal**

Transdermal fentanyl has been used extensively, and a wide range of dosing options (ranging from 12- to 100-µg-per-hour patches) makes this route particularly useful in cancer pain and palliative care.\textsuperscript{106} Most individuals experience relief for 3 days, although approximately 25% of patients will consistently report increased pain on the third day, despite adequate use of breakthrough medications. These patients benefit from changing the patch more frequently (every 48 hours). Equianalgesic dosing with other opioids has been unknown; a recent study suggests that a 100-µg patch is approximately equivalent to 240 mg of oral morphine equivalents.\textsuperscript{107} Fentanyl is another option when considering opioid rotation, and several reports suggest the resolution of delirium when patients are converted from other opioids to transdermal or intravenous fentanyl.\textsuperscript{108,109} Fever, diaphoresis, cachexia, morbid obesity, and ascites may have a significant impact on the absorption, predictability of blood levels, and clinical effects of transdermal fentanyl, although studies are lacking. There is some suggestion in open-label and retrospective studies that transdermal fentanyl may produce less constipation than long-acting morphine.\textsuperscript{106,110} A small subset of patients will develop skin irritation due to the adhesive in any patch. Because most topical antihistamines consist of an oil base which would prevent patch adherence, the use of an aqueous based steroid inhaler (intended for the management of asthma) applied prior to patch administration can preclude skin reactions and allows the patch to remain in place.

**INTRACTABLE PAIN OR UNMANAGEABLE ADVERSE EFFECTS OF TREATMENT**

Although most pain at end of life can be well managed with available
therapies, intractable pain or unmanageable adverse effects can occur that can lead to incredible suffering. In some cases, pain escalates due to rapidly increasing disease burden. At other times, pharmacokinetics of the opioids and other analgesics are altered by organ dysfunction associated with the dying process, leading to inadequate relief.

**Effect of Organ Dysfunction on Pharmacokinetics**

Organ dysfunction at the end of life will alter the absorption, distribution, metabolism, and elimination of analgesic agents, thereby influencing the efficacy of the drug. People with advanced malignancy or other life-threatening illness may undergo changes in any of these phases as a result of extensive disease. Little is known about the alterations in absorption of opioids that occur when people are dying. Factors such as shortened gastrointestinal transit time may delay absorption of oral opioids, particularly long-acting or sustained-release compounds.

Distribution of the drug is in part dependent on plasma proteins within the vasculature, body fat stores, and total body water. These can all be significantly altered in patients who are cachectic and dehydrated at the end of life. Aging patients are known to have decreased volume of distribution of morphine and fentanyl. Additionally, methadone binds avidly to $\alpha_1$ glycoprotein, which is increased in advanced cancer. This leads to decreasing amounts of unbound methadone and a delayed onset of analgesic effect.

Metabolism of drugs can be changed by advanced age, liver dysfunction, and other factors that are widespread in palliative care. Excretion can be altered as renal failure occurs, particularly because most opioids, with the exception being methadone, are primarily excreted by the kidneys. Patients with renal failure or those receiving dialysis might benefit from the use of agents that are more readily dialyzable, such as fentanyl, as opposed to morphine or codeine. Research is needed regarding the effect of advanced disease and the dying process on the pharmacokinetics of analgesics, particularly opioids.

**Myoclonus**

One consequence of altered pharmacokinetics at the end of life is the
development of myoclonus. Myoclonus is a sudden, uncontrollable, nonrhythmic jerking of the extremities. This can be extremely distressing, causing fatigue and sleep disruption and exacerbating the patient’s pain. Furthermore, myoclonus can progress to the development of uncontrolled seizures.\textsuperscript{113} Myoclonus has been reported to occur after surgery to the brain,\textsuperscript{114} in acquired immunodeficiency syndrome,\textsuperscript{115} after hypoxia,\textsuperscript{116} and after chlorambucil administration.\textsuperscript{117} However, myoclonus at end-of-life care is most commonly associated with opioids. Controversy exists regarding whether this is dose dependent and how much of this effect is from parent drug versus metabolites. Most reports of opioid-related myoclonus implicate higher doses, although it has been reported to occur in patients receiving low doses of opioids, particularly hydromorphone.\textsuperscript{118,119} Other opioids that have been implicated include methadone\textsuperscript{120} and fentanyl.\textsuperscript{121} Myoclonus has also been reported during withdrawal from transdermal fentanyl.\textsuperscript{122,123}

The underlying mechanism of opioid-induced myoclonus is poorly understood. Myoclonus and seizures have been reported to occur in patients receiving high-dose morphine or hydromorphone administration.\textsuperscript{124} However, Fainsinger and colleagues\textsuperscript{125} describe a case of myoclonus occurring with stable hydromorphone dosing in the face of acute renal failure. A retrospective chart review found that in terminally ill patients receiving parenteral hydromorphone, the dose and duration of drug were associated with the development of myoclonus, whereas age, gender, and diagnosis were not.\textsuperscript{126} These findings point to the role of accumulating neuroexcitatory metabolites that are poorly excreted either due to prolonged dosing, high doses, or concomitant renal failure. The 3-glucuronide metabolites are implicated as contributing to these neuroexcitatory effects.\textsuperscript{127} Both morphine-3-glucuronide (M3G) and hydromorphone-3-glucuronide (H3G) are believed to produce excitatory behaviors, including myoclonus, allostynia, and seizures. In a study of cancer patients who developed allodynia and myoclonus during morphine infusions, M3G levels were elevated.\textsuperscript{124} Case reports suggest that M3G and H3G plasma levels are greatly increased in the presence of renal failure, with the ratio of metabolite to parent compound four times higher than the ratio seen in patients with normal renal function.\textsuperscript{128,129} However,
one prospective study found no relationship between myoclonus and renal function. In rodent models, H3G has more potent neuroexcitatory effects when compared with M3G. However, a pilot study of people in hospice receiving morphine and experiencing myoclonus revealed no elevation in M3G levels.

Regardless of the underlying cause, treatment is imperative. The goal is to significantly reduce the dose of the opioid, and this is usually accomplished by rotation to an alternate opioid. Methadone has been used as an alternative agent with success, although other opioids may be easier to titrate and methadone also has been found to produce myoclonus. Other strategies include adding adjuvant analgesics and using interventional techniques (e.g., spinal drug administration, nerve blocks) to potentially reduce the amount of total systemic opioid. Ketamine has been suggested as beneficial to rapidly reduce systemic opioid dose. Little research is available regarding agents used to reduce myoclonic jerking. Benzodiazepines, including clonazepam, diazepam, and midazolam, have been recommended. The mechanism of action of benzodiazepines is through binding to γ-aminobutyric acid type A (GABA_A) receptors within the central nervous system, leading to central nervous system depression. At higher doses, benzodiazepines may also limit repetitive neuronal firing, similar to several anticonvulsant compounds. Clonazepam may be useful in patients who can swallow, with doses starting at 0.5 to 1 mg by mouth every 6 or 8 hours, with upward titration as needed. Lorazepam tablets or solution can be placed sublingually if the patient is unable to swallow. Lorazepam and midazolam can be administered parenterally and are often indicated during the final hours of life.

**Intractable Pain at End of Life**

When pain is poorly managed despite aggressive titration of available therapies, several other options can be employed. First, thorough assessment is needed to rule out potentially reversible etiologies. Because the pain demands immediate attention, titration of the opioid therapy must be aggressive while carefully preventing and treating adverse effects. Additional therapies should be considered, such as corticosteroids, local
anesthetics, ketamine, and other therapies. Bringing in a team approach is crucial, including experts in pain and palliative care, as well as chaplains, social workers, psychologists, and others, to address patient and family suffering. When these interventions are unsuccessful, palliative sedation may be considered.

Intravenous Lidocaine
Systemic administration of local anesthetics, such as lidocaine, has been used to treat chronic pain. At subanesthetic doses, lidocaine blocks neuronal function in active or depolarized neurons without interfering with the normal function of other sensory or motor neurons. Although historically used as a monthly infusion in chronic pain clinics, similar protocols have been adapted for use in patients at end of life with intractable pain. The dosage is generally 1 to 3 mg/kg administered intravenously over 20 to 30 minutes. During the bolus infusion, pain intensity scores often decline significantly. If effective, a continuous infusion of 1 to 3 mg/kg/hour will be initiated. Immediate signs of toxicity include numbness around the lips or a sensation of thickness of the tongue. Due to the short half-life of lidocaine, the symptoms of toxicity are transient and easily reversible by lowering the infusion rate. However, toxicity has been reported at very low doses of lidocaine.

In concert with the goals of care at this time of life, cardiac monitoring is not usually performed nor are plasma levels of lidocaine obtained. If subcutaneous administration is indicated due to lack of venous access, the initial loading dose is administered over a longer time period (30 minutes to an hour) and the response may be delayed by a few minutes. If subcutaneous infusion is elected, more concentrated lidocaine solutions allow for lower volumes to be infused. If the bolus dose is ineffective or toxicity is unmanageable, the lidocaine challenge is discontinued and other pain relief modalities must be selected.

The lidocaine infusion technique has been reported to be effective in a child with cancer, using 35 μg/kg/min initially, with an increase to 50 μg/kg/min after several days. Other case reports suggest the efficacy of continuous intravenous lidocaine in pediatric patients with opioid-resistant cancer pain. The only randomized controlled trial of intravenous
lidocaine for neuropathic pain from cancer using 5 mg/kg over 30 minutes found no difference in analgesia.\textsuperscript{146} Much more research in this particular area is needed.

**Ketamine**

Ketamine is an N-methyl-D-aspartate antagonist that can be given by a variety of routes: oral, intravenous, subcutaneous, intranasal, sublingual, epidural, intrathecal, and topical. It has been reported to improve pain relief and reduce opioid requirements in a variety of pain syndromes associated with cancer and other life-threatening illnesses.\textsuperscript{147–149} Although it can be used earlier in the course of the disease trajectory, ketamine is most commonly trialed in the face of intractable pain at the end of life.

In a small (n = 10) study of cancer patients who reported pain unrelieved with morphine, a slow bolus of ketamine (0.25 mg/kg or 0.50 mg/kg) was evaluated using a randomized, double-blind, crossover, double-dose design. Ketamine, but not saline solution, significantly reduced the pain intensity in almost all the patients at both doses, with the greatest effect being in those treated with higher doses. Adverse effects included hallucinations in 4 patients and an unpleasant cognitive sensation in 2 patients. These adverse effects responded to diazepam 1 mg intravenously. Drowsiness was also significantly more likely to occur, particularly with the higher dose. The investigators concluded that ketamine improved morphine analgesia in a variety of difficult pain syndromes; yet, central adverse effects can limit the use of this therapy.\textsuperscript{149}

A study of young children and adolescents who were on high doses of opioids and had uncontrolled cancer pain examined the effect of adding a low-dose ketamine infusion. In 8 of 11 patients, ketamine infusions used as an adjuvant to opioid analgesia provided improvement in pain and was associated with opioid-sparing effects. This allowed reduction in opioid dose that ultimately improved social interaction during this important time.\textsuperscript{150}

The usual oral dose of ketamine is 10 to 15 mg every 6 hours. Because oral preparations are not commercially available in the United States, the solution used for injection is administered orally, usually mixed with juice or cola to hide the unpleasant taste. Parenteral dosing is typically 0.04
mg/kg/hour with titration to a maximum of 0.3 mg/kg/hour. When given parenterally or orally, the onset of analgesia is 15 to 30 minutes with a duration of effect ranging between 15 minutes and 2 hours. A general recommendation is to reduce the opioid dose by approximately 25% when starting ketamine to avoid sedation. Severe side effects are generally associated with doses of parenteral ketamine above 0.5 mg/kg and include psychotomimetic phenomena such as dysphoria, nightmares, hallucinations, excessive salivation, and tachycardia.

Although there are many small trials and case series that suggest efficacy from ketamine, a well-designed randomized controlled trial found no benefit. An updated Cochrane review concluded that there was insufficient evidence to conclude that ketamine improves the effectiveness of opioid treatment in cancer pain. Clearly, more research in this area is needed.

**Fears of Hastening Death**

Pain at the end of life may be poorly managed due to fears of causing respiratory depression. This is particularly true when family members administering opioids at home express fear about causing their loved one’s death. It can also occur in institutional settings where clinicians are uncomfortable ordering or administering therapeutic doses of drugs. Clinicians and family members also fear “giving the last dose” of an opioid. Education is desperately needed. Respiratory depression is rare in palliative care as most patients are opioid tolerant. A study of cancer patients undergoing parenteral opioid titration for severe pain revealed no change in end-tidal carbon dioxide, oxygen saturation, or respiratory rate. Sykes and Thorns evaluated 17 studies that examined the use of opioids at end of life. None of the five studies that explored opioid use and survival found any relationship. Their own earlier study also found no relationship between the dose or the timing of the opioid administration and the time of death. These authors conclude that the doctrine of double effect, which suggests it is ethical to employ a treatment intending to obtain its beneficial effect (e.g., analgesia) but at the same time recognizing that it may also have harmful effects (e.g., respiratory depression or death), is not relevant. They also argue that it is potentially
harmful to invoke this doctrine as it potentiates a myth: one that can lead to greater fear and unrelieved pain. A study from the National Hospice Database reported similar result: The dose of opioid had no appreciable impact on the timing of death in patients with far-advanced disease.\textsuperscript{156} Several other reviews found a similar lack of association between opioid doses or timing with survival.\textsuperscript{157,158}

**Suffering and Existential Distress**

It may be very difficult to distinguish pain from other causes of suffering in dying patients.\textsuperscript{159} Although the trend toward greater attention to pain is positive, there is frequently little attention to the role loss, burden, sadness, fear, isolation, and other existential concerns that can play at this time of life.\textsuperscript{160} Several studies support the need for more useful definitions and distinctions and to address the role of suffering in the individual’s life. For example, one study asked hospice patients about suffering in an open-ended interview, revealing that in the views of the 100 patients included in this study, relief of pain and relief of suffering are not the same.\textsuperscript{161} Another study of health care professionals revealed that suffering was viewed quite differently by chaplains, who defined this in spiritual terms, versus pain professionals, who placed existential issues in the context of pain.\textsuperscript{162}

Using semistructured interviews, 381 patients with advanced cancer were asked if they felt they were suffering and were also asked about physical symptoms, social concerns, psychologic problems, and existential issues. Approximately 25\% reported they were suffering at a moderate-to-extreme level. This suffering was strongly correlated with general malaise, weakness, pain, and depression. Thus, although many patients with advanced cancer do not consider themselves to be suffering, for those who are suffering, it is a multidimensional experience related most strongly to physical symptoms but with contributions from psychologic distress, existential concerns, and social-relational worries as well.\textsuperscript{163} The consequences of unresolved suffering are great, including a wish for hastened death. In a study of 96 terminally ill elders, 15 acknowledged significant suffering that resulted in a wish for a hastened death, and several had even considered strategies to accelerate the dying process. In
analyses of the interviews of these individuals, four critical themes emerged: perceived insensitive and uncaring communication of a terminal diagnosis by their health care professional, experiencing unbearable physical pain, unacknowledged feelings regarding undergoing chemotherapy or radiation treatment, and dying in a distressing environment.\textsuperscript{164}

Assessment of the whole person should be multidimensional, and an interdisciplinary team is best equipped to address these broad issues. In addition to a thorough pain and symptom assessment, patients should be asked about the meaning of their lives, their sense of hope, the goals they have for this time of their lives, and whether they are suffering. Suffering is a deeply personal experience, accompanied by a wide range of emotions and meanings.\textsuperscript{159} Inadequate assessment that only equates pain with suffering can lead to inappropriate increases in opioids, without benefiting their existential concerns, while leading to increased toxicity.\textsuperscript{165}

When patients are identified as experiencing suffering, several interventions can be useful. Life review allows the individual to reminisce about life experiences, often leading to self-discovery of meaning in the contributions they have made. Some people benefit by developing letters or videotapes to loved ones to be read at a later date during anticipated landmark events in the loved one’s life, such as college graduation, marriage, or the birth of a child. One novel model to address psychosocial and existential distress in the dying is called dignity therapy.\textsuperscript{166,167} This brief, individualized approach to end-of-life care allows patients to discuss issues that are most important to them and to describe the things they would most want remembered as death draws near. These discussions are recorded, transcribed, and developed into a document, which can be given to family or loved ones. In one study of people with advanced cancer, 76% reported a heightened sense of dignity, 68% reported an increased sense of purpose, 67% reported a heightened sense of meaning, and 47% reported an increased will to live.\textsuperscript{168} Family perceptions were also positive, with the majority stating that the document developed by the dying loved one helped during the grieving process and that the document would continue to be a source of comfort for their families and themselves.\textsuperscript{169} Those who are suffering often feel voiceless and having professionals witness and
listen to their concerns in an empathic manner can be extraordinarily therapeutic.

**NONPHARMACOLOGIC TECHNIQUES**

Nonpharmacologic therapies can be particularly useful during the final hours of life. Cognitive-behavioral techniques, physical measures, and education can be used as part of the multimodal treatment plan to reduce pain and suffering, although few have been tested in end-of-life care. The patient’s and caregivers’ abilities to participate must be considered when selecting any of these therapies, including their fatigue level, interest, cognition, and other factors. Cognitive-behavioral techniques include guided imagery, meditation, hypnosis, music and art therapy, and other complementary therapies.

Physical measures, including massage, reflexology, heat, and other techniques, can produce relaxation and relieve pain. In a small study of massage in hospice patients, reductions in blood pressure, heart rate, and skin temperature were noted, suggestive of a relaxation effect. A potential benefit of all of these therapies is the ability to include family members who are often seeking methods to provide comfort to their loved one.

Family involvement in all aspects of care is crucial. Family caregivers who rate their self-efficacy, or their ability to care for their loved one, as high report much lower levels of strain as well as decreased negative mood and increased positive mood. Ultimately, the caregiver’s self-efficacy in managing the patient’s pain related to the patient’s physical well-being. In dyads where the family caregiver perceived higher self-efficacy, the patient reported having more energy, feeling less ill, and spending less time in bed. As a result of these findings, Keefe and colleagues developed a partner-guided pain management training intervention that they tested in 78 advanced cancer patients who met criteria for hospice eligibility. Patients and their partners were randomly assigned to the intervention or to usual care as the control condition. The partner-guided pain management training protocol consisted of educational information about cancer pain with systematic training of patients and partners in cognitive and behavioral pain coping skills delivered in the patients’
homes over three sessions. The partner-guided pain management protocol significantly increased partners’ ratings of their self-efficacy for helping the patient control pain and other symptoms. These family caregivers also showed a trend toward reduced levels of caregiver strain.\textsuperscript{185}

Although case reports and open-label trials of cognitive-behavioral, physical measures, and educational interventions are reported to be very effective in relieving symptoms at end of life, more research is needed.\textsuperscript{170,186} Furthermore, most existing research has been conducted in patients early in the disease trajectory, so more research is needed to determine the potential value, no less the feasibility, of these interventions in the final days and hours of life.

Palliative Sedation

Although the majority of individuals with pain at the end of life can obtain relief with available therapies, some dying patients experience distressing symptoms that cannot be controlled. In these cases, palliative sedation may be considered. Several steps are crucial when implementing palliative sedation. First, the team must be confident that all other reasonable options have been explored, the disease is irreversible, and that death would be expected in hours to days.\textsuperscript{187} Second, the patient and family should be carefully informed about the risks and benefits of sedation, and they should provide informed consent and agree with these plans. The entire team (physicians, nurses, respiratory therapy, chaplains, social workers, and others involved in the patient’s care) must have the opportunity to discuss this option and agree as a team about the justification for the use of palliative sedation and the details of the care to be provided. These are generally complex cases that are emotionally stressful. All involved can benefit from talking about the complex medical, ethical, and emotional issues they raise. Decisions about hydration and nutrition as well as resuscitation status (most centers require that the patient has do not resuscitate orders) should be made prior to initiating sedation. Sedation may be delayed if the patient is awaiting the arrival of a family member from out of town. In some cases, light sedation may be used and reversed once the relative arrives and then restarted and increased once the patient
and loved one have had time to say goodbye. The American Academy of Hospice and Palliative Medicine offers a position statement to guide clinicians when opting to initiate palliative sedation.\textsuperscript{188}

The agent most commonly employed drug for palliative sedation is midazolam, although other benzodiazepines, propofol, or barbiturates can be administered (Table 109.3).\textsuperscript{187} Benzodiazepines have anxiolytic, muscle relaxant, sedative-hypnotic, anticonvulsant, antiemetic, and amnesic effects. Their mechanism of action is through binding to GABA receptors within the central nervous system leading to central nervous system depression. Midazolam is the shortest acting agent within this class, with an onset of action within 3 to 5 minutes after intravenous injection and a half-life of 1 to 4 hours. These attributes, rapid onset and relatively short duration, as well as the ability to administer it either intravenously or subcutaneously makes this a useful drug in instituting palliative sedation. Furthermore, it is stable with most other agents but is incompatible with corticosteroids such as dexamethasone, betamethasone, or methylprednisolone.

\begin{table}[h]
\centering
\begin{tabular}{|l|l|l|l|}
\hline
\textbf{Drug} & \textbf{Route} & \textbf{Bolus Dose} & \textbf{Continuous Infusion} \\
\hline
Midazolam & IV, SQ & 5 mg & Starting dose 1 mg/h; usual maintenance dose 20–120 mg/h \\
\hline
Lorazepam & IV, SQ, SL, PO & 0.5–2 mg PO, SL every 1–2 h; 2–5 mg SQ or IV & Starting dose 0.5–1.0 mg/h; usual maintenance dose 4–40 mg/h \\
\hline
Chlorpromazine & PO, IV, PR & 10–25 mg every 2–4 h & \\
\hline
Haloperidol & PO, IV, SQ & 0.5–5 mg PO every 2–4 h; 1–5 mg IV/SQ bolus & Starting dose 0.2 mg/h; maintenance 0.2–0.6 mg/h \\
\hline
Thiopental & IV & 5–7 mg/kg/h & 20–80 mg/h \\
\hline
Pentobarbital & IV & 2–3 mg/kg & Starting dose 1 mg/kg/h; titrate upward as needed \\
\hline
Phenobarbital & IV, SQ & 200 mg, can repeat & 25 mg/h; maintenance dose 25–66 mg/h \\
\hline
\end{tabular}
\caption{Doses of Agents Used in Palliative Sedation\textsuperscript{189,197}}
\end{table}
Propofol is an intravenous nonbarbiturate thought to enhance the activity of GABA. The advantages of propofol include rapid onset and short half-life. Although studies are lacking, the recommended dose of propofol to treat refractory pain/suffering is 1 to 2 mg/kg via intravenous injection over 5 minutes. The bolus may need to be repeated if the first injection is ineffective. Bolus doses are followed by a maintenance intravenous infusion of 2 to 10 mg/kg/hour, using the lowest dose needed to suppress symptoms. Propofol is recommended for intravenous administration; subcutaneous delivery has not been studied. Propofol contains soybean oil and egg yolk phospholipid and therefore is contraindicated for use in patients with egg hypersensitivity or soya lecithin hypersensitivity.

Family members must be provided sufficient information and support during this time. In a multicenter study conducted in Japan, bereaved family members of cancer patients who received sedation in seven palliative care units were surveyed. The families reported that 69% of the patients were considerably or very distressed before sedation. Although the majority of families were satisfied with the treatment, 25% expressed a high level of emotional distress. The factors associated with high levels of family distress were poor symptom control after sedation, feeling the burden of responsibility for the decision, feeling unprepared for changes in the patient’s condition, feeling that the physicians and nurses were not sufficiently compassionate, and a shorter time to their loved one’s death. Regular monitoring of patient distress with timely modification of the sedation protocol is vital, as is providing sufficient information and sharing the responsibility for the decision. Family members require emotional support to assist with their anticipatory and ongoing grief, although a recent observational study found no negative impact on the well-being of loved ones after witnessing palliative sedation. As the use of palliative sedation increases, guidelines should be developed across
settings and disciplines to ensure consistency. These guidelines must articulate that this therapy is not euthanasia but is rather directed toward treatment of symptoms.

Conclusion

The relief of pain during the final phase of life is vital for both the patient who is experiencing this pain and for those at the bedside witnessing this distress. All clinicians have the responsibility to learn how to assess pain in the cognitively impaired and how to employ effective pharmacologic and nonpharmacologic treatments. Empathic listening with attention to suffering and existential distress will help improve the quality of life of the dying. When pain remains severe, despite aggressive use of all appropriate options, the team must carefully consider the use of palliative sedation, along with the patient and their loved ones. All of this care involves the skills of a well-functioning interdisciplinary team, combining the expertise of each individual to provide optimal care to the most vulnerable of all of our patients.

CHAPTER 110

Ethical Principles that Support Decision Making in Pain Management: The Case of Stopping Opioids

FAYE M. WEINSTEIN, CLAUDIA KOHNER, and STEVEN H. RICHEIMER

New findings about long-term opioid use, as well as the new Centers for Disease Control and Prevention (CDC) Guidelines for Prescribing Opioids for Chronic Pain,¹ are encouraging physicians to consider tapering or weaning opioid treatment for chronic pain patients.²,³ This process of weaning opioids can be difficult for both the patient and the physician. The physical difficulties are addressed elsewhere, but the ethical and emotional difficulties are rarely discussed. Although there is information in the literature about ethical considerations and establishing trust with a patient when starting a patient on opioids,⁴ we also need to understand the issues involved in stopping opioid medication in a manner that maintains physician–patient trust and ethical practice. Using a practical framework to address these ethical and emotional issues can help the physician avoid missteps that may result in disruption to the physician–patient relationship and may lead to unwanted results, such as patient lack of receptivity to other treatment options, patient difficulty with the titration regimen, and/or patient dissatisfaction.

Background

Gunderman,⁵,⁶ a physician who writes on the ethics of the business of medicine and leadership in medicine, has used Erik Erikson’s ideals as a platform for his formulations. Erikson is credited with contributions to the
fields of psychology, religion, and ethics. Erikson’s version of the Golden Rule includes a “concern with universal justice and respect for the other, where every person deserves recognition and mutual regard.”

Following Gunderman’s lead, the authors of this chapter use Erikson’s ethical theory to help guide the physician–patient relationship during opioid cessation. Case vignettes of physicians taking patients off opioid medication, along with analyses of the vignettes, are presented in order to guide the reader in ethical analysis grounded in Erikson’s ethical theory. Tools for building mutuality in the physician–patient relationship are also covered.

MEDICAL ETHICS AND ERIKSON’S GOLDEN RULE
Medical ethics is typically discussed in terms of autonomy, beneficence, and justice. The authors of this chapter believe that Erik Erikson’s approach will provide a more practical framework.

Erikson presented his theory of the Golden Rule at the George W. Gay Lecture Upon Medical Ethics, at Harvard Medical School on May 4, 1962. Erikson’s reformulation of the Golden Rule emphasizes mutuality between the physician and patient. For Erikson, medical ethics involves not only rational decision making but also ideals related to a higher good. Ethical acts are grounded in a sense of justice, a universal sense of responsibility toward all human beings, and the need for mutual respect and recognition. Erikson emphasized partnership and mutuality in the physician–patient relationship, which provide the opportunity for growth in both the physician and patient and bidirectional trust between physician and patient. For Erikson, the Golden Rule encourages that “it is best to do to another what will strengthen you even as it will strengthen him—that is, what will develop his best potentials even as it develops your own.”

Two primary elements of Erikson’s Golden Rule are trust and mutuality. Investigating an ethical approach to a medical decision to stop the use of opioids begins with an understanding of these components of ethical practice.

TRUST
According to Erikson, over an individual’s life span, an “individual
develops the propensity for ethics as he passes through eight (developmental) stages." Developmental experiences in infancy involving trust with caregivers form the bedrock on which the later seven psychosocial stages will be experienced. To develop a sense of trust, infants must be able to count on their caregivers to feed them, soothe them, arouse or quiet them when needed, and mirror smiles and babbles. In an optimal environment, the infant learns that the world is generally a safe and consistent place and that people are mostly “good.” The infant gains the strength of “hope,” which is the perception that, even if there is waiting, one’s needs will be met and other people can be relied on to be responsive to the one’s needs. Over the life span, trust is transformed and provides a guiding principle for daily life and relationships with others.

However, people with less optimal early lives may learn that their needs will not be met and that people are unreliable; these individuals may develop mistrust in their relationships as adults. Chronic pain patients may have a greater likelihood of histories of early challenges in developing trust and, therefore, go through life burdened with vulnerability to mistrust.

Trust is one of the central features of the physician–patient relationship. Sass, a philosopher and ethicist, states that “trust becomes the overriding principle and virtue that establishes and safeguards all expert-lay interactions, particularly in the clinic.”

Patient trust in a physician manifests as the expectation that the physician will behave in a way that makes it safe for the patient to take the risk of sharing personal information. Dimensions of physician behavior on which patients are believed to base their trust in their physician are “competence, compassion, reliability and dependability, and communication.” Pearson and Raeke identify the importance of interpersonal trust, the trust built through repeated interactions with a physician within which the patient learns over time that his or her needs will be met in a predictable and consistent way despite changes in the medical environment that may threaten trust.

O’Neill also describes trust building as a dynamic activity and views physician trust as a partnership. Physician trust in a patient is not only determined by the trustworthiness of the patient but can also be influenced
by external factors, including media events, current research, racial bias,\textsuperscript{21,22} practices of colleagues, and the physicians’ own experiences.\textsuperscript{23} With each patient, the physician’s trust is based on the assumption that the patient’s motive is pain reduction and improvement in function and that the patient is truthful in his or her self-report of symptoms and prior treatment. Trust is confirmed via observation of patient adherence to a treatment plan, patient efforts at participation in treatment, and prompt patient communication with the physician if problems arise.\textsuperscript{4}

**MUTUALITY**

According to Erikson,\textsuperscript{10}(p231) the relationship between the parent and the infant involves mutuality, which is a bidirectional process by which the “partners depend on each other for the development of their respective strengths.” Relevant to the focus of this chapter, Erikson\textsuperscript{10}(p231) asserts, “The fact is that the mutuality of adult and baby is the original source of hope, the basic ingredient of all effective as well as ethical human action.” The parent tries to understand the variety of needs in the child in regard to soothing, eating, sleeping, and elimination. Parent and infant work to read each other’s signals and to learn to regulate the amount of time that passes between the expression of the need and satisfaction of the need. The work of creating mutuality of interaction and communication is characterized as a process of coordination, mismatch, and repair.\textsuperscript{24} Mutuality emerges from patterns of physical (e.g., eye gaze, proximity, offering food), verbal (patterns of speaking/vocalizing and responding), and affective (e.g., smiling) expressions. Erikson\textsuperscript{10} emphasized that through mutuality, the parent reinforces his or her own sense of trust or revisits issues of mistrust. Thus, mutuality is the focus on the relationship with others that becomes a source of information about one’s identity and interactions with others.

