Preclinical studies have augmented our understanding of the midline dorsal columns visceral pain pathway. The primary afferents for this dorsal column visceral pain pathway travel to cell bodies situated in the nucleus proprius and in the region of the spinal grey matter dorsal to the central canal of the spinal cord. From here, the axons ascend ipsilaterally along the midline portion of the dorsal columns prior to synapsing in the nucleus gracilis.\(^{100–102}\)

Midline myelotomy seeks to interrupt this dorsal column visceral pain pathway. Candidates for midline myelotomy include patients with intractable visceral pain associated with malignancy in the abdominal or pelvic region.

**SURGICAL TECHNIQUE**

Myelotomy can be performed percutaneously or with a limited open surgical technique.

**PERCUTANEOUS RADIOFREQUENCY LESIONING**

Kanpolat et al.’s\(^ {103}\) first reported the technique for performing percutaneous radiofrequency myelotomy. This procedure can be performed either at the occiput-C1 level or in the thoracic spine. As Kanpolat et al.\(^ {103}\) has reported better experience using a larger diameter electrode for myelotomy, a custom 26-gauge radiofrequency electrode of diameter 0.46 mm (Cosman Medical, Burlington, Massachusetts) is the electrode of choice. This compares with the cordotomy electrode of 0.33 mm in diameter which has also been explored for myelotomy.

A spinal myelogram is performed prior to the procedure to visualize the spinal cord, and the patient is positioned prone with head flexed under monitored anesthesia care.

Intraoperative CT guidance is used to target the space between the occiput and C1 level or the relevant thoracic level. The spinal needle is
advanced toward the midline of the spinal cord from a posterior approach. The radiofrequency electrode is introduced into the spinal cord parenchyma with the goal of advancing the electrode to the AP midpoint of the spinal cord (Fig. 44.19). Impedance measurements are used to confirm the presence of electrode in the spinal cord parenchyma, and sensory stimulation (100 Hz, 100 µs) is performed, which can elicit lower limb paresthesias, usually at voltages less than 0.2 V. Two radiofrequency ablations at 70° C to 80° C for 60 seconds are performed.

FIGURE 44.19 Myelotomy. Axial section of the thoracic spine showing the dorsal columns visceral pain pathway ascending bilaterally at the medial extent of the dorsal columns. A spinal needle is used to create a mechanical lesion during myelotomy.

OPEN LIMITED MYELOTOMY
A technique initially described by Nauta and others can be used to perform an open punctate myelotomy. Under general anesthesia, patients are placed in the prone position and the surgical level is confirmed using fluoroscopy. With the understanding that the goal of surgery is the interruption of an ascending pain pathway, a spinal level is chosen which is rostral to the source of pain. Based on previous reports, the T3 or T4 level is chosen for upper abdominal pain, and the T6 to T8 level is chosen for perineal pain. A single-level thoracic laminectomy is performed at the intended level of lesioning. As the procedure is performed in the thoracic spine which is stabilized by the rib cage, a wide laminectomy is performed.
to allow visualization of the root entry zone bilaterally. Visualization of the root entry zone bilaterally helps to confirm the midpoint of the spinal cord. A midline dural incision is made, and dural retention sutures are placed. Preservation of the midline dorsal vein is attempted in all cases by mobilization of the vein if it obscured the dorsal median sulcus. Once the midline is confirmed, the pia is coagulated with a microbipolar. A 16-gauge angiocatheter is used to create the lesion. The catheter portion of the angiocatheter assembly is cut to allow an exposed tip of 5 mm, the desired lesion depth. Four lesions are made in one location by rotating the angiocatheter 90 degrees between lesions. The goal is to create a lesion that extends 0.5 mm from the midline bilaterally, with a lesion depth of 5 mm. The dura is closed with running sutures without the use of dural sealants, relaying on meticulous fascial closure to prevent CSF leak. The patient is mobilized on the evening of surgery.

OUTCOMES
Clinical studies for patients undergoing limited midline myelotomy have shown satisfactory pain relief in the majority of patients, lasting a few weeks to over 30 months. The long-term durability of pain relief is difficult to assess given the short survival times due to the malignancy. Gildenberg and Hirshberg reported excellent outcomes in 12 patients undergoing open limited myelotomy as compared to 2 patients undergoing percutaneous mechanical myelotomy. Kanpolat et al.’s observed poorer outcomes in patients undergoing radiofrequency lesioning with smaller electrodes (0.25 mm diameter and 1 mm tip). Many reports, however, have not used a standardized outcome scale to evaluate pain relief, and therefore, a detailed comparison between open and percutaneous approaches is difficult to perform.

COMPLICATIONS
Motor complications when using image-guided percutaneous techniques are rare, given the opportunity for intraoperative motor stimulation and the relative distance of the corticospinal tract from the midline of the spinal cord. Using an open surgical technique is similarly safe, provided that care is taken to ensure the lesion is made in the midline.
We have found spinal cord motor and sensory monitoring to be a valuable adjunct to open punctate myelotomy.

As the lesion in myelotomy is between the dorsal columns, transient dysfunction of the dorsal columns can occur. This may manifest as decreased proprioception, sensations of coolness, or tingling. These side effects are generally mild and well tolerated.

**Dorsal Root Entry Zone Lesioning**

Dorsal root entry zone (DREZ) lesioning, an effective intervention for brachial plexus avulsion, has also been applied to the care of patients with cancer pain. DREZ may be considered for conditions such as radiation-induced brachial plexopathy and Pancoast tumors. However, in routine care of cancer patients, DREZ is not commonly used because it is a relatively large intradural operation which involves a multilevel laminectomy. The interested reader is directed to Gadgil and Viswanathan.\(^{111}\)

**IMAGE-GUIDED ABLATION OF PAINFUL BONE METASTASES**

Isolated bone pain secondary to metastatic tumor activity is typically treated with external beam radiation, analgesics (opioids and nonsteroidal anti-inflammatory agents), and systemic therapies including bisphosphonates, radiopharmaceuticals, corticosteroids, and chemotherapy (see Chapters 43, 46, and 48). A recent advance has been the use of radiologically guided needle placement into selected painful metastases to provide thermal destruction using radiofrequency energy,\(^{112}\) laser, and cryoablative\(^{113,114}\) techniques. Another technique is percutaneous alcohol injection using selective arterial embolization\(^{115}\) or direct tumor infiltration.\(^{116}\)

A multicenter study by Goetz et al.\(^{112}\) treated 43 patients who had failed standard therapy for painful osteolytic metastases with image-guided radiofrequency ablation. Ninety-five percent of patients had a clinically significant reduction in pain (VAS decrease of $\geq 2$ on a 10-point scale). Before treatment, the mean worst pain score was 7.9; after treatment, the
average worst pain score was 4.5 (P < .0001) at 4 weeks, 3.0 (P < .0001) at 12 weeks, and 1.2 (P < .0005) at 24 weeks. Pain interference scores and opioid consumption also improved during the 24 weeks of reported follow-up. Complications were seen in three patients: Two were not serious, whereas one involved an acetabular fracture following radiofrequency ablation to this area.

Summary

Interventional therapies have a well-defined and beneficial role in the treatment of appropriately selected patients with various cancer pain syndromes. Optimizing outcomes depends on timely referral with adequate assessment and patient selection; managing expectations of referring physicians, patients, and family members; assuring adequacy of postinterventional care; and an experienced, skilled interventionalist who will assume full responsibility for pre- and postintervention evaluation and follow-up care as indicated by the dictates of each patient’s circumstances.

References

Malignant diseases are generally associated with high morbidity, as both the disease and therapy tend to be invasive and may be life-threatening. Head and neck pain in cancer patients has various etiologies, including the tumor and/or metastases, surgical and cytotoxic therapies, or conditions unrelated to the cancer or its treatment (Table 45.1). Reportedly, pain is present in head and neck cancer (HNC) in 50% or more of patients before diagnosis, 80% during treatment, and 70% posttherapy. In one-third of treated patients, pain continues for longer than 6 months, and its severity is higher than in the pretherapy period.

HSV, herpes simplex virus.
One of the most common cancer-related pain-producing conditions affecting the head and neck region is ulcerative upper aerodigestive tract mucositis. Mucositis can be a dose- and rate-limiting toxicity of cancer therapy. Furthermore, mucositis can lead to new admission to hospital or extend admission to hospital and is the most debilitating patient-reported complication due to pain and effect on oropharyngeal function. This chapter reviews the pathogenesis of mucositis, mechanisms of pain in HNC, and current strategies for preventing and managing these algesic conditions. Pain due to HNC and/or mucositis includes multiple mechanisms that affect soft tissues, vascular, bone, and nervous system structures, including molecular mechanisms associated with reactive oxygen species (ROS), inflammatory mediators, neuropeptide release, and stimulation of sensory receptors. Phenotypic changes may occur, involving all levels of the sensory and autonomic nervous system, and are impacted by individual variables including genetic and psychosocial features. Understanding these mechanisms may lead to additional approaches for prevention and management of pain.

Pain Mechanisms Due to Local and Regional Cancer of the Head and Neck

TUMOR-INDUCED ALGESIA
A tumor may compress and/or invade adjacent tissues, affecting afferent nerves directly or through production of inflammatory cytokines. For example, potential mechanisms of musculoskeletal pain due to malignancy include periosteal pressure, invasion of nerves, vascular damage, microfractures of bone, and muscle spasm. Inflammatory mechanisms can be activated by both tumor cells and cancer therapies and include release of cytokines and other algesic molecules that induce pain in the tumor environment of hypoxia and low pH. Tumors and tumor necrosis release growth factors and cytokines that activate inflammation and nociceptive pathways. In HNC, inflammation is a major cause of pain, initiated by ROS, and release of mediators from tumor cells, leukocytes, platelets, endothelial cells, and immune cells resident in the affected tissue and sensory fiber stimulation (sensory and sympathetic). ROS may cause
endothelial cell damage and increase vascular permeability, whereas nitric oxide (NO) may induce second messenger mechanisms within neurons that may cause neuropathic pain. Oxidative stress activates transcription factors that cause upregulation of proinflammatory cytokines and may trigger apoptosis that release cell contents leading to increased inflammation and sensory stimulation.

Tissue inflammation increases circulating kallikreins leading to production of bradykinin (BK) that produces and amplifies pain induced by serotonin (5-HT). Glutamate is upregulated at sites of inflammation and affects amino-3-hydroxy-5-methyl-4-isoazolepropionic acid (AMPA), N-methyl-D-aspartate (NMDA), stimulating pain receptors. Furthermore, inflammation increases the expression and sensitivity of ion channels (such as sodium channels) on nociceptors, which may be stimulated, increasing pain sensation.

The low pH in solid tumors appears to be due to inflammation, tumor cell metabolism, and apoptosis. The release of cellular contents may cause pain due to activation of sensory neurons through acid-sensing ion channels (ASICs). In addition, cancer-induced activation of osteoclasts results in lower pH and dissolution of bone mineral.

Tumor necrosis factor (TNF) may activate cytokines and growth factors that play a significant role in inflammation and neuropathic pain. TNF is also a key mediator in mucositis. Nerve growth factor (NGF) production is mediated by interleukin (IL)-1β and is upregulated by TNF-α. NGF activates cutaneous mast cells, leading to release of inflammatory mediators that induce pain and may also activate the sympathetic nervous system. Norepinephrine (NE) causes hyperalgesia at sites of tissue injury.

Prostaglandins (PGs) synthesized by cyclooxygenase pathways (COX-1 and COX-2) are induced by inflammatory cytokines and growth factors. Increased levels of PGs are seen in locoregional tumors and in metastases. PGs cause sensitization of afferent nerve fiber including C-fiber and Aδ high-threshold mechanonociceptors and mediate hyperalgesia induced by BK and NE. COX-2 pathways are also upregulated in HNC and in mucositis.

Modulation of sensory transmission involves presynaptic upregulation of the primary signal by excitatory and inhibitory input from adjacent
neurons and from descending pathways. In addition to local modulation, second-order neurons and central pathways are also subject to modulation from higher centers. Modulation may be mediated by interactions with receptors including AMPA, NMDA, and by neurotransmitters including substance P (SP), 5-HT, NE-A, opioid, cholecystokinin (CCK), and γ-aminobutyric acid (GABA). Modulation of pain signaling is impacted by stress, learned behavior, social/cultural background, and acute pain. Perception of pain is impacted by attention, expectation, anxiety, and depression. Mucosal changes, hyposalivation, chronic infection, neurovascular changes, musculoskeletal changes, persisting/recurrent cancer, and secondary complications of cancer or therapy may result in chronic pain.

Neuropathic pain may result from insult to the peripheral nervous system (PNS) and/or the central nervous system (CNS), including alteration in sensory and autonomic function, and may result in peripheral and/or central sensitization. Surgery or cytotoxic and targeted agents may lead to neuropathy due to nerve damage due to surgery or inflammation, resulting in ectopic firing and changes in receptive field leading to neuronal excitability and spontaneous activity or “wind-up.” Neuronal hyperexcitability may be due to overexpression of sodium channels and activation of the NMDA receptor, which develops at voltage-gated sodium channels. Persistent input may also result in increased receptive fields in second-order neurons and centrally.

Interactions between the sympathetic nervous system and nociceptors are thought to be associated with neuropathic pain. Injured C-fiber terminals may atrophy and be replaced by Aβ fibers that may contribute to sensory abnormalities following peripheral nerve injuries. SP in Aβ fibers may be increased and lead to pain.

In addition to neuronal sensitization, TNF-α, IL-6, and IL-11 promote osteoclast formation, which may play a role in malignant bone pain. The effects of IL-1 are probably mediated by induction of NO, BK, and PGs and endothelin-1 (ET-1) that may cause pain in cancer involving bone. Prevention and treatment of pain based on increased understanding of cellular and molecular mechanisms may lead to novel approaches and improved pain prevention and management.
Pain Mechanisms Due to Chemotherapy and/or Radiotherapy

Peripheral neurotoxicity is associated with a number of chemotherapeutic agents, including vinca alkaloids, and platinum agents may lead to damage or loss of large myelinated sensory fibers. NGF and induction of lysosomal storage defects occur in the dorsal root ganglion (DRG) following the use of these agents. The taxanes (paclitaxel, docetaxel) cause microtubular aggregation leading to neuropathy and increase the risk of neurotoxicity when combined with platinum agents. Other agents including noncytostatic drugs used in cancer treatment (e.g., interferon, thalidomide) or in supportive care (e.g., amphotericin-B) may also induce sensory neuropathy. Drug-induced neurotoxicity is typically dose dependent and has an idiosyncratic tendency. Additive effects may occur from combinations of drugs.

Treatment of neuropathy focuses on use of centrally acting medications. Unfortunately, strategies for prevention of neuropathy are not well documented. Amifostine and lipoic acid have been assessed in the prevention of neurotoxicity caused by platinum agents. Melatonin was shown in one clinical trial to reduce chemotherapy-induced neurotoxicity, and the potential role of glutamine has been examined. Continuing study of approaches to prevent and manage cancer therapy-induced neurotoxicity are urgently needed.

Bisphosphonates are key medications used in the treatment of malignant disease involving bone and are commonly used in patients with multiple myeloma and metastatic breast, prostate, lung, and colon cancers. Benefits of bisphosphonate therapy include prevention of skeletal-related events, hypercalcemia of cancer, and reducing bone pain associated with malignancy. One of the acute side effects associated with bisphosphonate administration can be bone pain, including mandible pain that may present with vague symptoms, but can occasionally mimic dental pain. Since late 2002, bisphosphonates have been associated with avascular necrosis involving dentoalveolar bone. In cancer patients on bisphosphonates, the most frequent risk factor for bisphosphonate-associated osteonecrosis (BON) is dental extractions, but other dental procedures appear to be
Prevalence of BON is also associated with type and duration of bisphosphonate treatment. Pain associated with BON, when present, is usually associated with secondary infection of the soft and hard tissues surrounding the areas of exposed bone. Chronic BON can spread to involve nerve bundles (e.g., the inferior alveolar nerve) and produce nerve pain and/or numbness.

**Pain Due to Surgery**

Pain is common at the time of diagnosis for those patients with HNC but is typically of mild severity (Visual Analog Scale [VAS] 3/10). Surgical extirpation may alleviate pain, but more often, following treatment for HNC, pain increases due to the procedure and generally improves with healing of the surgical site. Furthermore, surgery on the neck is associated with fibrosis that may be increased with postoperative radiation therapy, leading to shoulder and arm pain.

Wittekindt et al. showed that subcutaneous botulinum toxin A may reduce chronic neuropathic pain following neck dissection. Botulinum toxin A achieves pain relief by preventing acetylcholine release at the neuromuscular junction. Further investigation of the potential effects on posttreatment fibrosis in the neck is warranted to guide clinical care.

Spread of disease to regional lymph nodes is a prognostic factor in HNC. Treatment for cervical metastasis traditionally includes resection of lymph nodes from levels I through V, the sternocleidomastoid (SCM) muscle, internal jugular vein (IJV), and spinal accessory nerve (SAN), known as radical neck dissection, originally described by Crile in 1906. Recent studies show that neck dissection has a negative impact on quality of life (QOL) and health status. It has been demonstrated that more extensive neck dissections are associated with higher shoulder-related disability. Fortunately, over the latter half of the 20th century, neck dissection has evolved to more conservative surgical approaches that has led to improved QOL; however, shoulder and neck pain after neck dissection continues to be a common cause of postoperative morbidity in HNC patients. It has been postulated that mechanical overload of the shoulder secondary to postsurgical change...
leads to shoulder pain.\textsuperscript{38} However, even with preservation of the SAN, patients may have shoulder pain.\textsuperscript{39,40} Dissection of level V lymph nodes (the posterior triangle of the neck) is associated with neck pain and shoulder pain.\textsuperscript{41}

Attention to the preservation of cervical sensory nerves and effect on QOL has been assessed. Roh et al.,\textsuperscript{41} in a retrospective cohort study of 53 patients treated with selective or modified radical neck dissection, suggest that cervical sensory root branch preservation reduces postoperative sensory deficits.

**Pain Due to Mucositis**

Oral mucositis is a frequent complication of cancer chemotherapy and radiotherapy. A five-stage model for oral mucositis has been proposed where ROS are generated during the initial phase,\textsuperscript{5,42–44} leading to cell damage and upregulation of secondary mediators by activation of nuclear factor-κB (NFκB) in the epithelium and connective tissue. NFκB increases proinflammatory cytokines such as TNF-α, IL-1β, and IL-6, which increases inflammation-causing algesia. NO may also be a key factor causing pain. The ceramide pathway has been implicated in amplification of oral mucositis and may modulate pain. Ulceration of the mucosa exposes nerve fiber endings, thus sensitizing the entire surface. Additionally, these ulcerations can become secondarily colonized/infected and further increase cytokine release and mucosal pain.

In addition to mucosal damage, radiation therapy affects bone by damage to osteocytes, osteoclasts, and osteoblasts. Further radiation irreversibly damages endothelial cells in the vasculature throughout the high-dose radiated volume, which may result in hypocellular, hypovascular, and hypoxic oral soft tissue. These changes increase the risk of soft tissue necrosis and osteonecrosis.

**EPIDEMIOLOGY**

Mucositis is the most common cause of oral pain during intensive treatment of cancer involving chemotherapy, radiation, or chemoradiotherapy\textsuperscript{45–73} (Table 45.2). Oral mucositis affects a majority of
patients on myeloablative conditioning regimens used in hematopoietic cell transplantation (HCT) and is essentially universal in patients treated with tumoricidal radiation therapy in the oropharynx. The increasing use of combined chemotherapy and radiation treatment modalities and generally more aggressive therapy protocols to improve cancer cure rates have increased the frequency, severity, and duration of oral complications.\textsuperscript{45,47,48,50,53,56,58,61,66,73}

TMD, temporomandibular disorder.

Recent advances in cancer therapy have produced a significant increase in the use of targeted therapies. These typically consist of disease- and cell-specific inhibition of enzymes or receptors that interferes with tumor growth or its microenvironment. The potential impact of targeted monoclonal antibodies and other tumor-specific targeting molecules on mucositis has not been fully documented. Prospective studies that assess mucositis as a primary or secondary outcome with targeted agents have not been conducted,\textsuperscript{74,75} although the pattern of oral mucosal involvement and dermatologic involvement appears different than that seen in traditional chemotherapy, suggesting that different mechanisms are involved. Targeted therapy adverse events are generally assumed to be milder than
those of cytotoxic agents. Nevertheless, these adverse events can be severe or even dose limiting. Most of these effects are cutaneous and commonly affect the oral mucosa.\textsuperscript{76} The oral effects generally consist of aphthous-like or, in the case of immune checkpoint inhibitors, lichenoid or bullous lesions and tend to be mild to moderate. However, lesions may become severe, particularly with the recently approved combination of immune checkpoint inhibitors.\textsuperscript{77,78}

Advances in cancer pain management and supportive care now include the use of antimicrobial prophylaxis/therapy and the use of growth factors to speed hematopoietic recovery; these therapies have increased the focus on oral mucositis as a significant and treatment-limiting complication.\textsuperscript{79–81} Oral mucositis is often coincident with therapy-related toxicity at other sites, including veno-occlusive disease in HCT\textsuperscript{73} and gastrointestinal toxicity.\textsuperscript{82} The potential for systemic infection caused by oral opportunistic and acquired flora associated with oral mucositis has been documented in studies of leukemia and HCT patients.\textsuperscript{83–86}

**PATHOGENESIS**

Intensive cytotoxic chemotherapy and radiation therapy directly affect the proliferation of epithelial cells leading to damage of the epithelium and submucosal tissues and potentially to loss of integrity of the mucosal barrier (Fig. 45.1 and Table 45.3). Epidermal growth factor (EGF) secretion may increase the risk of mucositis,\textsuperscript{87} and conversely, cytokines that reduce epithelial cell proliferation during cytotoxic therapy have the potential to decrease the severity of tissue damage. Interaction with cytokines produced in the connective tissue such as granulocyte-macrophage colony-stimulating factor (GM-CSF), TNF, IL-6, IL-11, and others may affect the extent tissue damage.\textsuperscript{79,82,88,89} The oral microflora may play a role in progression of mucosal damage, as suggested in studies of gram-negative bacterial flora in radiation-induced mucositis. The outcomes of microflora-associated mucosal damage are influenced by the potential effect of cancer therapies on the hematopoietic system and damage to local and systemic immune function. Resolution of mucositis may be dependent on production of pluripotential growth factors affecting epithelial and connective tissues.\textsuperscript{56,79–82} During resolution, cytokines
inducing epithelial cell proliferation and migration as well as angiogenesis also play a role.\textsuperscript{56,90–96} Pain associated with mucositis is dependent on the degree of tissue damage, sensitization of nociceptors, and secretion of inflammatory and pain mediators.

2356
In patients with HNC treated with radiation, pain intensity and pain interference scores directly correlate with mucositis severity. Symptoms increase at week 3, often peak at week 5, and persist for 4 to 6 weeks following the end of treatment. Concurrent chemoradiotherapy and intensified radiation protocols increase the severity and duration of oral mucositis.\textsuperscript{97–99} However, marked improvement may take up to 12 months posttreatment, with general functional and physical appearance slowly returning toward baseline level. Follow-up of oropharyngeal cancer patients (up to 1 year) treated with radiation showed that mouth pain is common (58.4%) and interfered with daily activities in approximately one-third of subjects.\textsuperscript{100}

**HEMATOPOIETIC CELL TRANSPLANTATION**

Ulcereative mucositis is the most debilitating patient-reported toxicity of HCT protocols and other treatments for hematologic cancer.\textsuperscript{58,59,64,66} Mucositis is compounded in patients with herpes simplex virus (HSV) reactivation and in those with poor oral hygiene.\textsuperscript{57,64,69,70,101} HSV prophylaxis has altered the frequency and severity of mucosal ulceration in HCT patients; however, even when acyclovir prophylaxis is used, oral ulcerative mucositis occurs in up to 75% of patients.\textsuperscript{59}

Mucositis symptoms can be increased in HCT patients with hyposalivation,\textsuperscript{67} and the related oral microflora and dental plaque changes may influence its severity.\textsuperscript{101–107} Intensive oral hygiene has been documented to reduce the severity and duration of oral mucositis.\textsuperscript{101} Studies have demonstrated that approximately 48% of the bacteremia cases in the early period post-HCT are associated with oral flora. Concerns about the risk of bacteremia secondary to gingival bleeding due to brushing and flossing in the first 3 weeks post-HCT are not supported by evidence. Septicemia was not increased in patients who continued intensive oral care.\textsuperscript{101} Immunoglobulins and other antimicrobial proteins in saliva are decreased after HCT conditioning, which may be an additional factor in the increased risk of mucosal infection.\textsuperscript{82}

Clinically, oral mucositis in autologous HCT patients becomes evident approximately 2 to 5 days after marrow infusion (day +2 to 5) with resolution in more than 90% of patients by day +15.\textsuperscript{59} Allogeneic HCT
patients generally show a slightly slower onset and slower resolution of mucositis. Damage to the mucosa typically presents in a bilateral pattern, primarily involving the nonkeratinized mucosa of the cheeks, lateral and ventral surfaces of the tongue, floor of the mouth, soft palate, and labial mucosa. The mucosal reaction may begin shortly after exposure to the conditioning regimen and progress to erythema and ulceration (Fig. 45.2; also see Fig. 45.1). Increased mucosal toxicity is usually seen in patients additionally conditioned for HCT with total body irradiation.66,68,79

![Image](image_url)  
**FIGURE 45.2** Severe ulcerated mucositis in a patient receiving an unrelated donor bone marrow transplant (day +14) requiring systemic opioid analgesic.

Oral pain (including odynophagia/dysphagia and trismus) closely parallels development and severity of mucositis. Ulcerative lesions usually result in moderate to severe discomfort, leading to difficult or impossible oral nutrition and loss of oral function. Grades 3 and 4 mucositis typically require parenteral feeding and topical and systemic analgesics, usually opiates. Medications for the neuropathic components of pain are typically administered in the setting of mucositis. Symptoms recede as oral lesions heal but may be persistent in cases of mucosal atrophy and neuronal sensitization.