Over the life span, mutuality is not exclusive to parent–child relationships but manifests in different types of adult relationships, where mutuality means “personal recognition, joint work, effective communication, and understanding and respect for each other’s roles.”\textsuperscript{25}(p741)

**MORALS AND ETHICS**
Erikson\textsuperscript{10} differentiated between morals and ethics, with ethics emerging developmentally later than morals. In early life, the child not only learns to trust whether needs will be met and comfort will be given. She or he also learns that caregivers are a source of limit setting. The child internalizes these prohibitions, forming the basis of morals, which are identified as behaviors based on fear of consequences, such as “threats of abandonment, punishment and public exposure, or a threatening inner sense of guilt, of shame or of isolation.”\textsuperscript{10(p222)} In adolescence, an individual starts to transition from moral to ethical behavior, with behaviors and relationships based on rigid ideas and ideologic devotion (e.g., “all my friends do this”). Finally, in adulthood, the individual can become less ruled by rigid ideals and becomes more able to act and relate to others on the basis of individual worth and dignity. According to Erikson,\textsuperscript{10} this is the development of the “ethical sense.”

Erikson’s distinction between morals and ethics resonates with Smith and Newton’s\textsuperscript{26} three-phase evolution of physician ethics. According to these authors, the Hippocratic Oath was the initial structure for the physician–patient relationship with the “notion of authority,”\textsuperscript{26(p47)} or paternalism, toward the patient. Following a cultural shift to individualism, the focus of ethical inquiry turned to patient autonomy, the second phase in Smith and Newton’s\textsuperscript{26} three-phase evolution of physician ethics. This led to rigid moral rules and formulas for the physician to follow in a heightened climate of the protection of patient rights. Smith and Newton\textsuperscript{26} consider this era as the “essential formative period”\textsuperscript{26(p44)} for the emergence of the third phase in their three-phase evolution of physicians ethics, one that is focused less on applying rules and more on valuing “mutuality,”\textsuperscript{26(p56)} “reflective experience,”\textsuperscript{26(p56)} and “goals of human dignity and dialogue”\textsuperscript{26(p56)}—concepts in line with the foci of this chapter.

Erikson’s ethical sense has particular relevance when tested during crises in which interactions with others trigger earlier psychosocial tensions about trust. A physician-initiated cessation of a chronic pain patient’s opioid prescription is potentially such a crisis. At this medical juncture, issues of trust, mutuality, and the ethical sense are salient for both patient and physician.

With its focus on trust and mutuality, Erikson’s Golden Rule can serve
as the ethical foundation for the navigation of the medical crossroad of cessation of opioid prescription in chronic pain patients. It provides a way to find resolution to the tension that arises in this situation, to manage the dynamic activity of trust, to build a partnership, and to promote mutual growth.

Case Vignettes and Analysis

Three cases—each involving a type of challenge faced by physicians who deal with cessation of opioid use for chronic pain patients—are presented and evaluated to assess whether Erikson’s tenets of trust and mutuality in his concept of the Golden Rule are evident or absent and whether the physician was functioning from a moral sense or an ethical sense.

Table 110.1 lists the criteria—in the form of questions—that will be used in assessing the cases for Erikson’s tenets of trust and mutuality in the “Analysis” section for each of the three cases. Criteria numbers in parentheses will be included in the analyses to link the concepts in the analyses to the criteria. The purpose of these criteria is to provide a framework for thinking about the basic concepts of Erikson’s ethical theory in relation to the three cases.

CASE 1: OPIOID-INDUCED HYPERALGESIA

Background and First Attempt at Change of Treatment Plan to Opioid Cessation

Ms. R is a 51-year-old married woman with a history of neck and low back pain. She had been treated for about a year by Dr. T for pain related to cervical and lumbar spondylosis, facet arthropathy, myofascial pain, and
fibromyalgia. Ms. R travels a long distance to see Dr. T, and she has communicated to her that it is worth spending the time in traffic to see her because Dr. T is the first doctor who really listens to her and takes her needs into account in making medical decisions. Ms. R’s pain medications had been oxycodone 30 mg four times a day, gabapentin 600 mg two times a day, and 50 μg fentanyl patch 50 μg per hour every 72 hours. Two visits prior to the visit that is the focus of this discussion, in response to a pain flare, Dr. T increased Ms. R’s medication to fentanyl patch 100 μg per hour every 48 hours. In the next visit, Ms. R reported an improved pain score. However, in the following visit, Ms. R was tearful, complained of worse pain, and reported 9 to 10/10 pain on the pain numeric rating scale, and she communicated that she was having trouble getting to the store, socializing, and dealing with her son’s move out of the home to college. As Dr. T reviewed prior notes in the computer, she responded that despite the increase in the opioids, Ms. R had not improved in pain level or in function. Dr. T added that the patient may have developed opioid-induced hyperalgesia. Dr. T concluded that the patient needed to titrate completely off the fentanyl patch and go on an opioid holiday before Dr. T could reevaluate Ms. R for the need to be on chronic opioids. Dr. T noted in the computer that Ms. R was very reluctant to follow her advice and told Ms. R that, at this point, she did not think there were other options, saying, “There is nothing more that I can offer you.” Dr. T looked up from her computer and recommended an immediate wean of fentanyl from 100 μg per hour to 75 μg per hour patch, decreasing to 50 μg per hour in 1 month, 25 μg per hour in 2 months, and then off. Ms. R said that she could not believe that Dr. T would do this to her at this point, as she is a parent, too, and from their time together, they have talked about the difficulty of a child leaving home. Dr. T and Ms. R had talked in previous visits about the patient’s son’s impending move from home. Dr. T encouraged Ms. R to find other coping mechanisms to deal with her pain, perhaps regular exercise, such as swimming. Ms. R became tearful, saying that she did not know what went wrong, that before Dr. T was so understanding, and now she is unwilling to help and is acting as if she does not know her anymore. Ms. R challenged the assessment of hyperalgesia and expressed fear that without opioids her pain could not be managed.
Physician Consultation with a Colleague
After the visit, Dr. T felt unsettled by the interaction with Mr. R and consulted with a colleague about the visit. Dr. T said that the visit “just felt wrong” despite her confidence in the treatment plan. She admitted that she felt betrayed by the patient’s resistance to her offer of help and that the patient no longer trusted her judgment. Her colleague asked her, “What was different for you in the visit?” Dr. T said that she felt disengaged from the patient and that she was “just doing the mission of medicine.” She reflected on what Ms. R’s experience of the interaction had been. She pondered whether Ms. R also felt accused of poor judgment or pressured about this sudden treatment change. Dr. T then recalled that she did not engage the patient in their usual discussion about family or how the patient could navigate yet another change.

Dr. T reflected on the themes of trust and betrayal that permeated both her and Ms. R’s perspectives. The consultation with her colleague and consequent self-reflection allowed Dr. T to not only attend to her own feelings but also to reevaluate the interaction with Ms. R.

Modification in Engagement with Patient and Treatment Plan following the Consultation and Reflection
During the next visit with Ms. R, Dr. T asked her how her son was doing. Ms. R smiled and responded, and in a few moments, they began to discuss the treatment plan from the last session. Ms. R reported that she felt that she could not yet stop the fentanyl patch, but she proudly reported that, despite sweating from the titration, she had decreased her oxycodone, showing Dr. T the bottle with many pills left over. Dr. T praised Ms. R’s success in cutting back on oxycodone. She requested Ms. R’s input on what timing for titration of fentanyl would enhance her continued success. Ms. R said that she is going to visit her son so she can see with her own eyes that he has settled in and is doing well. Ms. R expressed that waiting until after she visited her son would be helpful to her. Dr. T praised Ms. R for her self-reflection and insight regarding the postponement of titration until after her visit to her son. Dr. T utilized Ms. R’s perspective to reconsider the treatment plan and postponed weaning off of opioids. Dr. T prescribed a clonidine 0.1 mg patch to help with sweating and
communicated to Ms. R the plan to begin the titration after the visit to her son, when she has adjusted better to the stressors currently affecting her life.

**Analysis**

Within the framework of the ethical principles described earlier, we can see that in the visit in which Dr. T initially changed the treatment plan to stop opioid use, she failed to use trust-building modes of communication with the patient, which disrupted the trust that had been built in this physician–patient relationship (C3). Threats to trust in adulthood may trigger vulnerabilities that formed early in life and lead to frustration in the current situation. Despite this difficulty, Erikson’s Golden Rule suggests that challenges to trust, especially in a situation where there is disruption to an expected receipt of care, can be optimized by both the patient and the physician engaging in strategies to facilitate trust, to draw on the history of trust built in the physician–patient relationship (C3). During the disruptive office visit, Dr. T was driven by the pressure and frustration she felt about the appropriate use of opioids (her goal) and failed to consider how her stance would impact Ms. R (C1, C4).

Physicians may adopt various stances when engaging with patients during difficult encounters, especially if the physician feels his or her knowledge is being challenged or if the physician feels that his or her ability to treat the patient is being undermined. Many physicians act in a paternalistic fashion as a first-line response when perceiving urgency to minimize risk and harm. The ethical nature of this type of physician behavior is questionable because it fails to take into account the impact on the patient of the physician’s decision making. Time with patients is limited, creating additional pressure to adopt a forceful stance in order to quickly communicate a judgment so that the patient will make a behavior change. And for some physicians, offering up the rules of opioid prescribing is a stance to demonstrate the veracity of their decision. Lorenzetti et al. reinforce the need to adopt principles of empathy and effective communication and thus foster a relationship so that these stances are not needed.

In this case, Dr. T reinforced her decision via an ultimatum that Ms. R
must comply or nothing else would be offered in the relationship, which represented a failure to recognize Ms. R’s perspective (C4). This ultimatum left no room for Ms. R to consider the rationale behind the decision, and she responded as if she were being punished (C2).

In Dr. T’s efforts to provide what she identified as appropriate care, she did not consider that this represented to Ms. R a drastic change in care and in the relationship (C4). Dr. T did not interact with Ms. R as she had in the past, when the context and home life of the patient had been discussed, physician behaviors that promoted Ms. R’s trust in Dr. T (C3). Dr. T did not seem to be aware that this shift in style of engagement with Ms. R would be difficult for Ms. R (C4), and Dr. T may have assumed that Ms. R would automatically follow the titration plan. This lack of awareness by Dr. T was interpreted by Ms. R as a violation of the trust in how care was offered. The interaction shifted from being predictable and consistent—an interaction in which Dr. T’s empathy was accessible to Ms. R—to Ms. R coming to feel not being known and forced into a care plan not based on her needs (C1, C2, C3, C4). Unfortunately, with this breach of trust, Ms. R expressed reluctance to accept the change in treatment plan that Dr. T recommended (C2). Despite Dr. T’s attempt to provide education about the rationale for the change, Ms. R felt as if the “decision had nothing to do with her or her needs” (C4).

As a result of Dr. T’s consultation with a colleague, she was able to return to her previous fostering of trust and mutuality in her relationship with Ms. R. This made it more likely for Dr. T to achieve an ethical state with Ms. R (C5). A first step for Dr. T was to identify trust issues for both her and Ms. R (C3). This is a difficult step—it requires the physician to carefully examine the issues. It would be ideal if physicians could do this before a potentially problematic interaction, but at least a distraught patient can be a signal that the doctor should step back and reflect on interpersonal issues with a patient. In fact, Dr. T. took a close look at where she might have missed signals of need and distress from Ms. R. She also identified where there had been disruption in their usual relationship (C4). In the visit after the consultation, which from Dr. T’s side included the yield from Dr. T’s reflection on what had happened with Ms. R in the previous visit, Dr. T actively engaged with Ms. R, creating a dialogue, asking for
Ms. R’s perspective, and providing a direct response to Ms. R’s feedback (C3, C4). Dr. T validated for Ms. R her attempts to manage her feelings about her son’s transition (C4). With renewal of trust and mutuality in the engagement, the effectiveness and ethical quality of the treatment were both enhanced (C5).

CASE 2: CHANGE IN THE CENTERS FOR DISEASE CONTROL AND PREVENTION GUIDELINES

Background
The office manager of a family medicine practice received a call from the Risk Management Department about Mr. B, a patient of Dr. J. Mr. B’s complaint stated that his opioid medication had been stopped by Dr. J, a physician in the medical practice, because of the new CDC guidelines. Mr. B has a history of complex regional pain syndrome (CRPS) and had been treated by Dr. J for many years. The office manager recalled their struggle to find a treatment regimen that worked for Mr. B and Mr. B’s success at stopping smoking in an effort to control pain symptoms. Mr. B reported to Risk Management that Dr. J told him that Dr. J had become too scared of the CDC and Drug Enforcement Administration (DEA) to prescribe opioids any longer. Mr. B feared not getting adequate pain control without opioids. He started smoking again because he was so upset. Mr. B told Risk Management that Dr. J offered an epidural injection, but Mr. B is still waiting for the insurance company to authorize this treatment.

Analysis
In this case, the physician had difficulty coping with an unexpected change in prescribing guidelines. Dr. J felt angry and trapped. After many years of practice, based on then-current guidelines about the appropriateness of long-term use of opioids, he now had a large cohort of long-term patients who are taking opioids. With the change in CDC guidelines, based on new evidence of the pitfalls of long-term use of opioids, Dr. J felt that he was being blamed by the CDC for getting his patients dependent on a type of medication that is not good for long-term use.

Using the perspective of Erikson’s Golden Rule, Dr. J’s own sense of trust in the foundations of how to practice ethically in pain management
was threatened by shifting CDC guidelines. In this particular case, he may have been revisiting a crisis of trust similar to ones that he had experienced in prior situations where the rules had been changed. His frustration about the unexpected demands from the CDC guidelines impaired his ability to maintain trust in his prescribing of opioid medication. With Mr. B, he made an abrupt decision to stop prescribing opioids based on his perception of the rigid expectation of the CDC authority (meeting Dr. J’s goals), instead of engaging in self-reflection and trust-building communication with his patient (C1, C3). Dr. J’s conformity to a rigid ideology and his inflexibility in his application of the CDC guidelines left him lost in defensiveness and rejection of his patient, unable to shift into the “unique needs of the present moment” (C5). Dr. J functioned with the moral sense of young adulthood rather than with the ethical sense of later adulthood, leaving Mr. B feeling so abandoned by and angry at Dr. J (C2) that Mr. B filed a complaint against Dr. J.

Had Dr. J functioned according to Erikson’s Golden Rule, there would have been alternative approaches to dealing with the situation with the potential for more beneficial outcomes for this crisis. Specifically, had Dr. J reflected on his and Mr. B’s prior successful experience with smoking cessation, Dr. J could have talked to Mr. B about Mr. B having been able previously to tolerate a painful loss of a substance he had relied on, which would have been an interaction that would have strengthened both patient and physician (C5). This discussion could have laid a foundation for Mr. B facing the prospect of cessation of opioids. Furthermore, Dr. J could have reminded Mr. B that he had been able weather this challenge because of his trust (C3) in Dr. J and that after cessation of smoking, Mr. B had noted some reduction in his pain. By “renewing prior achievements in trust,” Dr. J could have helped Mr. B counteract his sense of distrust in his ability to manage the situation as well as his sense of distrust in the physician. This alternative approach could have avoided the breakdown in Mr. B’s trust in Dr. J and subsequent call to Risk Management (C3).

In terms of the threat of the change in CDC guidelines to Dr. J as a physician, another possibility would have been for Dr. J to reflect on how hard it is for him and for other physicians to cope with the change in CDC guidelines regarding prescribing opioids, especially when they were
taught and practiced is now being identified as wrong. He might have identified that all of these changes make him feel off-kilter and, in addition, that he has to get used to the change in his practice. Although this is difficult, he could have recalled that he had navigated similar challenges in the past. For instance, as a family medicine physician, Dr. J had had to change how he prescribed antibiotics. That transition had been difficult, but Dr. J had felt backed up by science and was able to adapt. If Dr. J could have identified that he has survived prior challenges, he could have drawn on these previous experiences to remind him of his achievements. He could have reapplied the same coping he had used to survive the other situations to the current situation, which would have strengthened both him and his patient (C5).

Applying the concept of mutuality would have been useful. Mr. B may have appreciated hearing Dr. J say that he saw how the change could be upsetting to the patient and that he (Dr. J) is distressed at the changing rules. This bidirectional sharing could have been strengthening for both patient and physician and could have contributed to both the effectiveness and ethicality of the handling of the crisis (C4, C5).

CASE 3: OPIOID PRESCRIPTIONS FROM OTHER PHYSICIANS FOUND IN CHECK OF STATE DRUG MONITORING PROGRAM

Background

Ms. A, a single woman in her 30s, came to Dr. S after extensive treatment by another pain specialist. She had chronic low back pain associated with post-laminectomy, or failed back syndrome. Her insurance no longer covered her prior physician. She was on high doses of opioids—higher than Dr. S usually prescribed. Her prior medical records documented Ms. A’s report that she had not responded to various spinal injections or to physical therapy, but she was stable on fentanyl patch, 75 μg every 3 days plus hydrocodone/acetaminophen 10/300 three times a day. Dr. S found himself struggling with issues of prejudging—Ms. A was heavily tattooed and not working, and there was no clear pain source for her chronic pain. Dr. S had to make a conscious effort to not to assume—based on appearances—that the patient was inappropriately seeking opioids. Dr. S
explained to Ms. A his concerns for safety given her opioid dose of approximately 180-mg morphine equivalents per day. He specifically addressed the issue of hyperalgesia and his long-term goal of her coming off opioids completely. Ms. A said that the only helpful treatment for her pain is opioids, and she did not want to come off of them completely. They agreed to go down slowly. Dr. S was willing to prescribe her medications if she would agree to lower her fentanyl dose over the next 2 months to 50 μg every 3 days. Ms. A also signed a standardized treatment agreement, which includes informing the signer that all controlled substances must be prescribed by Dr. S. Ms. A also signed that she understood that Dr. S would monitor her for usage of any controlled substances by any other provider.

Dr. S continued to prescribe these medications for the next year, until a check of the state drug monitoring program revealed three extra prescriptions for hydrocodone/acetaminophen 10/300 mg from other physicians. Ms. A’s violation of the treatment agreement led Dr. S initially to feel that Ms. A could not be trusted. However, he reminded himself that there is a difference between not being trustworthy at all and not being trustworthy to handle a specific drug. Ms. A might be trusted with other drugs and procedures.

Dr. S anticipated that when he brought the results of the check of the state drug monitoring program to Ms. A’s attention, she would angrily deny the problem and then storm out of the office, never to return. Dr. S braced himself for Ms. A’s anger at her next office visit. In fact, at first, Ms. A did deny the extra prescriptions, but not angrily, and then she apologized for the “mistake” and promised to not “mess up” again. Dr. S explained to Ms. A that she is not a safe candidate for opioids. He told her that he would be happy to continue to treat her but without opioids. Again, Dr. S braced himself for anger, but to his surprise, Ms. A said, “Okay doc,” and she continued to treat with Dr. S.

Over the next few months, Dr. S started Ms. A on physical therapy and pain psychology (which she discontinued after two sessions) and tried facet joint injections. Ms. A reported that none of these treatments was helpful, and after a few months, she started requesting that they resume opioids because the pain is so bad. Dr. S continues to wrestle with himself
that perhaps this is one of the relatively few patients who do benefit from long-term opioids, but he reminds himself and Ms. A that opioids are too seductive and dangerous for her. Ms. A is not happy that Dr. S continues to decline to prescribe opioids, but she has continued to treat with Dr. S, and the state drug monitoring program indicates that she is not receiving opioids anywhere else. Dr. S feels good that Ms. A has “stuck with me.”

Analysis
In this case, Dr. S’s insight and self-reflection, which laid the foundation for sound communications with Ms. A (C3), helped him to effectively and ethically deal with a variety of trust-related issues regarding opioid use and cessation. Some of the trust issues were related to himself, and others stemmed from the patient’s presentation and actions. The patient’s unclear pain source, use of a high level of opioids, and prejudicetriggering appearance caused concern for Dr. S about whether he could trust Ms. A. In order to clearly see and respond to her needs, Dr. S had to contain his initial reaction that she was an untrustworthy patient. However, Dr. S reflected on his impulse to mistrust and waited for more input before reacting. He saw that the patient spoke reasonably about her use of opioids and that her medical records correlated with her self-report. Dr. S’s capacity to wait created (1) a space for more information about the patient to emerge, (2) a physician–patient dialogue about safety, and (3) the patient signing a treatment agreement—three factors that had the potential to enhance mutual trust between patient and physician (C3). This trust may have helped Ms. A to agree to the initial titration of the fentanyl and have a reasonable reaction when confronted with obtaining opioids from other sources (C2). When Ms. A went against the treatment agreement, Dr. S initially felt a sense that she could not be trusted. However, he tried to understand her perspective of trying many treatments without results (C4). He reminded himself that there is a difference between not being trustworthy at all and being a person who cannot be trusted to handle a specific drug. Dr. S reasoned that Ms. A could be trusted with other drugs and procedures that he offered but not with opioids. His continued relationship with Ms. A enhanced his confidence in his decision not to prescribe opioids for her. Dr. S continues to feel good that the patient has
stayed in treatment with him (C5).

Of particular note in this case is Dr. S’s success in both avoiding behaviors that could have triggered feelings of abandonment in the patient and in implementing limit setting with the patient—in contrast with Case 1 and Case 2. This resonates deeply with Erikson’s Golden Rule. Dr. S’s way of engaging with Ms. A is like a parent with an infant who—through fostering trust and communicating mutuality—can instill in the infant the strength of hope. It is hypothesized that Ms. A could sense Dr. S’s commitment to working with her and that feeling his commitment helped her in accepting that he would no longer provide opioids as part of the treatment plan (C4).

Case 3, in contrast with Case 1 and Case 2, illustrates Erikson’s distinction between moral rules and ethical rules. The physicians in Case 1 and Case 2 were guided by moral rules, “fear of threats to be forestalled. These may be outer threats of abandonment, punishment and public exposure, or a threatening inner sense of guilt, or shame or of isolation.” Dr. S’s actions were based on a physician–patient relationship, grounded in ideals rather than rigid adherence to rules. This led to thoughtful action that girded both physician and patient for the vicissitudes of pain management in the face of opioid prescribing and cessation (C5).

Building Trust through Mutuality

Three tools can help physicians build trust through mutuality. These tools are especially helpful for physicians who treat chronic pain patients:

- Dialogue
- Empathy
- Narrative medicine

**Dialogue**

From the analysis of Case 1, we saw the patient’s loss of trust in the physician undermining the physician’s efforts to help the patient. Smith and Newton encourage “meaningful dialogue” between patient and physician. They encourage the physician to see the patient as a person, to
connect with that person, and to be a person (in addition to a physician) during the interaction.\textsuperscript{26}

Reflecting back on Erikson’s view of mutuality, what is needed is a willingness on the part of the physician to not only try to read the verbal and nonverbal signals of the patient but also to acknowledge, discuss, and reflect on them. Physicians who can engage in this type of dialogue may also ameliorate their own frustration and promote personal growth in the physician. Thus, both physician and patient may benefit from an ethical interaction. Allowing oneself to participate in dialogue with a patient can be an authentic way of connecting beyond the mask of professionalism. The realization of change is illustrated in Stephen Sondheim’s song “It Takes Two” from the musical “Into the Woods,” where the baker has become a better and different man by including his wife’s input and participation in a critical venture. The baker’s wife noted that the baker had become more “daring,” confident, “sharing,” and “openhearted.”\textsuperscript{30}

**EMPATHY**

Physicians who want to have mutuality in their interaction with their patients may need to be refreshed in the skills needed to do this. Empathy is a skill that can promote mutuality.

Hojat et al.\textsuperscript{31} uses Mercer and Reynolds’s 2002 paper “Empathy and the Quality of Care” to characterize four abilities that a physician uses to engage with a patient with empathy:

- **Cognitive.** The physician identifies and understands the patient’s emotional experience.
- **Emotive.** The physician imagines and relates the patient’s emotional experience to his or her own experience.
- **Moral.** The physician is motivated to express his or her understanding of the patient’s experience to the patient grounded in the physician’s humanity.
- **Behavioral.** The physician communicates to the patient his or her understanding of the patient’s experience.

Empathy training offers strategies to bring trust building and mutuality to a difficult physician–patient interaction.\textsuperscript{27} Specific communication strategies include (1) techniques to enhance physician–patient dialogue,
(2) active listening, (3) validating emotion, and (4) exploring alternative solutions. For instance, during the visit in which the physician in Case 1 decided to move toward cessation of opioids, the physician was facing her computer, not facing the patient. According to Ambady and Rosental, eye gaze and contact is needed for mutuality and for transmitting empathy.

Researchers believe that it is possible to teach and for physicians to learn and practice empathy, or at the very least act empathetically. A systematic review of published literature on empathy training interventions that were quantitatively evaluated to detect changes in empathy among medical students, residents, fellows, and physicians found that 66% (42 out of 64) of reviewed studies reported a statistically significant increase in empathy.

Practice of empathic techniques may help the physician become genuinely empathic. To further the goal of being able to “treat each patient as a person, not an illness,” the authors of this chapter suggest that pain physicians engage in team meetings that include discussions of the patients’ personal histories and the potential difficulties with connection with an individual patient.

**NARRATIVE MEDICINE**

Charon has written about the use of narrative theory and methods in the practice of bioethics. The goal of these methods, called narrative-based medicine (NBM), per Charon, is to “practice medicine with empathy, reflection, professionalism and trustworthiness.” It is a pathway toward the “authentic engagement [that] is transformative for all participants,” thus invoking the tenet of mutuality that anchors Erikson’s Golden Rule. She describes the contributions of NBM to both patient and physician. For the patient, NBM makes the patient feel better understood, more hopeful, and more comfortable asking difficult questions. For physicians who can engage with their patients using NBM, it makes the physicians a reflective practitioner with an enhanced ability to “identify and interpret their own emotional responses to patients, make sense of their own life journeys” and achieve a more accurate understanding of illness and suffering. Peterkin offers a list of
some of the basic physician behaviors of NBM, which include the following:
1. “Ask open-ended questions.”
2. “Do not interrupt.”
3. Ask about suffering
4. “Learn your patients’ stories.”
5. “View noncompliance as a blocked narrative, not as patient stubbornness.”
6. Ask the question “What do you think is going on?”
7. Ask yourself, “Where did we leave the thread of our story the last time?”

Charon recommends training in narrative skills as well as reading, reflective writing, and authentic dialogue with patients.

Conclusion

Crises in trust occur during physician–patient encounters involving opioid cessation. By addressing trust issues in these interactions via mutuality, physicians may be able to help with the ethical distress that comes with having to balance their patient’s best interests with cultural swings of the pendulum toward and away from opioid prescribing. Erikson’s Golden Rule provides a framework for navigating the challenge of cessation of opioids in chronic pain patients.

The Evolution of Pain Medicine as a Subspecialty

It is impossible for any physician to become an expert in every field. As knowledge expands and the need for detailed skills arises, the natural progression is for specialization to ensue. There has long been a discomfort with specialization despite an unflagging progression in that direction. The urge to both specialize and remain unspecialized dates back to the earliest recorded history of medicine. The first specializations were between the barber-surgeons and the internists, and a rivalry of sorts remains to this day. Writing about Ambrose Paré, the 16th century physician who elevated the role of the barber-surgeons to that of other physicians, the present-day surgeon and historian Sherwin Nuland reflects on the ongoing distinction between internist and surgeon:

Surgery is an exercise in the use of the intellect. Heckling internists, with tongues barely in check, would prefer that surgical specialists be viewed merely as dexterous craftsmen who carry out the routing errands assigned to them by their more cerebrally endowed medical overseers. I attribute this teasing raillery to a kind of good-natured fraternal envy, not so much of our celebrity status, but rather of the visibility of the cures we surgeons achieve and the particular personal gratification we have while doing it.

In the United States, anesthesiology has progressed toward further specialization, first with the establishment of critical care; then pain management (now called pain medicine); and more recently, pediatric anesthesiology, cardiothoracic anesthesiology, and obstetric anesthesiology. The addition of pain medicine as a subspecialty of anesthesiology is just one recent example of the growth of medical
specialties. With specialization comes a conscious effort to focus practice to become intricately familiar with a more limited realm. The obvious result is a loss of the skills and knowledge needed to practice in the broader parent specialty. In pain medicine, many now view this as a full-time vocation. The scientific meetings and journals that keep pain medicine specialists up-to-date have little overlap with those that are designed to serve anesthesiologists practicing in the operating room. The only common thread between the technical skills needed in the pain clinic and those required for anesthesiology in the operating room is expertise with neural blockade, which is one of several important skill sets needed in pain medicine. The rapid expansion of knowledge in the causes and complications of acute and chronic pain, particularly in the neurobehavioral sciences, has led to a growing recognition that the pain medicine practitioner must acquire a vastly different skill set than those practicing anesthesiology, including expanding their skills as diagnosticians.

Much has been written about the origins of pain medicine as a distinct discipline, and anesthesiologists have played a primary role since the start, as have specialists in neurology, psychiatry, neurosurgery, and physical medicine and rehabilitation. Anesthesiology really started with the introduction of effective general anesthetics in the mid-19th century, when surgical pain could be separated from operation. Almost 100 years later, the late John Bonica, an anesthesiologist and recognized father of the specialty we now call pain medicine, developed his career promoting multidisciplinary pain care and formal training of specialists. From his life’s work, we now have extensive ongoing efforts to recognize and treat pain effectively, to train subspecialists, and to conduct basic and clinical research to further our understanding of pain and its treatment. The International Association for the Study of Pain (IASP) founded in 1974; its US chapter, the American Pain Society; and the journal Pain are legacies left by Dr. Bonica for our patients. Dr. Bonica began his practice with a focus on regional anesthesia techniques but soon came to realize that these techniques were inadequate to meet the needs of his patients with chronic pain and that he could not incorporate the growing scientific evidence of the importance of neurobehavioral factors. This realization evolved to the
belief that developing the field of pain as a separate clinical discipline and treating chronic pain competently required the intellectual input and clinical skills of several other specialties. He published the first edition of this seminal textbook, *The Management of Pain*, toward that end in 1953.\(^4\)

It is noteworthy that IASP presidents have backgrounds from anesthesiology, dentistry, neurology, neurophysiology, neurosurgery, psychiatry, and psychology. All share a common intellectual passion and achievement, as well as clinical dedication, to developing pain research, teaching, and clinical care in pain medicine.

Accredited fellowship training in pain medicine is a relatively recent development. Prior to 1992, training was frequently obtained in academic anesthesiology departments, including those of John Bonica, Philip Bridenbaugh, Harold Carron, Daniel Moore, Prithvi Raj, Alon Winnie, and others, and subsequently in programs run by their trainees. These unaccredited programs advanced the specialty, widened interest in pain medicine as a career, and propagated anesthesiology-based pain care in smaller and smaller communities across the country. Other specialists also contributed to the development of the practice model of pain care. Many of the early leaders of pain medicine were from other specialties, and they trained fellows in unaccredited programs as well. Multispecialty entrance into pain medicine training became a tradition in several cities, including Boston, under Daniel Carr (Harvard, Massachusetts General) and Carol Warfield (Harvard, Beth Israel); New York, under Kathy Foley, Russ Portenoy, and Bob Breitbart (Memorial Sloan Kettering Cancer Center); and Seattle, under John Loeser, John Bonica’s successor (University of Washington), among others. For example, one of the authors (Rollin M. Gallagher) provided fellowship training in chronic pain rehabilitation at State University of New York at Stony Brook and Drexel University College of Medicine to doctors with residency backgrounds in neurology, psychiatry, physiatry, and family practice before accreditation was possible. Outside of the United States, with the notable exception of Australia, this type of informal training remains the rule for those seeking expertise in pain medicine. In the United States, the American Board of Anesthesiology (ABA) developed interest in certifying pain medicine training. The failure of coalition of the boards of anesthesiology,
psychiatry and neurology, physical medicine and rehabilitation, and neurosurgery in 1990 to form a conjoint American Board of Medical Specialties (ABMS) board led the ABA, under the leadership of Bill Owens in his roles on both the ABA and the Residency Review Committee (RRC) for Anesthesiology, and through his representations of the subspecialty to the ABMS, to begin accrediting formal training programs and certifying physicians in 1992 through the Accreditation Council for Graduate Medical Education (ACGME). Steve Abram and John Rowlingson were both key members of the group that assisted Dr. Owens in moving the new subspecialty forward.

The number of ACGME-accredited programs (Fig. 111.1) and the number of trainees in accredited programs have grown steadily over the past decade, reaching just under 100 training programs by 1999 that train just over 300 new pain specialists each year (Fig. 111.2). The ABA working in parallel with the ACGME developed a subspecialty certification examination in pain medicine, first named the “Certificate of Added Qualifications in Pain Management,” now titled “Subspecialty Certification in Pain Medicine.” The first exam was given in 1993. The number of candidates sitting for the examination has steadily grown since the first exam was given.
Chi-square test that 50% were women. The proportion of women who have been suspicious about the presence of a tumor, which is more frequent in women than in men. However, the proportion of women who were suspicious about the presence of a tumor was comparable to that of men (P = 0.90). The proportion of women who were suspicious about the presence of a tumor was not significantly different from that of men (P = 0.71).

When the proportion of women who were suspicious about the presence of a tumor was compared between Q2 and Q3, no significant difference was observed.

Physical medicine and rehabilitation. A 2015 snapshot of the distribution of board-certified pain specialties by primary medical specialty is shown in Figure 111.3. Equally important in the evolution of the discipline is the creation of academic physicians within the fellowships who undertake research programs to add new knowledge to this needed field of medical practice.

![Figure 111.3](image)

**Figure 111.3** Distribution of the primary medical specialty of physicians board certified in the subspecialty of pain medicine in the United States in 2015. (Data provided by the American Board of Anesthesiology.)

Pain and its consequences draw on resources from all medical disciplines. Dr. Bonica’s experiences during World War II suggested that each medical specialist had unique expertise to bring to patients suffering in pain, hence his consistent and effective promotion of a multidisciplinary process for pain care. Also thanks largely to Dr. Bonica, anesthesiology has led the development of formal training programs. Indeed, the majority of currently accredited programs reside within academic anesthesiology departments, and most program directors are anesthesiologists. Specialists from other disciplines have also focused their clinical and research efforts on pain. The most obvious example is neurology where the majority of clinical treatment and research about headache and peripheral neuropathy has arisen. Physical medicine and rehabilitation has also long had a focus...
and expertise in functional restoration, and physiatrists lead many chronic pain rehabilitation programs. And, of course, psychiatrists have been closely involved where pain, illness behavior, stress, depression, anxiety, and substance abuse overlap. During the last decade, specialists from these other disciplines have been seeking subspecialty training in pain medicine with increasing regularity.

The range of practitioners declaring themselves as pain medicine specialists is extraordinary; from clinics that provide largely or solely cognitive-behavioral approaches to chronic pain through functional restoration programs all the way to the type of clinic that offers nothing more than injections of various sorts. “Interventional pain medicine” is a term that has been coined for those techniques that involve minimally invasive treatments and minor surgery as part of their application, including neural blockade and implantable analgesic devices. Despite the paucity of scientific evidence to guide pain practitioners, particularly, evidence to support the use of many interventional modalities, many techniques appear to have efficacy based on limited observational data and have been adopted into widespread use. As practitioners, we are left to choose among available treatment modalities, often with only anecdote and personal experience to guide us in treating a group of desperate patients with intractable pain who are willing to accept almost any treatment, even those which remain unproven. There is no single practice pattern that any pain specialist can point toward as the correct way to treat patients with chronic pain. Training programs vary widely in the scope of what they train practitioners to do. The best pain medicine practitioners strike a reasonable balance between interventional and noninterventional management. This practice pattern is sustainable, and those adopting a balanced style of practice will be able to adapt to evolving scientific evidence that appears in support of pain treatment regardless of the type of treatment. A balance between treatment modalities also allows practitioners to switch from one mode to another or incorporate multiple treatment approaches simultaneously. Use of these interventional modalities is just a small part of the armamentarium of the skilled pain medicine practitioner.
Pain Medicine as a Primary Medical Specialty

Dr. Bonica developed his multidisciplinary clinic with the understanding that the expertise of several specialties was necessary to successfully manage chronic pain. A detailed history of the intellectual background of pain medicine and particularly Bonica’s work in the early development of the field can be found in Baszanger’s 1998 book, Inventing Pain Medicine.\textsuperscript{5}

The rationale for a separate specialty in pain medicine involves the documentation of many factors: public health need,\textsuperscript{6–8} a growing consensus of pain treatment as a human right,\textsuperscript{9} ethical difficulties that are at the heart of pain medicine practice,\textsuperscript{10,11} inadequate education\textsuperscript{3} and knowledge\textsuperscript{12} and a rapidly growing scientific and practice base,\textsuperscript{13} and the need to promote integrated pain medicine with primary care.\textsuperscript{14,15} The high costs of inadequately managed pain reverberate in our society’s health care crisis and are well documented. Emblematic of the same, it has been our citizens, the victims of inadequate pain management, who have decried this problem and demanded change through legislation at both a state and a national level when organized medicine, itself beset by competition among established specialties, cannot act. The rationale is scientific as well. Since the publication of John Bonica’s first edition of The Management of Pain in 1953, the problem of pain has challenged some of the best minds in science and medicine. In 1965, Melzack and Wall’s\textsuperscript{16} seminal paper in Science describing the gate theory of pain created a conceptual framework resulting in a relative explosion of science in the physiology, molecular biology, and pharmacology of acute pain and the epidemiology, neurobiology, pathophysiology, genetics, and treatment of chronic pain conditions and diseases at the levels of soma, spinal cord, and brain. Today’s pain medicine physician is armed with a tremendous knowledge base as a foundation for the myriad of effective medications, behavioral therapies, physical therapies, neural blockades, neuromodulatory devices, and cross-cultural complementary and alternative treatments such as acupuncture and meditation. A growing number of pain medicine and other specialists in organized medicine believe that longer training, either a 2-year fellowship or a separate 3-year residency, is needed to learn how,
when, and in what combinations of these tools can be cost-effectively utilized to competently treat patients with chronic pain, to establish standards for training all physicians, and to lead the development of clinical research and health policy.\textsuperscript{17} Although each traditional medical specialty contributes to this knowledge base and skill set, their respective specialists are not trained to manage the entirety of the spectrum of chronic pain contributing to fragmentation not unification of care and failed public health. Table 111.1 outlines the special skills contributed by traditional specialties that converge to define the pain medicine specialist. This specialized knowledge, education, training, and multidisciplinary nature suggest that pain medicine’s evolution as a specialty is paralleling that of other disciplines, such as emergency medicine or physical medicine and rehabilitation. Knowledge and skills of the latter disciplines, initially fragmented, later coalesced into primary medical specialties because of the inability of multiple specialties to offer an integrated approach that would best serve patients, medical science, and public health.

The momentum to establish standards for pain medicine as a specialty is now global. For example, in 1998, the government of Australia formally recognized pain medicine as a specialty and endorsed training and credentialing requirements recommended by the newly formed Faculty of Pain Medicine of the Australian and New Zealand College of Anaesthetists. In 2007, the Section and Board of Anaesthesiology of the European Union of Medical Specialists (UEMS) initiated the establishment of the Multidisciplinary Joint Committee on Pain Medicine of the UEMS, which has created a certification examination in pain medicine (see further discussion of training in the European Union later in this chapter). Also in 2007, the Ministry of Health of the People’s Republic of China announced the designation of pain medicine as a separate specialty and that there will be a Department of Pain Medicine in all major hospitals in China (R. M. Gallagher and J.-S. Han, December
2007, oral communication). In the United States, the momentum for establishing residency training programs in pain medicine under a new residency review committee has never gained momentum. The simple rationale is that training for 1 year has proven to be inadequate, but the status of pain medicine will remain as a subspecialty with just 1 year of training until leaders in the field find a way to collaboratively improve the depth and breadth of training. Similar to a cardiologist learning the science and clinical practice related to the cardiovascular system, starting with primary prevention of heart disease, by identification and early intervention of risk, and primary and secondary treatment of actual heart disease, the pain medicine specialist who will train in the future could learn about the pain perception and modulation system, from the relatively simple peripheral nociceptor to the system’s complex neurobehavioral networks and about the pathophysiologies of this system.19,20

Training in Pain Medicine in Europe

In Europe, there is no systematic training in pain medicine for medical students. The lack of obligatory training leads to later deficiencies in clinical care. Some countries (e.g., Germany) have made efforts in establishing a core curriculum for medical students. However, the worldwide need for a thorough basic education in pain medicine is underestimated by most health care officials. The postgraduate training varies widely within Europe. This led to guidelines for anesthesiologist specialist training in pain medicine.21 In these guidelines, approved by the UEMS, pain medicine is considered to be an area of expertise in anesthesiology. However, simultaneously, it is mentioned that pain medicine is not claimed for anesthesiology alone. It is clearly stated that pain medicine is included in anesthesia specialist training. However, an additional qualification following basic anesthesia training is recommended. The multidisciplinary approach to pain is mentioned, and an initiative to set up a multidisciplinary joint committee on pain medicine within the UEMS has begun.

The proposed duration of pain medicine training is 3 months during the 5 years of basic anesthetic training required in the European Union. In
contrast to this relation representing only 5% of the total time of training, it is recommended to occupy a minimum of 10% of the multiple-choice questions on the European Society of Anaesthesiology’s European Diploma in Anaesthesiology and Intensive Care.

Some years ago, the Scandinavian Society of Anaesthesiology and Intensive Care Medicine established the Nordic education in advanced pain medicine. The clinical part lasts at least 3 months. The education includes, and this is unique in Europe, a scientific part.22

In April 2007, the Royal College of Anaesthetists (United Kingdom) established a faculty of pain medicine and stressed this as a major way point in the last 50 years.23 However, the question is raised: Should pain medicine strive to be a “stand-alone speciality,” or should it be linked to parent specialties like anaesthesiology? Additionally, is education also required for the public and the patients? Both the British and the Irish curriculum in pain medicine require similar training and examination. The candidate has to complete a total of 6 months training in pain medicine before ending up with a 2-day written and oral examination with review of actual clinical cases and a practical examination.

As early as 1992, the German Society of Anaesthesiology started a curriculum and specialist training in pain medicine. This included a 2-week theoretical course and a 1-year practical training requirement in a pain clinic. From this first example, a specialty open for all clinical disciplines has been developed. Since 1996, a specialty called “specialized pain therapy” has been established by the German Medical Assembly. A curriculum has been developed by the German Pain Society and approved by the German Medical Assembly. Similar to the Society of Anaesthetists, the specialization demands 1 year of clinical training in a certified institution and an 80-hour theoretical course. Additionally, to maintain specialty certification, physicians must attend multidisciplinary pain conferences regularly, where patients are presented and discussed between several disciplines, including at least one psychological discipline. In 2008, Austria introduced a similar specialty, and the German training is approved by the Austrian Medical Assembly.

The dramatic effect of a thorough education and programmatic work has been demonstrated in Catalonia in Spain within a project sponsored by the
World Health Organization. Symptom control and patient satisfaction were both improved, and a striking cost savings of many million Euros per year has been demonstrated as compared to the rest of Spain. Europe has lagged behind the United States in developing formal training for pain medicine specialists.

In 2016, the European Pain Federation EFIC developed a curriculum, predominantly based on the pain curriculum of the Faculty of Pain Medicine of the Australian and New Zealand College of Anaesthetists. The knowledge of the curriculum, pain assessment, and treatment skills are evaluated by a two-part examination: the European Diploma in Pain Medicine (EDPM). The examination is open to all qualified doctors who see and treat patients with pain who have appropriate clinical experience in pain assessment and treatment. The diploma aims to show that the fellow has a firm grounding in the basic skills and knowledge needed to assess and manage the many patients whose pain requires attention in all types of clinical scenario. The EDPM assesses the general knowledge of multidisciplinary pain management. Some countries in Europe have also approved the examination of the World Institute of Pain (WIP) to become Fellow in Interventional Pain Practice (FIPP) as an evaluation of the skills to select and perform interventional pain management techniques.

Training and Credentialing in Interventional Pain Medicine

In our rapidly changing world of modern health care, new technologies are appearing at a dizzying rate. Many of these new treatments require physicians to acquire detailed new knowledge and technical skills. The introduction of new techniques typically extends from centers in the public or private sector, where the ideas are conceived and tested in a limited realm among innovators. From there, anecdote can often take over, and many techniques in pain medicine have blossomed into widespread use with nothing more than word-of-mouth to propagate their use. The use of pulsed radiofrequency treatment for treatment of chronic pain after herniorrhaphy is one such example where clinical application has preceded detailed clinical testing.
In the United States and Europe, industry often leads innovation by testing and leading the introduction of new devices. When the innovation appears to have merit in limited trials, many devices have been introduced to the market with approval through the U.S. Food and Drug Administration’s (FDA) 510K “substantially similar device” process with little or no data regarding efficacy. Once on the market, the means by which practitioners decide to adopt new technologies, the speed of progression of these new techniques, and—of great importance—the means by which practitioners gain enough expertise to introduce new techniques into their own practices, are all highly variable and seemingly without any rational or consistent approach.

Interventional pain medicine is evolving as a distinct discipline that requires detailed new knowledge and expertise. Familiarity with radiographic anatomy for the conduct of image-guided injection and the minor surgical skills needed to place implanted devices such as spinal cord stimulators and implanted drug delivery systems are just a few of the techniques that practitioners must master. As we set out to introduce new interventional techniques to our own pain practices, we must assure that we have been properly trained to conduct these techniques to ensure safety and success.

Adequate exposure during the fellowship-training period to these newer treatment alternatives is necessary to assure appropriate application and optimize patient outcomes. Although we do not have scientific data that define the average minimum level of experience that will be necessary to achieve competence, especially for complex procedures that are associated with significant risks, logic dictates that there are a minimum number of these procedures that trainees should be exposed to during a fellowship. The ACGME has established requirements for average minimal numbers of epidural, spinal, and peripheral nerve blocks necessary for accreditation of anesthesiology residency programs. Other medical subspecialties also require a minimum number of specified procedures to achieve and maintain competence: Subspecialty training in gastroenterology has a requirement of performing a minimum of 100 esophagogastroduodenoscopies and 100 colonoscopies with polyp removal during formal training, and subspecialty training in
cardiovascular disease requires 100 cardiac catheterizations to demonstrate minimum proficiency. Indeed, in 2017, the ACGME’s RRC for Anesthesiology has accepted revised program requirements for pain medicine training programs that specify minimum exposure of trainees for various techniques. For those techniques that are now widely accepted as a core part of pain practice, we must assure that our trainees gain enough experience to conduct these procedures independently. One key element of the ACGME deliberations about unified pain training is to acknowledge that not all pain fellows will have experience in the wide variety of interventional techniques. Rather, it is hoped that these fellows will gain an understanding of all available options for patients with pain and yet demonstrate and have competence documented in only those techniques for which formal training is made available during fellowship training.

It is difficult to define the techniques that are core for a pain practitioner, but it does seem that detailed knowledge of radiographic anatomy of the spine and the minor surgical skills required to implant spinal cord stimulators and place permanent spinal drug delivery systems are among those skills most practicing pain physicians would expect a new graduate from a pain fellowship to emerge with. New techniques are appearing at a staggering rate, and we cannot rely on pain fellowship programs to provide all of the technical training that is needed. Stronger standards for minimal training following fellowship are also urgently needed. Some pain practitioners believe that all too many of their colleagues find it perfectly acceptable to attend a brief weekend course and then introduce a highly technical new treatment into practice without additional study, training, or oversight. The recent proliferation of new approaches to minimally invasive treatment of spinal pain and spinal cord stimulation all require unique knowledge and skills to be used safely and effectively. Practitioners themselves must take the lead in obtaining adequate training before proceeding with any new and unfamiliar technique. The weekend workshop is just a start, often a good start—the best will give practitioners a detailed understanding of anatomy; pathophysiology of disease related to the use of the new technique; patient selection; conduct of the procedure; outcomes; and avoidance, management, and recognition of complications. Here, we would like to
suggest a method for practitioners\textsuperscript{29} (Table 111.2): (1) study the new technique, the published literature, and gain a detailed knowledge of all aspects of the technique; (2) attend a workshop, preferably a hands-on cadaver-based workshop that allows introduction to the technique in as realistic a setting that can be assembled; (3) plan adequate time for your initial procedures; (4) get help at the bedside during initial conduct of new procedures—perhaps another experienced practitioner at your institution, an invited expert to assist, or team up with a colleague in a related discipline; (5) inform your patients that you are introducing a new technique and include this discussion as part of the informed consent process; and (6) examine your outcomes carefully in the initial stages of using any new technique and compare them with those of your colleagues and the published literature.

| TABLE 111.2 Suggested Training and Experience When Introducing a New Technique into Clinical Practice |

1. Study the new technique, the published literature, and gain a detailed knowledge of all aspects of the technique.
2. Attend a workshop, preferably a hands-on cadaver-based workshop that allows introduction to the technique in as realistic a setting that can be assembled.
3. Plan adequate time for your initial procedures.
4. Get help at the bedside during initial conduct of new procedures—perhaps another experienced practitioner at your institution, an invited expert to assist, or team up with a colleague in a related discipline.
5. Inform your patients that you are introducing a new technique and include this discussion as part of the informed consent process.
6. Examine your outcomes carefully in the initial stages of using any new technique and compare them with those of your colleagues and the published literature.

**Conclusion**

The field of evidence-based medicine has emerged as a new paradigm to guide practicing physicians. This field endeavors to educate practitioners about how to frame specific questions based on the clinical problems they are faced with every day. They then venture to the published scientific literature with focused questions about prevention, diagnosis, and treatment of a specific clinical condition. Many evidence-based medicine centers offer concise and periodically updated summaries about specific
clinical conditions. The idea is to get the best information available to the practicing clinician. It describes the best available evidence, and if there is no good evidence, it says so. In pain medicine, we are faced with an expanding array of treatment options that strikes us as logical developments that should provide pain relief for our patients. However, there is a dearth of clinical evidence to guide rational choice and application of the majority of these emerging treatments. So how are we to decide when to apply them?

Merrill\textsuperscript{30} presented a detailed analysis of the current state of evidence guiding the use of interventional treatments in the field of pain medicine. He points out the frequent flaws in existing studies (largely the lack of valid comparators, such as no treatment) and concludes that “the practice of invasive pain medicine teeters at a particularly critical juncture . . . crippled by a lack of vigorous self-evaluation of its role in the treatment of chronic pain.” Merrill\textsuperscript{30} goes on to detail the means by which we, as scientists and clinicians, can proceed to build a better body of evidence for the treatments we are using. But the field of pain medicine is young and early in development, and it is perhaps unreasonable to expect an accumulation of randomized clinical trials just yet.

New treatments evolve slowly in clinical medicine. Applying the scientific method in clinical medicine begins with an observation. Perhaps a chance observation that a certain drug typically used for another purpose provides analgesia to a given patient. If the drug is readily available, a clinician may choose to try treatment on other patients with similar presentations. If an academic sort, the clinician may choose to report the limited success in a case series. Case series are a valuable beginning: the very beginning of emerging new ideas. If the problem is uniform and prevalent enough, the new treatment may gain the attention of investigators willing to assemble a randomized clinical trial. All too often, sound treatments are never tested for lack of interest or funding. Those that are tested tend to be those under patent where a manufacturer proceeds with these large endeavors understandably in hope of financial return in the event the treatment proves useful. Patients who are suffering from severe and intractable pain are desperate, and they can easily be convinced that desperate measures, however new or unproven, are warranted.
How, then, are we to proceed? Our patients are begging for us to try anything that offers a glimmer of hope in reducing their pain, and we as scientists embrace the rigor of the scientific method and want desperately to do what is best for our patients. We have treatment after treatment that makes logical sense and shows early promise in case series and observational studies but little data that support an evidence-based approach to practice. The evidence-based medicine movement gives little guidance to practitioners whose tools are still under development. They simply remind us that no evidence regarding many of our techniques exists. Without declaring a moratorium on all of interventional pain, Merrill offers the individual practitioner advice: Monitor your own outcomes using valid measures, be more reflective and systematic in studying your own outcomes and patterns of care, and provide this information to your patients as part of the decision-making process. As pain practitioners, we have an expanding range of treatment options available to us, few with convincing evidence of efficacy superior to alternate treatments. We must evaluate each patient and use the limited evidence available to us today to guide compassionate and rational, if not evidence-based, use of therapy for our desperate patients.

ACKNOWLEDGMENTS

We would like to thank Michael Zenz, Rollin M. Gallagher, and David L. Brown, who contributed to this chapter for Bonica’s Management of Pain, fourth edition. We have built on the previous edition’s chapter to create this updated chapter.

27. Program requirements for residency education in cardiovascular disease. Available at:
This chapter seeks to provide the pain management specialist with an overview of emergencies and complications that may occur in the course of caring for patients with acute and chronic pain. Throughout this review, we will also emphasize strategies for decreasing risk, specifically, strategies for identifying specific risks and considering alternatives, understanding rare event analysis, and maintaining a comprehensive view of the patient when prescribing specialty specific interventions. A prudent first step for practitioners who will be managing emergencies related to pain therapies is to understand the incidence of each of these emergencies. However, because rates have been relatively low for serious complications, and because minor complications frequently go unreported, measuring the true incidence of most complications is not feasible.

The American Society of Anesthesiologists Closed Claims Project

In the United States, the American Society of Anesthesiologists Closed Claims Project offers a close look at serious adverse events secondary to pain management interventions that lead to malpractice claims, but no incidence can be calculated due to the lack of any knowledge regarding the overall frequency with which the interventions are performed. We can, however, make educated changes to our practice by evaluating trends in these closed claims.

A review of 1,037 total pain medicine malpractice claims of the database between 1980 and 2012 showed that most claims were related to
lumbar nonneurolytic injections (n = 273). Other claims included cervical nonneurolytic injections (n = 211); device implantation, management, or removal (n = 146); and medication management (n = 115). Looking just at the claims between the years 2000 and 2012 (n = 505), we find that most claims have trended toward cervical nonneurolytic injections (Table 112.1). Furthermore, the overall percentage of malpractice claims for pain medicine has increased from 3% of all anesthesia malpractice claims between 1980 and 1989 to 18% of all anesthesia malpractice claims between 2000 and 2012 as reviewed from the American Society of Anesthesiologists Closed Claims Project database. Outcomes in pain medicine claims have also grown increasingly more severe in nature over the years. Death and permanent disability increased from 21% of pain medicine claims in the 1980s to 55% of claims in the 2000s.¹

Nerve damage and pneumothorax were the most common adverse events leading to claims in interventional pain management claims (Fig. 112.1). Serious adverse events leading to brain damage or death occurred at a far lower rate than that seen in surgical and obstetric anesthesia claims. A closer analysis of the subset of claims associated with epidural steroid injections (ESIs) revealed that death and brain damage occurred only when local anesthetic or opioid (or both) were administered in conjunction with the steroid (Fig. 112.2). This likely reflects unintended delivery of local anesthetic or opioid to the subarachnoid space or simply the predictable effects of neuraxial opioids; resultant high spinal anesthesia or neuraxial effects of opioid could both have led to respiratory compromise and underscores the need for close observation following neuraxial administration of local anesthetic or opioid. Not infrequently, claims resulted from the maintenance of spinal drug delivery systems (20/276 claims or 7%); these claims often stemmed from refilling of implanted drug reservoirs with potent opioid by nonphysician personnel in the outpatient or home care settings.

Bleeding Complications

Spinal hematomas have been described in autopsies since 1682 but not as a clinical diagnosis until 1867.\(^2\) Within one decade of August Bier’s discovery of spinal anesthesia, the first known epidural hematoma as a complication of spinal anesthesia occurred in a 36-year-old male following unsuccessful neuraxial blockade for excision of a pilonidal cyst.\(^3\) In that case, repeated lumbar puncture revealed blood-tinged cerebrospinal fluid (CSF), and the patient subsequently developed paresthesias and weakness in both lower extremities. The introduction of heparin in 1937 and warfarin in 1941 introduced the possibility of anticoagulation contributing to epidural hematoma formation. Epidural hematoma is a rare but potentially catastrophic complication of spinal or epidural anesthesia or injections. Because the spinal column is an enclosed space, hematoma formation can cause compression and ischemia of neural structures. Bleeding may result from injury to the abundant epidural veins or may be arterial. A retrospective study of central neuraxial blocks in Sweden from 1990 to 1999 identified 33 spinal hematomas, during a period when approximately 1,260,000 spinal blocks and 450,000 epidural blocks were administered. In that study, the incidence of spinal hematoma was 1 in 200,000 after obstetric epidural blockade and 1 in 3,600 among female patients undergoing knee arthroplasty.\(^4\) At a single teaching hospital in Australia, data were collected prospectively over a 16-year period for all epidural catheters placed for postoperative analgesia. During that period, 8,210 epidural catheters were inserted, and 2 spinal hematomas (1:4,105) and 6 epidural abscesses (1:1,368) were diagnosed.\(^5\) In rare instances, spinal epidural hematoma has developed following chiropractic manipulation and acupuncture therapy.\(^6,7\) Factors that determine whether epidural hematoma results in injury to neural structures include the location in the spinal column (the level of the cauda equina is relatively resistant to injury, whereas the cervical spinal cord is not), and the rate at which the blood accumulates. Tarlov\(^8\) demonstrated in dogs that spinal cord injury due to spinal epidural hematoma depends on both the amount of pressure exerted on the spinal cord and the duration of that pressure elevation. Interestingly, some epidural hematomas cause significant injury.
despite the fact that their volume is significantly less than that typically used during epidural blood patch placement. Vertebral column neoplasms and vascular malformations are also risk factors. Patients who have an underlying coagulopathy or are being anticoagulated with warfarin, intravenous (IV) heparin, subcutaneous low molecular weight heparin, platelet-inhibiting medications such as clopidogrel or ticlopidine, platelet glycoprotein IIb/IIIa receptor inhibitors, or fibrinolytic agents are at elevated risk of spinal hematoma formation. It should also be noted that with the growing number of patients on novel anticoagulation agents, including but not limited to, apixaban, dabigatran, rivaroxaban, prasugrel, and ticagrelor, a careful consideration of guidelines and practice advisories are necessary prior to any neuraxial procedures. The incidence of spontaneous spinal epidural hematoma estimated by Holtås et al. was 0.1 per 100,000 people, and less than 1% of those with spinal hematomas had their spinal epidural space occupied by lesions. The etiology of these hematomas was unsurprisingly related to coagulopathies, vascular malformations, neoplasms, infections, minor vertebral traumas, and idiopathic causes. In addition, garlic has been shown to inhibit platelet aggregation and has been linked in one case to the development of a spontaneous epidural hematoma. Ginkgo biloba inhibits platelet-activating factor and has been linked to several cases of spontaneous intracranial bleeding, and ginseng inhibits platelet aggregation and prolongs both thrombin time and activated partial thromboplastin time, although the clinical significance of these findings remain unclear. Timely diagnosis of spinal epidural hematoma is critical but, in many cases, will be challenging. Many patients have few complaints initially, commonly developing progressively worsening back pain as the hematoma expands with or without the immediate or delayed appearance of focal neurologic deficits. A progressive neurologic deficit may develop over a variable interval and with variable severity. Typically, neurologic deficits evolve over the course of several hours, but in some instances, they may develop over several days. In some instances, neurologic deficit rather than pain may be the presenting sign. Physical findings of myelopathy, or the development of the Brown-Sequard syndrome, should be recognized as indicative of spinal cord compression and should prompt emergent
diagnostic evaluation and treatment. Intractable leg pain and cauda equina syndrome may develop as well. Urinary retention may precede urinary incontinence. When a spinal epidural hematoma is suspected, a thorough neurologic examination is mandatory. This examination should include evaluation of anal sphincter tone and direct examination in efforts to detect loss of perineal sensation. Furthermore, serial examinations should be performed at short intervals. Findings on physical examination will be variable depending on the level of the lesion. Unilateral or bilateral weakness and/or paresthesias may be present. Hyper- or hyporeflexia may also be present. Depending on the clinical context, the differential diagnosis may include spinal epidural abscess. Urgent laboratory studies should include a complete blood count with platelets as well as a prothrombin time and activated partial thromboplastin time. In addition, a blood bank sample should be sent for type and cross-match in preparation for surgery as well as in cases where fresh frozen plasma may be needed to reverse coagulopathies.