**HEAD AND NECK RADIATION THERAPY**  
Tumor-related pain is commonly present at the time of diagnosis of head and neck/oral cancer (85%), although the intensity is usually not severe.62,108 The presence and severity of pain are related to tumor stage
All treatment methods for HNC can result in pain. Surgical resection of tumor is followed by postoperative algesia, which is related to the extent of tissue removed and whether bone was involved. Chemoradiation therapy affects tissue in the field of radiation producing pain that increases gradually as the treatment advances. \(^{45,62,71,72}\) Radiotherapy-related mucositis is the most frequent complication in patients during radiation for HNCs (see Table 45.1; Figs. 45.3 and 45.4). Mucositis-related pain increases during radiation treatment and typically resolves within 1 to 2 months, or longer with combined radiation and chemotherapy. However, mucosal discomfort often continues for 6 to 12 months or longer, although the severity of pain decreases over time after treatment. \(^{62}\) Chronic complaints include mucosal sensitivity attributed to mucosal atrophy (33%), musculoskeletal syndromes (temporomandibular disorder, fibrosis) (25%), and neurologic syndromes attributed to deafferentation (16%) and neuropathy. \(^{62}\) The most common persisting complaints after radiation treatment include xerostomia (57%), pain involving the muscles of the jaw or joint (27%), and a 10% increased rate of dental caries. \(^{109}\) Chronic complications of radiation therapy were assessed in 676 HNC patients treated in a multicenter study, and 11% were reported to have severe complications (grade 3 or 4) involving the oral mucosa, bone, or muscle. \(^{110}\) These late complications were related to total radiation dose; complications in bone were more common with large radiation fields, and complications in bone and muscle were related to radiation fraction size. The severity of chronic mucosal damage may relate to severity of acute mucosal reaction.
FIGURE 45.3  
A: Initial tissue reaction in a patient receiving radiation therapy (dose received 1,400 cGy of planned 6,000 cGy) resulting in erythema and sensitivity of the right buccal mucosa.  
B: Late tissue reaction in the same patient receiving radiation therapy (total dose received 6,000 cGy) resulting in oral pain and mucosal ulceration within the radiation field.

cancer of the middle portion of the lateral border of the tongue.

**COMBINED RADIATION THERAPY, SURGERY, AND/OR CHEMOTHERAPY**

Treatment of locally advanced head and neck carcinoma is associated with significant complications affecting oral function. Hyperfractionated radiotherapy and chemotherapy may improve survival, but treatment is frequently limited by the severity of oral toxicity.\(^{45,48,50,61,111,112}\) Severe oral mucositis occurs in essentially all patients treated with accelerated fractionated irradiation for supraglottic cancer\(^2\) and in those treated with combined chemo radiation.\(^{111,112}\) Severe mucositis may cause considerable pain, limit or prevent oral intake, and may lead to suspension of cancer therapy.\(^{45,112}\) Intensity-modulated radiation therapy (IMRT) may be associated with less skin and mucosal damage\(^{113}\) but still results in significant ulcerative mucositis and symptoms.\(^{99}\) Helical IMRT is a newer technique for radiation delivery, which unfortunately does not appear to provide a better profile of side effects.\(^{114}\) Mucosal reactions in patients receiving radiation treatment for HNC are currently regarded as unavoidable side effects, but advances in knowledge of pathogenesis and new therapeutic models are expected to change this view, with prophylaxis, intervention, and improved symptom management.

The importance of fungal colonization and infection in radiation mucositis has not been clearly defined.\(^{115-117}\) One study showed fewer cases of candidiasis in patients on prophylactic fluconazole and a 50% reduction in the number of breaks in radiation therapy than those not provided prophylaxis with fluconazole.\(^{115}\) However, others have not found an association between candidiasis or oral colonization and mucositis during cancer therapy.\(^{115,117}\)

Targeted chemotherapy with monoclonal antibodies and small molecules is becoming part of current HNC protocols. The impact on mucositis has not been well defined, as mucositis has only been recorded with multiple toxicities and no studies have assessed mucositis using a validated scale as a primary or secondary endpoint. However, the available data suggest that oral mucositis is not more common than that seen with standard therapy, although it may occur less frequently and be less
Pain Assessment

Most studies use a VAS or various Likert scales to assess oral pain; some use the more extensive McGill Pain Questionnaire. The latter was compared with two different factor models in patients with oral mucositis pain after HCT, and it was recommended that a single pain rating may provide a better practical measurement. Patients may be unable or unwilling to complete lengthy questionnaires, particularly when their overall condition including pain is at its worst. Notwithstanding analgesic use, most of the variance in pain reports is explained by the severity of the mucositis rather than psychosocial variables.

Management of Oral Mucositis

Wide variation exists in quality of mucositis prevention and management studies. Many enroll a small number of patients, using outcome measures that are not validated, and may lack sensitivity. This makes assessment of outcomes difficult, mandating careful review of the methods employed in every study before generalizable conclusions can be drawn. Guidelines for the use of outcome measures and more refined study design and protocols in the management of mucositis are improving the value of more recent studies. Evidence-based guidelines have been developed and will continue to evolve as new approaches to prevention and management are studied.

Development of strategies for the prevention and management of oral mucositis has been enhanced by an improved understanding of the multifactorial nature of the condition (Table 45.4). Radiation shields are recommended during standard radiation therapy. The use of midline mucosa-sparing blocks for protection of the mucosa during radiation therapy, thereby reducing mucositis, resulted in less weight loss, fewer hospitalizations for nutritional support, and a trend toward fewer treatment interruptions (P = .07) than in control patients. The impact of IMRT on oral mucositis pain is not well understood, with reduced area of severe.
tissue damage but broader areas of low-dose radiation exposure.

Palifermin (Kepivance; Biovitrum Inc, Stockholm, Sweden) is the only approved agent for prevention of oral mucositis in HCT.\cite{17,129} Further study of patients with metastatic colon cancer treated with fluorouracil-based chemotherapy showed benefit of palifermin in reducing mucositis,\cite{130} suggesting broader potential application than currently indicated. Benzydamine (not available in the United States) is recommended for use in patients receiving radiotherapy (>220 cGY per day). Oral cryotherapy is recommended for prevention of mucositis in
those receiving bolus 5-fluorouracil (FU) or edatrexate treatments, or high-dose melphalan conditioning regimens for HCT. Low level laser therapy (LLLT), also called low-energy lasers have been studied in the prevention and management of mucositis associated with HCT and head and neck radiation with consistent positive findings across studies. LLLT, also known as photobiomodulation (PBM), affects the cellular redox status by changes in the mitochondrial metabolism and influences cytokine release and vascularization.

Pain Management

With only a small number of approaches documented to prevent the incidence or shorten the duration of oral mucositis, current clinical management depends on palliative approaches. The use of a stepped protocol for pain management is currently the most appropriate approach. The elements of this protocol include the progressive utilization of (1) basic oral care, (2) bland rinses, (3) topical anesthetic and mucosal coating agents, and (4) systemic analgesics.

BASIC ORAL CARE

A growing body of evidence is being accrued that supports the importance of maintaining oral care protocols to remove bacterial dental plaque from teeth and periodontal tissues during intensive cancer therapies. Patients should maintain good oral hygiene by brushing, flossing, and possibly using antimicrobial rinses.

BLAND ORAL RINSES

Although there are no studies demonstrating the effectiveness of normal saline or bicarbonate rinses in decreasing mucositis, they have been shown to reduce mucosal pain. Frequent use of bland rinses can provide relief for mild mucositis, help remove debris, and moisturize mucosal surfaces. However, some rinses may have the opposite effect. In a study of 40 patients undergoing radiotherapy to more than 50% of the oral cavity, half were randomized to an oral care protocol using either saline or hydrogen peroxide rinses, and the latter was associated with increased
mucosal sensitivity.\textsuperscript{139}

**TOPICAL ANESTHETICS AND ANALGESICS**

Topical anesthetics represent the next step in the strategy to manage mucositis pain. Although there are no studies specifically examining efficacy of various topical anesthetics, any agent that can be safely applied to oral mucosa to induce numbness and is tolerated by the patient can be used.\textsuperscript{65} Lidocaine viscous solution is frequently recommended, but other useful agents include benzocaine, dyclonine, and diphenhydramine. Topical anesthetics can cause mild initial irritation, obtund taste, and diminish the gag reflex if gargled or swallowed. Hence, swallowing of these agents to control pharyngeal pain is not generally recommended also due to possible systemic side effects and toxicities. Benzydamine has been shown to reduce mucositis and associated oral pain in radiation-induced mucositis by initially producing an anesthetic effect, which is also longer acting.\textsuperscript{65,72} Local applications of topical anesthetic creams or gels may be especially useful for localized painful mucosal ulcerations.

Topical analgesics have also shown effect in mucositis pain. Initial studies of topical morphine have shown analgesic effects,\textsuperscript{140} and doxepin in single and multidose studies has shown extended duration pain relief without burning sensation when applied to ulcerated tissue.\textsuperscript{141,142}

Coating agents used as oral rinses such as milk of magnesia and loperamide have been recommended frequently but have not been subjected to controlled studies.\textsuperscript{65,126} Sucralfate suspension has been studied in mucositis, but results have been inconsistent and its use for radiation or chemotherapy mucositis is not supported.\textsuperscript{71,143–145}

A number of mucosal coating agents or rinses have been licensed by the U.S. Food and Drug Administration (FDA) for the management of oral mucositis, including Gelclair (EKR Therapeutics, Bedminster, NJ), MuGard (Access Pharmaceuticals Inc, Dallas, TX), and Caphosol (EUSA Pharma Inc, Langhorne, PA). However, there is insufficient evidence to recommend their use for prevention or treatment of mucositis.\textsuperscript{146,147}

**TOPICAL ANTIMICROBIALS**

Early studies suggested that topical antimicrobials may have utility in
preventing oral mucositis, but follow-up research has failed to provide evidence to support their use.\textsuperscript{126} Chlorhexidine has been assessed in HCT patients in a number of studies, but conflicting results with its use in mucositis have been seen and the majority of follow-up studies do not demonstrate a prophylactic effect on mucositis.\textsuperscript{148} It is important to note that the effectiveness of chlorhexidine rinsing on plaque levels, gingival inflammation, and caries risk have not been endpoints in these studies, and the use of chlorhexidine for bacterial plaque control during cancer therapy may still be useful.

Studies of antimicrobial lozenges combining agents such as polymyxin, tobramycin, and amphotericin B in head and neck radiation therapy were shown in a single-center trial to be effective.\textsuperscript{103} However, follow-up studies to duplicate the benefit of using either topical antimicrobials or β-defensin, while reducing oral microbial colonization, did not significantly impact on mucositis.\textsuperscript{149–152}

**SYSTEMIC ANALGESICS**

Symptom management for oral mucositis often requires the use of systemic analgesics. Mucositis is the most common condition requiring the use of systemic opioid analgesics during cancer therapy.\textsuperscript{49} A wide range of agents can be used, including acetaminophen, nonsteroidal anti-inflammatory agents (NSAIDs), and opiates/opioids.

Systemic analgesics should be prescribed following the World Health Organization (WHO) analgesic ladder.\textsuperscript{65} These recommendations include the use of nonopioid analgesics alone, or in combination with opioids and adjunctive medications, based on pain severity and effectiveness of therapy (see Chapter 39). In patients with oral mucositis pain, topical approaches should be used initially and should continue to be used in combination with systemic analgesics in order that the best pain management can be achieved with the least potent and lowest doses of systemic pain medications. Studies have shown that optimum pain control may be achieved by moving directly from WHO ladder level I analgesics to titrated doses of WHO ladder level III analgesics. Improvement in pain control is achieved by combining level III analgesics with adjuvants at lower total doses of analgesics, and therefore, modification of the
analgesic ladder has been discussed. A number of different delivery methods can be used for delivery of systemic analgesics. Oral, transmucosal, transdermal (patches), intravenous, and suppository routes can be used. Patient-controlled analgesia (PCA) is recommended in pain management for hospitalized cancer patients with severe mucositis. A study of preteen children receiving HCT assessed morphine or hydromorphone PCA for mucositis or other painful conditions and found that children successfully mastered PCA to control pain associated with HCT. No instance of drug overdose or difficulty stopping the opioid was noted. As has been previously voiced, addiction is not a significant risk in these patients with severe and debilitating pain as is underuse and underdosing of analgesics.

Persisting high levels of pain are common even with controlled opiate dosing due to mucositis pain, and it has been suggested that the neuropathic component of pain must be addressed to provide improved pain control, with gabapentin showing additional effect.

**ANTI-INFECTIVE APPROACHES**

Infection may result in direct mucosal damage, initiating or complicating mucosal pain. Acyclovir prophylaxis in HSV-seropositive HCT patients is strongly supported in the literature as it prevents both viral reactivation and shedding (seen in 2.9% of patients) in most cases. Oral ulcerations may also be due to reactivation of cytomegalovirus (CMV) in HCT, and shedding of CMV was detected in 13.3% of CMV-seropositive patients. No correlation between severity of mucositis and serologic status of HSV or CMV was seen in patients provided acyclovir prophylaxis. Ganciclovir after stem cell transplantation has been shown effective in suppressing CMV infection, and acyclovir prophylaxis has also been shown to lower shedding of CMV by approximately half in these patients.

Bacterial infections are also common in the setting of immune suppression. Consecutive HCT patients at risk of streptococcal bacteremia were treated for 5 days with clindamycin and ceftazidime for the initial management of fever associated with severe oral mucositis. Bacteremia caused by viridans streptococci occurred in 70% of patients with severe
mucositis, and blood culture results were positive a day prior to fever in approximately one-third of cases, showing that mucosal ulceration predisposes to systemic infection by oral flora. Approaches to reduce mucosal damage will also reduce pain and infection risk and have been suggested as a better means of minimizing systemic infection as compared to antimicrobial approaches.86

In a series of patients with leukemia receiving HCT, fluconazole prophylaxis was compared with no prophylaxis,117 and a trend toward reduction in oropharyngeal colonization by Candida albicans was seen (P = .07). However, the clinical implications are unclear because no relationship was seen between Candida spp., antifungal prophylaxis, and mucositis, suggesting that Candida spp. was not involved in the etiology of mucosal damage in these patients.116 In a randomized controlled trial, fluconazole prevented systemic fungal infections (7% of fluconazole versus 18% of placebo patients)160 and the incidence of mucosal infection and oropharyngeal colonization by C. albicans was reduced.161,162 Therefore, although Candida may complicate oral mucositis and cause mucosal sensitivity and systemic infection, it does not appear to be a risk factor of mucositis.163

**Hyposalivation**

Preventing mucosal toxicity also reduces the pain of oral mucositis. Mucosal toxicity is a dose-limiting toxicity for patients on etoposide and may be related to direct effects of myeloablative doses of etoposide secreted in saliva.63 Twelve patients received propantheline, an anticholinergic agent, or placebo, and mucositis was less frequent and less severe (P = .05) in the propantheline arm. Another study investigated the effect of drug-induced hyposalivation on mucositis during HCT by comparing patients with historic controls.164 Propantheline was found to significantly reduce oral mucositis due to high-dose etoposide, although no effect was seen on esophagitis and enteritis. These findings suggest that for chemotherapeutics that are secreted in saliva, pharmacologically induced hyposalivation may decrease the exposure to the mucosa to the cytotoxic drug and thereby reduce local tissue damage. It is unclear whether this
strategy may apply to other regimens. These studies were small, and results must be interpreted cautiously.

**BIOLOGIC RESPONSE MODIFIERS AND CYTOKINES**

The effects of KGF-1 (palifermin) on mucositis are discussed above. Studies on KGF-20 (velafermin) have been terminated early due to the drug’s association with Parkinson disease.\(^{165}\)

A study on the effect of radiation on EGF in the oral cavity determined that the quantity decreased because of decreased volume of saliva and also decreased in concentration per milliliter of saliva as mucositis increased throughout the course of therapy.\(^87\) These findings suggested that EGF may represent a marker of mucosal damage and has the potential to promote resolution of radiation-induced mucositis. Further studies on this topic are necessary.

Mixed results on prevention of mucositis have been seen with GM-CSF in several human trials.\(^{79,82,89,90}\) Studies assessing granulocyte colony-stimulating factor (G-CSF) have also presented mixed outcomes. These results may be due to mucositis being a secondary endpoint in these studies that evaluated mainly the effects on white blood cells.\(^{56,90,91}\) Overall, these conflicting results do not provide sufficient information to recommend use of white blood cell growth factors for the treatment of mucositis.

**COGNITIVE AND BEHAVIORAL INTERVENTIONS**

Relaxation, imagery, biofeedback, hypnosis, and transcutaneous electrical nerve stimulation have been employed in the management of cancer pain with varying patient acceptance and efficacy.\(^{65,166,167}\) Cognitive-behavioral interventions in pediatric oncology and HCT included providing information before procedures and positive reinforcement after procedures and, less commonly, behavioral interventions such as rhythmic breathing, distraction, and imagery.\(^{168}\) Psychological services were primarily available on an as-needed basis, and support groups were not generally offered. Increasing emphasis on psychological support and techniques for pain management may be useful for patients during HCT.

A controlled clinical trial of psychological interventions in cancer-
related pain was conducted in 94 HCT patients with oral mucositis divided in four groups, and relaxation and imagery training was shown to reduce pain associated with oral mucositis. However, adding cognitive-behavioral skills to relaxation and imagery did not improve pain relief. The reader is referred to other chapters in this text for more detail with regard to psychological approaches to pain and an in-depth review of treatment of bone pain, use of nonopioid and opioid pharmacotherapy for cancer pain, radiopharmaceuticals, and interventional approaches to pain control in cancer.

Conclusion

Pain in the oropharynx of cancer patients has a significant impact upon treatment implementation, prognosis and QOL, and needs to be dealt with aggressively in order to prevent other comorbidities. Cancer and cancer therapy result in release of ROS, growth factors, cytokines, and enzymes that may cause nerve irritation or damage that may result in neurogenic acute and chronic pain. Anxiety and depression compound the pain experience. Mucosal damage, particularly in the presence of immunosuppression and neutropenia, may significantly increase the risk of systemic infection (Fig. 45.5). Oropharyngeal pain in cancer patients frequently requires systemic analgesics, adjunctive medications, and physical and psychological therapy, in addition to oral care and topical treatments (see Table 45.4). Good oral hygiene including tooth brushing and dental flossing reduces the severity of oral mucositis and does not increase the risk of bacteremia.
Clinically apparent mucositis is the result of drug toxicities, tissue damage, and inflammation. The primary event is cell damage from chemotherapy, radiotherapy, or both. Secondary influences include indirect toxicities resulting in immunosuppression, neutropenia, reactivation of latent viruses (herpes viruses), and opportunistic microbial (bacterial and fungal) infections. Salivary gland dysfunction caused by dehydration and direct effects of the cancer therapy on gland function may alter the local mucosal defenses. Because the etiology is multifactorial (see Table 45.3), approaches to prevention and treatment also have been multifactorial (see Table 45.4). Effective prevention and management of mucositis affect the pain experienced during cancer treatment, and when mucositis is present, symptomatic management is needed (Table 45.5).
TABLE 45.5 Symptomatic Management of Pain of Oral Mucositis

| Maintain good oral hygiene.  
| Prevent mucosal damage (see Table 45.4).  
| Coating agents (e.g., milk of magnesia, aluminum hydroxide gel [Amphojel], sucralfate, loperamide [Kaopectate], Gelclair, Caphosol)  
| Topical analgesic/anti-inflammatory (benzydamine)  
| Topical anesthetics/analgesics  
| Systemic analgesics  
| Adjuvant systemic medications  
| Adjuvant cognitive/psychological support  
| Physical therapy (rinsing, ice chips)  
| Miscellaneous agents |

Systemic analgesics remain an important mainstay in pain treatment along with topical analgesics and anesthetics. Pain management including adjunctive analgesics are often underutilized in HNC-related pain syndromes. Novel approaches of potential interest are agents that affect neurotransmitters that modulate pain such as SP and potentially ROS, cytokine production, PGs, and other neurotransmitters.

Biologic response modifiers offer the potential for prevention and to speed healing. Oral care and continuing good oral hygiene are recommended prior to and during cancer therapy. Keratinocyte growth factor (Kepivance) is the only approved and recommended medication for prophylaxis of mucositis in HCT. Benzydamine is recommended in head and neck radiation therapy, but it is not available in the United States. Oral cooling (cryotherapy) with ice chips is recommended for patients receiving bolus infusion, short half-life systemic chemotherapy. Available local agents of uncertain value include a coating agent (Gelclair) and a mineralizing oral solution (Caphosol), with MuGard, the best documented of these devices in mucositis. Meanwhile, a number of agents with different mechanisms of action are undergoing investigation. Of potential value is the use of PBM (LLLT), which has been shown in several studies to mitigate prevalence, severity, and duration of both chemotherapy and radiotherapy-induced mucositis.

Whereas antimicrobial approaches have been shown to not prevent mucositis, there may be a positive effect on dental and gingival health and on mucosal candidiasis. Other approaches that require further study include low-energy lasers and anti-inflammatory medications.

Epidemiology Review

Bone pain due to cancer is caused by primary bone tumors and those malignant diseases that commonly metastasize to the bones. Bone is the third most common site of metastasis after lung and liver. Metastatic bone pain most commonly results from cancers of the breast, prostate, and lung. Other malignancies involving bone are renal cell carcinoma, thyroid cancer, lymphoma, and multiple myeloma. The longer these malignancies persist, the higher the probability of finding bone metastases. Current therapies have increased survival time of patients suffering from many of these malignancies. This has resulted in an increasing prevalence of metastatic bone disease. Li et al. estimated that 279,679 (95% confidence interval: 274,579 to 284,780) US adults alive on December 31, 2008, had evidence of metastatic bone disease in the previous 5 years (Table 46.1). Breast, prostate, and lung cancers accounted for 68% of these cases.

Prostate cancer is very likely to metastasize to bone rather than other organs. Because patients are living longer than other patients with metastatic diseases, prostate cancer patients are at increased risk of having prolonged periods of pain secondary to bony invasion.

| TABLE 46.1 Estimated Number of Prevalent Cases of Metastatic Bone Disease in the National Commercially Insured Population Aged 18–64 Years, The National Fee-for-Service Medicare Population Aged ≥65 Years, and the US Adult Population on December 31, 2008, All Cancers and by Specific Cancer Types |

Vertebral involvement is the most common site of bony metastases. The incidence ranges from 30% to 70%. Most patients with metastatic disease of the vertebrae experience back pain.

Bony metastases compromise both the bone’s integrity and strength. In the vertebrae, this leads to the increased risk of a pathologic fracture, found most commonly in the elderly. Compression fractures affect between 8% and 30% of cancer patients with vertebral body involvement. In many cases, the fracture occurs without an initial traumatic event suggesting that vertebral load is an independent factor in the etiology of a pathologic fracture. Other factors that can lead to pathologic fractures include iatrogenic causes such as steroids, malnutrition-induced osteoporosis, bone mineral loss as a result of inactivity, and destruction of bone secondary to radiation therapy.

Complications from vertebral fracture include a redistribution of load across affected vertebral bodies creating the increased risk of fractures at adjacent levels, increased risk of embolic phenomena as a result of inactivity and pain, kyphosis-induced restriction of vital capacity, predisposition to atelectasis, and early satiety-induced anorexia. Because of this, bony metastases contribute significantly morbidity and decreased life span.
PATHOPHYSIOLOGY

Over the past 10 years, animal models for bone tumor growth, bone remodeling, and bone pain have demonstrated a correlation with many features found in human bony metastatic pain. Mouse studies using murine sarcoma cells injected into the intramedullary space of the femur demonstrate mechanical as well as movement-related pain behaviors. These behaviors\textsuperscript{15} increase with time and with increasing tumor-induced bone destruction offering a model that appears to replicate the human experience of how metastatic bone cancer contributes to bone pain. In normal mice, a nonnoxious stimulus to the femur does not elicit the synthesis of any tissue factors, whereas in mice with bone cancer, a nonnoxious stimulus elicits the synthesis of substance P, which binds to the neurokinin-1 receptor expressed in the spinal cord. Likewise, c-fos is not expressed at the level of the spinal cord in normal mice, but this protein is found in a population of mice with bony tumors.\textsuperscript{16}

Both osteolytic and osteoblastic changes in bone occur in some tumor types such as lung, breast, and renal tumors. A predominance of osteolysis is found in multiple myeloma and sarcomas, leading to increased destruction of bone with time. The predominant lesion in men with bone metastases from prostate cancer is osteoblastic which leads to increased numbers of irregular bone trabeculae weakening bone.\textsuperscript{17}

In the prostate model, colonies of malignant prostate tissue exist along the length of the intramedullary canal divided by newly formed bone.\textsuperscript{18} In the sarcoma model, there is no new bone formation, only destruction, which is greatest at the proximal and distal head with little to no destruction at the midshaft of the bone. The prostate model also demonstrates the formation of new bone along the length of the long bone involving diaphysis and proximal and distal endpoints with an increase of osteoclasts throughout the length of the intramedullary canal. These cells stimulate osteolytic remodeling inducing an inflammatory reaction mediated by macrophages. It is suspected that this macrophage-induced inflammatory activity may be the basis for neuropathic type of pain found in malignancies of the bone.\textsuperscript{19}

Multiple studies have demonstrated that the periosteum is richly innervated by both sympathetic and sensory nerve fibers.\textsuperscript{20,21} The
The periosteum receives the greatest amount of afferent sensory fibers per unit area in bone. In addition, the periosteum, bone marrow, and mineralized bone are also innervated by both sensory and sympathetic fibers.

Osteolytic animal models demonstrate microscopic fragmentation and disruption of the bony matrix secondary to tumor growth. In the osteoblastic model, there is evidence of destructive injury as well as an increase in the density of sensory fibers compared to normal bone. An increase in specific transcription factors has also been demonstrated, including activating transcription factor-3 (ATF-3). Expression of ATF-3 is usually detectable in peripheral nerve injury models. It is also expressed in the nucleus of sensory neurons damaged by osteolytic tumor cells. However, this transcription factor is not detectable in normal sensory neuron nuclei or in sensory neurons affected by peripheral inflammation. Animal models with increased ATF-3 demonstrate an increase in movement-related pain behavior. Gabapentin improved pain-related behavior in this model but did not change tumor growth, bone destruction, or changes in peripheral sensory fibers that were impacted by tumor infiltration. These changes suggest that pain experienced secondary to tumor infiltration is neuropathic.