Magnetic resonance imaging (MRI) is the preferred radiologic study for diagnosis of spinal epidural hematoma. On sagittal reconstructed computed tomography (CT) or MR images, a spinal epidural hematoma typically appears as a biconvex mass dorsal to the thecal sac, with tapering cephalad and caudal margins (Fig. 112.3). Associated spinal cord edema may also be seen. Acute hemorrhage is characterized by a marked decrease in signal intensity on T2-weighted images. Subacute hematoma is characterized by increased signal intensity on both T1- and T2-weighted images. The dura matter appears as a low-signal curvilinear structure separating the hematoma from the spinal cord on T2-weighted gradient echo sequences. In one retrospective study of 17 patients with acute spinal epidural hematoma, 10 patients’ T1-weighted images showed isointensity to the spinal cord, and in 7 patients, the hematomas were slightly hyperintense. T2-weighted images showed hyperintensity with areas of hypointensity. Other MRI findings included hematomas showing direct contiguity with the adjacent osseous spine in 13 patients. Posterolateral location of the hematomas was noted in 13 patients. Additional findings were capping of the epidural fat, compression of the epidural fat and ligamentum flavum, and compression of the thecal sac and/or cord. MRI
will also help to identify associated spinal cord tumors or arteriovenous malformations. For patients who cannot undergo MRI scanning or in cases where MRI scanning is not immediately available, CT, with or without myelography, is the study of choice. A spinal epidural hematoma appears as a biconcave dorsal mass typically extending over at least two vertebral levels (see Fig. 112.3). Lumbar puncture does not add to the diagnosis and may worsen the patient’s condition in some instances.

**FIGURE 112.3** Magnetic resonance imaging (MRI) of the lumbosacral spine demonstrating a lumbar epidural hematoma. Axial (A) and sagittal (B) reconstructed T2-weighted MRIs demonstrating a biconvex mass dorsal to the thecal sac extending from the cervicothoracic junction to the low thoracic area, with tapering cephalad and caudad margins, the typical appearance of an epidural hematoma.

When spinal epidural hematoma is entertained as a diagnosis, urgent neurosurgical consultation should be obtained. In a retrospective study of 30 patients who were treated for spinal epidural hematoma between 1979 and 1993, rapidity of surgical decompression of the spinal cord correlated with neurologic outcome. Patients who were taken to surgery within 12 hours of symptom onset fared significantly better than those whose surgery was delayed beyond 12 hours. In this series, the patients’ preoperative neurologic status was also predictive of outcome. Of note, in a series of 30 patients, of 8 patients who had complete loss of neurologic function (Frankel grade A), 6 improved with surgical decompression, and 2 of these regained normal function. Emergent surgical evacuation remains the standard of care and treatment of choice for spinal epidural hematoma. In
some instances, spinal epidural hematomas have been successfully conservatively managed, typically in patients whose neurologic examination was spontaneously, steadily improving.\textsuperscript{18}

**Infectious Complications**

Infectious complications may ensue following either peripheral or central neuraxial blockade, although the latter is more likely to lead to catastrophic sequelae such as meningitis or compression of neural structures. Both superficial and deep infections have been reported following epidural injections, facet joint injections, and trigger point injections. In the case of indwelling catheters, the risk of infection increases with increased duration of catheter therapy. One systematic review examining 4,628 cancer patients with indwelling catheters left in place for 7 days or more found that the incidence of deep infection was 1 per 2,391 days of treatment, or 0.4 per 1,000 catheter treatment days. The average catheter duration for these patients was shown to be 74 days with a deep infection rate reaching 2.8%. Four out of 57 of the patients with deep infections related to their indwelling catheters died from these infection complications.\textsuperscript{19} When comparing infection rates between cancer and noncancer patients, one study retrospectively examined 131 patients (80% cancer patients) and found no difference in infection rates of spinal cord stimulator and intrathecal drug delivery systems.\textsuperscript{20} In the case of implanted spinal cord stimulators and intrathecal drug pumps, a review of four prospective trials found 36 infections in 35 patients out of a total of 700 patients who underwent implantation. The overall infection rate was 5% with 57% to 80% of the infections in the trials involving the pump pocket, 13% to 33% involving the lumbar site, and 0% to 14% leading to meningitis.\textsuperscript{21} One study showed that a more skilled/experience operator had a lower infection rate (1.8%) compared to the less skilled/experienced (13%).\textsuperscript{22} All patients undergoing interventional therapies for pain treatment should be given explicit written postprocedural guidelines that include a clear description of the signs and symptoms that may herald an infection and a clear process for contacting pain clinic personnel on an urgent basis if such signs and symptoms develop.

5363
The source of the pathogen may be either external, as in the case of contaminated equipment or breaches in sterile technique, or internal, in the case of patients with local or systemic infections such as skin and soft tissue infections or bacteremia. It is not surprising then that occlusive postsurgical dressings and perioperative antibiotics have been shown to decrease the risk of infections. Risk factors for infection include diabetes, alcoholism, smoking, and immunosuppression. Similarly, infections in the epidural space may spread to other areas via hematogenous spread or local extension. Pathogens include skin flora such as Staphylococcus aureus and Staphylococcus epidermidis. In patients with implanted spinal catheters or devices, the incidence of methicillin-resistant S. aureus epidural infection is particularly high. Injury to the neural structures may occur due to direct compression by an abscess or due to ischemia caused by septic thrombophlebitis.

Initially, the patient with an evolving epidural abscess typically presents with back pain at the affected level of the spine. Subsequently, they may develop radicular pain corresponding to the involved level. They may then progress to development of motor and sensory deficits accompanied by bowel and bladder dysfunction and finally to frank paralysis. Back pain will be present in roughly three-quarters of patients, fever in almost half, and neurologic deficits in about one-third. Thus, the classic triad of back pain, fever, and neurologic deficit is seen in only a minority of patients. Both the duration of symptoms prior to presentation and the rate of progression of symptoms can be highly variable. Spinal epidural abscesses typically extend over three to four vertebral levels; however, in rare instances, they may involve the whole spine. Laboratory studies should include a complete blood count with differential as about two-thirds of patients will have leukocytosis. Erythrocyte sedimentation rate and C-reactive protein are almost always elevated, although neither of these tests is specific. Blood cultures should be sent prior to the administration of antibiotics and approximately 60% of patients will be bacteremic. When lumbar puncture is performed, CSF analysis shows elevated protein and pleocytosis in three-quarters of patients. Gram staining and culture of CSF are negative in the majority of patients. Lumbar puncture adds little to the diagnosis and entails risk of causing meningitis if the needle traverses the
epidural abscess en route to the thecal space; CSF should be analyzed if myelography is undertaken.

MRI with IV gadolinium is the study of choice to evaluate possible epidural abscess (Fig. 112.4). MRI is highly sensitive for diagnosing epidural abscess and allows evaluation of the dimensions of the abscess which facilitates surgical planning. If MRI is contraindicated or is not readily available, CT myelography is also quite sensitive but is more invasive. Plain x-rays or CT scan of the spine without myelography may demonstrate diminished disk space and/or bony destruction suggestive of discitis and osteomyelitis. These conditions coexist with epidural abscess in up to 80% of cases. Urgent surgical drainage accompanied by administration of systemic antibiotics is the standard of care for epidural abscesses. In rare cases, percutaneous drainage with systemic antibiotics or antibiotic treatment in the absence of surgery may be undertaken.
FIGURE 112.4 Magnetic resonance imaging of the lumbosacral spine demonstrating epidural abscess. This is a 64-year-old who presented with worsening axial low back pain 2 weeks following lumbar epidural injection of steroid for treatment of acute radicular pain. Axial (A) and sagittal (B) T1-weighted images. Axial (C) and sagittal (D) T2-weighted images. Axial (E) and sagittal (F) T1-weighted images following intravenous administration of gadolinium. These findings are compatible with diskitis/osteomyelitis at L2–L3, with enhancement of the anterior epidural space and a focus of high T2 and low T1 signal in the left anterior epidural space consistent with epidural abscess.

Superficial infections typically present with local erythema, pain,
swelling, and, in some cases, purulent discharge. In some instances, superficial infections associated with catheters can be managed with local drainage and antibiotics without removing the catheter. Some cases of superficial infections and pocket site infections following implantations of spinal cord stimulators and intrathecal drug pumps have been successfully managed using oral and parenteral antibiotics that correspond to antimicrobial sensitivities on the basis of wound cultures, although the implanted device has been left in place. However, as other authors have noted, device-related infections are rarely completely eradicated without removal of the device in question. This observation mirrors the extensive experience with infected cardiac pacemakers. In all cases, a high degree of vigilance must be maintained to the possibility that a device-related superficial or pocket infection may spread to the neuraxis with catastrophic results. In the event that signs of infection such as erythema, swelling, fluctuance, or tenderness progress along the course of an implanted lead or catheter, the device with all associated hardware should be surgically removed on an urgent basis. Similarly, urgent device removal should be undertaken if the patient displays signs of systemic infection such as fever or chills, or signs of possible meningitis such as fever, neck pain and stiffness, severe headache, or altered mental status. At the time of surgery, separately labeled wound cultures should be sent from all surgical sites, and all surgical sites should be extensively irrigated. As with spinal epidural hematoma, the patient’s preoperative neurologic function is the best predictor of final neurologic outcome. For any patient where there is a significant concern for systemic infection or meningitis, antibiotics should be administered immediately and should not be delayed until cultures can be obtained. Empiric antibiotic coverage should provide coverage of Staphylococcus species, preferably with vancomycin to ensure coverage of methicillin-resistant S. aureus, Streptococci species, and should also provide coverage of gram-negative microbes with a third- or fourth-generation cephalosporin (such as cefepime or ceftriaxone) or equivalent. When the etiologic agent has been identified, antibiotics should be directed toward the specific pathogen. Five percent of patients with spinal epidural abscesses die secondary to sepsis or other infectious complications signifying the importance of early
Local Anesthetic Systemic Toxicity

Lidocaine and bupivacaine are amide local anesthetics which are widely used in interventional pain management procedures due to their relative safety. Lidocaine is of relatively lower potency and has a rapid onset of action and an intermediate duration of action. Nonetheless, the potential for lidocaine associated systemic toxicity due to excessive dose, inadvertent intravascular administration, or unanticipated rapid absorption is well recognized. Bupivacaine is of higher potency but has a slower onset and prolonged duration of action. Local anesthetics, including lidocaine and bupivacaine, bind sodium channels and inhibit the sodium permeability that underlies action potentials in both neurons and cardiac myocytes. Local anesthetic inhibition of sodium permeability increases with repeated depolarization. In addition to binding sodium channels, local anesthetics will bind potassium and calcium channels as well as N-methyl-D-aspartate receptors, β-adrenergic receptors, and nicotinic acetylcholine receptors. Indeed, local anesthetic toxicity may be mediated in part through binding to these channels and receptors. In general, the anesthetic potency of a local anesthetic correlates with its central nervous system (CNS) toxicity. Local anesthetics appear to cause cardiac toxicity through several different mechanisms including inhibition of calcium and potassium channels and inhibition of β-adrenergic receptors and epinephrine stimulated cAMP formation. Local anesthetics prolong cardiac conduction in a dose-dependent fashion. With increasing serum concentration, bupivacaine provokes QT prolongation, ventricular tachycardia, and ventricular fibrillation. Risk factors for the development of local anesthetic toxicity include the extremes of age, end-organ dysfunction (hepatic, renal, and cardiac), and pregnancy. The threshold dose of local anesthetic required to provoke seizures is affected by the route and rate of injection, the rate of increase of serum drug concentration, the presence of acidosis, and whether the patient is awake or anesthetized. Local anesthetic toxicity may result from systemic absorption of excessive doses following local infiltration; however,
toxicity more commonly occurs due to inadvertent intravascular injection. Intra-arterial injection poses a greater risk of CNS and cardiovascular toxicity than IV injection because, in the latter case, passage through the lung allows for some clearance of the drug. In the case of intra-arterial injection, doses as small as 2.5 mg of bupivacaine or 15 mg of lidocaine have resulted in seizures when injected into the carotid or vertebral arteries, and this is felt to result from direct delivery of the local anesthetic to the brain.\textsuperscript{34,35}

In the event of lidocaine toxicity, CNS symptoms typically precede cardiovascular symptoms.\textsuperscript{36} CNS symptoms are initially characterized by inhibitory neuronal blockade leading to excitatory manifestations such as perioral numbness, a metallic taste, tinnitus, restlessness, confusion, a sense of impending doom, visual disturbances that are most commonly described as oscillations of objects in the visual fields, shivers, tremors, and tonic-clonic seizures (Fig. 112.5). Sympathetic stimulation is also observed during this phase, with resultant tachycardia and hypertension.\textsuperscript{37} In patients who are receiving procedural sedation with benzodiazepines or other sedatives, the excitatory phase of local anesthetic toxicity may not be apparent. The excitatory phase is followed in episodes of severe toxicity by a depressed phase characterized by coma and respiratory arrest. Cardiovascular toxicity develops at higher serum levels and may include profound bradycardia, arrhythmias, contractile dysfunction, and asystole.\textsuperscript{31} In the case of bupivacaine, doses that are insufficient to provoke seizures will provoke cardiac arrhythmias.\textsuperscript{38}

![Relationship between plasma concentration of lidocaine and the development of signs and symptoms of local anesthetic toxicity.](image)

**FIGURE 112.5** Relationship between plasma concentration of lidocaine and the development of signs and symptoms of local anesthetic toxicity.

Treatment of local anesthetic–induced seizures focuses on maintaining
the airway and oxygenation. The injection or infusion of local anesthetic must be stopped immediately. Lorazepam, midazolam, thiopental, or propofol may be used to terminate the seizure. Cardiovascular depression with resultant hypotension due to local anesthetic toxicity should be treated with IV crystalloids and vasopressors such as norepinephrine, or phenylephrine. In the event of severe contractile dysfunction, epinephrine should be administered. If cardiac arrest occurs, advanced cardiac life support (ACLS) protocol should be pursued, although if epinephrine is used, small initial doses (≤1 μg/kg) are preferred and vasopressin is not recommended. Successful resuscitation following cardiac arrest due to bupivacaine toxicity has included the administration of IV lipid emulsion. A 20% lipid emulsion may be administered as a 1.5 mL/kg bolus followed by a 0.25 mL/kg/min infusion for 30 to 60 minutes. A repeat bolus is often administered for persistent cardiovascular collapse. It should be noted that the lipid emulsion infusion should be continued for at least 10 minutes after hemodynamic stability is achieved. Current evidence suggests that lipid emulsion works as a carrier to scavenge local anesthetic away from high blood flow organs that are most sensitive to local anesthetic toxicity (i.e., the heart and brain) and redistribute it to organs that store and eliminate the drug (i.e., muscle and liver, respectively). In the presence of persistent cardiovascular collapse associated with local anesthetic administration, urgent institution of cardiopulmonary bypass can be lifesaving. The American Society of Regional Anesthesia and Pain Medicine recently published their most recent Practice Advisory on Local Anesthetic Systemic Toxicity, and this includes an up-to-date and comprehensive review of this topic.

UNINTENDED DESTINATIONS FOLLOWING LOCAL ANESTHETIC ADMINISTRATION

The direct effects of local anesthetics are critically dependent on where they are applied. Inadvertent intrathecal injection of local anesthetic can result in a high thoracic or cervical level of sensory and motor block or total spinal anesthesia, with transient loss of consciousness and respiratory arrest. This is most likely to occur during cervical injections or when a large volume of local anesthetic is used during lumbar injections. Signs
and symptoms of a high spinal progress rapidly and most typically include flaccid paralysis, apnea, hypotension, bradycardia, and dilated pupils. They initially include symptoms of sympathectomy, presenting as light-headedness, dizziness, nausea, and vomiting. In addition, the patient may develop air hunger due to loss of intercostal muscle activity, followed by phrenic nerve paralysis and eventually apnea due to blockade of the respiratory center in the brainstem. Blockade of the cardioaccelerator fibers at T1 to T4 or of the medulla may inhibit sympathetic positive chronotropic effects resulting in bradycardia, hypotension, or arrhythmias. Blockade of the Edinger-Westphal nucleus with subsequent loss of efferent parasympathetic activity produces dilated, nonreactive pupils. In the case of subdural injection, symptoms develop more slowly, typically 15 to 30 minutes after injection, and are commonly asymmetric. When symptoms do occur, they may progress to respiratory and cardiovascular collapse as with intrathecal injection. When a high spinal occurs, ventilation with 100% oxygen with a bag valve mask must be initiated if phrenic nerve blockade or apnea is present. Endotracheal intubation may be required to maintain ventilation or protect the lungs from aspiration. Bradycardia and hypotension should be treated with crystalloids and atropine, ephedrine, phenylephrine, or epinephrine. The patient may remain awake but paralyzed during a high spinal, so reassurance that the condition is temporary is warranted as is consideration of administration of an anxiolytic agent.

**VASOVAGAL REACTIONS**

Vasovagal reactions, which may include frank syncope, are one of the most common emergencies encountered in a pain center. Fortunately, these episodes typically have a benign natural history. Sir William Gowers first used the term vasovagal in 1907, and vasovagal syncope is now accepted as the most common form of syncope, accounting for two thirds of syncopal episodes presenting to the emergency department. The pathogenesis of vasovagal syncope remains uncertain, but the current understanding is that it results from venous pooling and reduced venous return and that vigorous contraction of the heart’s chambers when they are inadequately filled provokes the Bezold-Jarisch reflex, resulting in
paradoxical hypotension and bradycardia. At the onset of a vasovagal reaction, patients typically appear pale and diaphoretic and complain of light-headedness, sweatiness, nausea, and tunnel vision. Myoclonic jerks may accompany vasovagal syncope and may be clinically indistinguishable from seizure activity. If a patient exhibits signs of a vasovagal reaction during an interventional pain treatment procedure, the procedure should be halted, and the patient should be placed supine if not already in that position. Care should be taken to ensure that the patient will not fall and sustain a secondary injury. Randomized trials have demonstrated that leg crossing, and isometric arm exercises can help prevent progression to vasovagal syncope. Most cases of vasovagal syncope will resolve spontaneously and will require only conservative measures. In the event that blood pressure and heart rate continue to decline, an IV line should be placed, crystalloids and oxygen administered, the patient should be placed on a cardiac monitor and a vasopressor, such as ephedrine (in 5- to 10-mg increments) or an anticholinergic drug such as atropine (0.4 to 1 mg) should be administered.

Complications Associated with Intrathecal Drug Delivery

When drugs are delivered via the intrathecal route, complications may arise either due to withdrawal or due to administration of an excessive dose. In the case of intrathecal baclofen administration, withdrawal may be particularly severe and can even be fatal. Baclofen is an analogue of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). It acts as an agonist of the GABA$_B$ receptors in the brainstem, dorsal horn of the spinal cord, and other CNS regions. Although the mechanism of intrathecal baclofen withdrawal is not established, it may be due to diffuse disinhibition of GABA$_B$-modulated pathways. Although the most common manifestation of under dosage of baclofen is pruritus and return of the patient’s spasticity, abrupt baclofen withdrawal may result in a life-threatening syndrome characterized by fever, tachycardia, labile blood pressure or hypotension, malaise, dysphoria, and hallucinations followed by coma, rebound spasticity more severe than the patient’s baseline,
hyperreflexia or rigidity, paresthesias, priapism in males, and seizures. If not treated adequately and promptly, the patient may develop rhabdomyolysis, brain injury, kidney and liver failure, and disseminated intravascular coagulation. In some cases, death ensues. The differential diagnosis of intrathecal baclofen withdrawal includes infection, neuroleptic malignant syndrome, serotonin syndrome, malignant hyperthermia, and autonomic dysreflexia. Paradoxically, the diagnosis may be more difficult to make in more severe cases of withdrawal. Symptoms of intrathecal baclofen withdrawal typically present 1 to 3 days after interruption of baclofen delivery. Interruption of baclofen delivery may be due to an exhausted drug reservoir after missing a scheduled refill, pump malfunction, catheter kinking or disruption, or mistakes in drug formulation or pump programming. Restoration of adequate intrathecal baclofen delivery by addressing pump problems or by lumbar puncture or drain represents the most definitive therapy. If the pump catheter remains intact, intrathecal baclofen may be administered via the side port. Evaluation of the pump should be performed with the manufacturer’s interrogation device. If interrogation of the pump does not reveal the underlying problem, a catheter dye study should be undertaken and the pump should be refilled with medication at the correct concentration. To conduct a catheter dye study, radiographic contrast is administered through the side port of the infusion device to assess the integrity and position of the intrathecal catheter. Oral and enteral baclofen administration (up to 120 mg per day of baclofen in six to eight divided doses in adults), accompanied by IV benzodiazepine administration should be undertaken until intrathecal baclofen delivery is restored. Oral and enteral baclofen alone are often insufficient to treat withdrawal from intrathecal baclofen. Continuous or intermittent infusions of diazepam or midazolam may be rapidly titrated upward until muscle relaxation, cessation of seizure activity, and normal blood pressure and temperature are restored. Propofol infusion and chemical paralytic agents may also be used in the intubated patient. The patient should be treated in a setting where critical care monitoring and ventilator and cardiovascular support is available. In some cases, patients with hyperthermia have been treated with dantrolene. In case reports, cyproheptadine has proven helpful. In contrast, baclofen
overdose typically presents with somnolence, hypothermia, comas, seizures, respiratory depression, hypotonia, and arrhythmias. Treatment consists of intubation and artificial ventilation as indicated and immediately turning off the pump with the manufacturer’s programmer or, if this is not available, emptying the pump reservoir. In cases where the overdose is detected within the first few hours, withdrawal of 30 to 40 mL of CSF via the catheter access port of the pump may reverse the overdose. Phystostigmine may reverse drowsiness and respiratory depression (adult dose 0.5 to 2 mg IV over 5 to 10 minutes, may repeat every 10 to 30 minutes as required; pediatric dose 0.02 mg/kg IV, less than 0.5 mg per minute, may repeat every 5 to 10 minutes as required up to 2 mg maximum).

**OPIOID WITHDRAWAL**

Opioid withdrawal can also occur in patients receiving intrathecal drug delivery or systemic opioids and typically manifests with anxiety, insomnia, yawning, diaphoresis, lacrimation, rhinorrhea, mydriasis, myalgias, piloerection, nausea, vomiting, diarrhea, and abdominal cramping. In patients for whom ongoing opioid therapy is indicated, treatment consists of resuming opioid therapy. In some cases, an alternate route of administration may be necessary, such as IV and/or transdermal delivery for a patient who is no longer able to take oral medications. In cases where opioid therapy is not indicated, symptoms of opioid withdrawal may be mitigated with α₂-adrenergic agonists such as clonidine (0.1 to 0.3 mg orally per dose every 6 to 8 hours increasing to a maximum of 1.2 mg per day) or lofexidine (0.4 to 0.8 mg orally per dose increasing to a maximum of 2.4 mg per day). α₂-Adrenergic agonists may cause hypotension, fatigue, lethargy, and dry mouth. Nausea and vomiting may be treated with IV fluids and antiemetics such as metoclopramide or prochlorperazine. Diarrhea and colicky abdominal pain may be treated with loperamide or hyoscine butylbromide. Agitation may be treated with benzodiazepines, although a careful consideration of risks is necessary anytime concurrent benzodiazepines and opioids are prescribed. It should be noted that opioids are not a first-line or routine therapy for chronic, noncancer pain. The Centers for Disease Control and Prevention
(CDC) Guidelines for Prescribing Opioids for Chronic Pain include several recommendations for determining when to initiate or continue chronic opioids for chronic pain. Complications from opioid withdrawal are often avoidable simply from a proper assessment prior to clinical prescription. In assessing potential risks, the CDC recommends that clinicians should review their respective state prescription drug monitoring program data periodically during opioid therapy for chronic pain, ranging from every prescription to every 3 months.58

**Anaphylactic and Anaphylactoid Reactions**

At the turn of the 19th century, Charles Richet and Paul Portier coined the term anaphylaxis when they observed that several dogs died following repeat challenges with Physalia extracts during experiments that they reported while guests on Prince Albert of Monaco’s yacht in the Mediterranean Sea.59 In an anaphylactic reaction, the inciting allergen binds to previously formed immunoglobulin E (IgE) on the surface of previously sensitized mast cells and basophils. These cells release mediators such as histamine, leukotrienes, prostaglandins, bradykinins, and thromboxanes that cause markedly reduced vascular tone, increased mucous membrane secretions, and increased capillary permeability.60 Anaphylactoid reactions produce a similar and often indistinguishable clinical picture but are not IgE mediated. Anaphylactoid reactions occur through nonimmune-mediated release of mediators from mast cells and/or basophils or result from direct complement activation.61 Generalized hypersensitivity reactions may be divided into grade 1 or mild reactions, grade 2 or moderate reactions, and grade 3 or severe reactions.62 Grades 2 and 3 correspond with anaphylaxis and are clinically similar to anaphylactoid reactions. Grade 1 reactions are defined by generalized erythema, urticaria, periorbital edema, or angioedema. Grade 2 reactions are characterized by dyspnea, stridor, wheezing, nausea and vomiting, dizziness or presyncope, chest or throat tightness, or abdominal pain. Grade 3 reactions are defined by cyanosis or an oxygen saturation less than or equal to 92%, hypotension, confusion, collapse, loss of consciousness, or incontinence. Cutaneous manifestations such as erythema, itch, and
urticaria are present in almost all cases, although they may be quite subtle. Therefore, when the diagnosis is unclear, it is crucial to fully undress the patient and carefully examine the skin. In one retrospective study of 1,149 cases of generalized hypersensitivity treated in the emergency department, 250 cases were assessed as being due to medications; 145 cases were believed to be due to antibiotics, with the majority being β-lactam antibiotics. Nonsteroidal anti-inflammatory drugs were implicated in 32 cases, narcotics in 11 cases, radiologic contrast in 7 cases, angiotensin-converting enzyme (ACE) inhibitors in 4 cases, vaccines in 4 cases, and other or unclear medications in 47 cases. The median interval between drug administration and fatal collapse is 5 minutes. The differential diagnosis of anaphylactic and anaphylactoid reactions includes asthma attack, scombroid poisoning, angioedema either secondary to ACE inhibitors or hereditary, panic attack, and vasovagal syncope (these last two conditions do not cause urticaria, angioedema, or bronchospasm).

There are no randomized trials of therapies for these potentially fatal reactions, so most treatment recommendations are on the basis of consensus. The patient undergoing an anaphylactic or anaphylactoid reaction should be administered high flow oxygen. Intramuscular (IM) epinephrine should be given early to all patients with signs of a systemic reaction such as hypotension, airway edema, or dyspnea (0.3 to 0.5 mg, 1:1,000, IM repeated every 15 to 20 minutes if there is no clinical improvement). If the reaction appears to be severe and/or imminently life threatening, IV epinephrine should be given (0.1 mg, 1:10,000, IV over 5 minutes, followed by an IV infusion of 1 to 4 μg per minute as needed). Patients receiving epinephrine should be monitored in an emergency department or intensive care unit. Aggressive fluid resuscitation with isotonic crystalloids such as normal saline should be undertaken. One liter to 2 L should be rapidly infused. Antihistamines such as diphenhydramine should be given (25 to 50 mg per dose IV or IM) as well as H2 blockers (e.g., cimetidine 300 mg IM or IV). Bronchospasm should be treated with inhaled β-adrenergic agents such as albuterol and/or IV/IM epinephrine. High-dose IV corticosteroids should be administered early, although their therapeutic effects are seen 4 to 6 hours after administration. Other therapies which may be considered in anaphylaxis or anaphylactoid reactions...
reactions include vasopressin, which has been beneficial in case reports for severely hypotensive patients, atropine in the setting of severe bradycardia, and glucagon for patients who are unresponsive epinephrine, particularly if they are taking β-blockers. Pumphrey, who attempted to identify and analyze every fatal anaphylactic reaction in the United Kingdom since 1992, stresses the importance of keeping patients supine with their legs elevated.

**CATASTROPHIC NEURAL INJURIES AND THE ADMINISTRATION OF PARTICULATE STEROIDS**

In the cervical spine, the carotid and vertebral arteries lie in close proximity to the stellate ganglion, the cervical facet joints, and the cervical intervertebral foramina. The anterior spinal artery provides the principal vascular supply to the spinal cord. The anterior spinal artery arises rostrally from the vertebral arteries and receives input from six to nine radicular arteries. It is located at the anterior central sulcus and supplies the anterior two-thirds of the spinal cord. The posterior spinal arteries supply the posterior one-third of the spinal cord. They are paired and run just medial to the dorsal roots. The arteria radicularis magna (more commonly referred to as the artery of Adamkiewicz) is the largest of the radicular arteries. It is most commonly located at T10 on the left side but may occur anywhere from T8 to L2 and occurs on the right in 17% of subjects. In addition, the ascending cervical artery and the deep cervical artery each furnish spinal branches that enter the intervertebral foramina. These spinal branches not only supply the vertebral column but also give rise to radicular arteries that accompany the dorsal and ventral roots of the spinal nerves (Fig. 112.6). In some individuals, the radicular arteries are substantial in size and reinforce the anterior spinal artery. Such reinforcing arteries can occur at any cervical level and those radicular arteries that supply the spinal cord are termed spinal medullary arteries. If reinforcing radicular arteries are compromised by a transforaminal injection, infarction of the cervical spinal cord could ensue. If the vertebral or carotid arteries are entered, infarction of the brainstem and portions of the brain supplied by the posterior circulation may ensue, causing stroke, often resulting in death.
The first report of a complication attributed to cervical transforaminal injection of steroids described a patient who died from a spinal cord infarction. The location of the infarction implied that a radicular artery that reinforced the anterior spinal artery had been compromised, but no evidence was offered about the mechanism by which the artery had been compromised. Images of the placement of the needle were not published.

Reports of spinal cord infarction following cervical or lumbar transforaminal injection of steroid have appeared, and this topic has been reviewed in detail. Vertebral artery injection with subsequent stroke involving the posterior circulation has also been reported. A similar case of massive infarction involving the posterior cerebral circulation following injection of particulate steroid during attempted intra-articular atlantoaxial joint injection is shown in Figure 112.7.
Cerebrovascular accident following intra-arterial injection of particulate steroid during attempted intra-articular atlantoaxial (C1/C2) joint injection. A: Lateral fluoroscopy imaging demonstrating needle position adjacent to the C1/C2 facet joint. B: Axial magnetic resonance imaging (T1 FLAIR sequence) of the brain. Frontal (C) and axial (D) computed tomography angiography of the vertebral arteries; arrows point to a small filling defect within the left vertebral artery adjacent to the left C1/C2 facet joint, suggesting the point of needle entry into the vertebral artery. The proximity of the vertebral artery to the C1/C2 facet joint is immediately apparent from the images.

The exact mechanism of spinal cord injury following transforaminal injections has not been determined. As analyzed using MRI, the pattern of injury strongly implicates a reinforcing radicular artery. Spasm of the artery would seem to be an unlikely mechanism because it is inconsistent with the vasodilatory effect of local anesthetic agents when applied to arterial walls. Embolism of particulate steroids ranks as the leading hypothesis, but direct evidence is still lacking. In cases involving the vertebral artery, a similar uncertainty remains. The injection of contrast medium cannot be an explanation; in the past, direct puncture of the
vertebral artery has been used for angiography. Steroid embolism remains the most likely explanation.