Osteolytic metastases in breast cancer secrete parathyroid hormone-related peptide (PTHrP) which, in turn, binds to the parathyroid hormone-related peptide receptor (PTHR1) on marrow stromal cells, resulting in the production of receptor activator of nuclear factor-κB ligand (RANKL). RANKL stimulates osteoclast differentiation which then demineralizes bone, leading to increased levels of insulin-like growth factor 1 (IGF-1) and TGF-β from bony matrix, supporting neoplastic proliferation increased PTHrP supporting growth of metastatic disease. This is exploited in the advent of the new antibody to RANKL denosumab that is used to combat bony metastatic proliferation and complications caused by it.

Osteoclastic-induced changes in pH also play a role in bone pain. Tumor cell growth can exceed its vascular supply leading to tumor cell death and further decrease in tissue pH and more pain. Additionally, as tumors grow, associated inflammatory cells which may comprise as much as 80% of the tumor mass reduce local pH. This localized decrease of pH in the bony matrix will lead to an increased absorption of bone as manifested by...
osteoclastic activity. The administration of a transient receptor potential vanilloid (TRPV) antagonist within the mouse model correlates with a decrease in pain behaviors in all stages of tumor growth, suggesting a new potential therapeutic target to reduce cancer-related bone pain. Tumor cells also produce formaldehyde through a demethylation process by serine hydroxymethyltransferase and lysine-specific histone demethylase 1. When the cancer cells migrate into the bone marrow, formaldehyde leads to upregulation of the transient receptor potential vanilloid subfamily member 1 (TRPV1) in the peripheral nerve fibers. IGF-1 produced by osteoblasts also increases TRPV1 receptors that contribute to neuropathic pain associated with cancer spread.

Osteoprotegerin (OPG) is a secreted soluble receptor, which is a tumor necrosis factor receptor (TNFR). This receptor prevents the activation of osteoclasts via a binding–sequestering of the OPG ligand. This has been shown to decrease the amount of pain-related behavior in the mouse sarcoma model. The monoclonal antibody (AMG-162) can inhibit bone destruction by reducing osteoclast function leading to a reduction in inflammatory-mediated changes in the dorsal root ganglion (DRG) which has been correlated with bony metastatic pain.

Inflammatory cells associated with tumor stroma secrete a variety of compounds that sensitize or excite afferent neurons. Compounds include prostaglandins, tumor necrosis factor-α, endothelins, interleukin-1 and interleukin-6, epidermal growth factor, transforming growth factor-β, and platelet-derived growth factor. Receptors for these factors are directly expressed by afferent neurons. All may play a role in bone pain suggesting new targets. In clinical practice, only prostaglandin and agents targeting endothelin have been used to control metastatic bone pain. Prostaglandins play a role in both sensitization and excitation of nociceptors via direct binding to the prostanoid receptor.

Nerve growth factor (NGF) is a neurotrophic factor expressed in tissue following nerve injury by both the nerves injured as well as surrounding tissues. Upregulation of NGF is thought to be a component in the hyperalgesia following nerve injury. Anti-NGF therapy could be effective in the control of pain related to bone cancer. In the osteolytic sarcoma mouse model, anti-NGF antibody demonstrated effectiveness in
attenuation of pain behaviors and was found to be more effective than acute administration of 10 and 30 mg/kg doses of morphine sulfate.\textsuperscript{28}

**EVALUATION OF THE PATIENT WITH BONE CANCER**

The two most important imaging modalities in the evaluation of malignancy of the bone are plain radiography and radioisotope bone scans.

**Radiography**

Radiographic studies should be ordered first in the evaluation of patients with complaints of bone pain in the context of malignancy. Radiographic patterns fall into osteolytic, osteoblastic, or mixed presentation. Osteoblastic lesions appear opaque and sclerotic. Osteolytic lesions appear more radiolucent compared to surrounding bone. Risk of fracture is greatest if more than 50\% of long bone is involved.\textsuperscript{7,29}

**Bone Scan**

Radioisotope bone scans are very good at identification of multifocal lesions.\textsuperscript{30} Radioisotopes accumulate in areas of new bone growth and are diminished in areas of metastasis secondary to decreased blood flow to the area. Cancers such as melanoma and multiple myeloma may have false negatives when reviewed on bone scan secondary due to their lack of reactive bone activity.

**Computed Tomography**

Computed tomography (CT) offers improved spatial resolution in the evaluation of cortical bone destruction.\textsuperscript{31} CT is beneficial in evaluation of the three-dimensional characteristics of diseased bone identified by plain radiographs and isotope scans. CT scan evaluations are optimal to study the pelvic and shoulder girdles and spinal lesions. Additionally, CT-guided needle biopsies can be used to identify cell types.

**18F-FDG-PET-CT**

The visualization of glucose metabolism by positron-emission tomography with 18F-fluorodeoxyglucose, coupled with a simultaneously obtained CT (18F-FDG-PET-CT), is now a standard diagnostic technique in oncology.
In patients with highly metabolically active cancers such as lung cancer or malignant melanoma, PET-CT with FDG has replaced other techniques for the detection of bone metastases. In highly active tumors, bony metastases can be detected with high sensitivity and specificity.\textsuperscript{32}

**Magnetic Resonance Imaging**
Magnetic resonance imaging (MRI) provides better contrast resolution in defining soft tissue and marrow involvement. Also, it can define vascular relationships without contrast enhancement.\textsuperscript{31} MRI is very beneficial in the evaluation of tumor infiltration of muscle and bone marrow, spinal cord compression, and lesions which are otherwise insufficiently imaged by the previously listed approaches.

**TREATMENT**
The site and distribution of bone metastases and the skeletal sequelae, such as pathologic fracture and spinal cord compression, can impact the patient’s prognosis. The focus of treatment should be directed at tumor regression, relief of cancer-related symptoms, and preservation of functional capacity. In some cases, metastatic disease is so advanced that it is resistant to both chemotherapy and radiotherapy. When metastatic involvement cannot be completely treated, the best way forward is to focus on symptom management. Impaired neurologic function, pathologic fractures, and debilitating pain are the most important reasons for aggressive treatment. Palliation may employ radiotherapy, radiopharmaceuticals, chemotherapy, hormone therapy, bisphosphonates, calcitonin, analgesics (opioids and antiinflammatory drugs), adjuvant analgesics (e.g., corticosteroids), and surgery.\textsuperscript{33} Details for these interventions are found elsewhere.

Analgesic medications provide pain relief during therapy with more definitive modalities (e.g., surgical fixation, radiation therapy) as well as when malignant bone pain is resistant to other modalities of treatment. Conventional administration of opioids and nonsteroidal anti-inflammatory drugs (NSAIDs) may not produce adequate analgesia because of the incidental and intermittent nature of pain a patient might experience. These medications also have dose-limiting side effects. NSAID use is often
limited by the risks of gastrointestinal (GI) bleeding and inhibition of platelet function, especially in patients with low platelet counts and taking steroids. In these latter patients, a cyclooxygenase-2 (COX-2) inhibitor may be preferred (see the following section). Patients can have renal and cardiovascular complications with both selective and nonselective NSAIDs. These patients are also prone to having comorbidities that may place them at increased risk of complications, particularly patients undergoing cancer chemotherapy and with advanced disease. Targeted pharmacotherapeutic and interventional approaches can be used to improve these risk–benefit ratios. The remainder of this chapter focuses on those therapies that have been studied specifically for the treatment of cancer-related bone pain to supplement material presented elsewhere in this text.

**CYCLOOXYGENASE-2-SPECIFIC INHIBITORS**

COX-2-specific inhibitors (coxibs) have demonstrated efficacy in the treatment of chronic and acute pain comparable to traditional (nonselective) NSAIDs without the severity of GI complication during short-term use or platelet inhibition effects. The superior safety profile of coxibs in conjunction with similar efficacy of conventional NSAIDs supports their use in analgesic regimens for bone cancer. Many tumors express the COX-2 isoenzyme, which is involved in the synthesis of prostaglandins. In the murine sarcoma model, acute administration of a selective COX-2 inhibitor attenuated both ongoing and movement-evoked bone cancer pain, whereas chronic inhibition of COX-2 significantly reduced ongoing and movement-evoked pain behaviors and reduced tumor burden, osteoclastogenesis, and bone destruction by >50%. COX-2 is expressed in 40% of human invasive breast cancers, and bone is the primary site of metastasis in cases of breast cancer. COX-2 inhibition also inhibited bone metastasis in both a prevention and treatment regimen. This suggests COX-2 produced in breast cancer cells are significant in supporting progression of osteolytic bone metastases in patients with breast cancer, and that COX-2 inhibition may halt this process. Furthermore, COX-2 inhibition may benefit iatrogenically caused tumor progression. COX-2 inhibitors, such as celecoxib, have also been shown
to increase apoptosis and decreased progression of osteosarcoma cell lines.\textsuperscript{39}

Morphine has been shown to stimulate angiogenesis supporting tumor growth in mice. COX-2 inhibition can prevent tumor growth without compromising opioid-dependent analgesia in a murine breast cancer model. Chronic morphine treatment alone stimulated angiogenesis in breast cancer with a corresponding increase in metastasis and reduced survival, whereas coadministration of a coxib prevented these morphine-induced effects and improved analgesia over either agent independently.\textsuperscript{40}

\textbf{CORTICOSTEROIDS}

Corticosteroids are established analgesics in the treatment of pain secondary to metastatic bone pain. This analgesia is thought to occur through the blockade of cytokine synthesis that contributes to both inflammation and nociception.\textsuperscript{41,42} The analgesic benefits of corticosteroids are dose-dependent and limited in their duration of activity. In a small uncontrolled study, approximately 40\% of patients with metastatic prostate cancer were found to have analgesic benefit with the administration of oral corticosteroids. This was speculated to be secondary to suppression of hormone-sensitive disease that was stimulated by weak androgens of adrenal origin by negative feedback on secretion of adrenocorticotropic hormone.\textsuperscript{43} Dexamethasone is the most commonly used agent because it has the least effect on mineralocorticoid activity.

\textbf{BISPHOSPHONATES}

Bisphosphonates are pyrophosphate analogues which bind to hydroxyapatite bone mineral surfaces acting to inhibit osteoclasts and thus bone resorption.\textsuperscript{44} The optimal dose for this class is a function of the disease stage.\textsuperscript{45}

Oral clodronate given to patients with breast cancer metastatic to bone reduced the frequency of skeletal events by more than one-fourth.\textsuperscript{46} In two randomized placebo-controlled trials comparing monthly pamidronate infusions to placebo infusions showed that skeletal morbidity rate could be reduced by 30\% to 40\%.

A large, randomized, multicenter trial using intravenous (IV) zoledronic
acid demonstrated a reduction of 20% in the risk of developing skeletal-related events compared with pamidronate for patients with breast cancer. Moreover, these trials demonstrated for the first time that a bisphosphonate significantly reduces the occurrence of skeletal events in hormone-refractory prostate cancer, non–small-cell lung cancer, and a large range of solid tumors. Evidence from in vitro studies have shown that bisphosphonates are able to directly affect tumor cell growth.

Of the available bisphosphonates, IV zoledronic acid has demonstrated the broadest clinical activity and is approved in many countries for the treatment of bone metastases from all solid tumors. The indications for bisphosphonate therapy in breast cancer patients include correction of hypercalcemia and the prevention of cancer treatment-induced bone loss.

In phase III clinical trials, denosumab, a human antibody to RANKL, is highly effective for preventing complications in patients with bone metastasis from prostate cancer, breast cancer, and other solid tumors. In addition, it decreased treatment-related bone loss in patients treated with androgen deprivation therapy for prostate cancer and women with breast cancer who are treated with aromatase inhibitors. Limited postmarketing analysis has raised concerns regarding denosumab because of the potential for osteonecrosis of the jaw.

Bisphosphonates, although effective in decreasing bony complications due to bone metastases in prostate cancer, breast cancer, and other solid tumors, can cause extensive side effects.

Highly selective matrix metalloproteinase inhibitors inhibit osteoclastic and bone tumor cell lines but not osteoblasts. They are also more effective in promoting tumor apoptosis compared with the standard-of-care bisphosphonate, zoledronate.

Bisphosphonates are now a routine part of therapeutic regimen for metastatic bone pain, and at least 50% of patients report clinically relevant analgesic effect. Placebo-controlled trials with oral or IV bisphosphonates have shown that prolonged administration can reduce the frequency of skeletal-related events by 30% to 40%. The superiority of zoledronic acid compared with pamidronate has been shown by a multiple-event analysis in a large randomized trial. The short infusion time of zoledronic acid also constitutes a convenient therapy. Flu-like symptoms, which are
manageable with standard treatment, do occur. Renal monitoring is recommended, with dose reductions for patients with renal dysfunction. Osteonecrosis of the mandible has been reported in patients receiving bisphosphonates and might be avoidable with appropriate dental care.\textsuperscript{56}

**CALCITONIN**

The hormone calcitonin has the potential to relieve pain and also retain bone density, leading to a decreased risk of fractures. However, there is limited evidence to support the routine use of calcitonin for pain secondary to bony metastases.\textsuperscript{57} Data suggests that calcitonin offers adjuvant analgesia in the treatment of bone pain related to metastatic disease.\textsuperscript{58,59}

A human clinical trial prospectively entered 22 patients to evaluate the efficacy of salmon calcitonin in controlling pain related to bone metastasis.\textsuperscript{60} Other controlled clinical trials of salmon calcitonin in the treatment of cancer-related bone pain have shown equivocal analgesic results without evidence of reducing complications due to bone metastasis or improving quality of life or survival.\textsuperscript{57,61} Like many pain-relieving strategies, there is considerable interpatient variability in responses. In those patients who are not responding well to other first-line approaches, a trial of calcitonin may be reasonable, but close follow-up should ensure that benefits outweigh risks.

**OPIOIDS/OPIATE ANTAGONISTS**

Opioids continue to be an important means of treating metastatic bone pain, but new research offers a challenge as to which treatment plan may be most appropriate. In a murine sarcoma model of bone cancer pain, the effects of sustained morphine found that morphine-enhanced, rather than diminished, spontaneous and evoked pain, and that the effects were dose dependent and naloxone sensitive.\textsuperscript{62} Morphine increased ATF-3 expression only in DRG cells of sarcoma mice. Morphine did not alter tumor growth in vitro or tumor burden in vivo but accelerated sarcoma-induced bone destruction and doubled the incidence of spontaneous fracture in a dose- and naloxone-sensitive manner. Furthermore, morphine increased osteoclast activity and upregulated interleukin-1β within the femurs of sarcoma-treated mice suggesting enhancement of sarcoma-
induced osteolysis.

These results suggest morphine may increase pain, osteolysis, bone loss, and spontaneous fracture as well as markers of neuronal damage and expression of proinflammatory cytokines. The data from this study suggest the need to understand the long-term effects of chronic opioid therapy for cancer pain.

**ADJUVANT ANALGESICS**

The pain of bone cancer can be refractory to traditional treatment modalities. This may be the result of neuropathic changes in involved bone tissues. In animal models of bone-invading malignancies, evidence for peripheral nerve injury provides the pathophysiologic rationale for the use of agents typically used to control neuropathic pain in the control of bone cancer pain.\(^{63}\)

**N-METHYL-D-ASPARTATE ANTAGONISM AND \(\alpha_2\) AGONISTS**

Administration of \(\alpha_2\) agonists (dexmedetomidine and clonidine), N-methyl-D-aspartate (NMDA) antagonists (MK-801 and ketamine), and morphine were examined in a mouse sarcoma bone cancer pain model.\(^{64}\) As expected, morphine produced a significant analgesic effect, and the \(\alpha_2\) agonists produced analgesic effects with an efficacy similar to that of morphine but only at doses that produced severe sedation. MK-801 demonstrated little analgesic effects, whereas ketamine yielded an analgesic effect with the same efficacy as morphine. The authors concluded that \(\alpha_2\) agonists produce an analgesic effect only at a sedative dose. Ketamine, but not MK-801, is associated with an analgesic response without overt side effects, suggesting that non-NMDA effects may be responsible for ketamine’s analgesic efficacy in this model. Applicability of these findings to humans remains untested.

**HORMONAL THERAPY**

Progression of metastasis from breast, prostate, and uterine malignancies is hormone dependent.\(^{65,66}\) Antihormonal treatment reduces an important stimulus for growth and is a common form of adjunctive therapy in breast,
prostate, and endometrial cancers.67 Estrogen and estrogen analogue therapy in patients with breast cancer controls symptoms in 25% to 50% of patients temporarily.68 Antihormonal therapy improved pain in 70% of patients with widespread bone metastases from prostate cancer.69 Therapy with estrogens is efficacious but may take 30 to 60 days before complete palliation. However, serious adverse effects may exceed overall benefits. Although hormone therapy with androgen receptor antagonists (e.g., flutamide) or antigrowth factor agents (e.g., luteinizing hormone-releasing hormone analogs of somatostatin and 5-reductase inhibitor) can be used to induce tumor regression, the palliative effect may not offer long-term benefit as hormone-refractory elements continue to proliferate.70

RADIONUCLEOTIDES
Analgesic effects from radionucleotides are not dependent on tumor destruction per se but are thought to result from inhibition of pain mediators from normal bone cells. Therapeutic responsiveness is greatest in osteoblastic lesions. Multiple different agents have been used for palliative treatment of cancer-related bone pain, including phosphorus-32, strontium-89, yttrium-90, samarium-153, and rhenium-186. Phosphorus-32 has been used for more than 30 years and relieves the pain from osteoblastic metastases in approximately 80% of treated patients.71 Myelosuppression caused by this agent has led to the development of newer agents. Strontium-89 is a bone-seeking radionuclide, whereas samarium-153 is a bone-seeking tetraphosphonate. Both agents have been shown to have efficacy in the treatment of painful osseous metastases from prostate cancer, breast cancer, and, perhaps, from non–small-cell lung cancer. As many as 80% of selected patients72 with painful osseous bony metastases from prostate or breast cancer experience some pain relief following strontium-89 administration.73 Additionally, 10% or more may become pain free, and the average duration of clinical response typically ranges from 3 to 6 months with minimal myelosuppression as compared to phosphorus-32.74

PROCEDURAL INTERVENTIONS
In addition to pharmacotherapy, interventional therapies can be used to relieve the pain associated with bone cancer. Examples include procedures such as intralesional injections, nerve blocks, intraarticular injections, radiofrequency rhizotomy, and vertebroplasty.

**Intralesional Injection**

In a study of patients with rib metastases or involvement of the ribs by multiple myeloma, infiltration of tender areas with methylprednisolone provided significant reduction in pain-related symptoms in over half the cases. Of 20 assessable patients, 11 became pain free within 10 days with recurrence of pain in only 1 of these patients; in 8 others, the pain was considerably improved. The procedure was well tolerated, and there were no complications. This technique has also been used to treat mandibular lesions in which surgical excision of tumor would risk destabilizing the affected bone. This technique may be applicable to other areas of metastasis. Additionally, localized injection of corticosteroid, local anesthetic, and even baclofen have been reported to offer clinically meaningful relief in areas of secondary muscular spasm.

**Percutaneous Vertebroplasty/Kyphoplasty**

Vertebral bony metastases are seen in 30% to 70% of all bony lesions. These metastases compromise the strength of involved bone leading to pathologic vertebral fractures even in the absence of trauma. Additional causes of fractures include osteoporosis, malnutrition, radiation, and steroid administration. Vertebroplasty offers the potential of pain relief. In comparison, patients who have a nonmalignant basis for pathology of the bone such as osteoporosis, reports of analgesic benefit in cancer patients are not as high but are still significant with ranges reported between 50% and 80%. This may be explained by the widespread nature of metastatic disease and the multifactorial origins of pain. The mechanism by which vertebroplasty provides pain relief is not completely understood but could be secondary to fixation of mobile bone fragments and/or thermal neurolysis secondary to the exothermic reaction of methylnmethacrylate cement yielding temperatures in excess of 70° C.
Rhizotomy
Minimally invasive neurodestructive techniques have been demonstrated to be effective in a number of malignancies, specifically of visceral and neuropathic nature. Techniques involve radiofrequency lesioning, cryotherapy, and chemical neurolysis using phenol, alcohol, and hypertonic saline. Because pain from bony metastasis has a neuropathic component, these techniques offer an option in the control of cancer-related bone pain. Other diagnoses where this approached can be applied to include chordoma, osteoid osteoma, and osseous metastasis. Studies of radiofrequency lesioning of bony and soft tissue malignancy have reported significant palliation of pain.81–84

ASSOCIATED PROCESSES
Avascular Necrosis
Avascular necrosis can be found in survivors of cancer who have been exposed to corticosteroid therapy. Pain is the result of weight bearing on the affected joint. In an MRI study of patients having survived childhood cancer, 67% of patients demonstrated osteonecrosis at the ankle.85

Postoperative Frozen Shoulder
In postthoracotomy or postmastectomy patients, pain leads to an increased risk for the development of frozen shoulder. The site may become an independent locus of pain and can be complicated by complex regional pain syndrome. Adequate mobilization of the joint with sufficient analgesia should be implemented soon following surgery to prevent this chronic, painful, and debilitating complication.86

GRANULOCYTE COLONY-STIMULATING FACTOR RELATED PAIN
Granulocyte colony-stimulating factor (G-CSF) is used to stimulate the production of granulocytes in immunocompromised patients following chemotherapy and radiation. Bone and generalized muscle pain is a common complication, which can last for 10 or more days.87 Effective analgesia can require opioids.88 G-CSF also induces an inflammatory reaction through undefined cellular signaling and histamine release.89
Increased histamine levels cause nociceptive C-fiber–mediated pain and edema formation within bone leading to pain. Antihistamines such as terfenadine and astemizole have anti-inflammatory properties in addition to their potency as histamine-1 antagonist and can be used to treat bone pain secondary to G-CSF therapy.

**Conclusion**

The bony skeleton is the most common location for metastatic cancer and leads to a very high incidence of morbidity including severe pain (spontaneous and provoked), hypercalcemia, pathologic fracture, and spinal cord and or nerve root compression. Bone pain is frequently undertreated. Approximately 80% of patients experienced pain before palliative therapy. Progress in understanding the prevention and treatment of cancer-related bone pain is being made. There are many therapies available to treat pain caused by infiltration of cancer into bone.

Major skeletal-related events occur in cancer patients on average every 3 to 6 months. The prognosis of metastatic bone disease is dependent on the primary site. Breast and prostate cancer survival is measured in years; in lung cancer, survival may be measured in months. Severity and duration of tumor involvement in bone cancer are predictors of outcome and can be measured by bone-specific markers. Studies have demonstrated a significant correlation between the rate of bone resorption, clinical outcomes, skeletal morbidity, and overall life expectancy. Improved understanding and treatment will not only improve the quality of life of cancer patients but also improve long-term outcomes.

Epidemiology Review

In 2004, 1.4 million Americans were diagnosed with cancer. This number equals approximately 4,000 new diagnoses per day. In the same year, over 500,000 American deaths were attributed to cancer, accounting for 22% overall mortality.\textsuperscript{1} Currently, more than 10 million individuals in the United States carry the burden of a cancer diagnosis, which is 3% of the population.\textsuperscript{2} Approximately 50% of patients who carry a diagnosis of cancer report pain as a symptom of the disease process. This percentage increases to 75% of patients reporting pain in the advanced stages of disease.\textsuperscript{3,4}

In 2016, it is estimated that there are 1,685,210 new cases of cancer in the United States, and 595,690 people will die from the disease. The number of people living beyond a cancer diagnosis reached nearly 14.5 million in 2014 and is expected to rise to almost 19 million by 2024. Approximately 39.6% of men and women will be diagnosed with cancer at some point during their lifetimes (based on 2010 to 2012 data).\textsuperscript{5} The prevalence of pain in cancer varies widely depending on the stage of cancer, type of cancer, and treatment received. The pooled prevalence is about 50% with the highest prevalence in head and neck cancer patients (70% 95% CI, 55% to 80%).\textsuperscript{6}

With competent management, cancer pain can be eliminated or well controlled in 80% to 90% of cases, but nearly 1 in 2 patients in the developed world receives less than optimal care. Worldwide, nearly 80% of people with cancer receive little or no pain medication.\textsuperscript{7} Trends in death rates for all cancer sites combined from 2000 to 2014 showed a decrease. Death rates decreased statistically, significantly from 2000 to 2014 by
1.8% (95% CI = −1.8% to −1.8%) on average per year among men and by 1.4% (95% CI = −1.4% to −1.3%) per year among women.\textsuperscript{8}

After patients come to terms with the diagnosis of cancer and the implications of their disease, most patients and their families will express concern about the pain and suffering they will experience as their disease progresses. Commonly asked questions include how much pain will there be and can it be controlled?\textsuperscript{9} Unfortunately, despite evidence that cancer pain can be controlled, it is managed poorly in many cases. Multiple factors limit adequate treatment of cancer pain, including misperceptions of disease processes, misconceptions regarding pain medications and procedures, professionals inadequately trained in pain management, failure to consult specialists trained in contemporary pain management methods, and social stigma around opioid use, including fears of addiction by patients, family members, and professional health care providers.\textsuperscript{9} Also, many common cancers in the advanced stages of disease when pain is highly prevalent are incurable, and survival may be measured in months, not years. Whereas health care professionals may only measure survival duration as a meaningful treatment outcome, patients and families may measure outcomes in terms of improvement in quality of life, alleviation of pain, and relief of other associated symptoms related to cancer and treatment.\textsuperscript{10}

Because pain syndromes arise from cancer therapies (including chemotherapy, radiation therapy, or surgery), patients who survive their primary malignancy may be left with pain secondary to an iatrogenic process. Chemotherapy may induce a painful peripheral neuropathy. Neuropathy is well described with vincristine, platinum, taxanes, thalidomide, bortezomib, and other agents. Pain secondary to radiation may appear years to decades after completion of radiotherapy. Pain syndromes following surgery may present after mastectomy, amputation, thoracotomy, or other surgical approaches to malignancies (see Chapters 41, 42, 45, and 48).\textsuperscript{11}

**Characteristics of Visceral Pain**

**ANATOMY AND PHYSIOLOGY**
Visceral pain is caused by disorders of internal organs such as the stomach, kidney, gallbladder, urinary bladder, and intestines as well as changes in the central nervous system. Pain can result from distension, impaction, ischemia, inflammation, or traction on the mesentery and can be associated with symptoms such as nausea, fever, malaise, and pain. Growth of visceral tumors disrupts normal physiologic processes secondary to compression and invasion of adjacent structures. Progression of disease may be asymptomatic until a critical event manifests (e.g., obstruction of a hollow viscus). Under these conditions, the first symptom a patient may experience is pain.

Visceral pain is unique in quality of presentation when compared to pain that arises from musculoskeletal structures of the body. Visceral pain is usually vague in its presentation and may be confused by referral to a variety of somatic locations secondary to viscerosomatic convergence. The phenomenon of viscerosomatic convergence refers to the diffuse nature of visceral pain and its referral to superficial structures due to the convergence of visceral and somatic afferents on the same dorsal horn neurons and secondary hyperalgesia. Symptoms may seem out of proportion to physical examination and imaging. Additionally, visceral pain may be attributable both to the malignancy itself and to chemotherapeutic and radiation therapies. Increased pain following symptomatic relief may suggest the local recurrence of disease or a new locus of disease requiring repeat evaluation of the patient.

Some features of visceral nociception may offer a better understanding of the experience of patients with visceral pain. Visceral pain is more frequently accompanied by an autonomic response than is somatic pain or pain from skin injury, unless the pain is referred visceral pain mimicking somatic pain. There is a poor correlation between the extent of visceral tissue damage and the severity of pain experienced. Visceral pain is poorly localized because of poor representation within the primary somatosensory cortex. The majority of visceral afferents are specific to motor or reflex responses with few neural afferents that are specialized for pain transmission. Those afferents that are specialized for pain are sparsely distributed throughout the viscera; both high-threshold nociceptors and low-threshold “silent” nociceptors are invoked in the pain experience.
Studies have demonstrated multiple visceral pain mechanisms as well as the mechanisms by which one class of visceral pain may relate to other sources of malignant pain. There are four primary classes of visceral pain:

1. Mechanical: caused by stretch of visceral structures (bowel lumen or hepatic capsule)
2. Ischemic: caused by tumor invasion or compression of visceral blood supply
3. Inflammatory: humoral mediators of inflammation released secondary to tumor infiltration of visceral structures
4. Neuropathic: compression or invasion of neural structures supplying the viscera

Surgery, chemotherapy, or radiation therapy of cancer can also be responsible for iatrogenic damage of the viscera, associated visceral structures, or nerves. Applying a stimulus that causes tissue damage (e.g., cutting, burning, or pinching) to skin or muscle reliably produces the perception of pain, but these stimuli do not reliably evoke reports of pain when applied to visceral structures. Pain secondary to distension of a hollow viscous, such as in the case of bowel obstruction, does not necessarily produce a similar perception when applied to surface structures. In controlled studies, visceral pain can be consistently demonstrated by mechanical distension of hollow organs using distending fluids or balloon devices. These modalities of inducing pain most closely reproduce the natural or pathophysiologic processes causing pain. Mechanical distension can be specifically applied to a given organ structure in isolation of other structures, mimicking processes involving the gastrointestinal, biliary, and urinary tracts which may occur from tumor obstruction (or adhesions) in these sites. Distension of organ capsules, such as the splenic, renal, or hepatic capsule, has also been demonstrated to produce profound pain. On the other hand, gentle or slow but progressive distension or obstruction may not produce pain until a critical point in which ischemia or rupture results. Torsion or stretch on mesenteric structures or omentum may produce states of ischemia, infarct, and inflammatory response producing reports of severe pain.

Inflammatory processes in visceral structures may produce pain as a result of ischemic response, but some tumors may produce inflammatory
mediators with no inciting ischemic event. Both prostaglandin E$_2$ and serotonin have been demonstrated as independent chemical stimuli in the production of pain as malignancy invades adjacent structures.\cite{21-23} Experimental studies have demonstrated that the application of inflammatory chemical stimuli can evoke pain behaviors, yet specific mechanical means of eliciting pain have been limited in their translation to studies of other visceral structures.\cite{24}

Ischemic pain has also been described as occurring secondary to occlusion of visceral vasculature or by compression of visceral structures by tumor growth. When tumor growth exceeds vascular supply, necrosis may result, inducing a variety of inflammatory processes.\cite{23} Inflammatory mediators, such as hydrogen ions, kinins, prostanoids, leukotrienes, or other cytokines, are initiators of visceral pain. These chemical agents also sensitize neurologic afferents of organ structures amplifying nociception associated with mechanical stimuli. In general, healthy viscera are typically insensate to pain, whereas superficial structures are continually sensate.\cite{24} When diseased, however, visceral organs produce pain severe enough to be incapacitating to other physical activity. Pain from surface structures of the body evokes reflexive motion in the classic “fight or flight” response, whereas the sensation of visceral pain discourages motion or physical activity. Anecdotal evidence supports an association between pain of visceral origin and emotional response and is commonly held to be more anxiety-provoking than pain from somatic structures. Some argue that this anxiety comes from a patient’s inability to visualize the cause of the pain.\cite{25} Anxiety scales are reported higher in patients with visceral pain ratings of 2 on a scale of 10 when compared to a higher rated pain experience with visible cause on a superficial structure.\cite{26} Furthermore, some symptomatology is more common in patients with visceral pain. Perception of both nausea and dyspnea are more commonly associated with pain of a visceral organ. An autonomic response to visceral pain is far more common than to pain of superficial structures.\cite{27,28}

Psychological processing of visceral pain is distinct from that related to somatic pain. There are a low number of visceral nociceptors compared with somatic nociceptors. There is a lack of specialization of visceral afferents. Many visceral afferents are polymodal nociceptors. Viscera have
unique ascending tracts through the dorsal column and poor representation within the primary somatosensory cortex.\textsuperscript{29,30} Viscera have significant input through the medial thalamus to the limbic cortex, amygdala, anterior cingulate, and insular cortex, which influence the affective aspect of pain perception.\textsuperscript{31} Viscera also have a close association with autonomic nerves. The perception of visceral pain may be disproportionate to pathology exhibited by physical examination or imaging. As an example, a small nephrolith may offer some of the most severe pain states, whereas extensive cancer metastasis may evoke little or no discomfort. Disorders such as chronic pancreatitis demonstrate very little correlation between laboratory studies and flares in pain perception. Disorders such as irritable bowel syndrome and noncardiac chest pain syndrome appear to lack a definitive histopathologic basis for the discomfort and pain.\textsuperscript{32,33}

Many models exist for visceral pain including intraperitoneal injection of a chemical, distension of hollow organs (cecum, colon, rectum), distension of the gallbladder and associated biliary system, and distention or chemical stimulation of the bladder and other urinary tract structures, as well as distension, compression, or traction on reproductive organs. However, lesions studied in one organ are limited in that they are specific to a given stimulus and do not necessarily translate to application in other visceral structures.\textsuperscript{34}

**SENSITIZATION**

Sensitization occurring secondary to the repeated presentation of visceral stimuli has been noted in human psychophysical studies as well as in animal studies. Repeated presentation of the same visceral stimuli produces increasing strength of response in neuronal, cardiovascular, and visceromotor reflex responses. Inflammation of visceral structures increases the magnitude of response to a given mechanical stimulus and decreases the stimulation thresholds for the evocation of nociceptive responses.\textsuperscript{35} Inflammation of visceral structures significantly modifies behavioral, neuronal, autonomic, and motor responses to visceral stimulation in experimental models. This model mirrors clinical circumstances because inflammation in visceral structures frequently leads to reports of pain.\textsuperscript{36}
Painful conditions such as mucositis, esophagitis, gastritis, pancreatitis, and colitis all exhibit mucosal inflammatory changes. The inflammatory sensitization may take place at primary afferents. These afferents are normally nonreactive to most stimuli and have been described as “silent” in nonpathologic states. However, in the context of an inflammatory tissue response, they become spontaneously active and highly reactive to mechanical stimuli. Silent afferents may comprise 50% of the neuronal sample in a visceral organ but are infrequently noted in superficial or cutaneous structures. Lack of baseline sensitivity in normal viscera may be secondary to sparsity of visceral afferentation. There are fewer afferents per unit area than similar measures of cutaneous afferents. Because of this sparse innervation, increased activity may be necessary to cross a threshold for perception. Spinal neurons responsive to visceral stimuli also change their responsiveness to visceral stimuli in the presence of inflammation. The cause of this behavior is unknown, although voltage-gated sensitization by the transient receptor potential vanilloid 1 (TRPV-1) and tetrodotoxin-resistant (TTX-R) receptors may play a role. Increased afferent activity, altered intrinsic properties of dorsal horn neurons, and altered modulatory influences or some combination may all serve a role in the process. Dorsal column pathways have been demonstrated to play a role in visceral nociception but not in cutaneous nociception. The results of multiple studies suggest that visceral pain requires a sensitization process both in the periphery and the spinal cord.

LOCALIZATION
Visceral pain is classically thought of as deep and diffuse in presentation. Localization of the pain generator can be difficult to identify by physical examination. Superficial pain, in contrast, can be elicited by examination with precise localization and with consideration to the site of the body examined; pain locus can be identified within millimeters. Moreover, surface pain loci reliably localize to the same site, never migrating to other body areas, in the absence of neural injury.

Visceral pain is characterized as migratory in its presentation, often perceived in several loci simultaneously or migrating regionally in spite of localization of pathology. This is evident in the presentation of
appendicitis. Furthermore, the perception of pain associated with visceral pathology is not normally localized to the organ itself but to somatic structures that receive afferent inputs at the same spinal segments as the visceral afferent entry. For this reason, visceral pain is classically described as either unlocalized pain or as referred pain that may have two separate features. Sensation of the diseased viscera is transferred to a surface site (e.g., an ischemic myocardium can be felt in neck and arms) or additional sites may become hypersensitive to inputs applied directly to those other sites (e.g., flank muscle becomes sensitive to palpation with urolithiasis). This latter phenomenon is referred to as secondary somatic hyperalgesia.

Psychophysical studies of internal organ sensation have focused on a given organ using simple stimuli, correlating the given stimuli to a given organ with perception at the respective site of stimulus. Other psychophysical studies using visceral stimuli have examined the referred sensations described by subjects. These studies have often failed to contrast referred pain to a body surface with cutaneous sensations at the same surface. Patient illustrations of referred sensations tend to extend over large surface areas, whereas studies using cutaneous stimuli generate pinpoint localization to highly precise sites.

The phenomenon of secondary somatic hyperalgesia produced by visceral pathology has been compared to sites of sensitivity with lesions produced by herpes zoster. These initial studies were fundamental to the development of dermatomal mapping. In visceral disease processes, multiple dermatomes have been identified suggesting that secondary somatic hyperalgesia is widely distributed (i.e., poorly localized).

Recent psychophysical studies have attempted to compare visceral with nonvisceral pain. In one study, the sensation produced with balloon distension of the esophagus was compared to thermal stimulation of the mid-chest skin. Subjects perceived larger areas of sensation for esophageal distension than for intensity-matched, heat-evoked sensation on body maps. Temporally, there was also a difference. A rapid response was noted with heat stimulus, whereas there was poor correlation with the esophageal stimulus and the perception of the sensation. Intense visceral discomfort remained after discontinuation of the distending apparatus but not after
discontinuation of the cutaneous stimulation. Visceral sensation was concluded to be diffuse both spatially and temporally. Corollary observation of cerebral blood flow identified that similar cerebral areas were activated by both stimuli.

When evaluating the patient in visceral pain with malignancy, the early presentation may be misleading with vague midline discomfort. It may be poorly localized and accompanied by both an emotional response and autonomic event. Later in the evolution of disease process, patients may complain of somatic or referred pain hypersensitivity at the spinal level of the visceral nociceptor terminus. Referred pain is sharp and localized. It is often associated with allodynia and muscle spasm. Furthermore, visceral hypersensitivity may induce the perception of pain in another organ receiving innervation from the same spinal segment.

**VISCERAL AFFERENTATION**

Visceral primary afferents differ significantly from cutaneous primary afferents in both number and pattern of distribution. Visceral sensory pathways are organized into nerve fascicles and cell body groupings extending from prevertebral regions to contact viscera predominately via perivascular pathways. Cell bodies of visceral primary afferent nerve fibers are located in the visceral dorsal root ganglia of the thoracic and upper lumbar spine, but the peripheral axons of these neurons follow a circuitous path to visceral organs passing via the paravertebral sympathetic chain and ganglia as well as nerve fascicles that are termed the cardiac and splanchnic nerves. The splanchnic nerves are divided into the greater, lesser, least, thoracic, and lumbar divisions. The pelvic nerves arise from dorsal root ganglia at sacral levels, accepting sympathetic chain input before innervating urogenital structures.

Visceral sensory processing also differs from cutaneous sensory processing because visceral neuronal synapses exist at cell bodies of prevertebral ganglia such as the celiac ganglion, superior mesenteric ganglion, and pelvic ganglion, producing changes in local visceral function outside central control. The gastrointestinal tract is also supplied by an independent enteric nervous system relating to functions of digestion and absorption. In the pelvis, structures receive dual innervation with afferents
from lower thoracic to upper lumbar segments and from sacral segments. Testicle and ovary embryologically originate in the superior aspect of the abdomen and, therefore, receive thoracic innervation. The urinary bladder has a similar thoracolumbar innervation with sensory inputs extending up to the T10 level but also receives sacral inputs (the pelvic nerve) with other tissues originating from sacral dermatomes (rectum, genital structures).

Pelvic organs also receive efferent and afferent connections from the vagus nerve and local ganglionic circuitry, resulting in a complex and diffuse neuroanatomy. Afferents with endings in a focal visceral site may have cell bodies in the dorsal root ganglia of 10 or more spinal levels in a bilaterally distributed fashion. In contrast, cutaneous afferents from a particular body surface arise from only 3 to 5 unilaterally located dorsal root ganglia.

Visceral receptors are located in mucosa, serosa, and muscle of hollow organs as well as visceral mesentery. They are not reported in parenchyma of solid organs. The specialized receptors that discriminate a variety of stimuli in somatic structures are absent in viscera. The mesentery, however, does contain Pacinian corpuscles. Hollow organs contain specialized low-threshold and high-threshold mechanoreceptors. Low-threshold receptors serve a basic regulatory function, whereas high-threshold receptors are activated only with noxious mechanical stimuli. Visceral nociception results from summation of nociceptive input to regulatory low-threshold receptors and noxious high-threshold and silent nociceptors rather than activation of stimulus-specific nociceptors.40

**ASCENDING PATHWAYS**

Visceral afferent fiber activation causes an increase in nitric oxide synthase in the dorsal horn of the spinal cord, causing expression of the oncogene c-Fos in laminae I, V, VII, X of the dorsal horn within the thoracolumbar spine. Similar upregulation is seen in the amygdala and paraventricular hypothalamic nuclei and consequent elevation in norepinephrine production within the locus ceruleus.

Features of visceral pain processing differing from somatic processing include dorsal column ascending secondary sensory afferents, the spinal
trigeminal to parabrachioamygdaloid tract, and the spinothalamic pathway. In the visceral system, both ventrolateral and dorsal column postsynaptic neurons have a role in nociception. Ascending tracts synapse at the lateral thalamus first, then limbic centers, and then somatosensory cortex. Whereas somatic nociception is represented somatotopically within the primary somatosensory cortex, visceral pain is represented in the secondary somatosensory cortex and poorly represented within the primary somatosensory cortex. Visceral pain is well represented in the limbic system, including anterior cingulate gyrus, insular cortex, and amygdala, suggesting a basis for the strong emotional component of visceral pain. Whereas visceral pain elicits decreased patient activity, nausea, and hypotension, somatic pain elicits agitation, reactive activity, and hypertension. Nociceptive activity within the gastrointestinal tract induces inhibition of dorsal motor neurons of the vagus within the medulla leading to gastroparesis and nausea.

Visceral Pain Syndromes

Although most pain associated with malignancy is diffuse and chronic, most acute pain syndromes in cancer are secondary to diagnostic or therapeutic interventions. Some tumors generate an acute onset of pain, which may be the result of a perforation of a hollow viscus or rupture of a visceral capsule. Any sudden onset of pain warrants a comprehensive pain assessment. Following is a list of possible pain syndromes that may be encountered by the health care provider.

ORAL MUCOSA

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a mucocutaneous disorder accompanying non-Hodgkin lymphoma and chronic lymphocytic leukemia. It is characterized by widespread shallow ulcers, hemorrhagic crusting of the lips, conjunctival bullae, and may be accompanied by pulmonary lesions, occurring secondary to autoantibodies directed against desmoplakins and desmogleins.41
Oropharyngeal Mucositis and Stomatitis

Mucositis and stomatitis should be distinguished as two separate processes (also see Chapter 45). Oral mucositis is an inflammation of oral mucosa resulting from chemotherapeutic agents or ionizing radiation, manifesting as erythema or ulcerations. Stomatitis is any inflammatory condition of oral tissue, including mucosa, dentition, periapices, and periodontium, including inflammation secondary to infection of oral tissues. Mucositis appears 7 to 10 days after initiation of high-dose cancer therapy and is generally self-limited when uncomplicated by infection, resolving 2 to 4 weeks after completion of chemotherapy. In order to standardize assessment, a variety of scales have been created to grade the level of stomatitis by characterizing alterations in lips, tongue, mucous membranes, gingiva, teeth, pharynx, quality of saliva, and voice. The clinical syndrome usually involves the oropharynx but may involve other gastrointestinal mucosal surfaces such as the esophagus, stomach, or intestine, producing such symptoms as odynophagia, dyspepsia, or diarrhea. Any mucosal damage may become superinfected with microorganisms, most commonly Candida albicans and herpes simplex.42

Radiotherapy may also induce mucositis. Doses of radiation in excess of 4,000 cGy frequently cause ulceration with pain lasting several weeks following treatment.43 Acute pain associated with radiotherapy can be caused by acute radiation toxicity causing inflammation and ulceration of skin or mucous membranes. The syndrome produced is dependent on the exposed field.44,45

MEDIASTINUM

5-Fluorouracil-Induced Anginal Chest Pain

In patients receiving 5-fluorouracil (5-FU) infusions, ischemic chest pain may develop. Painful events are more common in patients with a history of coronary artery disease and are likely secondary to coronary vasospasm.

Pleura

Lung tumors, with or without chest wall involvement, may produce visceral pain. In a large case series of patients with lung malignancies, pain was found to be unilateral in 80% of patients and bilateral in 20% of
patients. Patients with hilar tumors reported sternal or scapular pain. Patients with tumors involving the upper and lower lobe experienced referral of pain into the shoulder and lower chest, respectively.\(^{46,47}\)

Additionally, some lung malignancies generate ipsilateral facial pain, thought to be secondary to noxious stimulation of vagal afferent neurons.\(^{48–51}\)

### Pancoast Syndrome

Pancoast syndrome is caused by malignant neoplasms of the superior sulcus of the lung with destructive lesions of the thoracic inlet and involvement of the brachial plexus and cervical sympathetic nerves (stellate ganglion).\(^{52,53}\) Patients report severe pain in the shoulder region radiating toward the axilla and scapula along the ulnar aspect of the muscles of the hand, and patients may also develop atrophy of hand and arm muscles, Horner syndrome (ptosis, miosis, hemianhidrosis, enophthalmos), and compression of the blood vessels with edema.\(^{54}\)

Ninety-five percent of patients have either squamous cell or adenocarcinomas. Small cell carcinoma is found in fewer than 5% of cases in most series. Along with these symptoms and signs, additional predictors of poor prognosis are weight loss, supraclavicular fossa or vertebral body involvement, disease stage, and surgical treatment.\(^{55,56}\)

These bronchopulmonary tumors may invade the bony structures of the chest. The first or second thoracic vertebra or the first, second, or third ribs may be invaded. One review has described rib erosion in 50% of patients. The tumor may invade the first or second thoracic vertebral bodies or intervertebral foramina, extending to the spinal cord, and resulting in cord compression. The subclavian vein or artery may also be invaded. Advanced tumors may involve the recurrent laryngeal nerve, phrenic nerve, or superior vena cava (SVC).

### PANCREAS

#### Midline Retroperitoneal Syndrome

The most common cancer-related causes of upper abdominal retroperitoneal pain are pancreatic cancer and retroperitoneal lymphadenopathy, particularly celiac lymphadenopathy. These disease
processes elicit afferent activity via injury to deep somatic structures of the posterior abdominal wall, distortion of pain-sensitive connective tissue, vascular and ductal structures, as well as local inflammation and direct infiltration of the celiac plexus. Patients report pain in the epigastrium, in the low thoracic region of the back, or both. Pain is described as diffuse and dull, exacerbated with recumbency, and improved by sitting forward. Computed tomography (CT), magnetic resonance imaging, or ultrasound scanning of the abdomen may reveal the disease process.

**Pancreatic Cancer**

Patients with pain secondary to unresectable pancreatic cancer report severe abdominal pain radiating into the back. This pain is often refractory to analgesics, even strong opioids. Pain may be accompanied by obstructive jaundice (yellowing of the skin and eyes, itching, dark urine, clay-colored stool) and occurs more frequently when the cancer is located at the head of the pancreas. Other associated symptoms may include weight loss, anorexia, fatigue, and a change in bowel habits (constipation or diarrhea). Controlled trials support the use of neurolytic celiac plexus block with superior results in terms of pain relief over analgesics alone (see Chapter 44 and discussion of celiac plexus block in the following discussion).

**LIVER PAIN**

**Hepatic Distension Syndrome**

The liver has many nociceptive structures including the liver capsule, blood vessels, and biliary tract. Afferents from these structures travel via the celiac plexus, the phrenic nerve, and the lower right intercostal nerves. Hepatic metastasis typically causes pain when the tumor stretches the capsule. Patients with intrahepatic metastases or hepatomegaly secondary to cholestasis may report discomfort in the right subcostal region or right midback or flank. Patients may experience referred pain to the right neck, shoulder, or scapula. Patients describe the pain as a dull ache exacerbated by movement, pressure in the abdomen, and deep inspiration. Associated symptoms include anorexia and nausea. Physical examination reveals a hard, irregular subcostal mass, which is dull to percussion, and
descends with inspiration. Diagnostic ultrasound or CT may reveal a space-occupying lesion.

Analgesics are the first line of therapy for pain control with drug selection and titration a function of the extent of hepatic compromise. Corticosteroids reduce hepatic edema and liver pain. If a tumor is chemosensitive, chemotherapy may be the treatment of choice. Hormone therapy may decrease hepatomegaly from liver metastasis but may take several months to accomplish a goal of pain relief. As with pancreatic cancer, celiac plexus block may provide definitive relief. Two randomized controlled trials (RCTs) have demonstrated hepatic irradiation to be effective in palliation of hepatic pain in 80% of patients with a reduction of systemic symptoms in half as many patients.60

INTESTINAL PAIN

Chronic Intestinal Obstruction
In patients with abdominal or pelvic cancers, intestinal obstruction causes diffuse abdominal pain. Pain may be secondary to smooth muscle contraction, mesenteric tension, and ischemia of the bowel wall. Obstruction may be due to tumor, autonomic neuropathy, ileus, metabolic abnormality, or medication. Pain may be continuous or intermittent (colicky) and may be associated with vomiting, anorexia, and constipation.

Peritoneal Carcinomatosis
The peritoneal cavity, enclosed by visceral and parietal peritoneum, is the largest potential space in the body. Any pathologic process involving the peritoneal cavity can easily disseminate throughout this space by means of unrestricted movement of fluid and cells. Primary malignant diseases arising from the peritoneal cavity include malignant mesothelioma, cystic mesothelioma, and primary peritoneal carcinoma. Carcinomatosis can cause peritoneal inflammation, mesenteric tethering, and malignant adhesions and ascites, all of which can trigger nociceptive activity. Patients most commonly report abdominal pain and distension. Mesenteric tethering and tension appear to cause a diffuse abdominal or low back pain. Tense malignant ascites can produce diffuse abdominal discomfort and a distinct stretching pain in the anterior abdominal wall. Adhesions
can also cause obstruction of a hollow viscus, with intermittent colicky pain. CT scanning may demonstrate evidence of ascites, omental infiltration, and peritoneal nodules.

**Radiation Enteritis**
Acute radiation enteritis may develop in as many as 50% of patients receiving pelvic or abdominal radiotherapy. Patients with small intestinal involvement complain of cramping abdominal pain and have associated nausea and diarrhea. Patients receiving pelvic radiotherapy may develop proctocolitis, associated with pain, tenesmus, diarrhea, mucous discharge, and bleeding. These symptoms may resolve shortly after completion of therapy or may last as long as 6 months.

**Intraperitoneal Chemotherapy Pain**
Approximately 25% of patients receiving intraperitoneal chemotherapy may develop transient mild to moderate abdominal pain and complain of fullness or bloating. A second group of patients (approximately 25%) may experience pain severe enough to require opioid analgesia or discontinuation of therapy. Pain is secondary to chemical serositis or infection. Infectious peritonitis is accompanied by fever and leukocytosis in blood and peritoneal fluid.

**PELVIC PAIN**
Malignancy-related pelvic pain not due to bone metastases is most often secondary to presacral recurrence of rectal carcinoma or secondary to pelvic recurrence of cervical cancer. Lumbosacral plexus infiltration is common, resulting in severe pain with a significant neuropathic contribution. Analgesics or interventional therapies should be implemented according to protocols and guidelines (see Chapter 43).

**Malignant Perineal Pain**
Perineal pain may be secondary to tumors of the colon or rectum, female reproductive tract, and distal genitourinary system. A report of perineal pain following therapeutic resolution of malignancy may be a precursor of recurrence and should prompt complete evaluation. Pain preceding
evidence of disease may be secondary to microscopic perineural invasion of an insidious malignant process. Patients report pain to be constant and aching, exacerbated with sitting or standing. Associated symptoms may include tenesmus or bladder spasm. If tumor invades musculature of the pelvis, patients may complain of a constant aching in the pelvis, which is exacerbated with standing. Examination of the pelvic floor may demonstrate tumor.