The guidelines for the conduct of cervical transforaminal injections are designed to guard against these complications. These guidelines stipulate that the needle must be accurately and correctly placed. Once the needle has been placed, a test dose of contrast medium should be injected and its flow carefully monitored during injection. That injection tests two things. First, under normal circumstances, it should show that the injectate is correctly flowing around the target nerve and into the lateral epidural space. Simultaneously, but more critically, it shows if an intravascular injection has occurred.

Neurologic complications of transforaminal injections are typically catastrophic. They are clinically obvious on the onset of spinal weakness and numbness. Spinal cord infarction due to embolization of a radicular artery is clinically indistinguishable from the anterior spinal artery syndrome, also known as Beck syndrome. Patients develop abrupt onset of weakness below the level of the infarction, flaccid paralysis, areflexia, loss of pain and temperature perception, and atonic urinary bladder. Position and vibratory sensation will typically be relatively intact. Preserved proprioception at symptom onset has been associated with better outcomes. In contrast to cerebrovascular infarction, spinal cord infarction is frequently painful. Patients may experience a radicular or back pain, and some cases, spinal cord infarction will mimic angina pectoris. Later in the clinical course, the patient may develop spasticity, hyperreflexia, Babinski responses, and clonus. In the setting of possible acute spinal cord infarction, the differential diagnosis may include spinal cord compression by a mass lesion such as a spinal epidural or subdural hematoma or abscess, or a herniated nucleus pulposus. When spinal cord infarction is suspected, emergent MRI of the spinal cord should be undertaken to rule out the presence of any space-occupying lesion that may be amenable to surgical decompression. If spinal cord infarction is present, sagittal T2-weighted MRI scanning performed at least 4 hours after symptom onset commonly reveals “pencil-like” hyperintensities and cord enlargement. Diffusion weighted imaging is particularly sensitive for detecting ischemic changes in the spinal cord. Common diagnostic
pitfalls include failure to image higher levels of the spinal cord when the patient develops a sensory level that is caudal to the infarction.

One collaboration between the U.S. Food and Drug Administration (FDA), an expert multidisciplinary working group, and 13 specialty stakeholder societies reviewed existing evidence and produced a consensus to enhancing the safety of neuraxial injections.\textsuperscript{75} A few of these notable endorsed clinical considerations included the following:

A. Cervical and lumbar interlaminar ESIs should be performed using image guidance, with appropriate posteroanterior, lateral, or contralateral oblique views and a test dose of contrast medium.

B. Cervical and lumbar transforaminal ESIs should be performed by injecting contrast medium under real-time fluoroscopy and/or digital subtraction imaging, using an anteroposterior view, before injecting any substance that may be hazardous to the patient.

C. Cervical interlaminar ESIs are recommended to be performed at C7–T1 but preferably not higher than the C6–C7 level.

D. Particulate steroids should not be used in therapeutic cervical transforaminal injections.

E. A face mask and sterile gloves must be worn during the procedure.

F. Moderate-to-heavy sedation is not recommended for ESIs, but if light sedation is used, the patient should remain able to communicate pain or other adverse sensations or events.

There is no emergency management known to reverse spinal cord infarction. Many of the principles guiding treatment of acute spinal cord infarction are derived from experience treating ischemic cerebrovascular accidents. Initially, emphasis should be placed on reducing the likelihood of secondary injury to the spinal cord by preventing hypotension and/or hypoxia. In addition, rapid triage and transport to a definitive care facility with appropriate imaging, critical care, and surgical capabilities should be undertaken. In the case of ischemic cerebrovascular accidents, induced hypertension to achieve a mean arterial pressure of 20% to 30% above baseline or to achieve a predefined target mean arterial pressure has been advocated, although this therapy remains controversial.\textsuperscript{76} Although aspirin has been advocated for the treatment of spinal cord infarction related to atherosclerotic disease or dissection, principally on the basis of its use in
the treatment of ischemic stroke, there does not appear to be a role for antiplatelet or anticoagulant therapy in the treatment of spinal cord infarction presumed secondary to embolization of particulate steroids. In a prospective study of 77 patients with acute neurologic deficits secondary to spinal cord injuries, patients treated with 7 days of volume resuscitation with crystalloids, transfusion of blood products to maintain a hematocrit greater than 32, as well as dopamine and norepinephrine (Levophed) as needed to maintain a mean arterial blood pressure greater than 85 mm Hg had better neurologic outcomes than historical controls. This therapy has not been studied in prospective randomized controlled trials. One 2014 meta-analysis examining over 13,000 patients found that blood pressure reduction started within 7 days of acute stroke led to an increase in risk of mortality within 30 days, although it had no effect on long-term mortality. Treatment of nonpenetrating acute spinal cord injury with methyl prednisolone remains controversial despite evaluation in three large, prospective randomized double-blind controlled trials. At the current time, there is insufficient evidence to advocate routine administration of methylprednisolone to patients with acute spinal cord infarction. Standard measures to prevent complications of acute paraplegia should be implemented, including measures directed at prevention of deep venous thrombosis and pulmonary embolus, as well as bladder catheterization if indicated. Early consultation with physiatrists should be undertaken in order to optimize functional recovery and prevent development of spasticity and decubiti.

Conclusion

Although emergencies in the pain clinic are quite rare, when they do occur they can be catastrophic and even deadly. The pain specialist should be familiar with the most common complications and their mechanisms as well as techniques that can be used to reduce the risk of said complications. Familiarity with common complications, including their clinical presentations and natural histories, will facilitate prompt recognition and treatment, thereby improving the chances of good outcomes. Pain specialists should educate patients about specific signs and
symptoms of complications that may ensue from their treatment and provide them with clear instructions for reaching members of the pain clinic staff or emergency health care providers in a timely manner, both during clinic hours and on evenings and weekends, in order to achieve prompt identification and treatment of complications when they arise.

The specialties of both emergency medicine and pain medicine are relatively new members of the modern house of medicine. The first academic department of emergency medicine was established in 1971, and the American Board of Medical Specialties recognized emergency medicine as a distinct specialty by conferring primary board status only 30 years ago. The numbers of visits to US emergency departments (EDs) have increased markedly over the past decade. From 2005 to 2015, the annual ED visit volumes increased from 115.3 million to 136.3 million, a 20% increase following a similar increase in the previous decade. There are more than 34,000 active board-certified emergency physicians, 31,000 of whom are represented by the American College of Emergency Physicians (ACEP).

EDs provide care for patients with an extraordinarily broad range of illnesses and injuries associated with both acute and chronic pain. Pain is common in the ED, with up to 42% of ED visits being related to painful conditions. It is commonly believed that injury and trauma are responsible for the majority of ED visits associated with pain; however, this impression is misleading. A landmark multicenter study of adults presenting to EDs in the United States and Canada with moderate to severe pain found that two-thirds of patients presentation with pain from medical, rather than traumatic, conditions. Major categories of discharge diagnoses reported in this study appear in Figure 113.1.
FIGURE 113.1  Major categories of discharge diagnoses among patients presenting to the emergency department (ED) with moderate to severe pain. Note: Other diagnoses present for 243 patients. URI, upper respiratory tract infection; UTI, urinary tract infection. (Data from Todd KH, Ducharme J, Choiniere M, et al. Pain in the emergency department: results of the Pain and Emergency Medicine Initiative (PEMI) multicenter study. J Pain 2007;8[6]:460–466.) In the United States, the ED serves as a safety net for our fragmented health care system. Pain is but one of many conditions for which emergency physicians not only treat acute clinical presentations but also care for those with chronic or recurrent painful conditions who are unable to access other parts of the health care system. Emergency physicians also frequently manage pain in the course of performing emergent diagnostic and therapeutic procedures.

This chapter discusses the prevalence of acute and chronic pain in the ED, its assessment, barriers to adequate pain treatment, the influence of substance use disorders and aberrant drug-related behaviors on ED pain practices, as well as a variety of commonly employed pain treatment and procedural sedation modalities. Space limits prohibit a discussion of the wide variety of specific painful conditions that present to the ED.

The Prevalence of Pain in the Emergency Department

Pain is the most frequent reason for seeking ED treatment, and as a part of the presenting complaint, pain accounts for over 70% of visits to US EDs.3–5 A study conducted by Tanabe and Buschmann,6 found that among adults treated at one Chicago ED, 78% presented with a chief complaint related to pain. Of these patients, only 47% received analgesics. For patients receiving analgesics, an average of 74 minutes elapsed from the
time of arrival to the time of treatment.

Cordell et al.\textsuperscript{4} reported an analysis of secondary data from an urban, tertiary-care ED using explicit data abstraction rules to determine the prevalence of pain and to assign painful conditions into standard categories. With inclusion of all age groups, they found evidence of pain in 61\% of patients. Pain was the chief complaint for 52\% of patient visits. After excluding patients less than 5 years of age for whom chart reviews are obviously less reliable, almost 70\% of patient encounters involved pain complaints.

Although the high prevalence of pain among ED patients is well documented, the underlying conditions responsible for pain in this population are less well characterized. In Cordell et al.’s\textsuperscript{4} retrospective study, 11\% of patients presenting to the ED were judged to be suffering from pain that was chronic in nature. In a larger prospective multicenter study conducted in the United States and Canada, 44\% of ultimately discharged patients presenting to the ED with pain reported underlying chronic pain syndromes. In one-half of these cases, the ED visit was prompted by an exacerbation of this chronic pain condition. Importantly, patients with chronic pain reported three to four times the number of annual physician visits when compared to those without chronic pain. Median and mean durations of symptoms for those reporting chronic pain syndromes were 24 and 52 months, respectively.\textsuperscript{3} For physicians who view themselves as experts in the management of acute medical and surgical emergencies, chronic pain may represent a less familiar condition with which to contend.

EDs frequently treat patients with chronic or recurrent pain who are often frustrated by a lack of information about ongoing pain management and poor access to specialty-level care. In a 2007 study, 500 US adults with chronic or recurrent pain and an ED visit within the past 2 years were interviewed.\textsuperscript{7} Sixty percent were female, their median age was 54 years, two-thirds were under the care of a physician, and 14\% were uninsured. They reported an average of 4.2 ED visits within the past 2 years. Relatively large proportions reported pain relief during the ED visit, and 57\% endorsed that “the ED staff understood how to treat my pain” as “definitely true.” Although over three-fourths of patients felt receiving that
additional information on pain management (82%) or referrals to specialists (74%) was “extremely” or “very” important, only one-half reported receiving such referrals (46%) or information (55%). A significant minority (11%) reported that the “ED staff made me feel like I was just seeking drugs.” The majority (55%) were “very” or “completely” satisfied with their medical treatment, whereas 24% were “neutral” to “completely” dissatisfied. In multivariate models, greater age, male gender, higher level of education, shorter waiting time, use of imaging, and pain relief contributed to patient satisfaction with ED care.

Findings from this survey provide a more precise estimate of the prevalence of ED use associated with chronic and recurrent pain in the United States. The final survey incidence rate of adults reporting a recent ED visit for chronic or recurrent pain was 15% of all those reached by phone. Given the US adult population of approximately 225 million, this survey incidence rate suggests that 34 million adults meet our criteria of an ED visit within the past 2 years for chronic or recurrent pain. Within this population, approximately 43%, or 15 million people, experience recurrent pain, whereas 57%, or 19 million people, have underlying chronic pain syndromes.

Pain management in the ED has received increased emphasis over the past two decades, including increased emphasis on patient satisfaction surveys, and The Joint Commission’s emphasis on analgesia. There have been a large number of important findings showing that analgesia in the ED is often inadequate, including an Institute of Medicine report, leading to emphasis on improving pain treatment. This emphasis has likely resulted in improvements in pain treatment in the ED but may have had the unintended consequence of increasing the use of opioids in the ED and after ED care.

The high prevalence of acute and chronic pain in the ED, and the increased emphasis on its treatment, has led to the question of the role of EDs in the increasing use of opioids in the United States. Among 20- to 29-year-olds, emergency medicine ranks third among specialties in terms of the number of opioid prescriptions, writing 12% of the total number of prescriptions. In one study, 17% of ED patients were discharged with an opioid medication, the majority of which were small
pill counts and immediate-release formulations. A recent study found that for opioid-naive patients, the odds ratio for developing recurrent use after a single prescription for opioids versus a nonopioid prescription from the ED was 1.8. This is difficult to interpret because many of the patients who received an opioid may have had more pain or a more severe injury than those who did not, but it highlights the need for attention to the risk of recurrent opioid use when they are used. The risk of opioids from the ED on patients in the ED with chronic or recurrent pain who already use opioids is much likely larger but is difficult to quantify. This complicates pain treatment in the ED and makes it a difficult challenge for emergency physicians.

The increase in deaths associated with opioid abuse has heightened concern and has led to the development of some actions to decrease the risk to patients. This includes the U.S. Food and Drug Administration’s proposal for the establishment of physician education programs for the prescribing of long-acting and extended-release opioids as part of the national opioid risk evaluation and mitigation strategy (REMS) program. Statewide opioid prescribing guidelines, such as those developed by the Utah Department of Health and the Washington Chapter of the ACEP, and guidelines developed by individual physician groups have shown promise in decreasing opioid prescription overdoses. ACEP has also developed a policy on the use of opioids that clarifies the use of state prescription monitoring programs, the treatment of back pain with opioids, and the use of different opioids. As research advances and policies develop, the role of EDs in opioid abuse will be further explored and the effects mitigated.

The Assessment of Pain in the Emergency Department

Pain is inherently subjective and inevitably complex. Patients experience pain and suffering as individuals; clinicians assess it only indirectly. The emergency provider’s task is to use a commonly understood vocabulary and classification system in assessing pain so that our findings can be communicated consistently. Only by quantifying the pain experience in
meaningful ways can we move beyond practices that are influenced by myth and opinion toward a scientific approach to our many questions regarding the pain experience. This challenge is at the root of the difficulties in treating pain and not only in the ED; thus, issues surrounding pain assessment should have primacy in our attempts to understand our patients’ pain experiences.

EDs employ a number of practical unidimensional pain assessment tools. Viewing pain as the “fifth vital sign,” as encouraged by The Joint Commission on Accreditation of Health Care Organizations, has fostered the widespread use of such tools. For those without cognitive impairment, pain intensity is routinely assessed with either an 11-point numerical rating scale (NRS) or a graphical rating scale (GRS). The NRS is sensitive to the short-term changes in pain intensity associated with emergency care and is the most commonly employed pain assessment instrument. GRS or picture scales are particularly useful for populations with limited literacy, including children. The visual analog scale (VAS) is used by some EDs; however, this instrument is more commonly employed in research settings. There is no demonstrated advantage in using a VAS over an NRS in the ED setting; both are reliable and valid measures of pain intensity. A patient’s answer to the query “Do you want more pain medication?” however, has been shown to be an unreliable measure of pain or relief, and descriptive pain scales are likely to prove more accurate and reliable.23 Among nonverbal patients, including infants or those with cognitive impairment and dementia, a number of observational pain scales are available for use. Both the Face, Legs, Activity, Cry, and Consolability (FLACC) observational scale for use in very young children24 and the Pain Assessment in Advanced Dementia scale for use in the setting of advanced dementia25 are used with some frequency in the ED; however, adequate observational pain assessments are less the exception than the rule.

No matter the specific pain scale used, assessments should be repeated after therapeutic interventions and at the time of ED discharge. One multicenter study found that relatively few ED patients are reassessed after an initial pain score, reporting that fewer than one-third of ED patients presenting with moderate to severe pain had repeat pain assessments while in the ED.3 Despite efforts to promote pain intensity as an outcome
measure with which to judge the quality of ED pain practice, the finding that pain intensity is measured only once in most EDs may mirrors medicine’s traditional view of pain as a diagnostic indicator rather than an outcome deserving of attention in its own right.

Oligoanalgesia in the Emergency Department

Notwithstanding the clinician’s duty to provide compassionate care, pain that is not acknowledged and managed appropriately causes anxiety, depression, sleep disturbances, increased oxygen demands with the potential for end-organ ischemia, and decreased movement with an increased risk of venous thrombosis.26 Failure to recognize and treat pain may also result in dissatisfaction with medical care, hostility toward the physician, unscheduled returns to the ED, delayed complete return to full function, and, potentially, an increased risk of litigation.27 Although adequate analgesia in the ED would appear to be an important goal of treatment, the underuse of analgesics, termed “oligoanalgesia” by Wilson and Pendleton28 in 1989, occurs in a large proportion of ED patients. A variety of factors are felt to give rise to pain under treatment, and these are listed in Table 113.1.

</table>

Emergency medicine investigators have identified a number of risk factors for oligoanalgesia, ranging from patient factors to physician variation.29 As in other settings, the very young or old tend to receive less intensive treatment for pain in ED. Studies have documented oligoanalgesia and delays to analgesic administration among those of minority ethnicity for a variety of painful conditions, even when objective evidence for the presence of pain is obvious (e.g., long-bone
Although patients’ expectations for pain treatment and perceptions of pain intensity don’t differ by ethnic groups, when patients are matched for socioeconomic factors, differences have been noted in the manner in which patients of different cultural backgrounds express their pain. Differences in the interactions of physicians and patients of different ethnic groups have been described, and subtle differences within these interactions may affect the physician’s pain assessment. When affect, actual patient–physician interaction, and cultural expressions of ethnicity are removed from a case presentation, such as through written clinical vignettes, patients with similar pain tend to be similarly treated by physicians. Cultural discordance between the patient and the physician may hinder the ability of patients to confer an understanding of their pain to the physician.

Of course, any treatment of pain is dependent on the physician’s accurate assessment of the patient’s pain. In fact, the only predictor of treatment that Bartfield and colleagues found for ED patients with back pain was the physician’s assessment, regardless of the patients’ ethnicity, age, or insurance status. Disparities in the treatment of pain are more likely to result from variations in physicians’ assessment of pain intensity than variations in treatment among patients judged to have similar degrees of pain.

Although emergency physicians may be reluctant to accept a patient’s report as the most reliable indicator of pain, and disparities between patient’s and physician’s pain intensity ratings may lead to inadequately treated pain, even patients themselves may be reluctant to report the presence of pain and its intensity. This may be due to low expectations of obtaining pain relief, fear of analgesic side effects, and perhaps the notion that pain is to be expected as part of an underlying disease or from medical treatments. Some patients exhibit an inappropriate fear of addiction when prescribed opioids or fear the stigma associated with opioid use, even in the short term.

**Pain and Opioid Abuse in the Emergency Department**
ED personnel commonly identify patients who they feel are attempting to obtain opioids for illegitimate purposes. Although drug addiction occurs in all patient populations, it is likely that the ED sees a higher proportion of such patients than a typical office-based practice. Unfortunately, the true prevalence of addiction and aberrant drug-seeking behaviors in the ED is unknown and difficult to measure. When the prevalence of such problems is overestimated, oligoanalgesia is the predictable result.

Definitions

In discussing issues of chemical dependency and aberrant behaviors related to opioid use, a valid system of nomenclature is necessary for clear communication and measurement. Historically, the meaning of different terms has changed, particularly in light of the increased use of chronic opioid therapy for cancer and noncancer chronic pain conditions. In treating pain in this population of patients with chronic opioids, confusion over the concepts of physical dependence, tolerance, addiction, and pseudoaddiction may constitute a barrier to understanding and to appropriate treatment. These phenomena are discrete, and standard definitions may be helpful in caring for such patients. Currently accepted definitions of these include the following: Addiction is a primary, chronic, neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving. Physical dependence is a state of adaptation that often includes tolerance and is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. Tolerance is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug’s effects over time. Pseudoaddiction is a term which has been used to describe patient behaviors, including drug-seeking behavior, that may occur when pain is undertreated. Patients with unrelieved pain may become focused on obtaining medications, may “clock watch,” and may otherwise seem
inappropriately “drug seeking.” Even such behaviors as illicit drug use and
deception can occur in the patient’s efforts to obtain relief.
Pseudoaddiction can be distinguished from true addiction in that the
behaviors resolve when pain is effectively treated; the use of the term
pseudoaddiction has fallen out of favor, as it is difficult to discern between
the patient who finally achieves adequate pain control and the rare, but
worrisome, patient who initially presents with poorly controlled pain and
subsequently reports improvement but is actually diverting the opioids
prescribed for nonmedical use.

The term substance abuse is particularly problematic and resistant to
precise definition. The American Psychiatric Association has defined
substance abuse as a maladaptive pattern of drug use associated with some
manifest harm to the user or others. Other groups using consensus
methodology have defined abuse as any use considered to be outside of
socially accepted norms. Determining the bounds of “socially accepted
norms” within the broad range of social strata treated within any ED is a
difficult task. Physicians may believe that they “know abuse when they see
it,” and its identification may be influenced by subjective judgments that
may or may not correspond to socially accepted norms for the index
patient’s particular social group. Often, the term substance misuse is
applied to behaviors that are not perceived as particularly extreme (e.g.,
taking opioid analgesics to relieve symptoms other than pain such as
anxiety or boredom).

The difficulty in determining whether a given set of behaviors fall
within accepted definitions of substance use, misuse, or abuse has
important implications outside the clinical realm. Physicians may prescribe
controlled substances for the treatment of pain, whereas patients may use
these drugs to treat a broad range of symptoms with varying degrees of
relatedness to underlying pain syndromes and may, in fact, use drugs in a
manner totally unrelated to the physicians’ intent (i.e., to obtain euphoric,
rather than analgesic, effects). Given the unclear distinctions between use,
misuse, and abuse and a regulatory climate in which practitioners
prescribing patterns are increasingly scrutinized, emergency physicians are
required to be cautious when the need to prescribe opioids to patients with
whom they expect to have only a transitory relationship.
Using any definition, substance abuse is a highly prevalent problem in the ED.\textsuperscript{11,39} The National Survey on Drug Use and Health reports that in 2015, an estimated 10.1\%, of the population aged 12 years or older used an illicit drug during the month prior to the survey interview.\textsuperscript{40} Importantly, the survey documents a 13.6\% reported lifetime nonmedical use of pain relievers in 2014. To be considered nonmedical use, the respondent had to take drugs not prescribed for them or take them only for the “experience or feeling” they caused. Specific analgesics included Vicodin, Lortab, or Lorcet (combination analgesics containing hydrocodone); Percocet, Percodan, or Tylox (combination analgesics containing oxycodone); hydrocodone; OxyContin (extended-release oxycodone); methadone; and tramadol.

In contrast to the prominence of ED-based data collection systems in efforts to monitor deleterious outcomes associated with substance abuse, relatively few studies have systematically assessed substance abuse prevalence and treatment needs in the ED population.\textsuperscript{41} As an example, the Drug Abuse Warning Network is a federally financed, public health surveillance system that monitors drug-related ED visits and drug-related deaths investigated by medical examiners and coroners. This reporting system involves hundreds of hospital EDs throughout the United States and provides valuable data with which to monitor drug abuse trends. In contrast to this large monitoring research enterprise, relatively little focus has been given to use of the ED as a setting in which to intervene in substance abuse problems.

In a study of trauma patients, Soderstrom et al.\textsuperscript{42} assessed the prevalence of psychoactive substance use disorders in a large, unselected group of seriously injured patients treated in one Baltimore ED, using standardized diagnostic interviews and explicit criteria. Psychoactive substance use disorders were diagnosed using the Structured Clinical Interview, an instrument based on the Diagnostic and Statistical Manual of Mental Disorders. Of 1,118 patients consenting to the study, 71.8\% used alcohol, 45.3\% used illegal drugs, 18.8\% demonstrated active drug abuse or dependence, and 32.1\% demonstrated concurrent alcohol abuse or dependence.\textsuperscript{43} The high rate of substance use and abuse among trauma patients, and the fact that trauma usually is associated with pain that
requires treatment, complicates the treatment of pain from trauma.

Pain and “Drug-Seeking Behavior” in the Emergency Department

The preceding discussion makes clear the high prevalence of both pain and substance use disorders in the ED. Although acute and chronic pains are far more common than substance use disorders, it is inevitable that emergency physicians will frequently encounter patients presenting with both pain and substance use disorders. Professional discussions of pain treatment in the ED frequently center on concerns of being duped by such patients who fabricate painful symptoms in order to obtain opioids, so-called “drug-seeking behavior.” Drug-seeking behaviors may represent an entirely appropriate response by those with chronic pain who are routinely undertreated by the medical profession and for who comprehensive pain treatment centers are in short supply. Although the term drug-seeking behavior is poorly defined, it is used in the emergency medicine literature and will be used with acknowledgment of its imprecision.

Only a limited amount of emergency medicine research has addressed this problematic issue. In 1996, Zechnich and Hedges attempted to measure community-wide use of ED services by patients at high risk for drug-seeking behavior. In this retrospective, observational study, patients were categorized as exhibiting drug-seeking behavior if they sought care at a university hospital in Portland, Oregon, for a specific pain-related diagnosis (i.e., ureteral colic, toothache, back pain, abdominal pain, or headache) and were either independently identified on at least one other local hospital’s “patient alert” list or suffered a drug-related death during the year in question. After identifying 33 such patients, they determined the frequency of their ED visits at each of seven local hospitals and conducted detailed chart reviews of their visits at three of these hospitals. The patients identified as drug seeking were generally young, and one-half of drug seekers were female. This suggests that drug-seeking behaviors are exhibited (or identified) more commonly among female ED patients with substance abuse problems than among males. The 33 patients visited
EDs, urgent care clinics, or were hospitalized a total of 379 times over the study period, for an average of 12.6 visits per person annually. Interestingly, although chart reviews identified 17 patients who were told that he or she “would receive no further narcotics” at a given facility, these patients subsequently received controlled substances from another hospital in 93% of cases and from even the same facility in 71%. The authors suggested that information sharing between hospitals could help to identify drug-seeking patients and promote more consistent community-wide care and appropriate substance abuse interventions.

The need for information sharing has led to the development of statewide prescription monitoring programs. These programs allow physicians to determine whether a patient has received opioid medications regardless of their individual report, allowing easier identification of patients who are misrepresenting their current opioid use. Such monitoring systems are generally not required and are not universal, but data indicate they are successful, at least more so than the previous attempts at internal lists many EDs had used, and their use should be expanded. It has been shown that the use of such lists alters physicians’ prescribing behavior, both by increasing pain medications for patients who do not exhibit frequent use and identifying patients at risk for opioid abuse or dependence related to their treatment. Although early versions of these monitoring programs were difficult to access and use, they are becoming increasing usable and are becoming a typically step in the prescribing of opioids in the ED. Prescription drug monitoring programs are generally underused in EDs, and nationwide enrollment is low among emergency physicians. In order to improve this, an expert panel was convened by ACEP and made policy recommendations within these main themes: Enrollment should be mandatory, with an automatic process to mitigate the workload; registration should be open to all prescribers; delegates should have access to prescription drug monitoring program to alleviate workflow burdens; prescription drug monitoring program data should be pushed into hospital electronic health records; prescription drug monitoring program review should be mandatory for patients receiving opioid prescriptions and based on objective criteria; the prescription drug monitoring program content should be standardized and updated in a timely manner; and states
should encourage interstate data sharing.\textsuperscript{51}

It has been difficult to quantify the overall effect of such systems,\textsuperscript{13} and they run the risk of resulting in unfair treatment of the patient if the information is not used properly and it is a context appropriate to the patient.\textsuperscript{52} It is likely, however, that improved information will reduce risks to patients and improve care, both in terms of identifying patients who have developed substance abuse problems related to their pain treatment and in terms of avoiding misidentifying patients exhibiting behaviors that appear associated with addiction but are in fact exhibiting pseudoaddiction related to oligoanalgesia.

\textbf{Pain and Substance Abuse in the Emergency Department: A Balanced Perspective}

In managing pain, emergency physicians are responsible for beneficence as well as nonmaleficence. We must treat pain and ameliorate suffering while minimizing the extent to which our treatment strategies enable substance abuse by our patients. For the vast majority of patients presenting with a first episode of acute pain, whether from trauma, acute medical illness, or procedures performed in the ED, there is little danger of enabling substance abuse and a great deal of room for improvement in the quality of analgesic practices. For a small subset of ED patients, particularly for those presenting with chronic or recurrent pain syndromes, the physician may have legitimate concerns regarding underlying substance abuse or related disorder. Our task is to balance the often unclear risk of fostering substance abuse, and even diversion, in this subset of patients with the well-known and well-documented risk of under treating painful conditions.

Certainly, the presence of an obvious painful condition (e.g., appendicitis, fracture) should preempt concerns about illegitimate drug-seeking behaviors. Given the high prevalence of chronic pain and the widespread unavailability of chronic pain management resources, particularly for populations served by the ED, pseudoaddiction is the most likely cause for a large proportion of drug-related behaviors deemed aberrant. In particular, patient reports of distress associated with
unrelieved symptoms, aggressive complaining about the need for higher doses of analgesics, and unilateral dose escalation by the patient are suggestive of pseudoaddiction. Establishing the diagnosis of pseudoaddiction is particularly difficult if the patient has both pain and a comorbid substance use disorder; however, the two can coexist. The signature of pseudoaddiction is that aberrant behaviors disappear when adequate analgesics are given to control pain.

In dealing with complex chronic pain patients, the emergency physician practicing in isolation may exhibit symptoms of despair and direct his or her anger toward the patient with pain, resulting in more alienation of patients who may have already been abandoned by other sectors of the health care system. This is particularly likely to happen in communities without multidisciplinary treatment centers for either substance abuse disorders or chronic pain and for those with inadequate health care insurance. Thus, the patient with chronic pain joins the larger group of those with unmet health care needs that currently crowd our EDs. The hectic nature of emergency medicine practice often does not allow sufficient time for precisely characterizing patients with complex pain complaints, and clinicians may lump legitimate pain behaviors with the ploys of those seeking opioids inappropriately. Both groups of patients may be ultimately mistrusted and treated with disdain.

Aside from considerations of pseudoaddiction, chronic pain is often accompanied by mood disorders and psychiatric comorbidities that complicate the management of these challenging patients.\textsuperscript{26} The presence of aberrant drug-related behaviors in patients with borderline personality disorders may represent an expression of fear and anger or an attempt to cope with chronic boredom. Patients may use opioids and alcohol in attempts to lessen symptoms of anxiety, panic disorder, depression, or insomnia. Emergency physicians often receive limited training in dealing with such disorders and the specialty’s deficiencies in dealing with such problems have been documented.\textsuperscript{53} Psychiatric consultation, if available, may be useful in both suggesting alternative causes for aberrant behaviors and tailoring the physician’s therapeutic approach to deal with these complicating factors.

For some patients, aberrant drug-related behaviors represent criminal
intent to divert or sell controlled substances. The prevalence of behaviors occasioned by such intent is unknown, and it is likely that in many cases, multiple etiologies of aberrant behaviors coexist.\textsuperscript{37,54} Certainly, patients with active or past substance use disorders are at increased risk for injuries and illnesses that can lead to chronic pain (e.g., motor vehicle injury).