**Ureteral Obstruction**
Patients with tumor involving the pelvis may have pain due to tumor compression or infiltration of the distal ureter. Obstruction of the proximal ureter is less common and is associated with retroperitoneal lymphadenopathy, an isolated retroperitoneal metastasis, mural metastases, or intraluminal metastases. Cancers of the cervix, ovary, prostate, and rectum are most commonly associated with this complication. Other rare causes of ureteral obstruction include retroperitoneal fibrosis resulting from radiotherapy or graft-versus-host disease. Pain is described as dull, chronic discomfort in the flank often with associated radiation into the inguinal region or genitalia. However, patients may have obstruction without evidence of pain.

**Ovarian Cancer Pain**
Patients experiencing severe chronic abdominal or pelvic pain may be experiencing the harbinger of ovarian cancer. It is the most common presenting symptom and most common symptom of recurrence. Two-thirds of patients experience pain in the 2 weeks prior to the onset or recurrence of the disease. In patients who have been previously treated, it is an important symptom of potential recurrence.

**Tumor-Related Gynecomastia**
In patients complaining of breast pain or tenderness, there is a risk of occult tumor of the testes or lung. Human chorionic gonadotrophin (HCG)-secreting tumors of testis, including malignant and benign types as well as other HCG-secreting tumors, may produce breast tenderness or gynecomastia. Approximately 10% of patients diagnosed with testicular
cancer complain of gynecomastia or breast tenderness. 

**Intravesical Chemotherapy or Immunotherapy**

Patients receiving intravesical Bacillus Calmette-Guérin (BCG) therapy for urinary bladder transitional cell carcinoma experience a syndrome of bladder irritability. Patients report urinary frequency and painful micturition. In rare cases, patients receiving BCG therapy may develop a painful polyarthritis. Other intravesical chemotherapies, such as doxorubicin, may also cause a painful chemical cystitis.

**Corticosteroid-Induced Perineal Discomfort**

In patients receiving high-dose corticosteroid therapy, some may report an uncomfortable sensation of burning perineal pain.

**ADRENAL PAIN SYNDROME**

Patients with adrenal metastases of considerable size, common in lung cancer, may develop unilateral flank pain or abdominal pain. Patients report pain from this condition as highly variable, describing it as dull and aching to severe in presentation.

**Vascular Obstruction**

Hypercoagulability with thrombosis is the most frequent complication associated with malignancy and the second most frequent cause of mortality in malignant disease. A thrombotic event may occur in advance of the diagnosis of cancer by months or years; therefore, thrombosis should be considered as a marker for occult malignancy. Chemotherapy and hormone therapy are associated with an increased thrombotic risk. Additionally, deep vein thrombosis (DVT) is a more common postoperative complication in patients with malignancies than in other postoperative populations.

Hypercoagulability in malignancy is secondary to tumor cell expression of tissue factor and cancer procoagulant. Apoptosis of malignant cells or penumbra of nonmalignant cells affected by invading malignant tissue activates normally dormant tissue factor, initiating a coagulation cascade and formation of thrombus. Tumor proliferation, chemotherapy, hormonal
therapy, radiation therapy, and hematopoietic growth factors all increase apoptotic activity and increase the risk of thrombus. Factors contributing to the formation of thrombus include cytokine release, acute phase reaction, and neovascularization. Tumors associated with higher risk of hypercoagulability include tumors of the pelvis, pancreas, stomach, breast, and brain.

**Venous Thrombosis**

Patients with DVT most often present with pain and swelling of the lower extremity. Patients often report that pain is mild, dull and crampy, or a diffuse perception of pressure or heaviness. The calf is most often involved, but the sole of the foot, heel, thigh, groin, or pelvis may be the site of thrombus and pain. Exacerbating factors include standing or walking. Physical examination may reveal signs of DVT, including swelling, warmth, dilation of superficial veins, tenderness along venous tracts, and pain with stretching of the affected limb. Rarely, a patient may present with ischemia of the lower extremity or in worse cases, a gangrenous limb. This presentation may occur in the absence of arterial or capillary occlusion (phlegmasia cerulea dolens). Signs include severe pain, extensive edema, and cyanosis of the affected leg. Mortality varies but may be as high as 40% secondary to ischemia of the affected extremity or progression of thrombus to cause pulmonary emboli.

Only 2% of DVT cases involve the upper extremity with a low rate of associated pulmonary embolism. On physical examination, upper extremity DVT most often presents with edema, dilated collateral circulation, and pain. In patients with malignancy, central venous catheterization is the most frequent cause along with extrinsic compression by tumor.

**Superior Vena Cava Obstruction**

For patients with lung cancer and lymphoma, SVC obstruction develops with extrinsic compression of the SVC by tumor expansion or by enlarged mediastinal lymph nodes. Intravascular catheters are an iatrogenic cause, especially with left-sided ports where the catheter tip rests in the upper portion of the vessel. Physical examination reveals facial swelling,
dilated neck veins, and dilated chest wall veins. Less common patient reports of symptoms associated with SVC obstruction include chest pain, headache, and mastalgia.\textsuperscript{74}

**Acute Mesenteric Vein Thrombosis**

Acute thrombosis of the mesenteric veins is most commonly associated with hypercoagulability secondary to malignancy and more rarely secondary to venous compression by lymphadenopathy, extension of venous thrombosis, or iatrogenic hypercoagulable states.

**PAIN SYNDROMES RELATED TO INTRAVENOUS CHEMOTHERAPEUTIC AGENTS**

Chemotherapeutic agents may cause vascular pain secondary to venous spasm, chemical phlebitis, vesicant extravasation, and anthracycline-associated flare. Venospasm pain is not secondary to inflammation or phlebitis. Attenuation of symptoms may come from application of a warm compress or reduction of chemotherapeutic infusion rate.

Agents causing chemical phlebitis include amscarine, dacarbazine, carmustine and vinorelbine, potassium chloride, and hyperosmolar solutions. The pain and erythema associated with chemical phlebitis should be monitored closely because it shares many of the early features of vesicant cytotoxic extravasation that in later stages presents as desquamation and ulceration of cutaneous structures. Venous flare reaction is often associated with the use of anthracycline or doxorubicin and presents with local urticaria, pain, or stinging.

**Hepatic Artery Infusion Pain**

Patients receiving cytotoxic infusions directly into the hepatic artery often report diffuse abdominal pain.\textsuperscript{73} Pain is attributed to gastric ulceration, gastric erosion, or cholangitis. With no persistence of complications, resolution of pain occurs with completion of therapy.

**COMPLEX VISCERAL PAIN SYNDROMES**

Nontraumatic rupture of a visceral tumor may cause sudden, severe abdominal or pelvic pain and is most commonly associated with
hepatocellular carcinoma. Metastases from other tumors also cause visceral ruptures (e.g., kidney rupture from a metastasis from adenocarcinoma of the colon or metastasis-induced perforated appendicitis). Torsion of pedunculated visceral tumors may cause cramping abdominal pain.

**POSTRADIATION VISCERAL PAIN**

Postradiation therapy pain syndromes often involve both somatic and visceral structures, regardless of the target organ. Late effects, including connective tissue fibrosis, neural damage, and secondary malignancies, can occur long after completion of radiotherapy. A recent large retrospective cohort study revealed an association between previous pelvic radiation and hip fractures, with an increase in lifetime fracture rate from 17% (control) to 27% (radiation group). Pelvic pain after radiotherapy may be due to pelvic insufficiency fracture, enteritis, visceral dysfunction, or neural damage. Chronic pelvic pain has been reported as a consequence of prostate brachytherapy. Twenty percent of patients receiving brachytherapy have been reported to complain of dysuria 1 year after treatment.

**Radiation Enteritis and Proctitis**

In 2% to 10% of patients receiving pelvic or abdominal radiation therapy, chronic enteritis and proctocolitis may occur. The rectum and distal colon are more frequently sites of involvement. Onset may be as early as 3 months or as late as 30 years. Presentations may include proctitis (bloody diarrhea, tenesmus, and cramping pain), obstruction due to stricture formation, or fistulae to the bladder or vagina. Small bowel radiation damage typically causes colicky abdominal pain, which can be associated with chronic nausea or malabsorption. Barium studies may demonstrate a narrow tubular bowel segment resembling Crohn’s disease or ischemic colitis. Endoscopy and biopsy may be needed to identify recurrent cancer.

**Burning Perineum Syndrome**

Perineal discomfort may develop 6 to 18 months following pelvic
radiotherapy. Patients complain of burning pain in the perianal region and may involve the vagina or scrotum. For those patients with postabdominoperineal resection, phantom anus pain and recurrent tumor should be considered.

**Radiation Cystitis**
Radiation therapy used in the treatment of tumors of the pelvic organs (prostate, bladder, colon/rectum, uterus, ovary, and vagina/vulva) may produce chronic radiation cystitis.\(^\text{10}\) Symptoms of radiation injury to the bladder may be as minor as temporary irritation with voiding or asymptomatic hematuria, or as severe as gross hematuria, a contracted nonfunctional bladder, persistent incontinence, and fistula formation. Other signs and symptoms may include frequency, urgency, dysuria, hematuria, incontinence, hydronephrosis, pneumaturia, and fecaluria.\(^\text{10}\)

**POSTCHEMOTHERAPY VISCERAL PAIN**
Painful peripheral neuropathy is frequently a dose-limiting side effect of some chemotherapeutic regimens. Once the therapy is stopped, the neuropathic pain will resolve with or without symptomatic treatment. However, in a small number of patients, the neuropathy does not resolve and may continue to be intensely painful. Prevalence during treatment varies from agent to agent, with the intensity of treatment (dose intensity and cumulative dose), with other concurrent therapies such as surgery and radiotherapy, and with the use of combination chemotherapy. Estimates of prevalence range from 4% to 76% during chemotherapy treatment.

**Treatment**
In general, treatment for cancer-related visceral pain syndromes should adhere to standard cancer pain treatment guidelines (e.g., World Health Organization (WHO) Analgesic Ladder; American Pain Society Guidelines). The reader is referred to *Chapters 43, 44, and 48* for details of various pharmacotherapeutic, radiotherapeutic, and interventional treatment modalities. Therapies that target visceral pain mechanisms with some specificity that are not covered in detail in other chapters are
elaborated in the following discussion.

**N-METHYL-D-ASPARTATE RECEPTOR ANTAGONISTS**

Ketamine, which blocks N-methyl-D-aspartate (NMDA) receptors, can influence visceral hypersensitivity. Primary visceral hypersensitivity is attributed to a reduction in peripheral nociceptive thresholds. Two central processes mediate secondary visceral hypersensitivity: (1) plasticity of activated C fibers and (2) convergence of afferents at multiple levels and maintained by glutamate release that binds to NMDA receptors. NMDA receptor activation results in nitric oxide synthase expression, nitric oxide production, and prostaglandin production.

Through these mechanisms (and perhaps others), ketamine has been found to be useful in the management of pain states that are either poorly responsive to opioids and other analgesics or when there are dose-limiting adverse effects to other pain treatments. Ketamine use has been described, with variable success, in adults, pediatric patients, via intrathecal, parenteral, and oral routes, and in inpatient as well as outpatient settings.\(^{81–90}\)

**CORTICOSTEROIDS**

Dexamethasone inhibits neuronal nitric oxide synthase gene expression. It has been effective in treating visceral pain and bowel obstruction.\(^{91}\)

**GABAPENTIN**

Gabapentin has been demonstrated to reduce glutamate levels and reduces hypersensitivity associated with celiac pain.\(^{92}\)

**SHORT INTERFERING RNA THERAPEUTICS**

The discovery that short double-stranded RNA molecules can be used to induce RNA interference (RNAi) in mammalian systems has opened up several possible new avenues in treatment of pain. Gene silencing by small interfering RNAs (siRNAs) has been demonstrated in neurons, and several targets involved in pain perception have been identified can be modulated by these siRNAs. In the past decade, hundreds of molecular targets have
been identified for their roles in pain modulation, but most molecular
targets are not readily amenable to drugs with small molecules. In the past
years, RNAi has become the most widely used technology to suppress
gene expression. Effective delivery of nucleic acid-based therapeutic
molecules to the central nervous system remains a limiting step for RNAi,
and currently, transfection agents are being used via the intrathecal route to
deliver siRNA into spinal cord cells as well as dorsal root ganglion cells
and hence act on many possible targets for gene expression and
modulation including nerves and spinal cord regions affected by cancer
pain.\textsuperscript{93–95}

**T-TYPE CALCIUM CHANNEL ANTAGONISTS**

T-type calcium channels are expressed in many diverse tissues, including
neuronal, cardiovascular, and endocrine. T-type calcium channels are
known to play roles in the development, maintenance, and repair of these
tissues but have also been implicated in disease when not properly
regulated. T-type calcium channels found on peripheral and central
endings of primary afferent neurons are involved in nociception. Voltage-
gated calcium channels can be divided into two groups: high-voltage
activated calcium channels (L, N, P/Q, and R types) and low-voltage
activated calcium channels (T types).\textsuperscript{96} Li et al.\textsuperscript{97} showed that paclitaxel-
induced neuropathy causes hyperexcitability in dorsal root ganglion
neurons that is paralleled by increased expression of low voltage–activated
calcium channels or namely the T-type channels. Hence, there was great
excitement that antagonism of these channels could be of great promise in
the treatment of neuropathic pain. Additionally, Le Blanc et al.\textsuperscript{98} proved
that these T-type calcium channel blocker (CCB) antagonists restore
synchrony in thalamic burst firing and possibly alter the affective pathway
of pain.

Preclinical studies with ABT-639, a peripherally acting highly selective
T-type Ca\textsubscript{v}3.2 CCB, showed dose-dependent reduction of pain in multiple
pain models including arthritic, neuropathic, cancer- and capsaicin-
induced pain. However, the initial study results are still to be validated
through repeat studies. Wallace et al.\textsuperscript{99} compared the pharmacodynamic
effects of a single 100-mg dose of ABT-639, a peripherally active,
selective T-type Ca\(_{\text{v}3.2}\) channel blocker, with pregabalin. They used an intradermal capsaicin model to assess drug efficacy and demonstrated that a single 100-mg dose of ABT-639 had no effect on experimental pain induced by intradermal capsaicin injection. Hence, the jury remains out on T-type calcium channel antagonists.

**AMPA/KAINATE ANTAGONISTS**

Glutamate activates three subtypes of ligand-gated ion channel: the NMDA, (S)-2-amino-3-(3-hydroxy-5-methyl-4-isoxazolyl) propionic acid (AMPA), and kainate receptors. Animal studies suggest that AMPA and kainate receptors are involved in epilepsy, pain, and psychiatric disorders. Kainic acid activates nociceptors, and consequently, kainate receptor antagonists have a potential as analgesics. Receptors for AMPA (GluR1-4) are found throughout all superficial laminae of the dorsal horn pre- and postsynaptically. AMPA agonists augment responses of spinal neurons to noxious and nonnoxious stimuli. Kainate receptors (Glu 5-7; KA2) are expressed diffusely in the dorsal horn, mostly in lamina.\(^{100,101}\)

Gormsen et al.\(^{102}\) investigated the efficacy of NS1209, a test AMPA receptor antagonist and lidocaine in nerve injury pain. In a three-way RCT involving 13 patients comparing lidocaine, NS1209, and placebo, the authors found that like lidocaine, NS1209 was superior to placebo in alleviating some key symptoms of neuropathic pain (i.e., evoked types of pain, including mechanical and cold allodynia but not superior in alleviating spontaneous current pain). Possibly, more work is needed to delineate the disease mechanisms influenced by AMPA/kainate receptors before antagonists can be developed for the treatment of pain.

**P38 KINASE INHIBITORS**

p38 mitogen-activated protein kinases (MAPK) are serine/threonine protein kinases involved in the regulation and synthesis of inflammatory mediators and show great potential for the development of cytokine-targeted anti-inflammatory drugs. p38 inhibitors have been shown in preclinical models to decrease neuropathic pain, particularly where there is a substantial inflammatory component.\(^{103}\)

In a randomized control trial involving 43 patients with carpal tunnel
syndrome, radiculopathy or other causes of nerve trauma, Anand et al.\textsuperscript{104} demonstrated lower pain scores with acceptable side effects for the new drug dilmapimod. However, other clinical trials of these medications have found prolongation of QT intervals by these agents and have largely been unsuccessful. Further studies require results to be ratified for use in cancer neurogenic pain.

**CHEMOKINE RECEPTOR TYPE 2 ANTAGONISTS**

Chemokine receptor type 2 (CCR2) is a chemokine receptor that mediates monocyte chemotaxis and hence is thought to play a crucial role in inflammatory and neuropathic pain states. Abbadie et al.\textsuperscript{105} proved that mice with chronic pain showed activated CCR2-positive microglia in the spinal cord. They suggested that the recruitment and activation of macrophages and microglia peripherally and in neural tissue may contribute to both inflammatory and neuropathic pain states. Accordingly, blockade of the CCR2 receptor may provide a novel therapeutic modality for the treatment of chronic pain.

However, many trials including a recent one by AstraZeneca have failed. Newer emerging evidence suggests that alternate applications for CCR2 antagonists are possible. It has been shown that spinal CCR2 is upregulated in several neuropathic pain models and expressed by neuronal and glial cells in the spinal cord. Hu et al.\textsuperscript{106} investigated the expression changes and cellular localization of spinal CCR2 in a rat model of bone cancer induced by Walker 256 cell inoculation. The results indicated that mechanical allodynia progressively increased in bone cancer pain rats with increased CCR2 expressed by both microglia and neurons in the spinal cord. These results suggest that CCR2 may be involved in the development of cancer pain, and that targeting CCR2 may be a new strategy for the treatment of cancer pain.

**P2X PURINOCEPTOR 3 ANTAGONISTS**

P2X purinoceptor 3 (P2X3) receptor subunits are expressed prominently and relatively selectively in so-called C- and Aδ-fiber primary afferent neurons in most tissues and organ systems, including skin, joints, and hollow organs, suggesting a high degree of specificity to the pain sensing
system in the human body. P2X3 antagonists block the activation of these fibers by adenosine triphosphate (ATP) and reduce ATP sensitization of peripheral pain neurons. In addition, P2X3 is expressed presynaptically at the central terminals of C-fiber afferent neurons, where upregulation and sensitization of pain signals by ATP occurs. This is also potentially blocked by P2X3 receptor antagonists. Another exciting prospect offered by these agents is the potential of decreased side effects due to the selective expression of P2X3, with a lesser risk of affecting the gastrointestinal and renal systems that remain limiting factors for many other existing medications. Gilchrist et al. also suggested in their murine model study that there is increased expression of P2X3 receptors in tumor growth in rats with hence increased potential for ATP activation and bone cancer pain. This study opens avenues for possible use of P2X3 antagonists in bone cancer pain.

Newer research has suggested that a potentially significant pathway for the transmission of cancer visceral pain would be the highly specific postsynaptic dorsal column, which have been shown to express neurokinin receptors (neurokinin-1 [NK-1]) in the event of visceral stimulation that help propagate cancer visceral pain. Surgical lesioning of the dorsal column is potentially difficult, and hence, pharmacologic lesion of the pathway may be an alternate choice. Evidence has shown that spinal dorsal column neurons start to express NK-1 receptors after visceral stimulation, suggesting new targets for the development of pharmacologic strategies for the control of visceral pain. Wang et al. suggested that targeted cytoxin composed of substance P coupled to the cytotoxic ribosome inactivating protein, saporin, might selectively destroy spinal postsynaptic dorsal column neurons expressing NK-1 receptors, to help improve intractable visceral pain of cancer origin.

Gillespie et al. also demonstrated that there is increased NK-1 receptor signaling in colitis associated with cancer further suggesting that there is potential in antagonizing this transmission in the treatment of visceral cancer pain. However, this therapeutics is still in its infancy, and many more studies are needed for further ratification before this group of drugs can be of clinical significance.
NEWER OPIOID DERIVATIVES FOR THE TREATMENT OF CHRONIC PAIN

Opioid agonists act on the \( \mu \), \( \kappa \), and \( \delta \) receptors. Of the \( \mu \), \( \delta \), and \( \kappa \) subtypes of opioid receptors, most analgesia is thought to derive from \( \mu \) activation.

Cebranopadol

Cebranopadol is a new opioid agonist that is under development by the Grünenthal company in collaboration with Depomed of United States. It is a full agonist at the nociceptin/orphanin pathway (NOP) and at \( \mu \) and \( \delta \) receptors, whereas being a partial agonist at the \( \kappa \) receptor. Conventional opioids are currently the mainstay of visceral cancer pain treatment. However, their efficacy is limited by potential side effects due to effects on the gastrointestinal, respiratory, and central nervous systems as well as the potential of addiction and tolerance.\textsuperscript{111,112}

In animal studies, drugs acting at the nociceptin/orphanin receptors do not generate typical opioid-like side effects and may even ameliorate supraspinal opioid-related side effects when administered concurrently with an opioid. Hence, an agonist at the NOP and the opioid receptors would be particularly useful in the treatment of visceral pain with a more favorable side effect profile.\textsuperscript{113}

In a bone cancer pain murine model, Linz et al.\textsuperscript{114} demonstrated that cebranopadol caused dose-dependent increased pain withdrawal thresholds that reached statistical significance after 30- and 60-minute intervals.

However, there is evidence to suggest that cebranopadol is more effective in neuropathic rather than nociceptive bone cancer pain. Animal studies indicate that cebranopadol is more effective in experimental models of chronic neuropathic pain (e.g., streptozotocin-induced diabetic polyneuropathy and spinal nerve ligation models) compared to acute nociceptive pain (bone cancer pain and tail-flick test).\textsuperscript{115} In the rat, there are strong indications that cebranopadol shows limited depression of breathing also which has been shown to be significant in comparison to conventional opioids.\textsuperscript{116} Moreover, tolerance and addiction are less likely with cebranopadol than with conventional opioids due to slower metabolism and pharmacokinetic profile.\textsuperscript{117}
In the rat, tolerance to morphine develops quickly, and in a study by Lambert et al., rats were completely tolerant to morphine (8.8 mg/kg intraperitoneal [IP] daily) in 11 days. In contrast, an equianalgesic dose of cebranopadol (only 0.8 µg/kg IP daily) was still effective for a further 15 days, or 26 days in total. Hence, cebranopadol presents great potential in the treatment of cancer pain with a better side effect, tolerance, and dependence profile.

PROCEDURAL INTERVENTIONS

Ganglion Impar Block
The ganglion impar is a solitary retroperitoneal structure located at the level of the sacrococcygeal junction. This unpaired ganglion marks the end of two sympathetic chains. The ganglion receives sympathetic and parasympathetic fibers at the lumbar and sacral levels, providing sympathetic innervation to portions of the pelvic viscera and genitalia. Visceral pain in the perineal area associated with malignancies may be effectively treated with neurolysis of the ganglion impar (also known as Walther ganglion). Patients who will benefit from this block frequently present with a vague poorly localized pain that is frequently accompanied by sensations of burning and urgency. The ganglion impar block is useful to the management of sympathetically mediated pain in the perineum, rectum, and genitalia. It has been primarily used for malignancy; however, it has been used for treatment of associated syndromes such as radiation enteritis, proctalgia fugax, and reflex sympathetic dystrophy.

The ganglion impar is close in proximity to the rectum. There is increased risk of contamination through the needle track as the needle is removed. Infection and fistula are possible complications in patients who are already immunocompromised or have received radiation to the perineum.

Thoracic Sympathetic Ganglion Block
Preganglionic fibers of the thoracic sympathetics exit with respective thoracic paravertebral nerves from the intervertebral foramen. After exiting the intervertebral foramen, thoracic paravertebral nerves branch looping dorsal through the same foramen to provide innervation to the
spinal ligaments, meninges, and respective vertebra. The paravertebral nerve at this level also affects the thoracic sympathetic chain through myelinated preganglionic fibers of the white rami communicantes. Preganglionic and postganglionic fibers synapse at the level of thoracic sympathetic ganglia. Postganglionic fibers provide sympathetic innervation to the vasculature, sweat glands, and pilomotor muscles of the skin as well as the cardiac plexus and terminate in distal ganglia as they course up and down the thoracic sympathetic trunk.121

Block of the thoracic sympathetic ganglion is useful for evaluation of sympathetically mediated pain to the thoracic and upper abdominal viscera, the thorax, and the chest wall. Differential blockade may serve as a prognostic indicator of the benefit to be expected from lesioning of the thoracic sympathetic ganglion. The block has been used in the past to treat intractable abdominal pain as well as intractable cardiac pain. It has also been demonstrated to be effective in the treatment of acute herpes zoster, postherpetic neuralgia, and phantom breast pain following mastectomy. Thoracic sympathetic chain destruction may be used to relieve pain in pain syndromes that have been improved by local anesthetic block.122

Because of the close proximity to the pleural space of the exiting nerve roots at the thoracic level from sympathetic ganglion, pneumothorax is a possible complication. The pleural space lies lateral and anterior to the thoracic sympathetic chain. The lower cervical ganglion fuses with the first thoracic ganglion to make the stellate ganglion. Caudad in the thoracic chain, thoracic ganglia move further anterior resting along the posterolateral surface of the vertebral body. Other possible complications include accidental injection of the epidural, subdural, and subarachnoid space. Infection is of greater concern in patients with malignancy because of their immunocompromised state.

**Interpleural Catheters**

The role of interpleural analgesia (IPA) in both acute and chronic pain management is still undergoing clinical scrutiny. Original work with this technique showed that IPA could provide analgesia in patients with subcostal incisions and fractured ribs.

The technique for insertion of an interpleural catheter is relatively easy,
and an epidural tray can be utilized. Local anesthetics (0.5% bupivacaine or 2% lidocaine) have been traditionally utilized via intermittent bolus or a continuous infusion. Interpleural phenol has been described as an alternative for the treatment of visceral pain associated with esophageal cancer. This may be an effective technique to treat visceral pain associated with cancer of the esophagus, liver, biliary tree, stomach, and pancreas.

For analgesia associated with cancer, continuous infusions of bupivacaine or intermittent bolus doses of bupivacaine may also provide adequate analgesia. Higher concentrations of bupivacaine increase the risk of toxicity.

Complications are secondary to needle or catheter injury or are secondary to the neurolytic agent injected in the interpleural space. Pneumothorax may occur in 2% of patients, and lung injury has been reported when a rigid catheter is used. Phrenic nerve palsy may occur following this block resulting in respiratory failure. Thus, bilateral blocks should be avoided. Doses of phenol should be limited; systemic effects from drug absorption may occur because the pleural membranes are highly vascularized.