Finally, although federal regulators and state medical boards do not perceive emergency medicine as a specialty prone to inappropriate prescribing, and investigations of emergency physicians are rare, if not unheard of, many emergency physicians express fears of such scrutiny or sanctions related to prescribing or administering opioids. Although this concern is often voiced, it seems likely that this fear represents concern about other, less obvious physician uncertainties related to pain management and substance abuse disorders. Emergency physicians may be concerned about being overburdened by the inherent difficulties of managing patients with complicated pain syndromes and the potential of coexisting substance abuse disorders.

**The Example of Sickle Cell Disease**

The condition that best exemplifies the problem of ED-based pseudoaddiction is sickle cell disease. Vaso-occlusive pain crises are the most common reason for ED visits by patients with sickle cell disease, and the genetics, molecular biology, and pathophysiology of this disease are relatively well understood. Although the management of sickle cell vaso-occlusive pain crises is viewed as challenging by emergency physicians, it has been a relatively neglected area of research investigation by the specialty.\textsuperscript{55}

Despite our understanding of the sickle cell disease process, many health professionals are reluctant to prescribe adequate doses of opioids for these patients experiencing pain largely due to addiction concerns, and that care is frequently insufficient and delayed.\textsuperscript{56} In one survey study, 53% of emergency physicians were of the belief that more than 20% of patients with sickle cell disease were addicted to opioids, whereas only 23% of hematologists shared this belief. Also, in this survey, 35% of hematologists reported that they followed pain management protocols
when treating painful crises as compared to only 17% of emergency physicians.\textsuperscript{57,58}

Nurses’ attitudes regarding the prevalence of addiction among this patient population are even more extreme, with 63 respondents reporting that addiction was prevalent.\textsuperscript{59} Thirty percent of nurses in this survey reported that they were hesitant to administer high-dose opioids for painful vaso-occlusive crises. A hesitant approach to ED opioid administration in the setting of vaso-occlusive pain crises will predictably lead to continued pain, increased anticipation of pain, and increased patient anxiety. This experience may generate pain-avoidance manifestations by patients that are interpreted by physicians as aberrant drug-related behaviors. Eventually, larger doses of opioids may be administered to control pain that is spiraling out of control with resultant excessive sedation. This apparent sedation in the setting of a painful condition may reinforce the physician’s disbelief in the reality of his or her patient’s initial pain reports.

It has been demonstrated that this cycle of inadequate care can be broken by the institution of pain management protocols that emphasize continuous opioid infusions and sustained courses of orally administered controlled-release opioids. Tanabe et al. demonstrated in several studies that the addition of nurse-initiated protocols, including the use of high-dose opioids, and provider education led to improvements in pain management.\textsuperscript{55,56,60,61}

\textbf{Pain Treatment and Procedural Sedation in the Emergency Department}

Effective pain management involves both pharmacologic and nonpharmacologic modalities. Simply asking about pain and validating the pain reports impacts patients’ satisfaction with ED pain management. In one study, patient satisfaction with pain management was predicted more strongly by the perception that ED staff asked about pain than by the actual administration of an analgesic.\textsuperscript{62} Other nonpharmacologic modalities, such as reassuring the patient that pain will be addressed; immobilizing and elevating injured extremities; and providing quiet,
darkened rooms for patients with migraine headaches, are important aspects of quality pain management. Pharmacologic therapies should begin as soon as is practical after presentation to the ED. Analgesic protocols allowing early pain treatment can decrease the time to effective treatment and improve patient outcomes.63,64

Analgesics may be administered by a variety of routes; however, the vast majority of medications are administered by the oral or parenteral routes. Oral therapies are most commonly employed as they are convenient and inexpensive for patients who can tolerate oral intake.64 When pain is severe, analgesics must be given immediately and titrated to effect, generally by parenteral routes. The intravenous, rather than intramuscular, route is indicated in this context. Intramuscular injections are painful, do not allow for rapid titration, exhibit unpredictable absorption, and result in a slower onset of drug action. Unless intravenous access is elusive, there is little to recommend the intramuscular route. In general, it is inappropriate to delay analgesic use until a diagnosis has been made. In the case of acute abdominal pain, for which surgical dogma historically discouraged adequate analgesia, studies report no deleterious effect of intravenous opioid therapy on our ability to make appropriate diagnoses.65

**Specific Treatment Modalities**

Analgesics are the most commonly administered class of drug in the ED. The National Center for Health Statistics reports that analgesics account for the top three therapeutic classes of drugs used in the ED (Fig. 113.2).40 The majority of analgesics administered were opioids (59%); morphine being the most commonly used analgesic (20%), followed by ibuprofen (17%) (Table 113.2).

NONOPIOIDS

Commonly used ED analgesics include opioids, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs). When opioids are required for pain treatment, nonopioids should be included in order to
potentiate the opioid analgesic effect and decrease the severity of side effects. Unfortunately, nonopioid agents exhibit an analgesic ceiling effect and cannot be titrated to effect. This limits their usefulness in the setting of severe or fluctuating pain; however, they should be used as an adjunct to opioid therapies unless otherwise contraindicated.

Acetaminophen is indicated for mild to moderate pain and is often combined with opioid agents. Acetaminophen, unlike NSAIDs, has no antiplatelet activity or anti-inflammatory effect. Although a great deal of attention has been paid to acetaminophen hepatotoxicity, especially in the setting of chronic malnutrition, alcoholism, or liver disease, such effects are uncommon, particularly when contrasted to the underappreciated high prevalence of NSAID-related adverse effects.

NSAIDs, including salicylates, act to inhibit prostaglandin synthesis by interfering with cyclooxygenase enzymes. They frequently cause gastritis and gastrointestinal (GI) bleeding, cause platelet dysfunction, and can precipitate renal failure in patients with renal insufficiency or volume depletion, a particular concern in the elderly or those presenting to the ED with hemodynamic instability. They have a ceiling effect at relatively low doses. Ketorolac, the only parenteral available in the United States, is commonly used in the ED and is felt to be particularly useful in the setting of renal colic. One study of renal colic in the ED found that a combination or ketorolac and morphine resulted in superior analgesia and reduced adverse effects when compared to the use of either agent alone. A recent study by Motov et al. demonstrated that at dose of 10 mg intravenously has similar analgesic efficacy as 15 or 30 mg, indicating that is likely the safest dose for emergent therapy.

**OPIOIDS**

Opioid combination analgesics are commonly used for moderate to severe pain. Although the opioid component in these agents does not exhibit ceiling analgesic effects, the nonopioid component dose must be limited; thus, one cannot titrate these analgesics. The convenience of combination therapy must be balanced against this limitation. Hydrocodone and oxycodone combination agents are associated with less nausea and vomiting and are preferable to codeine combinations agents. Also,
significant proportions of the population are poor metabolizers of codeine, which must be metabolized to morphine in order to manifest analgesic effects, further limiting its effectiveness.

The tramadol/acetaminophen combination agent is indicated for acute pain; however, experience with this agent in the ED setting is limited. In one recent trial of acute ankle sprains presenting to the ED, the tramadol/acetaminophen combination agent had comparable clinical utility to that of hydrocodone with acetaminophen.\textsuperscript{68} Tramadol’s mechanism of action is unclear: It binds only weakly to opioid receptors and inhibits the reuptake of both norepinephrine and serotonin.

Opioids are the mainstay of ED therapy for moderate to severe pain, and morphine is the standard of comparison for all agents of this class. If contraindicated due to allergy or other sensitivity, hydromorphone or fentanyl may be substituted. These opioids can be rapidly titrated intravenously to control severe pain, allowing early institution of an oral regimen. Fentanyl has the advantage of being relatively short acting and is preferred in the setting of multiple trauma, head injury, and potential hemodynamic instability. Intravenous morphine is the standard of treatment for severe pain in the ED. Morphine 0.1 mg/kg bolus has been found to be safe but not usually adequate to effect pain relief.\textsuperscript{69} Repeat boluses of 0.05 mg/kg every 5 minutes until pain relief represents a safe incremental strategy. In patients with impaired hepatic function in the elderly, hydromorphone may be superior to morphine because it has less active metabolites. Oral oxycodone has shown to be comparable to intravenous morphine and when compared to the time of ordering has a similar time to analgesia to intravenous morphine due to the time needed to place the intravenous line.\textsuperscript{64} It is more difficult to titrate, however, requiring 20 to 30 minutes between doses to observe the full effect rather than 10 to 15 minutes needed for morphine. A common strategy in a patient in severe pain is to start oral oxycodone before the intravenous line is placed and then switch to an intravenous opioid titrated to pain relief.

Agonist-antagonist opioids, such as nalbuphine and butorphanol, have mixed effects on opioid receptor subtypes, exhibiting ceiling effects on both analgesia and respiratory depression. Because clinically important respiratory depression is distinctly rare in the setting of acute pain
treatment, it is difficult to justify their routine use. One possible exception is for patients with advanced pulmonary disease. A particular drawback is that one cannot titrate these drugs to maximal effect because of analgesic ceiling effects. Additionally, these drugs are contraindicated and will induce withdrawal symptoms in patients who are physically dependent on opioids, either because of opioid therapy for chronic pain, methadone maintenance therapy, or active opioid addiction.

PATIENT-CONTROLLED ANALGESIA
The use of patient-controlled analgesia (PCA) has been described in emergency medicine for both adults and children. Although no specific advantage has been found over the titration of opioids, PCA is at least as effective in relieving pain. In the setting of high demands on nursing resources, PCA could serve to ensure that patients’ pain treatment needs are addressed in a timely fashion. In addition, patients admitted from the ED to inpatient hospital beds often experience a “pain window” between the last dose of an analgesic in the ED and the first dose administered on the hospital ward. Wider use of ED PCA might obviate this common problem.

ALTERNATIVE DELIVERY ROUTES
Multiple alternative delivery routes for the administration of pain medications have been described. The use of nebulized fentanyl has been described and holds promise as a route of opioid delivery that can be initiated before an intravenous line has been placed. In addition, intranasal ketamine and intranasal ketorolac have been described and have shown promise. Nebulized pain medications, especially for children who have severe pain but have not had an intravenous line placed, could be of use in the ED.

PROCEDURAL SEDATION AND ANALGESIA
Patients often present to the ED in need of painful or complex procedures that require patient cooperation and must be done emergently. Procedural sedation and analgesia (PSA) practices and policies have evolved rapidly in the ED, and this is a growing area in the practice of emergency
PSA in the ED is complicated by the occurrence of unpredictable concurrent events as well as time and space constraints of the ED. Furthermore, unlike most patients who undergo sedation in other settings, patients in the ED typically have an unpredictable “nothing by mouth” (NPO) status, often have concurrent severe systemic disease, and usually are in severe pain before the procedure begins.

The indications for ED PSA range from pain control for short painful procedures to the need for patient compliance with a complex emergency procedure. The typical target sedation level for ED PSA ranges from minimal through moderate and deep sedation, depending on the demands of specific procedures. Deep sedation can inadvertently result in the patient achieving a level of sedation consistent with general anesthesia, but this is not an intended target level of ED PSA.

Minimal sedation describes a drug-induced state during which patients are sedated but are still able to respond appropriately to verbal commands (according to their developmental age) and whose eyes remain open. Depending on the agent, it is possible to achieve amnesia of the procedure at this level of sedation, but by definition, patients will still respond to their surroundings. It is generally performed for procedures that require patient compliance but are not typically intensely painful when performed with local anesthesia. Minimal sedation is typically used for procedures such as lumbar puncture, evidentiary exams, simple fracture reductions (in combination with local anesthesia), and the incision and drainage of small abscesses.

During minimal sedation, cardiovascular and ventilatory functions are generally maintained, although patients should be monitored for inadvertent oversedation to deeper levels using oxygen saturation monitors and direct observation. Agents typically used for minimal sedation include alfentanil, fentanyl, midazolam, combinations of the two, and low-dose ketamine.

Moderate sedation is performed on patients who would benefit from a deeper level of sedation to augment the procedure. Moderate sedation describes patients sedated to the point at which their eyes are closed but they open in response to verbal commands (appropriately to their developmental age) alone or to light tactile stimulation. Patients at this
level usually have an intact airway and maintain ventilatory function without support. As with minimal sedation, inadvertent over sedation to deeper levels can occur with moderate sedation.\(^{80,81}\) Appropriate monitoring including oxygen saturation, cardiac monitoring, and blood pressure measurements should be done throughout the sedation, and direct observation of the patient’s airway should be maintained throughout the procedure. Agents used for moderate sedation in the ED include propofol, etomidate, ketamine, and the combination of fentanyl and midazolam.

Deep sedation is performed on patients who would benefit from a deeper level of sedation, often in order to complete a procedure already begun that requires more patient relaxation than was achieved at a lighter level of sedation. Generally, amnesia of the procedure is similar between moderate and deep sedation, and it is not necessary to sedate patients to a deep level only to obtain amnesia.\(^{82}\) Deep sedation is achieved in the ED with the same agents as moderate sedation; the difference is in the intended level of sedation. Monitoring requirements for deep sedation are similar to those for moderate sedation.

End-tidal carbon dioxide monitoring has also been described in ED PSA,\(^{83,84}\) and it is generally regarded as the monitor most comparable to direct observation of the patients airway for detecting changes in the patients ventilator patterns,\(^{85}\) especially in patients receiving high-flow oxygen to prevent hypoxia.\(^{85}\) Deeply sedated patients can develop respiratory depression but generally maintain a patent airway and adequate ventilation.\(^{80,86,87}\) Patients sedated to this level can progress to a level of sedation consistent with general anesthesia. This can occur after the procedure for which the patient was sedated has been completed. Pain is a powerful stimulant, and after it is removed due to the completion of a procedure or the application of local anesthesia, patients may progress to a deeper level of sedation. There is some evidence that the inadvertent progression to general anesthesia occurs more frequently in patients targeted for deep sedation than in those undergoing moderate sedation.\(^{82}\) For this reason, and the fact that the occurrence of procedural recall is similar between moderate and deep sedation, it is usually safer to use moderate sedation than deep sedation in the ED unless the procedure requires progressively deeper levels of sedation to complete successfully,
such as the reduction of hip dislocations.

Patients who progress to an unintended level of sedation consistent with general anesthesia are not arousable, even to pain. The ability to independently maintain ventilatory function is usually impaired, and patients often require assistance in maintaining a patent airway. Patients can quickly progress to the level of general anesthesia using agents commonly employed for moderate and deep sedation, and physicians performing ED PSA must be prepared to provide ventilatory support until the patient’s level of consciousness has improved and they are able to protect their airway and ventilate normally.

In order to decrease the likelihood of aspiration, patients who are undergoing moderate or deep sedation in the ED are often kept NPO. Regardless of the target depth of sedation or the agent administered, there is insufficient evidence to support specific fasting requirements prior to procedural sedation. A guideline for emergency physicians has made recommendations for the proper risk stratification of patients based on their last oral intake. In general, the risk of aspiration from recent oral intake increases with the depth of sedation and must be balanced with the urgency of the procedure when deciding whether or not to delay sedation due to recent oral intake.

Patients who have not had oral intake other than clear liquids for 3 hours prior to their procedure have a low risk of aspiration at any level of sedation. In patients with recent oral intake in need of an emergent procedure, the risk of aspiration is unlikely to outweigh the risk of delaying the procedure. Because the risk of aspiration likely increases with the depth of sedation, it is prudent to target the lightest level of sedation feasible for the necessary procedure. For nonurgent procedures where a time delay is unlikely to have a negative effect on the patient, patients who have eaten more than clear liquids in the prior 3 hours should have the procedure delayed until 3 hours after their last intake. For urgent procedures falling in between emergency and nonurgent procedures, lighter levels and shorter durations of PSA should be used as the size of oral intake taken within 3 hours of the procedure increases.

Patients who are intoxicated, especially with alcohol, can be especially difficult to sedate. They often have food in their stomachs, and the
achieved level of sedation can be difficult to predict. In emergent reductions, this increases their risk but does not change the procedure. In patients who can safely have the procedure delayed, intoxicated patients may benefit from a delay in their sedation until the progression of their mental status (getting worse or getting better) can be ascertained through observation.

ED PSA is necessarily used for patients who are medically healthy or have uncomplicated coexisting medical conditions (American Society of Anesthesiologists Physical Classes 1 and 2) and those who have more significant or life-threatening coexisting medical conditions (Classes 3 and 4). PSA for critically ill children has been described using ketamine\textsuperscript{88} and in adults using propofol or etomidate.\textsuperscript{89} The degree of respiratory depression noted in these patients was similar to patients with physical status scores of 1 or 2, but an increased rate of hypotension was seen in physical status 3 and 4 patients who received propofol. It may be that ketamine and etomidate are better suited for the emergent sedation of critically ill patients, but there is not yet sufficient data to make a definite recommendation.

The ventilatory status of sedated patients must be monitored. This is generally accomplished with pulse oximetry, capnography, and direct observation of the patient’s respiratory effort. Pulse oximetry is a sensitive measure of oxygenation. If a patient receives supplemental oxygen prior to starting PSA and during the procedure, this monitor may not be as sensitive to changes in the patient’s ventilatory status. End-tidal carbon dioxide has been recommended as an additional modality for the monitoring ventilatory status.\textsuperscript{84–86,90} It provides a graphic display of ventilatory status that can be used to detect respiratory depression before it becomes clinically apparent. In the event of hypoventilation, the end-tidal carbon dioxide value increases as the respiratory rate decreases. In the event of increasing airway obstruction, the baseline end-tidal carbon dioxide value decreases along with a blunting of the waveform due to increased mixing of the nasal expiratory sample with ambient air due to the turbulence from the obstruction.

Ketamine use has been described in adults and children undergoing ED PSA.\textsuperscript{91,92} Ketamine is a dissociative anesthetic that provides 15 to 20
minutes of sedation when given intramuscularly, with a return to baseline mental status in 30 to 60 minutes. It can be given in doses of 1 to 4 mg/kg intramuscularly and should be combined with atropine 0.01 mg/kg to prevent hypersalivation. The 1 mg/kg dose achieves minimal sedation sufficient for such procedures as lumbar puncture, dressing changes, and simple laceration repair. Doses from 2 to 4 mg/kg result in increasingly deeper levels of moderate to deep sedation. Patients sedated with ketamine usually maintain a patent airway and ventilate normally. Patients receiving ketamine should be monitored for respiratory depression and rare occurrences of laryngospasm. Emergence phenomena, unpleasant perceptual experiences as patients regain consciousness, have been described in both adults and children. The addition of 0.1 mg/kg of midazolam to ketamine has been described to prevent emergence phenomena, but no difference in the occurrence of emergency phenomena has been found with its use. Intravenous ketamine is also used for ED PSA at doses of 1 mg/kg with an onset of 1 to 2 minutes, followed by moderate sedation lasting 8 to 12 minutes. The adverse effects of intravenous ketamine are similar to those of intramuscular use.

The combination of fentanyl and midazolam has been used for minimal, moderate, and deep sedation in the ED. This combination results in longer periods of sedation than other agents and carries a higher rate of respiratory depression than other commonly used agents. Although adequate for minimal sedation, the high level of respiratory depression and long duration of action makes this combination less useful for moderate or deep sedation. Dosing for minimal sedation has been described as 0.1 mg/kg intravenous midazolam followed by 0.05 mg/kg intravenous fentanyl, with repeated fentanyl boluses every 1 to 3 minutes until the patient is adequately sedated. The sedation typically lasts 30 to 60 minutes with a return to baseline mental status by 45 to 120 minutes. This method of PSA requires direct ventilatory monitoring.

Pentobarbital is a sedative agent typically used for minimal to moderate sedation for radiologic procedures. This agent has no analgesic properties and patients who appear sedated after its administration can be aroused with less stimuli than is typical for many of the other agents used in ED PSA, which is an excellent characteristic for preventing over
sedation for radiologic procedures, but is of limited utility for painful procedures. The medicine is administered at 2.5 mg/kg intravenously, followed by 1.25 mg/kg every 5 minutes until adequate sedation is achieved. Pulse oximetry should be used; however, the rate of respiratory depression is lower than for other agents.

Methohexital has been used for moderate and deep PSA. It is a very short-acting agent with excellent amnestic properties. It is administered at 1 mg/kg intravenously with 0.5 mg/kg repeat boluses every 1 to 2 minutes as needed. It has an onset of 30 seconds, with sedation lasting 2 to 4 minutes and returning to baseline within 5 to 10 minutes. It has been associated with respiratory depression and a quick progression to deeper levels of sedation than intended and can cause oversedation even when carefully titrated. It should therefore be used with close ventilatory monitoring. Compared to propofol, methohexital is similarly effective and safe with single bolus use but is less safe than propofol when multiple doses are required. It should be used principally for very brief procedures expected to last less than 2 to 4 minutes, such as the reduction of simple fractures and dislocations.

Propofol is well described for ED PSA. It is administered as a 1 mg/kg bolus with repeat boluses of 0.5 mg/kg every 2 to 3 minutes until the patient achieves the desired level of sedation. The sedation persists 2 to 5 minutes after a single bolus and longer for patients receiving multiple boluses, with a return to baseline within 10 to 15 minutes. This medication has been associated with rates of clinically apparent respiratory depression from 4.0% to 7.7% in ED PSA. As with similar agents, close ventilatory monitoring is required. Propofol causes hypotension in critically ill patients and should be used with caution in hemodynamically unstable patients.

The combination of propofol and ketamine has also been described. It has been shown to have decreased rates of recovery agitation than ketamine alone, and less hypotension than propofol alone. It is likely that the combination of agents can decrease the associated risk of adverse events and potentiate the benefit of the drugs but that it must be tailored to the needs of the individual patient.

Etomidate is also frequently used for ED PSA. It is given as a single
bolus of 0.1 to 0.3 mg/kg, with an onset of sedation in 30 to 60 seconds and sedation lasting 7 to 10 minutes. It is not associated with hypotension and is more commonly used when this is an issue; however, its use is associated with myoclonic jerking in up to 25% of patients. This adverse effect can complicate the procedure for which the patient has been sedated, making it inferior to propofol for the sedation of healthy patients. Etomidate, in single boluses of 0.3 mg/kg, has been shown to cause transient adrenal suppression, but no significant changes in cortisol levels occur, and the significance of this finding remains unclear. It has been shown to cause less hypotension in severely ill patients requiring sedation and is likely a better choice in these patients until they are stabilized despite the unclear risk of adrenal suppression.

Evolving Emergency Department Pain Management Practice

Pain management practices in the ED continue to evolve. The ACEP, emergency medicine’s principal specialty organization, established its first general policy statement regarding analgesic practices in 2004.\textsuperscript{103} Prior to this, data from the National Hospital Ambulatory Medical Care Survey showed that, from 1997 to 2001, there was an impressive 18\% increase in analgesic use in US EDs (from 47.2 to 56.2 mentions per 100 visits), with marked increases in both NSAID agents and opioid analgesics.\textsuperscript{104}

At the local level, adoptions of pain management guidelines and quality improvement processes have demonstrated dramatic improvements in practices. In one 3-site study, rates of ED analgesic treatment increased from 54\% to 84\% over 1 year as a result of individual and group feedback.\textsuperscript{105} In a study from one Swiss ED, educational programs and guideline implementation led to marked increases in pain intensity documentation, analgesic administration, reduction in pain intensity scores, and improved patient satisfaction over a 4-month period.\textsuperscript{106}

We do not know the reasons for the rapid evolution of ED pain management practice. Policy and regulatory initiatives, institutional quality improvement programs, increased attention to the opioid abuse epidemic in the United States, pharmaceutical marketing campaigns,
educational efforts, and new knowledge from basic and clinical research are all likely to be influential factors. No matter the cause, emergency medicine pain research is increasing at a rapid pace, and ED pain management practices will continue to evolve.

Conclusion

Relieving pain and reducing suffering are primary responsibilities of emergency medicine and much can be done to improve the care of ED patients in pain. Emergency physicians and nurses continue to refine their approach to the problem of pain, and in time, the current large amount of variability in ED pain practices will no doubt lessen. Clinicians, researchers, and policy makers continue to define specialty-specific standards for emergency medicine pain practice in an effort to both improve the management of pain in emergencies and to decrease the risk to patients from the medications used. Ongoing quality improvement initiatives, education, and research are essential to achieving these goals.

Pain, Analgesia, and Critical Illness

Pain is ubiquitous among critically ill patients, yet the nature of critical illness and intensive care unit (ICU) care presents many unique challenges to effective pain management.\textsuperscript{1–10} A central responsibility of all ICU clinicians is to provide comfort and mitigate unpleasant sensations including pain as well as anxiety, dyspnea, and other forms of distress.\textsuperscript{11–17} Experts have provided guidance regarding managing pain in the ICU, often within the paradigm of sedation and analgesia. In this chapter, we focus on the unique aspects of pain and analgesia in the ICU within the context of a comprehensive textbook on pain.\textsuperscript{11–14,17–20}

ICUs are filled with patients who have suffered critical illness or injury and the accompanying discomfort. Many patients have undergone surgery or experienced trauma or burns and are likely to have pain as a direct result of tissue injury and related management such as dressing changes and wound care. Other patients have localized inflammation due to infection or have neuropathies or other specific conditions that produce pain. The majority of ICU patients undergo routine care which can contribute to discomfort or frank pain. Such interventions include the presence of indwelling tubes (i.e., nasogastric, endotracheal, bladder, and rectal tubes) or vascular catheters that can induce pain during their insertion and in some cases continue to produce discomfort by their mere presence.\textsuperscript{3–5,21,22} Even simple tasks that are routinely performed many times each day—such as tracheal suctioning or turning of the patient from side to side—are reported as painful by ICU patients.\textsuperscript{5,9,22,23}
The nature of critical illness and ICU care can complicate various aspects of pain management. For example, the sensation of pain may be intensified by the concomitant anxiety, sleep deprivation, and delirium.\textsuperscript{23–33} It is clear that all of these conditions are commonplace among critically ill patients. Further, immobility and impaired communication can intensify anxiety and perception of pain. Newer integrated approaches to optimize patient comfort and hasten recovery comprehensively address analgesia as well as efforts to reduce anxiety yet avoid oversedation, improve sleep quality, prevent delirium, speed liberation from mechanical ventilation, and enhance rehabilitation and mobility.\textsuperscript{34–40}

Pain is often poorly recognized and quantified, further challenging effective pain management.\textsuperscript{11,12} This can be the result of impaired communication due to a reduced level of consciousness from sedative medications or difficulty with phonation and movement due to oral tubes, physical restraints, or paralysis. Although the presence of pain may be inferred as a result of unexplained autonomic hyperactivity (i.e., tachypnea, tachycardia, or hypertension), these signs have many other causes and thus are nonspecific for pain.\textsuperscript{11} Clinicians’ evaluation of patients for possible pain include observing behaviors such as grimacing or rigid body positioning, but these are less reliable as sedation deepens.\textsuperscript{11,22,41–55} Overt agitated behavior, a not infrequent occurrence among critically ill patients, is typically attributed to delirium, particularly due to alcohol or sedative drug withdrawal, but can also be the result of inadequately managed pain.\textsuperscript{56–63}

Pharmacologic management of pain is more complex in the ICU than in many other settings.\textsuperscript{11–14,17–20} The majority of ICU patients have organ dysfunction. In particular, the utilization of many opioid and nonopioid analgesics is impacted by the high prevalence of impaired hepatic metabolism or renal clearance, problems with enteral or transdermal drug administration, and concerns for drug interactions with the extensive list of medications required for many ICU patients.\textsuperscript{64–67} Recognition and amelioration of adverse effects of analgesics and other medications is often more difficult because of ongoing organ dysfunction and concomitant medical problems as well as the large number of medications utilized. In
particular, the high prevalence of impaired gastrointestinal mobility from opioids becomes far more than just the inconvenience and discomfort of constipation and can impact administration of nutrition and enteral medications; can worsen respiratory function; and can lead to additional treatment, tests, and interventions. These many ICU factors elevate the complexity of pain management.

In the ICU setting, opioid administration is often performed for purposes beyond pure pain management, that of providing comfort and tolerance of the ICU interventions along with sedative drugs—called analgosedation. This approach relies on titration of both sedative-hypnotic and opioid analgesic drugs to improve the patient’s tolerance of mechanical ventilation and other aspects of the ICU environment and routine ICU care. The target is comfort without oversedation and is often best achieved with a balanced approach that allows selection of medications that are preferred for a specific patient (e.g., organ dysfunction or hemodynamic compromise) and can minimize adverse effects of medications by using lower doses and potentially synergistic effects. Some clinical trials have demonstrated better outcomes when such an approach is used. Although titration of the opioid component to a pain reduction target remains operative, the overall level of consciousness and patient–ventilator interaction often influences the dosing of both sedative and analgesic infusions. Thus, somewhat uniquely to the ICU setting, “pain management” also encompasses management of “analgosedation” and tolerance of mechanical ventilation and other ICU interventions.

Successful management of pain, provision of comfort, and timely recovery from critical illness are highly dependent on the multiprofessional care team implemented in many ICUs. Pain management in particular relies on the effective partnership between the treating physician, the bedside nurse, and the clinical pharmacist. This includes designing a treatment strategy that is patient focused with consideration of the patient’s unique analgesic needs and factors like organ dysfunction that influence management. Implementation is enhanced through standardized approaches, order sets, guidelines, and other tools plus ongoing communication and review. The comprehensive ICU team also includes
physical therapists, nutritionists, respiratory therapists, and others who contribute to missions of comfort and rapid recovery. Further, utilization of expert consults from palliative care or pain management services can make an important difference in selected patients. Accordingly, effective pain management in the ICU brings the advantages, but also challenges, of a team-based approach.\(^\text{34–40}\)

A final consideration as to the unique aspects of pain management in the ICU is that the physiologic consequences of untreated pain may be particularly detrimental in critically ill patients who already have ongoing shock, tissue injury, and organ failure producing a complex state of physiologic disruption.\(^\text{75}\) Pain can cause neurohormonal derangements, catecholamine release, stress response, cytokine production, and other physiologic derangements. These and other pain-induced changes can promote hypercoagulability, altered glucose control, myocardial ischemia, hemodynamic compromise, immune system dysfunction, excessive inflammation, ventilator asynchrony, and disrupted sleep.

There is strong motivation from multiple standpoints to effectively detect and manage pain in a multiprofessional and patient-centered approach. Some of these manifestations are listed in Table 114.1. The core evidence-based recommendations directly related to pain and analgesia from the Society of Critical Care Medicine (SCCM) are displayed in Table 114.2 and form the basis of management.\(^\text{11}\)

TABLE 114.2 2013 SCCM Pain, Agitation, and Delirium Guidelines: Statements and Recommendations for Treatment of Pain in the Intensive Care Unit (ICU)

- ICU patients frequently experience pain at rest, with routine ICU care and in association with devices and procedures (B).
- Pain should be routinely monitored in all adult ICU patients (+1B).
- The Behavioral Pain Scale and the Critical-Care Pain Observational Tool are the most valid behavioral pain scales in medical, postoperative, or trauma (with the exception of brain injury) adult ICU patients who are unable to self-report pain (B).
- Vital signs may be used as a cue (+2C) but should not be used alone in the assessment of pain (+2C).
- Preemptive analgesia should be used in adult ICU patients prior to procedures (+2C), including chest tube removal (+1C).
- First-line therapy: intravenous opioids for nonneuropathic pain (+1C)
- Consider nonopioid analgesics as adjunctive therapies to reduce opiates and related side effects (+2C).
- Treat neuropathic pain with gabapentin or carbamazepine (+1A).
- Thoracic epidural anesthesia/analgesia should be considered for abdominal aortic aneurysm postoperative patients (+1B) or patients with traumatic rib fractures (+2B).
- Analgesia-first sedation should be used in mechanically ventilated adult ICU patients (+2B).

NOTE: The quality of evidence for each statement and recommendation was ranked as high (A), moderate (B), or low/very low (C). The strength of recommendations was ranked as strong (1) or weak (2) and either in favor of (+) or against (−) an intervention.

Evaluation and Monitoring of Pain in the Intensive Care Unit

Effective pain management begins with the assumption that pain is common among ICU patients and that caregivers should systematically and repeatedly evaluate each patient for the presence of pain, its intensity, and its characteristics.\textsuperscript{11–13,16,41} Unfortunately, research confirms that caregivers tend to underrecognize pain and often fail to preemptively treat pain.\textsuperscript{21} Accordingly, clinicians should err on the side of presuming pain is present. Repeated assessment is desirable because conditions change over time and pain management is more effective at an early stage than after pain has become established and more severe.

Ideally, pain should be described in regard to location, duration, type,
exacerbating and relieving factors, and intensity. Pain should be also be considered by subtype—including somatic, visceral, and neuropathic—because manifestations and management can be different. For example, somatic pain is typically dull and aching, often localized, and responds well to opioids and nonsteroidal anti-inflammatory drugs (NSAIDs). In contrast, visceral pain is often cramping and colicky and may respond to anticholinergic therapy, whereas the burning and shooting neuropathic pain is often best treated with antidepressant and anticonvulsant agents. Repeated and thorough evaluation helps to determine the cause and to appreciate prior responses to therapy.

Because pain is a subjective interpretation by an individual, the ability of that individual to communicate the presence and magnitude of pain is important in guiding evaluation and management when possible. Many ICUs employ a strategy of daily interruption of sedation, even in unstable sedated patients, and this brief period of greater awareness by the patient presents an opportunity for communication about pain. Although detailed verbal communication about the presence, intensity, and character of pain is ideal, it is often not possible with ICU patients and the use of simple tools can enhance communications of the presence and intensity of pain. These simple tools, such as numerical rating scales and a series of cartoon faces ranging from smiling to crying like the Wong-Baker FACES scale, can facilitate communication via pointing or nodding by the cognitively intact but nonverbal patient. A simple horizontal 0-to-10 numerical scale with enlarged font was judged to be feasible and valid in one comparison of tools. Other techniques to improve the process of self-reporting of pain include adding descriptive words to the numerical scale, explaining the tool and correcting errors with each encounter, providing needed glasses and hearing aids, and ensuring adequate time for instructions and patient response. Use of a scale that incorporates descriptive pictures, like the FACES scale, can help overcome language barriers as well as mild cognitive dysfunction.

Many ICU patients are cognitively impaired, and self-reporting pain is not feasible. For these patients, utilizing a structured evidence-based approach to infer the presence and severity of pain based on observation can be performed. Tools have been developed based on observed
behaviors that have been correlated with self-reported pain and/or with responses to noxious stimuli in prior research.9,21,44–46 Various combinations of behaviors have been assembled into structured assessment tools—most include facial expressions, body position and movement, and patient–ventilator interaction. Contraction of facial muscles associated with grimacing correlates particularly well with noxious stimuli.22 The early work in pain assessment for noncommunicative ICU patients was with infants and young children, resulting in the development of the COMFORT Scale, the FLACC Observation tool, and others.41,76,77 Subsequently, a variety of pain assessment tools for nonverbal critically ill adults have been developed, validated, and critically reviewed.11,41,47,48 Published pain observation tools for adults in the ICU care include the Critical-Care Pain Observation Tool (CPOT); the Behavioral Pain Scale (BPS); the Behavioral Pain Scale for non-intubated patients (BPS-NI); the Nonverbal Pain Scale (NVPS); the Pain Behavioral Assessment Tool (PBAT); and the Pain Assessment, Intervention, and Notation (PAIN) tool.49–55 Additionally, the Adaptation to the Intensive Care Environment (ATICE) tool incorporates facial grimacing as one of five components.78 Following comprehensive testing of psychometric properties and issues of relevance and implementation, the CPOT (Table 114.3) and BPS (Table 114.4) scales were recommended in the 2013 guidelines as the most valid and reliable behavioral pain scales for monitoring pain in adult medical, postoperative, or trauma ICU patients who are unable to self-report and in whom motor function is intact and behaviors are observable.11 Because these tools all rely on behavioral responses to noxious events, their validity can be influenced by other factors, particularly sedative medications. Specifically, both scores of CPOT and BPS decrease and validity falls with deepening sedation.50,55 Given the inexact nature of pain evaluation in noncommunicative patients, investigators continue to explore new ways to detect pain including detection of specific muscles during facial movements like grimacing,22,79 and various measures of autonomic response to nociceptive stimulation including heart rate variability, pupillary dilatation reflex, and skin conductance.80,81

In addition to observable behaviors, pain is often accompanied by readily observed physiologic responses such as tachycardia, hypertension, and tachypnea. However, these changes in vital signs are inconsistently associated with pain, are effected by many confounding factors (such as β-adrenergic antagonists or other medications), and lack specificity for pain with many other common causes including dyspnea, anxiety, and fever. Accordingly, 2013 guidelines recommend against the use of vital signs (or observational pain scales that include vital signs) alone for pain assessment in adult ICU patients. Clinicians should, however, regard unexplained tachycardia, tachypnea, and hypertension as potential clues to the presence of pain, prompting further pain assessment. Other potentially useful approaches include assessing the patient’s response to a trial of analgesic medication and use of surrogate (such as family members) report. It should be considered, however, that surrogates may lack reliability and accordingly should not be the sole source for monitoring.

Managing Pain and Analgesia in the Intensive Care Unit

The provision of adequate pain control is a core practice for all ICU patients. Ensuring pain relief to patients not only relieves human suffering but additionally mitigates the negative short- and long-term physiologic effects caused by untreated pain. Unfortunately, pain remains inadequately treated in many patients. Some of the barriers to providing adequate pain
relief include difficulty with accurate pain assessment, a lack of understanding of dose and dose titration of opioids, presence of adverse effects from opioids, and variations in attitudes toward use of opioids (particularly in patients with an underlying opioid use disorder). Increased education on use of pain assessment tools and a comprehensive understanding of the pharmacokinetic and pharmacodynamic properties of various pain medications may help improve overall outcomes with regard to the treatment of pain in hospitalized patients. Structured approaches and aids such as order sets and guidelines can reduce variability in practice.

A considerable challenge during management is balancing adequate pain control against the adverse effects of medications, particularly opioids, in a diverse ICU patient population. Clinicians should consider a multimodal approach to pain control, as some pain may not be responsive to opioid therapy. Proposed opioid-sparing approaches include prioritizing intermittent opioid boluses over continuous infusions when possible, using patient-controlled analgesia when appropriate, and using nonopioid medications when clinically feasible (i.e., low-dose ketamine, α2 agonists such as clonidine and dexmedetomidine, acetaminophen, NSAIDs, and local treatments such as lidocaine patches). Adjuvant nonpharmacologic therapies (i.e., music therapy, relaxation techniques) also play a complementary role and should be considered to help decrease the use of opioids. Pharmacologic and other approaches are discussed in detail in the following section, along with approaches to integrate analgesic practices with related care.

PHARMACOLOGIC TREATMENT OF PAIN IN THE INTENSIVE CARE UNIT: PARENTERAL OPIOIDS

The objective of administering opioids in the ICU is to improve patient comfort and outcomes for critically ill patients. The opioid class is considered first-line therapy for ICU patients experiencing nonneuropathic pain. This class of medications acts primarily on the μ-opioid receptor to provide analgesia. Opioid receptors are found in the central nervous system within the locus ceruleus, ventral medulla, and substantia gelatinosa of the dorsal horn; they are also found in peripheral tissue of neural and nonneural origin. Most opioids have lipophilic properties and
undergo extensive first-pass metabolism, allowing for rapid transference across cell membranes and rapid onset of activity. Important variations in pharmacokinetics and dynamics exist between individual opioids (i.e., drug metabolism, drug interactions, protein binding, lipophilicity, adverse effects) as well as with individual physiologic conditions (i.e., cirrhosis, renal disease, opioid tolerance, older age, genetic polymorphism). These characteristics should be thoughtfully considered when choosing and titrating an opioid medication.

The impact of the adverse effects of opioids on clinical outcomes in the ICU is becoming increasingly recognized. Examples of adverse effects of opioids include respiratory depression which may delay time to extubation, development of constipation or ileus causing delays to nutrition goals and impairing ventilation and oxygenation, altered mental status including oversedation that can delay progression to liberation from mechanical ventilation, mobility and strength, and the potential for opioid withdrawal or dependence if receiving opioids for a prolonged period of time.

Opioids, like other medications administered for prolonged periods, can manifest protracted durations of effect. Analgesia and sedation can persist for days to weeks after sustained infusions are discontinued, and it is common for patients with hepatic or renal disease to experience oversedation. Evidence-based therapeutic recommendations favor bolus dosing and daily interruption of sedative and analgesic medications except for the dying and those with uncontrolled pain.

No specific opioid agent has been demonstrated to be preferable in all ICU patients or across all clinical entities. Selection of initial analgesic therapy should be based on individual patient characteristics and knowledge of prior opiate exposure, experience, and side effects, when available. As is the case for all medications first introduced to the patient in the ICU, it is important to de-escalate opioid doses in a fashion that does not promote withdrawal symptoms but uses the lowest effective dose aiming for transition to nonopioid agents if possible. The devastating impact of the ongoing opioid abuse epidemic certainly provides strong motivation for vigilance in opioid de-escalation.
Fentanyl
Over the last 20 years, fentanyl has supplanted morphine as the most commonly used analgesic in adult ICUs in the United States and is commonly used throughout the world.\textsuperscript{89–91} Fentanyl is a potent opioid from the phenylpiperidine class with an onset of action of 1 to 2 minutes and a short duration of action when used in intravenous (IV) bolus form in healthy individuals. It is highly lipophilic and highly protein bound. Fentanyl exhibits a three-compartment distribution model, distributing readily into both muscle and fat tissue. Prolonged IV fentanyl infusions (i.e., >7 days) have led to protracted clearance times and delayed awakening.\textsuperscript{92} Fentanyl is devoid of the histamine release seen upon initiation of morphine and therefore is recommended over morphine for patients who are hemodynamically unstable. Clinicians should still use caution in hypotensive patients; however, as studies have demonstrated hypotension associated with fentanyl use, particularly when fentanyl is given in conjunction with other sedatives or when given rapidly in an IV bolus form.\textsuperscript{93}

Fentanyl undergoes hepatic metabolism via the cytochrome P450 3A4 isoenzyme, and potential for drug interactions is high causing either inhibition or induction of fentanyl clearance. Fentanyl has a high hepatic extraction ratio; therefore, clearance will be more affected by blood flow through the liver than by intrinsic liver function.\textsuperscript{65} Accumulation of the parent drug can occur in patients with cirrhosis, and monitoring for oversedation is recommended.\textsuperscript{65} The presence of chest wall rigidity has been described frequently with fentanyl in the pediatric population; it has been reported as a rare but significant adverse effect in adults.\textsuperscript{88}

Synthetic opioids from the phenylpiperidine and diphenylheptane classes (i.e., fentanyl, methadone, meperidine, remifentanil, tramadol) exhibit a dose-related increase in norepinephrine release from sympathetic nerve endings and inhibition of neuronal uptake of norepinephrine. These opioids also block reuptake of serotonin and have serotonin receptor agonist activity. This increase in central norepinephrine and serotonin levels can thereby predispose a patient to dangerous reactions if these opioids are administered with serotonergic agents (i.e., antidepressants) or monoamine oxidase inhibitors (i.e., linezolid).\textsuperscript{92,94–98} Reactions include
serious autonomic and neurologic changes, such as hypertension, tachyarrhythmias, severe hyperpyrexia, spontaneous or inducible clonus, and coma; death has been reported in severe cases. In cases of drug overdose from a serotonergic agent or monoamine oxidase inhibitor, or if there are concerns for serotonin syndrome, certain opioids including fentanyl should be avoided.\textsuperscript{99}

These drug interactions need careful consideration if a patient requires an opioid for acute pain control, along with reinitiation of the outpatient antidepressant to avoid withdrawal. Therapeutic options may include starting a lower dose of the serotonergic antidepressant, although this may not prevent withdrawal from the antidepressant, or choosing an alternative to fentanyl (i.e., hydromorphone, morphine, nonopioids). The combination of a monoamine oxidase inhibitor with fentanyl or tramadol should be avoided altogether due to a high risk and severity of adverse events.

Critical care guidelines recommend the choice of opioid be based on specific drug and individual patient characteristics.\textsuperscript{11,12} Despite the aforementioned concerns with variable kinetics and drug interactions in a critical care patient, fentanyl has become the most commonly used opioid in adult ICUs, likely due to its quick onset of action, lack of active metabolites, and guideline recommendation over morphine for the hemodynamically unstable patient.\textsuperscript{11} Clinicians should familiarize themselves with the pharmacokinetics and dynamics of fentanyl, as it continues to be highly utilized in adult ICUs.

**Hydromorphone**

Most studies reporting use of IV hydromorphone infusions in the acute adult ICU setting are retrospective or observational in nature. Short- and long-term effects of hydromorphone infusions have not been well described in the adult ICU literature. Although fentanyl is generally the recommended opioid of choice in the acute adult ICU setting, clinicians may opt to use hydromorphone over fentanyl for various clinical scenarios including prior chronic outpatient use of hydromorphone, tachyphylaxis to fentanyl, better pain control with hydromorphone over fentanyl, and the need to administer a serotonergic agent or a monoamine oxidase inhibitor concomitantly.
When administered IV, hydromorphone has an onset of activity of 5 to 10 minutes and a duration of activity of 3 to 4 hours. Hydromorphone is only 10% to 20% protein bound (because it undergoes phase 2 hepatic glucuronidation), has less potential for metabolically based drug interactions, and has more reliable clearance in hepatic failure. Glucuronidation of hydromorphone produces the metabolite hydromorphone-3-glucuronide (H3G). The H3G metabolite is devoid of analgesic activity; however, it maintains neurotoxic effects such as cognitive dysfunction, agitation, confusion, hallucinations, tremors, clonus, and seizures. As glomerular filtration rate (GFR) declines, H3G accumulates up to fourfold the initial concentration. Occurrence of neurologic toxicities was seen in approximately 20% of patients with GFR <60 mL per minute in a study of palliative care patients with chronic renal insufficiency. Starting doses of hydromorphone should be adjusted for renal dysfunction, and patients should be closely monitored for signs of neurotoxicity if receiving high doses or continuous infusions of hydromorphone in the presence of renal failure. Hemodialysis clears hydromorphone; however, close monitoring of neurotoxic effects should still be observed for patients on dialysis.

**Morphine**

Morphine has historically been the opioid of choice for acute pain and is still commonly used in adults ICU patients around the world. Morphine is a low-cost medication with effective analgesic and euphoric effects, making it an attractive alternative in many acute clinical scenarios. Critical care guidelines recommend morphine as an acceptable first-line agent for pain in the ICU but advise that morphine may cause hypotension due to systemic release of histamine. Both animal and human studies have demonstrated significant histamine and nitric oxide release with morphine, with subsequent decreases in systemic vascular resistance, bronchospasm, and urticaria.

Morphine is metabolized in the liver to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), both of which are subsequently cleared by the kidneys. Similar to the hydromorphone metabolite H3G, M3G does not have analgesic activity but can cause severe neurotoxic
symptoms such as cognitive dysfunction, tremors, and seizure activity. However, the M6G metabolite is 2 to 8 times more potent than morphine as an analgesic. These metabolites can exhibit prolonged effects in patients with renal dysfunction and in patients receiving dialysis; therefore, scheduled dosing and continuous infusions are not recommended in those settings. In critically ill patients, the altered protein binding resulting from malignancy, renal impairment, and hepatic failure may also alter morphine pharmacokinetics and make dosing titration challenging.

**Remifentanil**

Remifentanil is a selective μ-opioid receptor agonist approved for use in anesthesia induction and maintenance that may have advantageous properties for ICU care. The novelty in this agent, in contrast to fentanyl, is that remifentanil is metabolized by multiple ubiquitous esterases, and its half-life is not known to be prolonged by critical illness nor organ dysfunction. Due to its pharmacokinetic properties, this agent has a terminal half-life of less than 30 minutes and may reduce the incidence of prolonged sedative complications seen with continuous infusions of other opiates. Short-duration studies demonstrate reduced duration of mechanical ventilation when this agent is compared to other opiates. Remifentanil can cause bradycardia and hypotension, potentially limiting its use in the ICU. It has been used in traumatic brain injury and neurosurgical settings with favorable effects on neurologic function assessment and a dose-dependent reduction in coughing associated with endotracheal suctioning. Concern remains, however, that the rapid offset of this agent may lead to withdrawal and agitated behavior. In one study, remifentanil was associated with a higher rate of moderate or rebound pain upon cessation of a 72-hour infusion compared to fentanyl (33% vs. 9%). There was no difference in mean extubation time in this short-term study. Other published reports suggest remifentanil may be associated with more rapid recovery from respiratory failure. In one randomized controlled trial (RCT), patient who received remifentanil had shorter duration of mechanical ventilation (3.9 vs. 5.1 days). In a 2017 meta-analysis of 23 RCTs of adult mechanically ventilated ICU patients, remifentanil was associated with shorter duration of mechanical
ventilation, shorter time to extubation after sedation cessation, and shorter ICU length of stay (LOS).  

**PHARMACOLOGIC TREATMENT OF PAIN IN THE INTENSIVE CARE UNIT: ADJUVANT THERAPY**

**Ketamine**

Ketamine has been used for decades in bolus IV form for procedural sedation and analgesia, rapid sequence intubation, and brief operating room (OR) cases. It is a well-established anesthetic agent and produces a qualitatively unique state referred to as “dissociative anesthesia.” This dissociative anesthesia has been described as having a spectrum of effects, including hypnosis at lower doses, deep sedation and coma with higher doses, potent antinociceptive effects, increased sympathetic tone, and intact respiratory and airway tone. Added benefits include maintenance of normal gastrointestinal motility and less respiratory depression compared to opioids. At the bedside, these clinical effects could prove beneficial for unstable ICU patients and has prompted increased interest in sustained infusion ketamine in the ICU setting.

Ketamine provides these effects via multiple mechanisms including blockade of the N-methyl-D-aspartate (NMDA) channels, neuronal hyperpolarization, δ- and μ-opioid agonism and opioid potentiation, effects on the nitric oxide guanosine monophosphate system, reduction in cholinergic modulation, and central release of dopamine and noradrenaline. Ketamine has a large volume of distribution due to its lipophilic properties but is not highly protein bound. It has a quick onset of action (<5 minutes) and a short duration of activity in bolus form (5 to 15 minutes depending on dose). Hepatic and renal dysfunction can cause accumulation and prolong ketamine’s duration of activity.

Emergence from the dissociative effect of ketamine can illicit reactions such as hallucinations, agitation, confusion, and delirium. This emergence reaction may be mitigated by giving a benzodiazepine prior to ketamine boluses or upon discontinuation of continuous ketamine infusions. Because ketamine is a sympathomimetic producing increased levels of circulating dopamine and norepinephrine, ketamine should be avoided in patients with concomitant cardiovascular disease or myocardial infarction.
Ketamine may also increase pulmonary vascular pressures and therefore should be used with caution or avoided in this patient population. Reports of prolonged ketamine use (>24 hours) in the ICU are limited to a few small studies. The optimal dose, duration, monitoring parameters, and how ketamine fits into the armamentarium of medications used for analgesia and sedation in the adult ICU remain unclear. Reported ketamine doses described for use in the ICU vary but generally range from 0.05 mg/kg/hour to 0.4 mg/kg/hour, with a maximum of 1.2 mg/kg/hour when used for severe pain. Potential benefits of ketamine include additional pain control (opioid sparing), reduced airway resistance, increased lung compliance, minimal effect on respiratory drive at low to moderate doses, and intact gastrointestinal motility.

**Methadone**

Methadone is a unique analgesic with multiple mechanisms of action which contribute to its antinociceptive effects. These mechanisms are centrally mediated through agonism at the μ-opioid receptor, antagonism at the NMDA receptor, and inhibition of serotonin and norepinephrine reuptake. The primary indications for use of methadone include chronic pain and prevention of opioid withdrawal. Using methadone for acute pain is challenging secondary to the need for slow and gradual uptitration every 2 to 3 days. More frequent titration can lead to higher than expected drug levels with respiratory depression and oversedation as the drug gradually reaches steady state.

Methadone is highly lipophilic leading to its relatively quick onset of action, a “drug-depot” effect throughout the tissues, and an extended half-life. Methadone is highly bound to plasma proteins, in particular to α₁-acid glycoprotein. The dosage forms for methadone include oral tablets, suspension, and an IV formulation. The potency of the IV dose is approximately twice that of the oral dose. There are multiple considerations when using methadone in a complex ICU setting. Methadone undergoes hepatic clearance; therefore, accumulation can occur in acute or chronic liver dysfunction and lower doses should be used. It is a major substrate of enzymes CYP 3A4 and 2B6 and a minor substrate of CYP 2D6, 2C9, and 2C19; thus, medication profiles should be
closely scrutinized for multiple drug interactions. Concern for QTc prolongation exists for methadone, which can be problematic in an ICU setting where other risk factors for QTc prolongation are often present (multiple medications which prolong QTc, electrolyte abnormalities, underlying cardiac disease). Common medications which will increase methadone levels, thereby increasing risk for QTc prolongation and serotonin syndrome, include azoles, macrolides, antipsychotics, and antidepressants. The U.S. Food and Drug Administration (FDA) has issued a boxed warning for the use of methadone with benzodiazepines, as this combination has resulted in significant respiratory depression, profound sedation, coma, and death. If using methadone in the ICU, an electrocardiogram should be routinely monitored and electrolytes such as potassium, magnesium, and calcium be maintained within the normal range. Patients admitted to ICU from home while receiving chronic methadone treatment and patients in opioid withdrawal may necessitate initiation of methadone in the hospital or ICU—but with significant caution.

Other Analgesics and Adjuvant Agents
Other agents may have a role in the ICU, but many possess properties that limit their utility in critical care settings. Meperidine is associated with neuroexcitation due to a metabolite, normeperidine potentially producing seizures, and thus is rarely used in the ICU setting. It has been used in the short term for shivering associated with general anesthesia or to abate drug-induced rigors. Meperidine should not be given for more than 1 day or at a cumulative dose over 600 mg. Codeine is converted to morphine in order to be active, but a proportion of the population lack the necessary enzymatic mechanism. Oxycodone is pharmacologically similar to morphine but is only available in oral preparations. Oxycodone, along with hydrocodone, have been associated with a high abuse potential in the United States. Consideration for the patient’s medical and social history (i.e., history of opioid abuse) should be taken into account upon initiation of these medications.

Ketorolac is an IV nonsteroidal anti-inflammatory medication that may be useful for anti-inflammatory effects but produces gastrointestinal
toxicity and increases the risk for gastrointestinal bleeding that limits its use to less than 5 days at a time or not at all in ICU patients already at risk for bleeding. Corticosteroids and adenosine may have opiate-sparing effects as adjuvant therapy but have not been evaluated in the ICU. Lidocaine has also been used as an effective adjuvant for complex or neuropathic syndromes but may be limited in the ICU due to its arrhythmogenic properties.\textsuperscript{124} Acetaminophen is a weak analgesic that carries the risk of hepatotoxicity with chronic use that similarly restricts its utility in the ICU.

Clonidine is an $\alpha_2$-receptor agonist that provides mild sedation and mild analgesia but is an antihypertensive and can cause hypotension. Its cousin, dexmedetomidine, is a selective $\alpha_2$-receptor agonist with sedative properties similar to benzodiazepines and propofol but, in contrast to other sedatives, has analgesic properties and can be opioid sparing, is sympatholytic potentially producing prominent bradycardia as well as hypotension at higher doses, is associated with a more alert state relative to anxiolytic properties, and has minimal effect on respiratory drive.\textsuperscript{125,126} It does not bind $\gamma$-aminobutyric acid (GABA) receptors. In a meta-analysis of 24 RCTs comparing dexmedetomidine to alternative sedative drugs, ICU LOS was shorter with dexmedetomidine, whereas duration of mechanical ventilation was not significantly different.\textsuperscript{127} Clinical trial results suggest that when compared directly to midazolam, dexmedetomidine may be associated with lower prevalence of delirium.\textsuperscript{128}

Anticonvulsants (i.e., gabapentin, carbamazepine) are recommended in guidelines in combination with opioids for confirmed neuropathic pain.\textsuperscript{11} However, anticonvulsants have not been studied extensively in the ICU population, and there is a potential for significant adverse effects and drug interactions, requiring close monitoring and follow-up. If the patient is discharged home on an anticonvulsant for neuropathic pain, close follow-up should be performed by the outpatient provider.

**NONPHARMACOLOGIC MANAGEMENT OF PAIN IN THE INTENSIVE CARE UNIT**

Nonpharmacologic modalities are incompletely studied and infrequently used in the ICU but have the potential to improve pain management.\textsuperscript{11,12}
Complementary therapies include distraction therapies, behavioral modification, touch therapy, meditation, music therapy, acupuncture or acupressure, and massage, among others. Simply providing information can be beneficial. These approaches are generally safe, easy to provide, and inexpensive; however, evidence of benefit sufficient to justify routine use is weak, and their true impact on pain should not be overestimated.85–87

REGIONAL ANESTHETIC APPROACHES TO PAIN IN THE INTENSIVE CARE UNIT
Regional anesthesia and analgesia (RAA) includes continuous epidural analgesia and/or anesthesia (central neuraxial techniques) and continuous peripheral nerve or plexus block. These techniques are reviewed in detail in Chapter 52 and will only be commented on briefly here. RAA techniques provide medication delivery in close proximity to the spinal cord or nerves and thus can result in parenteral opioid sparing, which is associated with less respiratory depression and gastrointestinal hypomotility, and other benefits. These techniques do, however, introduce new issues related to needle and catheter placement and maintenance as well as physiologic derangements related to local anesthetic block and epidural drug administration. Critically ill patients are probably at higher risk for RAA-related complications due to a higher incidence of coagulopathy, thrombocytopenia, sepsis, and hemodynamic instability.

Utilization of RAA techniques in the ICU setting is largely limited to surgical patients who are postoperative or injured. The availability of and success with these techniques is probably closely tied to cumulative experience and expertise of local experts. Peripheral nerve blocks can be useful for anatomically localized pain such as limb injury or operation, but there are few RCTs in ICU patients on which to base recommendations. The largest body of evidence is related to epidural techniques but even that is quite limited. Recommendations regarding RAA published in the 2013 SCCM guidelines were limited by availability of high-level data for ICU patients, but recommendations were provided in several specific scenarios.11 Thoracic epidural anesthesia and analgesia for postoperative analgesia in patients with abdominal aortic surgery received a strong
recommendation as superior to IV opioids.\textsuperscript{129} High-level evidence was also available to compare lumbar epidural analgesia to IV opioids in the same population but no benefit was demonstrated, and RAA was not recommended.\textsuperscript{130} ICU patients with traumatic rib fractures had superior pain and fewer cases of pneumonia when treated with thoracic epidural analgesia than IV opioids but experienced more hypotension, and this form of RAA was endorsed with a weak recommendation for managing pain from traumatic rib fractures.\textsuperscript{131,132} There was insufficient evidence to support RAA in any other ICU clinical setting including after thoracic operations and nonvascular abdominal operations and for medical ICU patients.\textsuperscript{11}

Integrated Analgesia Management in the Intensive Care Unit

Pain management and analgesia is a central theme in the comprehensive care of the critically ill patient. The key concepts supported by published evidence and recommended by experts (see Table 114.2) form the framework of integrated analgesia management. First, pain should be routinely monitored in all adult ICU patients, using behavioral pain scales in those who are unable to self-report. Second, preemptive analgesia should be used prior to procedures because it is more effective to prevent pain than to control it once it has developed. Third, analgesia-first sedation (analgosedation) should be used in mechanically ventilated adult ICU patients. Fourth, IV opioids are first-line therapy for nonneuropathic pain, but consider nonopioids analgesics to reduce opioid dosage and side effects, and treat neuropathic pain with gabapentin or carbamazepine.\textsuperscript{11}

The following sections will provide additional detail about using combination therapy with opioid analgesics and sedative-hypnotic agents with emphasis on analgesia-first sedation (analgosedation), followed by discussion of the role of analgesia in comprehensive care that integrates management of analgesia, sedation, delirium mitigation, liberation from mechanical ventilation, and mobility and rehabilitation.

**ANALGOSEDATION IN THE INTENSIVE CARE UNIT**
Analgesic and sedative drug therapy of critically ill, mechanically ventilated patients should focus on careful selection and titration of drugs to achieve optimal patient comfort while avoiding the adverse impact of excessive or unnecessarily prolonged sedation. The use of structured approaches to sedation and analgesia via algorithms and protocols has achieved a prominent place in ICU practice. There are several common themes. One theme is to focus first on analgesia, as discussed earlier. The 2013 guidelines suggest that analgesia-first sedation be used in mechanically ventilated adult ICU patients. Asking first about pain, before the patient has been sedated and cognitively impaired, is advantageous. Additionally, several RCTs have demonstrated analgesia-based sedation to be associated with shorter duration of mechanical ventilation in comparison to hypnotic-based sedation. Strom et al. randomized mechanically ventilated adult ICU patients to bolus morphine (analgesia-based, limited sedation) versus morphine plus propofol for the first 48 hours and then midazolam (sedation + analgesia) and found shorter duration of mechanical ventilation and ICU LOS but threefold more agitation when sedative drugs were minimized.