**Surgery**

Referral for surgical options should be pursued with diagnosis and treatment of pain in malignancy at any time during the course of care. Surgical objectives in the palliation of cancer include staging of disease, control of disease, control of pain and associated symptoms, reconstruction, and rehabilitation. Patients interested in and capable of tolerating surgical options should be referred to a surgeon for consideration of options, even if there are nonsurgical options available. If no intervention is recommended, the patient will have an understanding for the surgical referral and have a sense of closure with regard to the variety of options available for palliation. Surgical consult is particularly valuable in the areas of wound management, complicated issues with regard to nutrition, and discussion of progression of disease.

There is no standard set of procedures for the palliation of malignant visceral pain. The operations available are a reflection of the subjective pain experience of the patient, the specific stage of the disease, and the
anatomic effects of the disease. Often, other distressing symptoms may be the reason for surgical management as well as the complaints of pain. The given surgical option should palliate as many symptoms as possible without altering benefit–risk ratios. The most important preoperative measure involves reassurance to the patient that preparation is complete and that postoperative analgesia has been considered. This is best achieved with close coordination with the partnering anesthesia team and preoperative consultation regarding analgesic options. Furthermore, the operative encounter may be the foundation for continued postoperative pain management options.

Malignancy presenting with pain is likely to be advanced in nature. Resection of an organ or portion of an organ for management of pain is reasonable even in the case of uncontrollable disease, especially if the disease is resectable or partially resectable. There is little data, however, comparing the efficacy of resection with nonoperative approaches.

In visceral disease, surgical resection has proven effective for the relief of dysphagia, odynophagia, and chest pain in patients with esophageal carcinoma; the relief of painful ulceration in those with gastric carcinoma; and the preemptive control of jaundice, pain, and duodenal obstruction in those with pancreatic carcinoma.

Surgery can promote comfort as well as eliminate pain. Mechanical bowel obstruction may be expected in as many as 15% of cancer patients. Pain is a reflection of the severity of the distension, the nature of the primary neoplasm, and the level of obstruction. Resection has also been offered on occasion for relief of pain associated with carcinoma of the kidney. In some situations, nephrectomy may be considered to prevent pain, hematuria, and constitutional effects of the disease. In patients with large bladder masses, total or partial organ resection may be a consideration in cases where more conservative options have been considered. Stent placement may relieve severe pain secondary to malignant ureteral obstruction by tumors of the prostate, cervix, bladder, and colon. If stent placement is not an option, percutaneous nephrostomy may be effective.

Debulking of functional tumors of the liver may be beneficial in patients with carcinoid to decrease such symptoms as flushing and diarrhea.
Debulking has also been used in patients with metastatic gastrinoma, ovarian cancer, and large and small bowel malignancies. Finally, drainage of ascites, which may develop in as many as half of cancer patients, may relieve associated symptoms such as bloating, diffuse abdominal pain, dyspnea, nausea, early satiety, and gastric reflux.

Dorsal Myelotomy for Treatment of Intractable Visceral Cancer Pain

Neurosurgical interruption of midline visceral pain pathway can help control severe visceral pain without causing significant adverse neurologic sequelae in patients with advanced visceral cancer. However, surgery is not without side effects, and often, this approach is used when conventional pharmacologic treatment has failed. Hwang et al. demonstrated a technique of punctate midline myelotomy (PMM) for the treatment of cancer pain refractory to opioids. In their study, a PMM at the T3 level was performed in six patients who experienced severe visceral pain caused by hepatobiliary or pancreatic cancer. In a small study involving six patients, follow-up periods ranged from 2 to 18 weeks after operation. All six patients had immediate pain relief after operation. Although the pain recurred from 2 to 12 weeks later in three patients, the severity of recurrent cancer pain was markedly decreased.

Kim et al. also attempted a high thoracic myelotomy in their palliation attempt in the treatment of severe pain due to stomach cancer. Under general anesthesia, patients received high thoracic midline dorsal column myelotomies after T1 or T2 laminectomy. In their study, they demonstrated clinically significant decrease in pain scores after the procedure, although one patient developed paresthesia and posterior column signs below the level of myelotomy without analgesia and another paresthesia responsive to corticosteroids. They concluded that dorsal column myelotomy at a high thoracic cord level effectively controls severe abdominal pain and should be considered as a new palliative operation for patients with severe visceral pain.

Hypophysectomy and Cancer Pain

Destruction of the pituitary stalk has been a long established palliative
approach to the treatment of severe refractory cancer pain especially due to widespread metastases and also in bone cancer pain in breast cancer. Surgical, stereotactic instillation of alcohol in to the sella turcica and other methods of chemical hypophysectomy have been long established in cancer pain treatment. A proposed mechanism is that or its associated neurophysins act as central pain transmitters. The production of these transmitters is decreased or abolished by chemical or surgical hypophysectomy through the destruction of hypothalamic nuclei.126–128

Conclusion

Failure to assess and treat cancer pain, whether of somatic, visceral, neuropathic, or mixed types, is still a common problem among patients in all stages of malignant disease. Barriers to adequate care have been discussed in previous chapters. Notwithstanding needed improvements in clinician education, access to pain and supportive care specialists, among other needed systems improvements, and similar to other causes of cancer pain, relief of pain in patients with visceral malignancies or treatment-related visceral pain syndromes should be organized as part of a comprehensive interdisciplinary approach to care. Visceral pain cannot be exclusively managed with pharmacotherapy, and the resources of several medical and supportive care disciplines should be considered with each patient so that pain management can be tailored to the individual requirements of each patient according to his or her unique constellation of clinical and social circumstances.

CHAPTER 48
Radiotherapy and Chemotherapy in Cancer Pain Management
NORA JANJAN

Introduction

“Cancer pain is best controlled by removing the cancer or causing it to regress.”¹ This succinct principle stated by palliative medicine specialist Dr. Neil MacDonald is a useful framework from which to consider the role of palliative chemotherapy and radiotherapy in the management of symptomatic disease. In the year 2016, 1,685,210 new cancer cases were diagnosed, and about 595,690 cancer-related deaths occurred. National expenditures for cancer care in the United States totaled nearly $125 billion in 2010 and are projected to reach $156 billion in 2020.²

There has been substantial progress in cancer incidence and mortality. The incidence of cancer from 2009 to 2013 was stable in women but decreased by 2.3% per year in men. An overall 13% decrease in cancer deaths occurred between the years 2004 and 2013.²³ Death rates decreased for 11 of the 16 most common cancer types in men and for 13 of the 18 most common cancer types in women; this decline in cancer death rates included lung, colorectal, female breast, and prostate cancer. The 5-year survival rate for breast cancer increased from 18.7% between 1975 and 1977 to 33.6% between 2006 and 2012. The improvements in 5-year survival rates also included meaningful increases in survival with distant-stage disease.³ Deaths due to breast cancer declined almost 40% between 1989 and 2015, averting 322,600 deaths.⁴⁵ This trend can be attributed to the persistent efforts in research, early detection of disease, and treatment advances. Cancer and its treatment, however, still result in a significant burden of symptoms like pain.

Cancer has a negative impact on almost all cancer patients’ domains of
daily living. Quality-of-life measurements have been shown to predict survival and add to the prognostic information derived from the Karnofsky performance status (KPS) and extent of disease. Physical symptoms including pain, dry mouth, constipation, change in taste, lack of appetite and energy, feeling bloated, nausea, vomiting, weight loss, and feeling drowsy or dizzy often portend a poorer prognosis. Palliative care is an integral component of cancer treatment with a goal to effectively and efficiently relieve symptoms and maintain the maximum functional and emotional well-being for the duration of the patient’s life.

Recognizing the value of the early integration of palliative care, an American Society of Clinical Oncology clinical practice guideline states that the standard for oncology care includes the control of the symptoms of cancer and its treatment from diagnosis to death. Data supporting this guideline includes nine randomized controlled trials and five secondary analyses from these trials that demonstrate the effectiveness of dedicated palliative care services early in the treatment of cancer. Essential components of palliative care may include symptom management, education about the cancer and its prognosis, clarification of treatment goals and assistance with medical decision making, coping needs, and coordination of care.

Applying these principles, a prospective trial in 171 newly diagnosed advanced lung or noncolorectal gastrointestinal cancer patients evaluated the key elements of early palliative care from 2,921 clinic visits. The initial cancer therapy was chemotherapy (80.7%) or radiotherapy (19.3%). Patients randomly assigned to at least monthly visits in the palliative care clinic had assessments performed at baseline and at 24 weeks. Most of these palliative care visits addressed symptom management (74.5%) and coping (64.2%). By 24 weeks, patients who more frequently addressed treatment decisions were less likely to initiate chemotherapy ($P = .02$) or be hospitalized ($P = .005$) in the 60 days before death. With a higher proportion of visits addressing advanced care planning, hospice care was more frequently used ($P = .03$) (Fig. 48.1).
FIGURE 48.1  Content of palliative care (PC) visits across the illness trajectory. PC clinicians recorded the content they addressed after each visit. Reported proportions for the final three visits are restricted to decedents. Reported proportions for the initial three visits exclude visits that were also among the final three visits. Reported proportions for middle visits represent averages across all available middle visits. Relative to the initial three visits, the final three visits increasingly addressed treatment decisions ($P < .001$), advance care planning ($P < .001$), and disposition ($P < .001$) but decreasingly addressed rapport ($P < .001$) and illness understanding ($P < .001$). (From Hoerger M, Greer JA, Jackson VA, et al. Defining the elements of early palliative care that are associated with patient-reported outcomes and the delivery of end-of-life care. J Clin Oncol 2018;36[11]:1096–1102. Reprinted with permission. Copyright © 2018 American Society of Clinical Oncology. All rights reserved.)

Application of palliative care principles has a profound impact on the physical and psychological comfort of the patient and their caregivers. These palliative care principles also have a profound socioeconomic impact given that the highest costs incurred in health care are at the end of life. Referral to a specialty palliative care service only occurred in 298 (30%) of 978 patients. Of these 298 patients, only 94 (9.6% of the total) had an early referral, whereas the remaining 204 patients (21% of the total) had a late referral to the palliative care service. Early delivery of palliative care resulted in lower rates of inpatient admission in the last month of life (33% vs. 66%), lower rates of intensive care unit (ICU) stay in the last month of life (5% vs. 20%), fewer emergency department visits in the last month (34% vs. 54%), fewer instances of hospice service less than 3 days (7% vs. 20%), and lower rate of inpatient death (15% vs. 34%). The direct
cost of inpatient medical care in the last 6 months of life with early palliative care was less than among those with late palliative care ($19,000 vs. $25,700).\textsuperscript{16}

At the Johns Hopkins Medical Institutions, the palliative care unit and palliative care consults had a positive financial impact of $3,488,863.10. Palliative care consultations alone, with 60% of these involving cancer patients, saved $2,765,218.00. The 30-day readmission rate was cut from 15% to 10%. Hospice care was arranged in 57% of palliative care consultation patients as compared to only 27% if a palliative care consult was not requested.\textsuperscript{17}

The early integration of palliative care services significantly reduces health care utilization during end-of-life care. Insurance claims during the last month of life from 6,568 cancer patients from a Surveillance, Epidemiology, and End Results (SEER) database between 2007 and 2015 were reviewed. At baseline, at least one imaging scan was performed in 48.9%, and 56.3% of patients were hospitalized; only 31.4% of patients younger than 65 years were enrolled in hospice. With changes in health care and reimbursement policies over this time frame, the administration of chemotherapy and/or radiotherapy, diagnostic imaging, and hospitalization rates declined (Fig. 48.2).\textsuperscript{18}

Palliative chemotherapy has been an ambiguous term and mostly refers to chemotherapy given when the likelihood of cure was minimal. In the true sense, palliative chemotherapy means that systemic therapy is delivered to relieve symptoms and improve quality of life regardless of stage of disease or the likelihood of remission or cure. The primary outcomes of most studies involving disease-modifying systemic agents, however, do not have symptom relief as a major endpoint. Although virtually all systemic agents used in cancer have been surveyed for impact on quality-of-life, the results of these quality-of-life surveys are rarely reported. Reduction in the size of the tumor, which is the intended goal of
chemotherapy, should intuitively decrease cancer pain. However, because the therapeutic benefits of chemotherapy are limited by their own toxicities, the risks versus benefits need to be weighed as part of treatment planning and decision making on a case-by-case basis.

Palliative radiation often is used near the end of life to relieve pain and obstruction from tumor. To achieve the most benefit, palliative radiation should be administered to prevent or relieve symptoms before they become severe. If referral for palliative radiation is delayed until the patient becomes extremely debilitated and/or the lesion has progressed significantly, often the possibility of any benefit from palliative radiation is lost. Demonstrating this, a retrospective study of 1,424 patients with metastatic cancer was conducted between 2010 and 2015 found that 11.3% had received palliative radiation therapy before ICU admission. The in-hospital mortality rate was 36.7% for palliative radiation patients compared to 16.6% of other patients with metastatic cancer. After ICU admission, only 21.1% of patients previously treated with palliative radiation received additional cancer treatment.\textsuperscript{19}

The median length of survival is critical to evaluating response to and determining the appropriate recommendations for palliative therapy. The most common application of palliative radiation is in management of pain related to bone metastasis. Seventy percent of metastatic bone lesions are painful and debilitating. The goal of treatment is to relieve pain, restore functional ability, and prevent pathologic fractures. In prostate cancer, the distribution of bone metastases has prognostic significance. Survival is longer when the metastases are restricted to the pelvis and lumbar spine or if there is a response to salvage hormone therapy, but lower if metastatic involvement is outside the pelvis and lumbar spine irrespective of response to salvage hormone therapy.\textsuperscript{20–22} Survival rapidly declines once visceral metastases develop.\textsuperscript{23–25}

The location of the metastasis can also be a limitation in the effectiveness of a palliative radiation. Metastatic involvement of weight-bearing bones and those used in functional activities are often less likely to respond completely to palliative interventions due to applied mechanical forces put on them. Pain relief is achieved in 73% of spine metastases, 88% of limb lesions, 67% of pelvic metastases, and 75% of metastases to
other parts of the skeleton.\textsuperscript{26–28}

Palliative therapy has become a recognized subspecialty within radiation oncology.\textsuperscript{29} Despite the establishment of multiple palliative medicine programs in the country and the proven efficacy of palliative radiotherapy for symptoms, radiotherapy is often underutilized due to long radiation treatment schedules.\textsuperscript{26} Even with a relatively short life expectancy, palliative radiotherapy may be helpful, but less than 3\% of the patients in hospice care received radiation in one survey.\textsuperscript{30}

Conducting randomized trials among large patient cohorts, shorter radiation treatment regimens have enhanced quality of care by achieving equivalent symptom reduction when compared to longer radiation regimens and have significantly reduced the lengths of hospitalization ($P = .01$).\textsuperscript{31} Among 181 patients hospitalized for bone metastases between 2010 and 2016, a palliative care radiation oncology consult service recommended shorter palliative radiation schedules, increased palliative care utilization, and reduced hospital stays by 8.5 days. Median total hospitalization costs were $76,792 for patients with bone metastases before a palliative radiation oncology consult service was available and were reduced to $50,582 after the palliative radiation oncology consult service was formed.\textsuperscript{32} Cost of outpatient radiation therapy was evaluated from claims-linked data from 207 breast and 233 prostate cancer patients in 98 cancer treatment centers in 16 US states between 2008 and 2010. The mean total cost of radiation for bone metastases was $7,457 for breast cancer and $7,553 for prostate cancer patients.\textsuperscript{33}

More sophisticated and costly radiation techniques, like stereotactic and proton radiation, are available to treat patients expected to have a longer survival or those with complicated clinical presentations, like those near critical structures and in/near previously irradiated sites. Stereotactic radiation is not cost-effective for routine cases having an incremental cost-effectiveness ratio of $124,552 per quality-adjusted life years. However, stereotactic radiation does become cost-effective, with an incremental cost-effectiveness ratio of less than $100,000 per quality-adjusted life years, among patients with a median survival of over 10 months.\textsuperscript{34} More abbreviated radiation courses result in cost savings for less complicated clinical presentations. Ineffective therapy, however, incurs more personal
and economic cost resulting from the continued need for analgesics and the functional limitations caused by unrelieved pain and disability.\textsuperscript{35,36}

The most common barriers to radiotherapy still relate to the costs of radiation therapy and transportation difficulties. The selection of a radiation course or technique, like that for a systemic therapy, is dependent on the patient wishes, prognosis, and comorbidities.

**BONE DISEASE**

The annual prevalence of bone metastasis was determined to be 256,137 in the years 2000 to 2004. The direct cost for patients with bone metastasis was $75,329, and the incremental cost was $44,442 compared to patients with cancer without bone metastasis. The national cost burden for patients with skeletal metastasis was estimated at $12.6 billion which is 17\% of the $74 billion total direct medical cost estimated by National Institutes of Health (NIH).\textsuperscript{37} The prevalence of metastatic bone disease totaled 279,679 as determined by claims-based data from 2004 to 2008, with breast, prostate, and lung cancer accounting for 68\% of these cases.\textsuperscript{38}

Multidisciplinary evaluation of patients with metastatic disease to the bone allows comprehensive management of the associated symptoms, determines the risk for pathologic fracture, and helps coordinate administration of a wide range of available antineoplastic therapies (also see Chapter 46).\textsuperscript{39,40} Bone metastases can be treated with localized, systemic, or both kinds of therapies. Because localized treatments, like radiation and surgery, provide treatment only to a localized symptomatic site of disease, it is frequently used in coordination with systemic therapies such as chemotherapy, hormonal therapy, and bisphosphonates. Radiopharmaceuticals provide another systemic option that treats diffuse symptomatic bone metastases.\textsuperscript{39,41} Because the radiation is deposited directly at the involved area in the bone, radiopharmaceuticals, such as strontium 89 or samarium 153, can also be used to treat diffuse bone metastases or when symptoms recur in a previously irradiated site. Radiopharmaceuticals can also act as an adjuvant to localized external beam irradiation and reduce the development of other symptomatic sites of disease. A study was conducted among patients referred to a multidisciplinary bone metastases clinic between 2007 and 2015.
Independent of age, 62% of patients received palliative radiation, whereas surgical stabilization was required in 30% over the age of 66 years and in 39% of patients 65 years of age or younger.\(^{42}\)

Control of cancer-related pain with the use of analgesics is imperative to allow comfort during and while awaiting response to therapeutic interventions. Pain represents a sensitive measure of disease activity. Close follow-up should be performed to ensure control of cancer and treatment-related pain and to initiate diagnostic studies to identify progressive or recurrent disease. Pain, risk for pathologic fracture, and spinal cord compression are the most common indications to treat bone metastases with localized therapy including radiation and surgery.

**CLINICAL APPLICATIONS OF RADIATION THERAPY**
Radiotherapy can be delivered with curative or palliative intent. Curative treatment attempts to render the patient disease free of either primary or metastatic disease. Treatment with palliative intent is intended to control the symptoms of disease when the disease cannot be eradicated. A number of clinical, prognostic, and therapeutic factors must be considered to determine the most optimal treatment regimen for a course of palliative radiotherapy. Although any site of disease can be effectively palliated, treatment of bone metastases is one of the most common indications for palliative irradiation with external beam therapy. During the last year of life, one-third of patients receive radiation therapy, which decreased to 24.3% in the last 3 months of life and 8.5% during the last month of life. Although radiation with curative intent was delivered at a constant rate in 25% of patients, palliative radiation was administered at a supralinear rate over the last year of life in which the treatment of bone metastases and use of single-fraction radiation increased closer to death.\(^{43}\)

The limited radiation tolerances of normal tissues, such as the spinal cord, make it impossible to administer a large enough dose of radiation to completely eradicate most tumors. Palliative radiation should result in sufficient tumor regression to relieve symptoms for the duration of the patient’s life. Palliative radiotherapy is often combined with chemotherapy and/or surgery to optimize therapeutic outcomes from tumor-related pain, bleeding, visceral obstruction, or lymphatic and vascular obstruction.
Common sites include respiratory system structures, pelvis, skin and subcutaneous tissues, brain, and all bony structures. Potential relief of symptoms is a more important determinant for palliative radiation than whether lesions result from locally advanced or metastatic disease. Symptoms that recur after palliative radiation most commonly result from localized regrowth of tumor in the radiation field.\textsuperscript{44}

The palliative interventions recommended depend on the patient’s clinical status, burden of disease, and location of the symptomatic site. For either locally advanced or metastatic disease, these factors are indexed to the relative effectiveness, durability, and morbidity of each palliative intervention. Each patient’s prognosis represents the single most important factor in deciding the approach to palliative therapy.\textsuperscript{45}

Because patients with metastatic disease have a limited life expectancy, the number of radiation fractions prescribed for treatment with palliative intent depends on prognosis and not primary histology, so a lower total dose is given with palliative radiation over 1 to 2 weeks (hypofractionated radiation schedule). Based on the radiation tolerance of normal tissues, a low daily radiation dose (1.8 to 2.0 Gy) is given with conventional radiation; in contrast, large daily radiation fractions are given with hypofractionated radiation schedules. Hypofractionated radiation schedules for palliative therapy can range from 2.5 Gy per fraction administered over 3 weeks for a total dose of 35 Gy to a single 8-Gy dose of radiation. Most frequently, 30 Gy is administered in 10 fractions over 2 weeks. Especially among patients with short life expectancies, many centers administer 20 Gy in 1 week or a single fraction of radiation because the rates of pain relief, mobility, and frequency of pathologic fractures are similar to more protracted radiation schedules.\textsuperscript{46,47}

Palliative interventions not only should be limited in time relative to the patient’s life expectancy but should also be focused to limit toxicity. Available radiation techniques that focus the radiation to the symptomatic site should be applied to limit toxicity. Although the relative cost of more advanced radiation planning and treatment may be higher, the tolerance to palliative radiation is better, avoiding the costs of treating toxicities, especially for radiation portals that include mucosal surfaces. Among the radiation techniques that more precisely focus the delivery of radiation to
the tumor are intensity-modulated radiation therapy (IMRT), proton radiation therapy, and stereotactic radiation therapy (SRT).

Response of Tumors to Radiotherapy

TRACHEA, BRONCHI, AND LUNGS
Locally advanced primary or metastatic involvement of the lung often requires palliative intervention because cure is possible in only a few of these cases. A variety of symptoms, some of them emergent, can manifest because of tumor involvement of the lung. Pain can result from tumor invasion of the ribs and nerve roots of the chest wall. Vertebral involvement can be associated with spinal cord compression. Lower respiratory tract obstruction, bleeding, and pneumonitis can result from tracheobronchial tumor growth. Mediastinal infiltration can cause superior vena cava syndrome.

All of these clinical presentations can be palliated with external beam radiation that encompasses the disease that is evident on diagnostic images and that treats pain referred along involved nerve roots. Radiation schedules that administer 30 Gy in 10 fractions over 2 weeks, 20 Gy in 5 fractions, 2 fractions of 8.5 Gy 1 week apart, or 1 fraction of 10 Gy (depending on the patient’s life expectancy and ability to tolerate multifraction therapy) are typically prescribed to previously unirradiated sites.

Optimal palliation of patients with incurable lung cancer requires coordinated interdisciplinary care. For patients with stage III non–small-cell lung cancer who have a life expectancy of at least 3 months, have a good performance status, and no comorbidities excluding the administration of chemotherapy, administration of a platinum-containing chemotherapy concurrent with hypofractionated palliative thoracic radiation therapy is recommended over treatment with either modality alone.

Hemoptysis and chest pain can be effectively palliated with external beam radiation, although dyspnea and dysphagia are not as effectively relieved. If the area has been previously irradiated, techniques that exclude critical anatomic structures, such as the spinal cord, are applied. Other
approaches, like brachytherapy, stereotactic radiation, and proton therapy, can be used when the symptomatic site is well localized and accessible. Brachytherapy can be used to treat bronchial obstruction and bleeding by placing a radioactive source directly against the tumor under bronchoscopic guidance. In these cases, large doses of radiation can be delivered over a few minutes by a high-dose rate brachytherapy unit.\textsuperscript{48,49}

**PANCREATIC CANCER**

Palliative doses of radiation for unresectable pancreatic cancer have minimal to no impact on survival. Randomized trials have not shown any significant survival benefit when conventional radiation is used after chemotherapy for unresectable pancreatic cancer. Results from nonrandomized studies of 3 to 5 fractions that deliver a biologic equivalent dose (BED) of 53 Gy of stereotactic radiation (SRT) not only have less toxicity and a shorter treatment time but also a minimal impact on survival. However, when 15 to 25 fractions of SRT, which deliver a BED of 100 Gy, longer survival can be achieved with low toxicity. Based on the anatomic disease extension and the patient’s performance status and wishes, SRT can be tailored to effectively relieve cancer-related symptoms, and in specific circumstances, extend life.\textsuperscript{50}

**PELVIS**

Hemorrhage with or without obstruction or compression of viscera, lymphatics, vascular structures, and nerves commonly occurs with locally advanced or metastatic disease in the pelvis. Treatment may require emergent radiotherapeutic, surgical interventions, or both. Hemorrhage is commonly associated with tumors involving the rectum and genitourinary tracts. As with tumors in the lung, radiation is an effective means of stopping active bleeding. Colorectal cancers are often diagnosed among patients with unexplained bleeding. In patients who have locally advanced tumors with months to years of life expectancy, 40 Gy in 2.5 Gy fractions to 50 Gy in 2 Gy fractions have been used with the intent to stop bleeding, render the patient operable, and provide a chance for cure. With extensive metastatic disease, 30 Gy in 10 fractions or 20 Gy in 5 fractions is used to palliate symptoms of bleeding and obstruction. Colorectal tumor
involvement may also result in obstruction requiring stent placement to maintain the integrity of the visceral lumen while administering radiation. Diverting colostomy is occasionally required but is reported to have been avoided after chemohypofractionated irradiation.  

Tumors involving the cervix can hemorrhage and require emergent radiotherapeutic intervention. Superficial radiographs are applied directly to the bleeding cervix through a cone to treat the bleeding site and do not compromise later radiation of other pelvic structures. Usually, radiation doses between 5 and 10 Gy are administered in one to three applications of cone therapy. Brachytherapy also can be used to treat gynecologic tumors, especially in the vagina, cervix, and endometrium.  

Bladder cancers or tumors that secondarily invade the bladder can also result in significant bleeding that can be palliated by external beam radiation. Urinary obstruction commonly occurs with locally advanced pelvic cancers, especially with bladder, rectum, prostate, and cervical cancers. Occasionally, placement of a urinary stent, urostomy, or nephrostomy is required until sufficient tumor regression can be accomplished by radiation to reestablish integrity of the urinary tract. As with the bowel and gynecologic tracts, a bladder fistula, resulting from either the tumor itself or from tumor regression, is a concern.  

The pelvic lymph nodes and major blood vessels may become obstructed by tumor. This is most frequently seen when tumors arise in pelvic structures but can also occur with pelvic metastases from breast and other cancers. Lymph-vascular obstruction results in painful edema that is refractory to diuretic and other therapies. Other than pain and functional interference, when severe, fluid and electrolyte imbalances can occur. Pelvic radiation can relieve lymph-vascular obstruction through tumor regression.  

Pelvic tumors can also invade the sacral plexus and result in intractable pain. Tumor can track along nerve roots and can be associated with bony invasion of the sacrum. Pain caused by visceral, lymph-vascular, or both kinds of obstructions often respond more rapidly to palliative radiation than the more refractory neuropathic pain seen with sacral plexus involvement. Other radiotherapeutic approaches, such as brachytherapy, are extremely limited when the cancer persists or recurs after external
beam radiation. Interventional pain management techniques are frequently required to control pain associated with sacral plexus involvement (see Chapter 44).

The use of palliative radiation in colorectal, prostate, and breast cancer is common. Using SEER data of 39,619 patients between 2004 and 2011, half of the patients received radiation in the last 6 months of life, defined as the last 6 months of life. Of the patients who received radiation during the end of life (19,586), only 46% had not previously been treated with radiation. Surgery was performed at the end of life in 35% of the patients, with proportionately more patients undergoing both surgery and radiation. Radiation was administered during the last 14 days of life, in 5,723 patients (14%). Administration of radiation during the end of life strongly correlated with end-of-life chemotherapy use, including the last 14 days of life (36% of chemotherapy patients); by comparison, only 15% of patients were treated with radiation in the group that did not receive chemotherapy during the last 14 days of life. Especially during the last 14 days of life, treatment may cause increased burden without improving quality of life.52

SKIN AND SUBCUTANEOUS TISSUES
Tumors can cause ulceration of the skin and subcutaneous tissues that are often painful and distressing because of constant drainage. Representing a source for the development of sepsis in immunocompromised patients, localized radiation can be applied to destroy tumor and allow reepithelialization of the skin. Radiation that treats only the skin and subcutaneous tissues (electron beam therapy) is generally used to avoid radiation side effects to underlying uninvolved normal structures. Although usually 10 radiation treatments are given, the course of radiation can be abbreviated further, ranging from 1 to 5 days. Occasionally, these lesions are treated with brachytherapy. The radioactive sources can be placed in a mold that sits on top of the tumor and delivers treatment over a few minutes (high-dose rate) or a few days (low-dose rate).

BRAIN METASTASES
Radiation is used to relieve the symptoms of headache, seizure, nausea and vomiting, and neurologic dysfunction associated with brain metastases. In
patients with good performance status, surgery or radiosurgery followed by postoperative whole brain radiation is commonly administered. Radiation is generally with a total of 30 Gy in 10 fractions or 20 Gy in 5 fractions.53

Management of newly diagnosed single or multiple brain metastases, however, depends on the estimated prognosis and the aims of treatment, including survival, local treated lesion control, distant brain control, and neurocognitive preservation. Prognostic systems, such as recursive partitioning analysis and diagnosis-specific graded prognostic assessment, may assist in predicting prognosis. Single brain metastasis greater than 3 to 4 cm in size with a good prognosis (expected survival of 3 months or more), the lesion should be surgically resected followed by whole brain radiotherapy (WBRT) or surgical resection followed by intraoperative radiation or an SRT boost to the resection cavity. For a single metastasis less than 3 to 4 cm in size, multiple options exist including SRT alone, WBRT and SRT, WBRT and surgery, surgical resection, and SRT or intraoperative radiation boost. For anatomically unresectable or incompletely resected single brain metastases less than 3 to 4 cm in size, WBRT and SRT or SRT alone should be considered. With an unresected brain metastasis larger than 3 to 4 cm, WBRT should be considered.54

Multiple brain metastases, all of which are less than 3 to 4 cm in size with a good prognosis SRT alone if the multiple lesions are limited in number and location, WBRT and SRT, or WBRT alone are options. Other alternatives include WBRT alone or resection of large brain metastasis or metastases if it can be accomplished without causing significant mass effect or morbidity followed by postoperative WBRT.

With poor prognosis, patients with either a single or multiple brain metastases should be considered for palliative care with or without WBRT.

**Bone Metastases**

There are two major historical sets of experience with palliative radiation for bone metastases. The Radiation Therapy Oncology Group (RTOG) conducted a prospective trial that included a variety of treatment schedules (Table 48.1). To account for prognosis, patients were stratified on the basis
of whether they had a solitary or multiple sites of bony metastases. The initial analysis of the study concluded that low-dose, short-course treatment schedules were as effective as high-dose protracted treatment programs.\textsuperscript{55} For solitary bone metastases, no difference existed in the relief of pain when 20 Gy using 4-Gy fractions was compared with 40.5 Gy delivered as 2.7 Gy fractions. Relapse of pain occurred in 57\% of patients at a median of 15 weeks after completion of therapy for each dose level. In patients with multiple bone metastases, the following dose schedules were compared: 30 Gy at 3 Gy per fraction, 15 Gy given as 3 Gy per fraction, 20 Gy using 4 Gy per fraction, and 25 Gy using 5 Gy per fraction. No difference was identified in the rates of pain relief among these treatment schedules. Partial relief of pain was achieved in 83\%, and complete relief occurred in 53\% of the patients studied. More than 50\% of these patients developed recurrent pain, the fracture rate equaled 8\%, and the median duration of pain control was 12 weeks for all the radiation schedules used for multiple bony metastases. Prognostic factors for response included the initial pain score and site of the primary cancer.

\textsuperscript{a}The radiobiologic equivalent dose if administered at 2 Gy per fraction.

\textsuperscript{b}The complete response rate using the definition that excludes the use of analgesics and that accounts for retreatment.

In a reanalysis of the data, a different definition for complete pain relief was used and excluded the continued administration of analgesics. Using this definition, the relief of pain was significantly related to the number of
fractions and the total dose of radiation that was administered. Complete relief of pain was achieved in 55% of patients with solitary bone metastases who received 40.5 Gy at 2.7 Gy per fraction as compared with 37% of patients who received a total dose of 20 Gy given as 4 Gy per fraction. A similar relationship was observed in the reanalysis of patients who had multiple bone metastases. Complete relief of pain was achieved in 46% of patients who received 30 Gy at 3 Gy per fraction versus 28% of patients treated to 25 Gy using 5-Gy fractions. In most cases, the interval to response was 4 weeks for both complete and minimal relief of symptoms.

Three important issues are identified from the RTOG experience. First, the results of the reanalysis demonstrate the importance of defining what represents a response to therapy. Second, this revised definition of response showed that the total radiation dose did influence the degree that pain was relieved. The response rates and the radiobiologically equivalent doses are listed from the reanalysis in Figure 48.1 for each of the treatment schedules used. Patients treated with total doses of 40 Gy or more had a 75% rate of complete pain relief versus a 62% rate of complete pain relief for patients treated with total doses of less than 40 Gy. Third, the RTOG experience identified the amount of time that was needed to experience relief of pain after radiation for bone metastases (Table 48.2). It is important to note that only one-half of the patients who were going to respond had relief of symptoms at 2 to 4 weeks after radiation. This underscores the need for continued analgesic support after completing radiation. Consistently, it took 12 to 20 weeks after radiation to accomplish the maximal level of relief. That period of time may reflect the time needed for reossification. Radiographic evidence of recalcification is observed in approximately one-fourth of cases, and in 70% of cases, recalcification is seen within 6 months of completing radiation treatments. Recalcification is the basis of stabilization and prevention of fractures in the future. For pain relief, a short course of radiation is adequate; however, a longer schedule is recommended for adequate recalcification. Again, clinical context, with a focus on life expectancy, is a key determinant of radiation type, dose, and fractionation schedule.

NOTE: This prospective trial, conducted by the Radiation Therapy Oncology Group, randomized radiation dose and number of fractions and stratified the randomization on the basis of solitary or multiple bone metastases. Also listed is the radiobiologic equivalent dose if administered at 2 Gy per fraction.

**Single-Fraction Radiation**

A single large radiation fraction has demonstrated, in large multiple prospective randomized clinical trials, as effective in relieving pain as other radiation schedules that have more treatments. Radiobiologically, a single 8-Gy fraction would give the same side effects to late reacting tissues (i.e., tissues such as the spinal cord that do not regenerate) as if 18 Gy were given over nine treatments at 2 Gy per fraction. Because tumors and acute reacting tissues, such as the esophagus and other mucosal structures, respond differently than the late-reacting tissues, the radiobiologically equivalent dose to the tumor for a single 8-Gy fraction would be 12 Gy if 2 Gy fractions were used. The most common dose fractionation schedule used for palliative radiation in the United States is 30 Gy over 10 fractions. Radiobiologically, this is equivalent to 36 Gy at 2 Gy per fraction for late-reacting tissues and 32.5 Gy to the tumor. When a single dose of radiation was compared with a radiation schedule with multiple radiation fractions, no difference was reported in either how quickly symptoms resolved or the duration of pain relief. Pain relief
was achieved in 80% after treatment and 50% of patients at 6 months irrespective of the number of fractions. Complete response (CR) rates after a single 8-Gy fraction total 15% at 2 weeks, 23% at 4 weeks, 28% at 8 weeks, and 9% at 12 weeks postradiation.

Despite the radiobiologic differences in the dose administered, the similarities in response may be caused by tumor regression and reossification that occurs at 3 months. The RTOG experience showed that the maximum response to therapy was seen consistently at 3 months and was independent of dose administered.\textsuperscript{55,56} The disparity in the relationship between radiation dose and clinical response may also be attributed to limited follow-up in the single-fraction study because a significant proportion of patients in the study were lost to follow-up after 3 months.\textsuperscript{67–70} With longer follow-up, the response to a single radiation fraction may not prove to be as durable as multiple fractions that give high total radiation doses.\textsuperscript{76–78} These data demonstrate that prognosis needs to be linked to variables such as site irradiated, total radiation dose, and reirradiation.\textsuperscript{79}

A shorter radiation schedule, such as a single fraction, is advantageous for patients with poor prognostic factors. First, it is easier for patients with a poor KPS to complete therapy. Second, response rates are equal to single and multifraction therapy at 3 months because median survival is less than 6 months among patients with poor prognostic factors.\textsuperscript{67–75} The option of retreatment after a single fraction of radiation may also provide an advantage among patients with good prognostic factors as a means to periodically reduce tumor burden and control symptoms in noncritical anatomic sites. Higher radiation doses that provide more durable pain relief are considered warranted for patients with good prognostic factors who require treatment over the spine and other critical sites.\textsuperscript{80–86}

The projected length of survival is the critical issue to determine the optimal radiation dose and schedule for palliative radiation. In one study, only 12 of 243 patients were alive at the time of analysis, with approximately 50% alive at 6 months, 25% at 1 year, 8% at 2 years, and 3% at 3 years after palliative radiation. For breast cancer patients, the survival rates at these time points after palliative radiation were 60%, 44%, 20%, and 7%, respectively. For prostate cancer, the survival rates were
60% at 6 months and 24% at 1 year, and there were no patients who survived 2 years. This survival difference may be an important observation because unrelieved pain and the resultant sequelae of immobility may contribute to mortality as well as morbidity.

The number of fractions used during a course of palliative radiation was found to correlate directly with survival in a cohort of 1,292 patients. Median survival was 13.4 months, 9.8 months, 7.0 months, and 6.9 months for 15, 10, 5, and single-fraction palliative radiation regimens, respectively. Performance status and insurance status also directly correlated with median survival in this study. From this retrospective study, radiation oncologists appropriately selected palliative treatment schedules based on prognostic factors.

These findings were confirmed in a retrospective analysis of 297 patients who began palliative radiotherapy. Of this patient cohort, factors associated with 60 of these patients discontinuing palliative radiotherapy included low KPS, high number of fractions prescribed, and treatment site other than bone metastasis. However, the odds of discontinuing palliative radiotherapy decreased for every 10-point increase in KPS. Independent of all other factors, patients who discontinued treatment were more likely to die. Factors associated with a shorter survival also included low KPS, community practice location, multiple comorbidities, and treatment of brain metastasis (Fig. 48.3).
Between 2004 and 2007, only 17% of external beam palliative radiation courses were given in one to five radiation fractions, whereas from 2012 to 2016, 80% of patients received one to five radiation fractions. SRT was administered in 9.7% of patients and 5.8% with radiopharmaceutical therapy. At another institution between 2007 and 2012, less than 10 radiation fractions were administered in 83% of 339 patients during their final course of radiation.

With expanding evidence from multicenter prospective randomized clinical trials and changes in insurance reimbursement policies, the paradigm of palliative radiation for bone metastases has shifted.

**Stereotactic Radiation for Nonspine Bone Metastases**

Despite changes in insurance reimbursement policies, bone metastases
located in anatomic areas other than the spine also have been treated with SRT. The indications for SRT over conventional palliative radiation included an oligometastasis (63%), progression of an oligometastasis (17.3%), retreatment (2.4%), and other reasons such as anatomic location (17.3%). The most common prescriptions were 30 Gy per five fractions (30.2%) and 35 Gy per five fractions (42.5%). The median age of the patients was 66.4 years (range 36 to 86 years); most of the patients were male (60.5%), and prostate cancer was the predominant primary tumor. Bone metastases were most commonly located in the pelvis (41.5%), and almost half of the metastases were sclerotic. With a 13-month mean follow-up, an association was found between local recurrence and the tumor volume. Local recurrence rates were 4.7% at 6 months, 8.3% at 18 months, and 13.3% at 24 months. Radiographic evidence of a pathologic fracture was documented in 8.5% of treated metastases, with lytic lesions and female gender being a predictor for pathologic fracture.\textsuperscript{92}

\textbf{Reirradiation}

Many factors influence response to palliative radiation for bone metastases. Primary tumor site, performance status, and baseline pain score are among the factors predictive for pain response. The predicted response rates to palliative radiation range from 37.5% for patients with multiple adverse factors to 79.8% for patients with the fewest adverse factors.\textsuperscript{93} Genetic factors may also help to identify the patients who will respond to palliative radiation and improve resource utilization. Single-nucleotide variants involved in DNA repair, inflammation, cellular adhesion, and cell signaling have significant association with radiation response.\textsuperscript{94}

The radiation schedule used for palliative radiation is influenced by the radiation tolerance of adjacent normal tissues as well as prognosis. Acute radiation toxicities are a function of the dose per fraction, total dose, and the area and volume of tissue irradiated. If mucosal surfaces, such as the upper respiratory and digestive tract, bowel, and bladder, can be excluded from the radiation portals, acute radiation side effects can be significantly reduced. This principle of minimizing radiation to uninvolved adjacent
tissues applies to the radiation given with curative intent (multiple small radiation doses over multiple weeks), palliative radiation, and reirradiation (few to one large radiation dose). Reirradiation is generally possible because the radiobiologic dose is relatively low after a single fraction of radiation, especially to a previously unirradiation site remote from critical structures like the small bowel or spinal cord. If high total radiation doses had been previously administered, reirradiation for persistent or recurrent pain is often challenging or precluded based on the limitations of normal tissue tolerance, especially near the spinal cord.

For bone metastases, reirradiation was necessary in 25% of patients who initially received a single 8-Gy radiation fraction, but all of these patients responded to the second dose of radiation for bone metastases. Pain relief in reirradiated patients was better in patients who had a longer pain-free interval after the initial single 8-Gy dose of radiation (≥4 months), a better performance status, and a single bone metastasis. There also was no significant difference in pain relief at 2 months or overall survival based on gender or age. Using an intention-to-treat analysis for the treatment of bone metastases with palliative radiation, similar response rates were found for single fraction (61%; 1,867/3,059 patients) and multiple fractions (62%; 1,890/3,040 patients). Ten randomized trials were reported since 2010, resulting in a total of 29 trials for analysis. Retreatment was more frequent in the single-fraction arm with 20% receiving additional treatment to the same site versus 8% in the multiple fraction arm. However, no significant difference was seen in the risk for pathologic fracture, the rate of spinal cord compression or acute toxicity rates at the treatment site.

Using SRT, reirradiation to a vertebral body can be safely accomplished with palliation of symptoms. When SRT is given at least 5 months after conventional palliative radiotherapy, and if the radiation dose to the thecal sac does not exceed a biologically equivalent radiation dose of 70 Gy normalized to a 2 Gy equivalent dose. Reirradiation with SRT can achieve favorable response rates if spinal cord radiation dose restraints (10 Gy to 10% of the spinal cord) are followed.

The results of reirradiation of vertebral metastases are favorable. Having no other therapeutic option, tumor recurrence in the spinal and paraspinal
areas in 372 spinal lesions were reirradiated using SRT. The time between the initial radiation course and the reirradiated course was a median of 9.8 months. The median survival was 6.9 months after the last radiation treatment (reirradiation), and median follow-up was 3.4 months (average of 21 months). Relief of pain and neurologic improvement was accomplished in 81%, and radiographic tumor control was evident in 71%. Adverse effects occurred in 11 patients, with radionecrosis and myelomalacia each occurring in 1 patient; 6% of patients had radiation associated vertebral compression fractures. 99

The specimens of 30 patients who underwent surgery after salvage SRT (sSRT) and primary SRT (pSRT) to the spine were compared. This 30 patient cohort (69.6% sSRT, 30.4% pSRT) were identified from 704 patients treated with SRT for vertebral metastases between 2006 and 2012. The mean time to surgery was 8.3 months for sSRT and 10.3 months for pSRT. The most common reasons for surgery were pain (12.5% sSRT, 71.4% pSRT), fracture (37.5% sSRT, 28.6% pSRT), and neurologic symptoms (68.8% sSRT, 42.9% pSRT). Neurologic symptoms were common with radiologic tumor progression but not with fractures. Radiologic tumor progression was seen in 71.4% sSRT and 42.9% pSRT, and it significantly correlated with pathologic evidence of viable tumor and tumor bed necrosis. Viable tumor was pathologically documented in 62.5% sSRT and 71.4% pSRT, although tumor bed necrosis was more common after sSRT (81.3% in sSRT, 42.9% pSRT). Sequelae of radiation included soft tissue necrosis (20.0% in sSRT, 28.6% pSRT), osteonecrosis (14.3% in sSRT, 16.7% pSRT), or bone marrow fibrosis (42.9% in sSRT, 33.3% pSRT). Pathologic fractures were increased with bone marrow fibrosis but not with either soft tissue necrosis or osteonecrosis. 100

**Pathologic Fracture**

The most significant complications of bone metastases relate to pathologic fracture and spinal cord compression. Pain that persists or that recurs after palliative radiation should be evaluated to exclude progression of disease, possible extension of disease outside the radiation portal that results in referred pain, and bone fracture. Although pure osteolytic metastases are
more likely to fracture than osteoblastic lesions, osteoblastic lesions, by definition, have an osteolytic component so that new bone can be formed. Reduced cortical strength can result in compression, stress, or microfractures associated with reduced cortical strength.

Serial radiography is useful in following postradiation disease progression and fractures. Pathologic fractures occur in 8% to 30% of patients with bone metastases. Proximal long bones are more commonly involved than distal bones. Consequently, pathologic fractures occur 50% of the time in the femur and 15% in the humerus (Fig. 48.4). The femoral neck and head are the most frequent locations for pathologic fracture because of the propensity for metastases to involve proximal bones and the stress of weight placed on this part of the femur. More than 80% of pathologic fractures occur in breast (50%), kidney, lung, and thyroid cancers.
FIGURE 48.4  A: An extensive lytic lesion in the proximal humerus. B: Prophylactic internal fixation performed to prevent pathologic fracture. This patient, who complained primarily of pain in the hip, would have been placed on crutches to reduce stress on the involved femur. A bone scan and radiography, obtained to exclude other sites of metastatic involvement, identified this lesion in the humerus. The humerus would have certainly fractured if all the patient’s weight had been displaced to the upper extremities with crutches.

Computed tomography (CT) was performed in femurs with bone metastases to determine risk for pathologic fracture. No difference in the CT scan was identified between femurs that fractured and did not fracture. However, when only the cortical bone was evaluated, the pathologic fracture group had a lower cumulative Hounsfield value compared to the no fracture and no fixation groups.\textsuperscript{102}

Approximately 10\% to 30\% of metastatic lesions in long bones develop a pathologic fracture that requires surgical intervention. Patients with pathologic fracture caused by bone metastases have clinical outcomes after surgical repair that are comparable with patients sustaining a traumatic fracture.\textsuperscript{103–106} Surgical management was performed in 184 patients with bone metastases to relieve severe pain, avoid impending or stabilize pathologic fractures between 2008 and 2016. Radiotherapy was previously administered in 77\% of the patients. Surgical management substantially improved functional outcomes and relieved pain as early as 2 weeks after surgery.\textsuperscript{107} However, poor prognosis is associated with hypercalcemia and ongoing severe pain from other metastatic bone lesions. Therefore, in those cases, the decision for surgical intervention should be weighed carefully based on a relative benefit to burden analysis.\textsuperscript{103}

Treatment of pathologic fracture or impending fracture depends on the bone involved and the clinical status of the patient. Indications for surgical intervention of pathologic fracture or impending fracture include these factors: (1) an expected survival of more than 6 weeks, (2) an ability to accomplish internal stability of the fracture site, (3) no coexistent medical conditions that preclude early mobilization, (4) metastases involving weight-bearing bones, and (5) lytic lesions more than 2 to 3 cm in size or metastases that destroy more than 50\% of the cortex.\textsuperscript{103–106} Intramedullary stabilization without resection of metastases using locking nails meets the requirements of palliative therapy. This procedure is less invasive and allows early weight bearing.\textsuperscript{106} Postoperative radiation is often given after
surgical fixation of a pathologic fracture to reduce risk of progressive
disease in the bone that could result in instability of the internal
fixation.\textsuperscript{104}

Significant technologic advances in interventional radiology also
provide additional options for the treatment of bone metastases. These
options include thermal ablation (destroy the tumor with heat) and
endovascular therapies (destroy the tumor through devascularization).
Additionally, interventional radiology can stabilize pathologic fractures or
impending pathologic fractures.\textsuperscript{108}

**Spinal Cord Compression**

Metastatic spinal cord compression (MSCC) is the most dreaded
complication of cancer. Pain is the initial symptom in approximately 90% of
patients with spinal cord compression.\textsuperscript{109} Paraparesis or paraplegia
occurs in more than 60%; sensory loss is noted in 70% to 80%; and 14% to
77% have bladder, bowel, or both kinds of disturbances.\textsuperscript{80,81,110} Six
predictive risk factors are associated with MSCC: the inability to walk,
increased deep tendon reflexes, compression fractures on radiographs of
spine, bone metastases present, bone metastases diagnosed more than 1
year earlier, and age less than 60 years. Patients with no risk factors had a
4% chance of developing cord compressions, and a patient with all six risk
factors present had an 87% chance of developing cord compression.\textsuperscript{103,104}
Breast, lung, and prostate cancer comprised 21% to 24% risk of
developing cord compression.\textsuperscript{111–113}

The clinical course of spinal cord compression resulting from malignant
melanoma is similar to that resulting from breast or prostate cancer. The
time from the original diagnosis of melanoma to the development of
metastatic spinal disease averages 32 months, and the average time is
reported to be 27 months from diagnosis of skeletal metastases to spinal
cord compression. The extent of the epidural mass influences prognosis
because a complete spinal block results in greater residual neurologic
impairment than a partial block. Median survival among patients with
spinal cord compression is 7 months, with a 36% probability for a 1-year
survival. For specific types of cancers, the mean survival time is 14
months for breast cancer, 12 months in prostate cancer, 6 months in malignant melanoma, and 3 months in lung cancer once epidural spinal cord compression is diagnosed.\textsuperscript{14,82,94} After the diagnosis of epidural spinal cord compression, the overall survival time averages 12 months, with a median survival time of 5 months. The vertebral column is involved by metastatic tumor in 40\% of patients who die of cancer. Approximately 70\% of vertebral metastases involve the thoracic spine, 20\% the lumbosacral region, and 10\% the cervical spine.

Using the Tokuhashi prognostic scoring system, 119 patients with epidural spinal cord compression were evaluated. Survival was 49 days in group 1, compared to 108 days in group 2. On multivariate analysis, better survival was also associated with breast, prostate cancer or lung cancers, nonvisceral metastases, and subsequent systemic chemotherapy.\textsuperscript{114,115} A total of 43 different prognostic factors were investigated in 142 articles to determine whether models could be develop to predict survival in patients with vertebral metastases. Only two prognostic factors, primary tumor and performance status, were found to be associated with survival. Survival was not influenced by age, gender, pathologic fracture, or the number and location of the vertebral metastases.\textsuperscript{116}

Weakness can signal the rapid progression of symptoms, and 30\% of patients with weakness become paraplegic within 1 week. Rapid development of weakness, defined as occurring in less than 2 months, most commonly occurs in lung cancer, whereas breast and prostate cancers can progress more slowly. Neurologic deficits can develop within a few hours in up to 20\% of patients with spinal cord compression.\textsuperscript{80–86,117,118} The severity of weakness at presentation is the most significant factor for recovery of function. The slower the rate of development of motor deficits, the better the functional outcome.\textsuperscript{110,119} If no neurologic deficits are present in a magnetic resonance imaging (MRI) scan proven spinal carcinoma, then radiation can preserve function. Patients with neurologic symptoms should be treated within 24 hours.\textsuperscript{120,121} Ninety percent of patients who are ambulatory at presentation are ambulatory after treatment. Only 13\% of paraplegic patients regain function, particularly if paraplegia is present for more than 24 hours before the initiation of therapy. Notwithstanding the high mortality associated with MSCC, more than 30\%
of patients who develop spinal cord compression are alive 1 year later, and 50% of these patients remain ambulatory if the syndrome is recognized and treated appropriately.