A second major theme is to tailor the sedation to the specific patient, including medication selection based on sedation goals (such as rapid arousal), avoidance of side effects (such as hypotension), and consideration of elimination issues (such as avoiding midazolam in a patient with impaired renal function). In addition to the opioid analgesic medications discussed previously, a variety of sedative drugs have a role in ICU sedation management. However, there is emerging evidence appears to favor using propofol or dexmedetomidine in preference to benzodiazepines in patients for whom continuous infusion sedation is needed. A meta-analysis limited to moderate- or high-quality RCTs demonstrated slightly longer ICU LOS with benzodiazepines in comparison to propofol or dexmedetomidine. Several studies deserve additional comment. A multicenter RCT comparing dexmedetomidine to midazolam demonstrated that dexmedetomidine was associated with shorter time to extubation, lower prevalence of delirium, and fewer infections but no difference in ICU LOS, mortality, or sedation quality. In the two phase-3 multicenter RCTs that compared dexmedetomidine to
midazolam, or propofol, patients randomized to dexmedetomidine had shorter duration of mechanical ventilation than with midazolam but not with propofol.\textsuperscript{134} Patient interaction (communication, arousability, cooperation) was better with dexmedetomidine than with either other agent, but hypotension and bradycardia were more common. Dexmedetomidine may offer advantages for managing agitation or hyperactive delirium, particularly that related to alcohol withdrawal.\textsuperscript{135–138} Propofol, the most widely used sedative agent in the United States,\textsuperscript{89} binds GABA and other receptors and produces sedative-hypnotic effects similar to benzodiazepines but no analgesic effects. It has rapid onset and offset of action but has the disadvantages of producing hypotension and depressed respiratory drive.\textsuperscript{139} Compared to benzodiazepines, propofol is associated with shorter duration of mechanical ventilation and shorter ICU LOS.\textsuperscript{140}

Another theme is to strive for a light level of consciousness and to avoid accumulation of medications and their active metabolites, thus reducing the likelihood of delayed awakening. This approach is strongly recommended in the 2013 guidelines\textsuperscript{11} based in part on studies like those of Strom et al.\textsuperscript{69} The underlying rationale for this approach arises from the observation that continuous IV sedation and analgesia is associated with delayed recovery from respiratory failure and longer LOS.\textsuperscript{141} Although a variety of sedation management strategies have been demonstrated to shorten the duration of mechanical ventilation, the most robust data supports the use of a sedation protocol or the implementation of daily interruption of sedation. Strategies that successfully promote a more alert state have been associated with less medication use and accompanying costs, less delirium, fewer tests for altered mental status, shorter duration of mechanical ventilation, fewer tracheostomies, and shorter time in the ICU and hospital.\textsuperscript{11,69,70,142–155} Abrupt withdrawal of sedative (and sometimes analgesic) medications is accompanied by severalfold increases in circulating catecholamines as well as tachycardia and hypertension, but no evidence of triggering cardiac ischemia.\textsuperscript{156} Daily interruption of sedation is also not followed by psychological complications like posttraumatic stress disorder.\textsuperscript{157} Patients who should probably not undergo daily interruption of sedation includes those with active seizures, alcohol withdrawal, worsening agitation, neuromuscular blockade, acute
myocardial ischemia, or elevated intracranial pressure.\textsuperscript{158}

**ANALGESIA AS A COMPONENT OF COMPREHENSIVE BUNDLED INTENSIVE CARE UNIT CARE**

Over the past decade, multiple RCTs have demonstrated the value of linking strategies for managing analgesia and sedation in ICU patients with related components of patient care including weaning and liberation from mechanical ventilation, reducing the prevalence and duration of ICU delirium, and promoting mobility and early rehabilitation. The improved outcomes associated with linking interruption of sedation (or spontaneous awakening trial [SAT]) with testing of the potential for ventilator liberation (spontaneous breathing trial [SBT]),\textsuperscript{158} so called “wake up and breathe,”\textsuperscript{159} illustrated the value of such an approach. Addition of early mobility and exercise to SAT and SBT has further improved outcomes including less delirium and more rapid recovery.\textsuperscript{160} Research and experience has shown that when incorporating these components collectively as a “bundle,” the patient has better outcomes, including decreased ventilator days, decreased incidence of delirium, and shortened hospital LOS.\textsuperscript{34–40} A crucial aspect of improving patient care revolves around successfully disseminating and implementing the results of compelling research findings through knowledge translation.

The ABCDEF approach (http://www.iculiberation.org) provides an effective framework for patient-centered integrated care, with the components depicted in Table 114.5.\textsuperscript{34,35} It is no surprise that a critical part of the ABCDEF bundle is “A,” which stands for assessing, preventing, and treating pain. The ABCDEF bundle also incorporate other components that are relevant to the treatment of pain, such as “C” (choice of sedating agent), not only focusing on analgosedation, to ensure pain is controlled, but also recognizing the potential need for short-acting sedatives as adjunctive agents to provide sedation, assisting in minimizing potential adverse side effects of opiate-only sedation. In addition, the importance of daily delirium screening (“D” in the ABCDEF bundles), which may be directly related to sedation choice, is emphasized in the ABCDEF bundles. Furthermore, the many benefits of early mobilization (“E” in the ABCDEF bundles) are also a treatment and pain preventative.
tool in itself for ICU-related pain, as the pain associated with immobility is a debilitating phenomenon that is often underrecognized. Collectively, one could argue that all the components of the ABCDEF bundle are either directly or indirectly intertwined and interrelated to pain in the ICU, including the direct assessment and anticipation of pain, the pain associated with endotracheal tubes that may be able to be removed sooner with daily awakening and breathing trials, or the pain that accompanies immobility. Therefore, it is imperative that a multimodal, interdisciplinary group become familiar with these guidelines and implementation tools that collectively represent best practice in intensive care medicine.

Pain and Analgesia at the End of Life in the Intensive Care Unit

Unfortunately, critically ill patients die in the ICU, and in some instances, the realization that the end of life is imminent occurs when the patient is receiving life-sustaining interventions such as vasopressors, mechanical ventilation, dialysis, and other life-support devices. The presence of pain, dyspnea, and other unpleasant sensations is not uncommon in the end-of-life setting, particularly with existing invasive ICU interventions, and achieving relief from distress becomes of paramount importance. The principles for pain management at the end of life are discussed in detail in Chapter 109.

In many such cases, the patient has ongoing analgesic and sedative therapy that can be titrated to achieve goals of relieve of pain and suffering without concerns for hemodynamic or respiratory consequences. Providers should administer pain medications and other palliative therapies for the
dying patient in the ICU, even if the possibility exists that such treatment could possibly hasten death.\textsuperscript{161–163} A doctrine of “double effect” supports adequate and aggressive palliation of pain to be differentiated from active hastening of death and ethically justifiable, as long as the provider’s primary intent is mitigating suffering.\textsuperscript{164–167}

It is imperative that a patient in the ICU die with dignity and that an individualized treatment plan be used at the end of life.\textsuperscript{161–163,166,167} This involves use of preemptive medications aimed at treating pain, dyspnea, anxiety, delirium, and any other symptoms that may be distressing to the patient. It is important that ICU clinicians discuss with family members or other individuals present what to expect during the dying process and continue to provide support to the patient and their family.\textsuperscript{166} Some practical recommendations for managing end-of-life issues in the ICU are noted in Table 114.6.

**TABLE 114.6 End-of-Life Care and Pain Management in the Dying Intensive Care Unit Patient**

- Clarify and document the goals of care.
- Notify interested individuals (surgeon, oncologist, specialty nurse, outpatient physician, or nurse).
- Emphasize to family that care continues but with new goals (i.e., care is not being “withdrawn” but rather is focused on dignity and comfort).
- Discontinue interventions and treatments that do not contribute to comfort (phlebotomy, imaging, remove nonessential devices, silence alarms).
- Provide sufficient analgesia, generally with systemic opioids (assure reliable intravenous access, take into account recent and/or chronic opioid use, avoid arbitrary maximum analgesic dosing, begin with a bolus of drug if planning to remove devices, including the endotracheal tube, that raise the possibility of discomfort).
- Educate and reassure family and staff that the purpose of opioids is to relieve and prevent suffering, not to hasten death.
- Consider removing the endotracheal tube because this can generally be done with no discomfort as long as adequately premedicated.
- Reassess regularly whether the goals of care (comfort) are being met and titrate pharmacologic agents and interventions (clinically examine for signs of discomfort), determine whether vital signs respond to interventions, and solicit family input: Do you feel your loved one is comfortable?
- Invite pastoral care, palliative care, or pain management specialists to participate, when appropriate.
- Consider transfer out of the intensive care unit, particularly to a palliative care unit, for continued comfort care.
Conclusions

Managing pain and providing effective analgesia are critical component of comprehensive care of our ICU patients. Although the core principles of pain management in general certainly apply in the ICU setting, the unique issues related to complex acute and chronic medical illness, organ dysfunction, communication difficulties, and integration with sedative therapy and life support provide sound rationale for utilizing a multiprofessional and patient-centered approach.

ACKNOWLEDGMENTS

The authors are grateful to Richard Mularski, MD, and Gregory Schmidt, MD, who are coauthors of the chapter “Pain Management in the Intensive Care Unit” published in the fourth edition of Bonica’s Management of Pain in 2009. Their work paved the way for this updated chapter on pain management in the ICU in the fifth edition of Bonica’s Management of Pain.

CHAPTER 115

The Future of Pain Medicine: An Epilogue

SCOTT M. FISHMAN and JAMES P. RATHMELL

The creation of this fifth edition of Bonica’s Management of Pain reflects a major collaboration among many of the world’s leading authorities in the basic and clinical sciences. As in prior editions, this text serves as a resource for those who seek to increase their understanding of this aspect of the human condition. However, it also provides an important reference point—an elaboration on how far we have come and how far we have to go in order to prevent, markedly reduce, and perhaps even cure the pervasive problem of pain as a cause of unnecessary suffering, debility, and economic hardship. As in the previous edition, we will again briefly look ahead to where this journey may—and should—lead us before the next edition of this textbook is written and reflect on what has happened since the last edition was published in 2010.

The future is unpredictable; nonetheless, there are many current trends that portend an optimistic course ahead. Foremost is the pivotal recognition that pain is much more than a symptom and that its consequences, in the acute or chronic form, may be devastating at every level of human health. This profound understanding continues to transform the perspective of modern medicine, offering greater possibilities for dealing with the burden of disease than ever before. Soon after publication of the prior edition of this text, the Institute of Medicine (now the National Academy of Medicine) published its landmark report entitled “Relieving Pain in America,” reporting that approximately 100 million Americans suffer with chronic pain. It highlighted that clinicians remain substantially undereducated about pain and ill prepared to respond.\(^1\) This education gap has increasingly been seen as a one of the major root causes of the current epidemic of prescription drug abuse, in that US clinicians were advised, if
not forced, to recognize pain as a fifth vital sign with woefully inadequate education, science, and clinical resources. Nonetheless, just as pain as the fifth vital sign was a well-intentioned but poorly executed intervention aimed at reversing decades of ignoring pain, the field of pain medicine continues to progress along a notable course. Prior to the first edition of this textbook, there were no pain specialists, pain journals, pain specialty organizations, pain advocacy groups, pain training programs, or laws or regulations specifically addressing the issues involved in delivering pain relief. At the time that the third and most recent edition of this text was written, the number of published reports in the realm of pain within the medical literature was a fraction of those today and there was no pain consortium at the National Institutes of Health (NIH). Clinical training of pain specialists was in its infancy, with minimal guidance from accrediting bodies. Certification of pain specialists through the American Board of Medical Specialties (ABMS) was available only to anesthesiologists, and the immense problem of pain management in primary care had barely been raised.

Ironically, in part due to increased attention related to the opioid crisis in the United States, recent unprecedented events suggest that we are on a trajectory toward improved knowledge about pain and increased commitment to pain relief, particularly care that is not solely focused on opioids. These events include increasing demands for standards for pain-related assessment and safe treatment in all health care facilities as well as mandates for improving education in pain and its management. There is little doubt that the future for pain management is inextricably linked to both science and education. Core competencies for all health professionals have now been established as a tool for educators to guide curriculum and for accreditors to base evaluation of educational institutions. Today, pain has growing representation in the NIH, and professional societies are working diligently to further increase this new commitment. Subspecialty clinical training has become much more integrative and multidisciplinary as a result of groundbreaking revisions to requirements set by the Accreditation Council of Graduate Medical Education (ACGME). Previously, such requirements were predominantly directed by the discipline of anesthesiology but have now been revised through an
extraordinary collaboration of multiple disciplines. Subspecialty training for a physician from any primary clinical discipline is now possible in accredited programs that lead to certification as a pain specialist by the ABMS. Similarly, the multidisciplinary field of palliative medicine is designated as a subspecialty that is intertwined within many ABMS primary specialties, a most recent example of medicine’s increasing assimilation of symptom management and quality of life interventions. Although pain medicine has also developed as a broad-based, multidisciplinary subspecialty, its place in the overall structure of the field of medicine as a whole is still in evolution. Reform initiatives are well underway to refine the position of this emerging discipline in effort to advance its research, education, and clinical missions. Great debate remains over whether pain medicine should evolve into a more robust subspecialty that integrates parts of many clinical disciplines or whether it should become a primary specialty in its own right, but little progress has been made toward changing the current training paradigm. How pain medicine is ultimately positioned will greatly impact the field of medicine’s ability to meet its fundamental obligations to mitigate suffering.

At the time of publication of the prior edition in 2010, the National Pain Care Policy Act of 2008 and 2009 ultimately became part of the US Affordable Care Act in 2010. Since then, we have witnessed unprecedented legislative and regulatory attention to pain and its treatment. Recent developments suggest that states and the federal government remain uncertain how to balance the needs of patients in pain to have appropriate access to controlled substances with safety concerns for the general public. Potential solutions have gained intense scrutiny by the pain and law enforcement communities, respectively. Over time, national policies by the U.S. Drug Enforcement Administration (DEA), U.S. Food and Drug Administration (FDA), and the overarching Departments of Justice and Health and Human Services will hopefully evolve into rational approaches that balance compassion and safety. Evidence suggests that the public health crises of prescription drug abuse and inadequate pain management are receiving unprecedented attention and action. The U.S. Department of Health and Human Services released a
National Pain Strategy for addressing the clinical, education, and research needs of current and future Americans in pain.\(^2\) Currently, the US epidemic of prescription opioid abuse and excessive opioid prescribing has led to a high pace of new legislative and regulatory attention. It remains unclear if upcoming legislative and regulatory actions will simply restrict opioid prescribing and access or improve the underlying educational deficiencies that drive most excessive prescribing. The Obama administration appeared to address the prescription drug abuse crisis as a public health issue, whereas the Trump White House seems to see the issue as more of a law enforcement problem. It remains to be seen if this raised awareness and action will translate to improved access to safer and more effective care for patients. Leading clinicians and scientists with expertise in pain recently issued a special publication through the National Academy of Medicine calling for clinicians to rationally counter the opioid epidemic.\(^3\)

The clinical practice of pain management, now more commonly termed pain medicine, has changed dramatically since the creation of this textbook in 1953. Under the direction of John Bonica, the establishment of specialized centers that focus on pain management arose from anesthesiology roots. These centers were initially based on an intensive multidisciplinary model of care. Despite several decades of research firmly establishing its effectiveness, such care is expensive and has been largely unsustainable. Centers dedicated to this model have faced drastic reorganization or become extinct.

These same anesthesiology roots of pain medicine also shaped another important aspect of the field. With the influx of anesthesiologists came a rise in the use of specific pain treatments that adopted regional anesthetic or injection based techniques. Although any action taken to manage pain should be considered an “intervention,” this new clinical arena based on more invasive procedures, such as analgesic injections in the spine or placement of implantable devices for pain, has been termed interventional pain medicine. Currently, some experts contend that general pain medicine and interventional pain medicine should be discrete disciplines with practitioners separated based on interventional and noninterventional pain practice. The heightened role of procedure-based pain practices, and some
of the drive to isolate this part of care from the rest of pain medicine, has almost certainly been driven by health care reimbursement systems, such as those in the United States, that reward practitioners with higher payment for procedural care than for almost all other aspects of pain care. Indeed, the reimbursement for pain specialists who perform procedural interventions is often many times that for those who treat the same group of patients and spend the same amount or more time with them but do not provide such interventions regardless of the level of evidence of predictive outcomes that might reasonably justify one type of care over another. With lucrative salaries in the private sector, too few of this new breed of interventional pain physician have stayed in the academic realm and fewer still have gone about conducting meaningful clinical trials to examine the efficacy of their interventions.

Major health reform appeared imminent in the United States back in 2010, and that remains the case in 2018. Pain medicine, particularly interventional pain medicine, stands at a crossroads as many of the treatments that are part of currently accepted pain practice are expensive but have little scientific evidence to support their efficacy. As the forces of health care reform and evidence-based medicine unite to guide clinical practice, many commonly used treatments are facing increased scrutiny by payers. The unbridled growth of interventional pain medicine has already moderated toward a more balanced form, where practitioners provide a broad range of interventional and noninterventional treatment for common pain conditions. Indeed, for economic, medical, social, and ethical reasons, the field has moved toward a more uniform discipline, in which individualized pain care is more similar than dissimilar based on a relatively broad spectrum of mainstream treatment options, with therapeutic choices based on weighing all available evidence and driven by the best interests of each individual patient. Since publication of the fourth edition, new clinical trials have appeared and numerous systematic reviews and clinical practice guidelines have been published highlighting the lack of evidence for sustained benefits from many interventions, such as spinal procedures including epidural steroid injections and radiofrequency ablation. This parallels heightened concerns about the lack of evidence for long-term safety and efficacy of pharmacologic analgesia. Evidence for
opioid use for chronic pain has been shown to be weak or inadequate despite mounting evidence that risks are higher than previously believed, and these risks increase markedly with dose. Taken together, as the field of pain medicine evolves, its evidentiary foundation will be an increasingly important factor in its credibility as a distinct discipline within medicine.

There is widespread agreement that existing systems are inadequate for training clinicians to treat pain. Despite this, today’s clinicians are armed with an unprecedented array of effective tools including pharmacologic, behavioral, and physical therapies; invasive procedures; and cross-cultural complementary and alternative treatments such as acupuncture and meditation. Bringing these and new tools to bear on all cases of pain will be a major challenge, requiring education for nonspecialist clinicians at the professional school and postgraduate levels. Mandating substantive pain education for all clinicians has been a missed opportunity that must be corrected. It is to be seen whether or not the US National Pain Strategy will lead to actions that address its pain management goals for improved clinical care, foundational and far-reaching education, and substantially increased research.

Pain will continue to be a pervasive problem for mankind, science will continue its exponential growth in knowledge of pain and its treatment, and society will increasingly recognize that pain management is integral to the humane and economically viable practice of medicine. The current medical, social, and economic crises in health care, if not medicine’s covenant to mitigate suffering, demand nothing less than systemic solutions to timely, integrated, and cost-effective pain relief. The current controversies and opportunities in association with better understanding and treatment of pain will likely push us toward a tipping point beyond which the very structure of medicine is likely to have to change.

Currently, medicine possesses greater knowledge and more tools to treat pain than ever before. Despite the inadequate treatment of pain, undereducation of clinicians, and underfunding of research, medicine is much further along today than it was even a decade ago—a trajectory that bodes well for the future. The optimal organizational structure of science and medicine for advancing understanding and treatment of pain is yet to be defined. But it will most certainly require transcending current barriers
that serve to fragment care, such as the illogical separation of the mind and body within the whole person or the splintering of core elements of pain management due to obsolete lines that separate one discipline from another. Change will likely be proportionate to the value we place on reducing suffering along with curing disease. Moreover, how general clinicians and pain scientists of the future are supported and trained and how the emerging discipline of pain medicine is positioned for continued development and integration throughout health care will greatly impact medicine’s ability to meet its mission to understand and treat pain. Looking to the future, we appear to be headed for sweeping change in health care that may well lead to new heights in medical research, education, and clinical care for pain that is safer and more effective. This, in the light of the remarkable progress that has already been made, is a signal that medicine is rediscovering its fundamental ethos, most assuredly, to cure when possible but to relieve suffering and provide comfort always.

Cordomyelotomy, 594
Cordotomy, 594, 1700–1701
  anatomy and physiology in, 1700
  for cancer pain, 727–728
  complications of, 728
  indications for, 727, 1700
  open thoracic, 1701
  outcomes of, 728, 1701
  percutaneous, 1657, 1700
    technique of, 727–728, 727f, 1700–1701
Core stability, 1486–1487, 1498t
Core values, of health care, 151–152
Corn
  hard, 1225–1226
  soft, 1226
Cornu ammonis, 70
Coronary artery disease
costochondritis v., 1189
in HIV/AIDS, 987
noncardiac chest pain in, 1034
Cortex (cerebral cortex), 65–70
  Brodmann classification of, 65
  functional areas of, 65
  integrative function of, 114
  multidimensionality of pain and, 65
  in pain–ANS interaction, 114
  schematic anatomic localization of areas, 66f
  sensory areas of, 55, 66–67, 66f, 108
  structures in nociceptive modulation, 55, 55t, 57
Cortical reorganization, 1497
Corticosteroids
  for acute chest syndrome, 965–966
  for acute pain, 831
  as adjuvant analgesics, 685
  for anaphylaxis, 1765
  for ANCA vasculitis, 547
  for ankylosing spondylitis, 1188
  for antiphospholipid syndrome, 548
  for bone pain in cancer, 746
  for bullous pemphigoid, 558
  for calcium pyrophosphate deposition disease, 497
  for cancer pain, 685, 686, 757
  and chemotherapy-related pain, 635
  for cluster headache prevention, 1026, 1027t
  for complex regional pain syndrome, 352
  for costochondritis, 1189
  for Dercum disease (adiposis dolorosa), 554
  for discogenic pain, 1274
  embolism of, 1765
  for epidermolysis bullosa, 558
  epidural injections of (See Epidural steroid injections)
  for epidural spinal cord compression, 1183

5564
for erythema nodosum, 554
for giant cell arteritis, 502, 1031
for gout, 500, 1224
for herpes zoster, 378, 1118
for intercostal neuralgia, 1186
intralesional injections, for bone pain, 747–748
for leukocytoclastic vasculitis, 546
for manubriosternal arthritis, 1190
neural injuries from injection, 1765–1767, 1767f
for osteoarthritis, 490
for pemphigus vulgaris, 557
perineal pain with, 756
for polyarteritis nodosa, 547
for polymyalgia rheumatica, 502
for postherpetic neuralgia prevention, 390
for psoriatic arthritis, 496
for pyoderma gangrenosum, 552
for reactive arthritis, 495–496
for relapsing polychondritis, 558
for rheumatoid arthritis, 493
for sacroiliac joint pain, 1276–1277
for spinal cord injury pain, 588
for sternoclavicular joint arthritis, 1189
for Stevens-Johnson/TEN syndrome, 557
for thoracic facet syndrome, 1188
for xiphoidalgia, 1190
for zygapophysial joint pain, 1274
Corticotropin-releasing hormone (CRH), 419
Cortisol
  in anger (negative emotions), 1394
  in fibromyalgia, 531
  in stress response, 79
Cost
  of intrathecal drug delivery, 713, 713t, 1630
  of opioid analgesics, 218–219
of radiation therapy, 765
Costal cartilage, chest wall pain from disorders of, 1189, 1198t

# Table of Contents

PART ONE: Basic Considerations 195  
CHAPTER 1: Intellectual Milestones in Our Understanding and Treatment of Pain 195  
Pain Understood as Part of a Larger Philosophy or Worldview 196  
Mechanistic Views of Pain 200  
19TH CENTURY—PAIN AS A SPECIFIC SENSE 202  
AFFERENT SIGNALING 207  
GATE CONTROL THEORY 209  
Treatments for Pain 211  
Cognitive Treatment for Pain 212  
Pharmacologic Treatment of Pain 214  
Anatomically Specific Treatments for Pain 215  
The Specialty of Pain Medicine 218  
ACKNOWLEDGMENTS 219  
CHAPTER 2: Pain Terms and Taxonomies of Pain 223  
Definition of Commonly Used Pain Terms 223  
Taxonomies 236  
EXPERT-BASED CLASSIFICATIONS OF PAIN 237  
CLASSIFICATION BASED ON ANATOMY 239  
CLASSIFICATION BASED ON DURATION 239  
CLASSIFICATION BASED ON THE ETIOLOGY OF PAIN 240  
CLASSIFICATION BASED ON BODY SYSTEM 241  
CLASSIFICATION BASED ON SEVERITY 241  
CLASSIFICATION BASED ON FUNCTIONING 242  
CLASSIFICATION BASED ON INTENSITY AND 242
ACTION POTENTIAL GENERATION 280
ACTION POTENTIAL PROPAGATION 283
TRANSMITTER RELEASE 284
Nociceptor Sensitization 286
Clinical Implications of Nociceptor Function 291
CHAPTER 4: Substrates of Spinal Cord Nociceptive Processing
Defining Nociceptive Systems 306
MODELS OF PAIN PROCESSING 306
METHODS OF NEURONAL CHARACTERIZATION 307
DEFINING NOCICEPTIVE SECOND-ORDER NEURONS 308
DEVELOPMENT OF SENSORY SYSTEMS 309
Targets of Primary Afferent Input 310
GROSS ANATOMY OF THE SPINAL CORD 310
SPINAL LAMINAE 312
FUNCTIONAL CHARACTERIZATION OF NOCICEPTIVE NEURONS 316
CLASSIFICATION ACCORDING TO SITE OF PROJECTION 318
Targets of Axonal Projections 318
INTRASPINAL PATHWAYS 318
SPINOPTHALAMIC TRACT 319
Ventrolateral (Anterolateral) Axonal Pathways 319
Neospinothalamic versus Paleospinothalamic 320
Laminar Distribution of Spinothalamic Tract Neurons 320
Functional Characterization of Spinothalamic Tract Neurons 322
Dorsolateral and Ventromedial Axonal Pathways 322
TRACTS 323

CHAPTER 14: Laws and Policies Affecting Pain
Management in the United States
Introduction
PREVALENCE OF UNRELIEVED PAIN IS A
PUBLIC HEALTH PROBLEM
BARRIERS TO THE SAFE AND EFFECTIVE USE
OF OPIOID ANALGESICS FOR PAIN
MANAGEMENT
POLICIES GOVERNING THE USE OF OPIOID
ANALGESICS FOR PAIN MANAGEMENT
International Treaties: Establishing Balance between
Drug Control and Medical Use
US Federal Law: Preserving Balance between Drug
Control and Medical Use
THE FEDERAL FOOD, DRUG, AND COSMETIC
ACT
US FEDERAL CONTROLLED SUBSTANCES LAW
The Controlled Substances Act Ensures Availability of
Controlled Substances for Medical Purposes
Medical Practice

The Controlled Substances Act Distinguishes Treatment of Addiction from Treatment of Pain, but Legal Definitions Create Confusion 722

The Controlled Substances Act and Regulations Do Not Limit Prescription Amount or Duration 724

Regulations Implementing the Controlled Substances Act Now Authorize a Greater Variety of Secure Disposal Opportunities for Controlled Substances 726

US State Laws: Striving for Balance between Drug Control and Medical Use 727

STATE PAIN POLICY DEVELOPMENT: AN EMERGING TREND 728

EVALUATING THE QUALITY OF STATE PAIN POLICY 731

Policy Evaluation Findings 731

A PROGRESS REPORT CARD TO MEASURE CHANGES IN THE QUALITY OF STATE PAIN POLICIES 739

Progress Report Card Findings 739

THE IMPORTANCE OF IMPROVING STATE PAIN POLICY 743

The Need to Implement and Communicate Policy 744

Considering Additional US Policies 745

Taking Diversion into Account 748

Conclusions 751

6005
Rationale 3972
Effectiveness 3973
BEFORE EVIDENCE-BASED MEDICINE 3973
ADVENT OF EVIDENCE-BASED MEDICINE 3975
SINCE EVIDENCE-BASED MEDICINE 3978
Discussion 3980
CHAPTER 75: Failed Back Surgery 3984
Causes of Failed Back Surgery 3985
MISMATCH: SURGERY NEEDED VERSUS SURGERY PERFORMED (“WRONG SURGERY”) 3985
INCOMPLETE EVALUATION AND/OR DIAGNOSIS (“RESIDUAL PATHOLOGY”) 3987
COMPLICATIONS 3988
TECHNICAL FAILURE 3989
RESIDUAL PATHOLOGY 3989
Spinal Pathology 3989
Extraspinal Pathology 3989
RECURRENT PATHOLOGY 3991
NEW PATHOLOGY 3991
Structural Etiologies of Failed Back Surgery 3991
FORAMINAL STENOSIS 3993
PAINFUL DISK (DISCOGENIC PAIN) 3994
DISK HERNIATION 3995
FACET JOINT PAIN 3995
Sacroiliac Joint Pain 3996
SPINAL STENOSIS AND AXIAL LOW BACK PAIN 3996
NEUROPATHIC PAIN 3997
EPIDURAL FIBROSIS 3998
DECONDITIONING 3998
Preoperative Versus Current Pain
Location of Pain (Especially Low Back Pain Versus Leg Pain)
Response to Mechanical Changes
Quality of Pain
TIME COURSE OF APPEARANCE OF PAIN
Preoperative Low Back Pain or Leg Pain Never Improves or Early Onset of Old Symptoms
New Leg Pain Soon after Surgery
Pain Improves but Recurs 1 to 6 Months after Surgery
Pain Improves but Recurs and Is Different
ROLE OF RADIOLOGIC EVALUATION OF FAILED BACK SURGERY
ROLE OF DIAGNOSTIC INJECTIONS
Anesthetic Injections
Provocation Disk Injections (Discography)
Treatments
NONSPECIFIC TREATMENTS
Rehabilitation and Exercise
Medications
SOME OF THE SPECIFIC TREATMENTS FOR SPECIFIC DISORDERS
Discogenic Pain
Facet Joint Pain
Sacroiliac Joint Pain
Spinal Stenosis
Neuropathic Pain
Lysis of Adhesions

Mood and Personality 4038

Functional Capacity and Activity Interference Measures 4039
Pain Beliefs 4040

ELECTRONIC PAIN ASSESSMENT PROGRAMS 4042
CHAPTER 77: Rational Pharmacotherapy for Pain

Drugs Are Both Underused and Overused in Pain Management

Pharmacotherapy Alone Is Rarely Optimal Therapy for Chronic Pain

EVERY USE OF MEDICATION FOR PAIN IS AN EXPERIMENT

PATIENT PREFERENCE: SYMPTOM CONTROL VERSUS SIDE EFFECTS

WHENEVER POSSIBLE TREAT THE CAUSE OF THE PAIN

SYNERGISM AND POTENTIATION

OUTCOMES ANALYSES OF PAIN PHARMACOTHERAPY

APPROVED DRUGS AND DRUGS FOR NONAPPROVED USES

RATIONAL PHARMACOTHERAPY