Pain can be present for months to just days prior to the onset of other neurologic dysfunction. Unlike degenerative joint disease, which primarily occurs in the low cervical and low lumbar regions, pain caused by epidural spinal cord compression can occur anywhere in the spinal axis and is aggravated by recumbency. Any cancer patient with back pain, especially with known metastatic involvement of the vertebral bodies, should be assessed for spinal cord compression. The risk of spinal cord compression exceeds 60% among patients with back pain and plain film evidence of vertebral collapse caused by metastatic cancer.\textsuperscript{122–126}

Radiographic determination of the involved spinal levels is critical to radiation treatment planning. Plain film radiography shows involvement of more than one spinal level in approximately one-third of patients. If the results of MRI, tomographic studies, and surgical findings are included, more than 85% of patients have multiple sites of vertebral involvement.\textsuperscript{80,81,122–126} For patients with known malignancy, a whole spine MRI is recommended as the preferred diagnostic modality.\textsuperscript{110,127,128} With plain radiography, the destruction of the pedicles is the most common finding that identifies spine metastases. In contrast, CT shows that the initial anatomic location of metastases is in the posterior portion of the vertebral body and that destruction of the pedicles occurs only in combination with involvement of the vertebral body (Fig. 48.5).\textsuperscript{125} Symptomatic patients with a normal vertebral contour and osteoblastic changes on plain film and bone scan should also be evaluated for spinal cord compression (Fig. 48.6). Osteoblastic bony expansion, commonly seen in both prostate and breast cancers, can result in spinal cord compromise as well as osteolytic vertebral compression fractures.\textsuperscript{124}
FIGURE 48.5  A: Computed tomographic scan showing involvement of the posterior aspect of the vertebral body resulting in partial spinal cord compression. B: Magnetic resonance imaging showing involvement of the posterior aspect of the vertebral body resulting in partial spinal cord compression.
Treatment of vertebral metastases has benefitted from less invasive surgical strategies, systemic therapy with checkpoint inhibitors, and advances in radiation therapy. Administered alone or postoperatively, SRT has allowed the delivery of tumoricidal radiation doses while sparing adjacent critical structures. A high-dose single (16 to 24 Gy) or hypofractionated (24 to 30 Gy in two to three fractions) SRT administers a significantly higher biologic effective dose over a shorter period of time than traditional external beam radiation. Radiation-induced spinal cord
injury from SRT is rare, with only 6 cases of radiation-induced myelopathy out of 1,075 cases in one study.\textsuperscript{129}

Emergency treatment of spinal cord compression includes corticosteroids, radiotherapy, neurosurgical intervention, or combinations of these three therapies. Radiotherapy is the treatment of choice for most cases of spinal cord compression and is a radiotherapeutic emergency (Fig. 48.7). Spinal cord compression resulting from metastatic tumor can be prevented or effectively treated when diagnosed early.\textsuperscript{80,81,122–126} Radiotherapy with shorter courses (e.g., 1 fraction with 8 Gy or 5 fractions with 4 Gy) is as effective as a longer course (e.g., 30 Gy in 10 fractions), but the longer courses have lower recurrence rates. A scoring system for survival based on prognostic factors can guide the type of radiation course.\textsuperscript{130} Patients with longer estimated survival time may benefit from the longer course of radiation. Pretreatment of lytic vertebral body disease, independent of the blastic component, predicts for subsequent SRT-induced vertebral compression fracture.\textsuperscript{131}
Neurosurgical intervention for MSCC involves spinal cord decompression accomplished by a laminectomy and is indicated in a variety of clinical presentations.\textsuperscript{80,81,121–128,132,133} These situations include rapid neurologic deterioration in the setting of tumor progression in a previously irradiated area in order to provide stabilization of the spine, tumor-induced paraplegia in patients with otherwise limited disease and good probability of survival, and to establish a diagnosis.

Prognostic factors for survival after surgery for spine metastases were evaluated in over 1,266 patients. Patients who survived less than 3 months after surgery for spine metastases were in significantly worse condition.
preoperatively with more emergency cases and lower performance status, more severe neurologic deficits, worse American Society of Anesthesiologists (ASA) scores, unfavorable tumor histology, and extraspinal and visceral metastases. By comparison, patients who survived more than 2 years after surgery had a better performance status, less severe neurologic deficits, better ASA scores, a more favorable tumor histology and less extraspinal extension, and fewer visceral metastases. Patients with one spinal level involved had a 34.9% 2-year survival compared to a 22.7% survival when two or more spinal levels were involved.\textsuperscript{134}

Adjuvant radiotherapy is often given to treat microscopic residual disease after neurosurgical intervention. A statistically significant improvement in functional outcome has been reported with laminectomy and radiotherapy in treatment of epidural spinal cord compression over either modality alone. In paraparetic patients who undergo laminectomy and radiation, 82% regain the ability to walk, 68% have improved sphincter function, and 88% have relief of pain. With radiation alone, 65% regained ambulation, 26% had improved sphincter function, and 70% had improvement of pain.\textsuperscript{121,132,134–136} Laminectomy, however, carries risks associated with surgery and anesthesia. Pain may worsen after laminectomy if operative procedures fail to stabilize the spine. Vertebral collapse may occur because of cancer or vertebral instability after cancer therapy (Fig. 48.8).
FIGURE 48.8  Compression fracture of the 12th thoracic vertebral body following an initial pain-free interval after palliative radiation. Vertebral weakness with rapid tumor regression resulted in a compression fracture that caused recurrent back pain because of spinal instability.

A total of 6,651 courses of radiation were prescribed to 3,782 patients with a median age of 66 years. The most commonly treated skeletal sites were the spine (56.8%) followed by the pelvis (18.2%). The primary sites of most bone metastases were genitourinary (26.5%), lung (23.8%), and breast cancers (21.9%). However, complicated bone metastases were associated with hematolymphoid malignancies (39.1%), lung cancer (34.2%), gastrointestinal (32.5%), breast (28.4%), and genitourinary (28.4%) cancers. Factors that complicated 32.1% bone metastases were neurologic compromise (18.7%), soft tissue mass (18.3%), and pathologic fracture (6.5%). The most common sites of bone metastases with complicating factors included the extremity (43.6%), skull (42.7%), and spine (39.2%). Although single-fraction radiation may be effective for uncomplicated bone metastases, more aggressive therapy is usually
warranted for bone metastases with complicating factors.\textsuperscript{137,138}

Paravertebral masses are most commonly associated with lung cancer and are rare in prostate cancer. Overall, approximately 20\% of patients with epidural cord compression have an associated paravertebral mass. Surgical resection combined with radiation therapy has been suggested to improve functional outcome when a paravertebral mass is associated with spinal cord compression. The overall survival is worse with lung cancer and sarcoma than with breast and renal cancer.\textsuperscript{136,139,140}

**RADIATION TOLERANCE OF THE SPINAL CORD**
Radiation tolerance is based on the dose per fraction, total dose, and the volume of tissue treated. The dose per fraction is the most important factor in the tolerance of tissues to radiation. Clinical and experimental experience has failed to demonstrate any difference in radiosensitivity in different segments of the spinal cord.\textsuperscript{141} The risk of radiation myelitis in the cervicothoracic spine is less than 5\% when 6,000 cGy is administered at 172 cGy per fraction or 5,000 cGy is given with daily fractions of 200 cGy per fraction. Especially among patients who have received chemotherapy, the total dose to the spinal cord is generally limited to 4,000 cGy administered at 200 cGy per fraction to minimize any risk of irreversible radiation injury to the spinal cord. The total dose is also an extremely important factor defining the radiation tolerance of the spinal cord. A steep curve based on total radiation dose predicts the risk of developing radiation myelopathy; a small increase in total radiation dose can result in a large increased risk for radiation myelopathy.\textsuperscript{141–143}

Retreatment of a previously irradiated segment of spinal cord results in high risk for radiation-induced myelopathy because other neurologic pathways cannot compensate for an injury to a specific level of the spinal cord.

The radiation tolerance of the spinal cord can be compromised by prior injury. Difficulty arises in differentiating pathologic and radiotherapeutic injury when there has been spinal cord compression. Vasogenic edema of the spinal cord and nerve roots can be caused by compression injury. Metastatic epidural compression results in vasogenic spinal cord edema, venous hemorrhage, loss of myelin, and ischemia. Vasogenic edema
results in an increased synthesis of prostaglandin E, which can be myelotoxic. Inhibition of this inflammatory pathway is one of the putative benefits of corticosteroids or nonsteroidal anti-inflammatory therapy. Other consequences of pathologic compression include hemorrhage, loss of myelin, and ischemia.\textsuperscript{141–143}

Two separate mechanisms of radiation injury result from white matter damage and vasculopathies. White matter damage is associated with diffuse demyelination and swollen axons that can be focally necrotic and have associated glial reaction. Vascular damage has been shown experimentally to be age dependent and can result in hemorrhage, telangiectasia, and vascular necrosis.\textsuperscript{141–143} Six major types of injuries have been shown experimentally to result from radiation to the spinal column. Five of these occur in the spinal cord and one in the dorsal root ganglia. The most severe spinal lesions, all of which are caused by vascular damage and result in neurologic dysfunction, include white matter necrosis, hemorrhage, and segmental parenchymal atrophy. The two less severe spinal lesions included focal fiber loss and scattered white matter vacuolization caused by damage to glial cells, axons, the vasculature, or all three; these less severe sequelae are seen with lower total doses of radiation and are less likely to result in neurologic dysfunction. In dorsal root ganglia, radiation damage included intracytoplasmic vacuoles and loss of neurons and satellite cells that could affect sensory function. These findings are distinct from the demyelination of the posterior columns associated with the self-limiting Lhermitte’s syndrome.\textsuperscript{144} Meningeal thickening and fibrosis can also be observed after radiation, but the clinical significance of this is unknown. Ependymal and nerve root damage from radiation is rare.

**CLINICAL MANAGEMENT**

Persistent pain after radiotherapy for vertebral metastases should be investigated to exclude the possibility of progressive disease inside or outside the radiation portal or mechanical spinal instability because of a vertebral compression fracture. Changes seen in the bone marrow on MRI after palliative radiotherapy initially include decreased cellularity, edema, and hemorrhage, followed by fatty replacement and fibrosis. These well-
defined changes on MRI after radiotherapy can be distinguished from those seen with progressive malignant disease.\textsuperscript{145–150}

SRT is increasingly used to treat vertebral metastases as it provides focused radiation to the involved vertebrae while limiting radiation injury to nearby mucosal structures. A retrospective study of 1,905 vertebral bodies treated by SRT in 791 patients between 2001 and 2013 resulted in a low rate of vertebral compression fractures. Radiation doses ranged from 10 Gy in 1 fraction to 60 Gy in 5 fractions. Although lytic lesions had a significantly increased risk for vertebral compression fractures, the overall rate was 8.4% including a single-fraction dose of 16 to 18 Gy.\textsuperscript{151}

The outcomes of spine SRT were evaluated in 127 patients with 148 metastatic lesions between 2003 and 2013. The 1- and 2-year actuarial rates for local control were 82.6% and 75.8%, respectively; for overall survival, these rates were 72.9% and 51.5%, respectively. When evaluated by histology, the 1-year local failure rates were 8.7% for thyroid cancer, 7.0% for breast, 26.6% for lung, and 39.6% for colon cancer. Non–small-cell lung cancer and colorectal cancer was a significant predictor of local failure when SRT was used to treat spine metastases.\textsuperscript{152}

Prior radiation portals may affect the ability to radiate spine metastases, especially in breast and lung cancer patients. Standard radiation portals currently used for breast cancer therapy infrequently treat the spinal axis. The upper thoracic and lower cervical region, however, may be irradiated in a field encompassing the supraclavicular nodes and axillary apex if significant axillary node involvement is documented. With techniques used in the past for breast cancer, the thoracic spine would receive a significant dose of radiation from a field that treated the internal mammary lymph nodes. Treatment of the mediastinum in lung cancer generally includes the majority of the thoracic spine treated to the maximum dose tolerated by the spinal cord.\textsuperscript{136} Unfortunately, previous radiation of the spine as part of definitive therapy does not reduce the risk for subsequent spinal cord compression as a consequence of persistent or recurrent disease. As spinal metastases occur in up to 40% of cancer patients, and median survival is less than 1 year, other options are available in previously irradiated patients. In select patients, including those with disease recurrence in a previously radiated area, interventional radiology
techniques such as vertebral augmentation and radiofrequency ablation have been effective in relieving debilitating pain and providing mechanical stability.\textsuperscript{153}

Surgical decompression is often the only available option for therapy because previously administered radiation may preclude further radiotherapy in the region of the malignant spinal cord compression. This is often the case in lung cancer because metastases are located in the thoracic spine in over 70\% of cases, and many of these patients have received mediastinal irradiation.\textsuperscript{140} Early involvement by the radiotherapist in the management of patients with suspected spinal cord involvement is important to allow time to obtain prior radiotherapy records; determine if further radiation is possible; and expedite the safest, most efficacious clinical decision-making process.

Based on clinical and radiographic grounds, leptomeningeal carcinomatosis must also be considered in the diagnostic evaluation. Leptomeningeal carcinomatosis occurs more commonly than clinically diagnosed. For example, only one-half of breast cancer patients with leptomeningeal carcinomatosis are diagnosed before death.\textsuperscript{154,155} Performing a lumbar puncture is a relative barrier to the diagnosis; at least three cerebrospinal fluid samples are necessary to cytologically exclude the diagnosis of leptomeningeal disease because in 10\% to 40\% of patients, the initial cerebrospinal fluid sample fails to document tumor cells.\textsuperscript{154} MRI can identify leptomeningeal disease among patients with normal cerebrospinal fluid cytology and is sensitive and specific in locating regions of nodular leptomeningeal involvement. Except in the case of nodular leptomeningeal involvement, in which localized radiotherapy may be of benefit as an adjuvant, intrathecal chemotherapy is generally the treatment of choice.\textsuperscript{155}

### Treatment of Diffuse Bone Metastases

Wide-field radiotherapy, systemic radionuclides, and bisphosphonates have been used to treat patients with disseminated bone metastases. These approaches are useful in augmenting the therapeutic effect of localized radiation and in preventing asymptomatic bony lesions from progressing.
Although usually not a significant consideration in localized irradiation, adequate bone marrow reserve is required for wide-field radiotherapy and systemic radionuclides. Bone marrow scans can be performed to determine the volume of functioning marrow and assess the feasibility of delivering wide-field radiotherapy or radionuclides.

**WIDE-FIELD RADIOTHERAPY**

Hemibody irradiation was previously used to treat diffuse bone metastases by administering one fraction of about 6 to 10 Gy or fractions of 3 Gy for 2 to 5 consecutive days to the upper, mid, or lower body. Fractionation reduces the need for premedication and allows for higher total doses to be delivered, but the effect on pain is equivalent to single-dose radiation.\textsuperscript{156–158} Response rates are consistently reported to be greater than 70%, and more than 20% of patients have complete relief of pain. In prostate and breast cancer patients, the overall response rate is 80%, and complete relief of pain is 30%, respectively.\textsuperscript{156–161} Approximately one-half of patients experience relief of pain within 48 hours of treatment, and the overall response rates equal 80% for all types of primary tumors. About 70% of the patients treated did not require further palliative irradiation for recurrent bone pain over the duration of their lives.\textsuperscript{157}

An RTOG study demonstrated that hemibody radiation reduced the time to disease progression and decreased the need for subsequent palliative radiation of bone metastases at 1 year of follow-up when compared with local field irradiation alone. These results from the RTOG study are consistent with other reported experience using hemibody irradiation.\textsuperscript{159–161} Median survival after hemibody irradiation was significantly better among patients who present with a good performance status. Approximately 90% of patients with a CR and 70% of patients with a partial response (PR) had a good to excellent performance status before radiotherapy. Prior systemic therapy does not influence response to wide-field radiotherapy. Symptomatic bone metastases that are refractory to chemotherapy or hormonal therapy are reported to have CR rates of 70% and PR rates of 24% with hemibody radiation. Symptoms are palliated in 88% of cases when a previously treated area is reirradiated. Premedication prevents nausea, and partial shielding minimizes lung dose and the risk for
radiation pneumonitis. Hematologic depression is limited. Toxicity is observed in less than 10% of patients, whereas 50% experience stabilization of disease at 1 year.

Hemibody radiation is currently rarely used for the treatment of metastases due to the potential toxicity to the visceral structures and the difficulties in treatment setup. Concerns regarding the permanent effects on bone marrow reserve also exist relative to the subsequent need for chemotherapy.

**RADIOPHARMACEUTICALS**

An alternative to hemibody irradiation for the treatment of widely disseminated bone metastases is the use of systemic radioisotopes. The most commonly used radiopharmaceutical in the treatment of bone metastases is strontium 89. Strontium 89 combines with the calcium component of hydroxyapatite in osteoblastic lesions. Many studies report effective palliation of pain lasting more than 6 months in 60% to 80% of patients with breast and prostate cancers. Improvements in functional status and quality of life have been observed, and approximately 20% of patients have complete resolution of pain. Pain control has been reported to be superior among patients with disseminated prostate cancer treated both with strontium 89 and local radiotherapy as compared with localized irradiation alone. Myelotoxicity resulting in 25% reduction of platelet and white blood cell counts represents the only significant toxicity associated with strontium 89, which is usually transient and reversible within 12 weeks. Hematotoxicity is more pronounced in patients with pretreatment platelet counts of less than or equal to $60 \times 10^3$, white blood cell counts of less than or equal to $2.5 \times 10^3$, or greater than or equal to 30% involvement of the red marrow–bearing bone. The radiation dose absorbed by the bone marrow is 2 to 50 times less than the dose administered by strontium 89 to the osteoblastic lesion. Radiation doses to metastatic bony lesions with strontium 89 can range from 3 to more than 300 Gy.

Clinical response to strontium 89 is comparable with wide-field radiotherapy. Response to strontium 89 therapy has been documented both subjectively and objectively. Subjective response, manifested as
symptomatic improvement, was reported by more than 80% of prostate cancer patients using a validated self-reporting tool. Objective evidence of response was documented by reductions in alkaline and acid phosphatase levels that corresponded with a decrease in evidence of active metastatic disease on sequential bone scans.\textsuperscript{179} Prior therapies for prostate cancer, including local radiation therapy and systemic chemotherapy or hormone therapy, do not influence toxicity or affect clinical response to strontium 89. Administered as an adjuvant to localized external beam radiotherapy in metastatic prostate cancer, strontium 89 has been shown to improve pain relief, reduce analgesic requirements, and delay progression of disease in prospective randomized clinical trials. Quality-of-life assessments demonstrated increased physical activity along with improved pain relief after strontium 89 was administered in conjunction with localized external beam radiation therapy.\textsuperscript{180,181} Cost–benefit analysis has also suggested an advantage to the administration of strontium 89 with reductions in costs of hospitalization for tertiary care.

Several other radiopharmaceuticals are available for clinical application including samarium 153, gallium nitrate, phosphorus 32, and rhenium 186.\textsuperscript{182–184} The therapeutic mechanism of action relates to the physical and biologic half-life in the bony lesion, the mean energy, and the delivered dose of the radiopharmaceutical. Table 48.3 summarizes some of the physical characteristics and clinical data for various radionuclides. Phosphorus 32 and strontium 89 emit pure $\beta$-rays (little penetration in tissue), whereas rhenium 186 and samarium 153 emit both $\beta$-rays and relatively high-energy $\gamma$-ray photons that penetrate tissue for some distance (103 to 159 keV).

Because samarium 153 has a γ-ray component, it is possible to directly image the distribution of the radiation dose. The scans after injection of samarium 153 are comparable to diagnostic scans obtained with technetium 99m. The mean skeletal uptake is over 50% of the dose. Nonskeletal sites receive negligible radiation doses, and complete clearance of radionuclide other than that absorbed by bone occurs within 6 to 8 hours of administration. In a double-blind placebo-controlled clinical trial, samarium 153 has been shown to be an effective agent in palliating painful bone metastases in breast cancer patients. Pain relief occurred within 1 week and lasted at least 16 weeks after administration. Approximately 65% of patients responded within the first 4 weeks, and 43% to 72% had relief of pain of at least 16 weeks’ duration. No significant bone marrow toxicities have been observed. Recommended doses range between 1.0 and 1.5 mCi/kg. In more than one-third of patients, multiple administrations are possible. These observations suggest potential suitability of this form of palliative therapy for patients with both intermediate and limited life expectancies who are not tolerating or responding favorably to other pain-relieving treatments.

Selectively concentrating in bone, the mechanism of action of rhenium 186 is similar to that of technetium diphosphonate 99m, which is used in diagnostic bone scans. This characteristic allows direct imaging of the deposition of rhenium 186 in bony metastases. The metastatic lesion receives a highly concentrated dose of radiation after the administration of rhenium 186, whereas the radiation dose to the marrow is limited to 0.75

[^P]: phosphorus 32; [^Sr]: strontium-89 chloride; 117[^mSn]: 117[^mSn](4+)diethylenetriaminepentaacetic acid; 186[^Re]: rhenium 186; 153[^Sm]: samarium 153; NR: no response.

Gy. Thrombocytopenia appears to be the dose-limiting toxicity but is mild, allowing therapy to be repeated.\textsuperscript{177} Phosphorus 32 has 77\% of patients experiencing significant relief of pain.\textsuperscript{179} The response rates and duration of response with phosphorus 32 are similar to wide-field radiation and strontium 89. However, the main disadvantage of phosphorus 32 is severe hematologic toxicity.

Clinical trials are ongoing to compare the conventional radiopharmaceuticals with newer radiopharmaceuticals and their effect in combination with bisphosphonates and chemotherapy. There is prolonged survival benefit in patients with hormone refractory prostate cancer if radiopharmaceuticals and chemotherapy are used in combination.\textsuperscript{185} Although bone marrow toxicity is relatively limited in the doses of radiopharmaceuticals currently administered either alone or in combination with other agents, future dose intensity studies may require hematologic support with colony-stimulating factors.

Sequential radiography and bone scans after hormonal and radiopharmaceutical therapy for breast and prostate cancers demonstrate an osteoblastic response that reflects remodeling of the bone in osteolytic osseous metastases.\textsuperscript{61,62} Approximately one-third of patients have evidence of increased tracer uptake on bone scans (flare) obtained 8 to 16 weeks after treatment. Of these patients with a flare response on bone scan, 72\% experience a response to the treatment. By comparison, only 36\% have a response to treatment when a limited response or no flare response is observed.

Relapse of disease has been associated with an increase in the osteolytic component. Osteoclast resorption in bone metastases is associated with the release of acid and acid-dependent proteases that dissolve the organic matrix of the bone. Gallium nitrate has been shown to inhibit accelerated bone turnover among patients with widespread bone metastases and has been clinically applied in the treatment of hypercalcemia. Preferentially accumulating in the cortical surface, which is the most metabolically active region of the bone, gallium nitrate acts to inhibit osteoclast resorption. Additionally, gallium nitrate increases the absorption of calcium and phosphorus and the incorporation of collagen into the bone.
Role of Palliative Chemotherapy

Chemotherapy can be used as an adjuvant to radiotherapy and/or surgery or as part of a combined antineoplastic regimen for primary treatment. Systemic chemotherapy has the advantage of ubiquitous distribution throughout the body, wherever the bloodstream might take a cancer cell. Thus, adjuvant chemotherapy is used in patients who appear cured after surgery but are suspected of having residual disease or micrometastasis. Adjuvant chemotherapy has proven effective in node-positive breast cancer, Dukes’ B2 and C colorectal carcinoma, stage III ovarian carcinoma, testicular carcinoma, non–small-cell lung cancer, Wilms’ tumor, osteogenic sarcoma, and anaplastic astrocytoma.186

Neoadjunct chemotherapy is used as initial chemotherapy in cancers that would be only partially curable by surgery or radiation. It is often administered with anal cancer, bladder cancer, esophageal cancer, laryngeal cancer, locally advanced non–small-cell lung cancer, and osteogenic sarcoma. The goals of this therapy are to (1) decrease the size of the tumor to be removed or radiated, (2) increase the likelihood that the tumor will be surgically extricable, and (3) decrease the likelihood of micrometastatic spread/seeding at the time of surgery.186 Systemic chemotherapy is the primary treatment for disseminated/metastatic malignant disease.

Based on the mechanisms mentioned earlier, the goal of systemic chemotherapy is to interrupt the division of rapidly dividing cancer cells. It is usually administered in multiple (usually 4 to 6) cycles every 3 to 4 weeks. The timing and dosing of chemotherapy are established to maximize malignant cell kill while at the same time not exceeding the body’s ability to regenerate the normally rapidly dividing cells that are “innocent bystanders” of the cytotoxic effects of chemotherapy, namely, the bone marrow progenitors, gastrointestinal epithelial cells, and hair follicles. The predominant effect of chemotherapy on the intestinal tract occurs in the first few days to a week after administration, whereas the peak effect on the blood progenitor cells occurs 10 to 14 days posttherapy. Thus, patients only require prophylactic antiemetics for the days around therapy, but they “nadir” their blood counts, with variable risks of
infection and bleeding, approximately 2 weeks after receiving treatment. Regardless of the setting of administration (primary, adjuvant, neoadjuvant, or combined modality), substantial evidence suggests that combination chemotherapy with agents that have different mechanisms of action as well as different (noncumulative) toxicities yields significantly higher efficacy than single-agent chemotherapy. On the basis of an extensive review of in vivo and in vitro laboratory research and clinical experiences acquired during the 1950s and 1960s, DeVita and Schein\textsuperscript{187} developed a set of basic principles of combination chemotherapy for cancer patients, and these are still the guiding principles today. Among the most important of these principles are the following: (1) All of the component drugs in a combination must have activity against the neoplasm being treated; (2) drugs must be administered at dosages close to the minimum effective dosage for each drug as a single agent or beyond, if possible; (3) drugs that interrupt the synthesis of cellular macromolecules at several sites can be combined for additive or synergistic effects on the various synthetic pathways; (4) drugs in combination should have as little cross-toxicity as possible; and (5) mechanisms of tumor cell resistance to two agents in combination must not be similar.

Since 2006, the U.S. Food and Drug Administration (FDA) has approved more than 110 new cancer drugs. Advances in therapeutic regimens include a reduction in the risk of breast cancer recurrence with more prolonged hormonal therapy and a regimen that significantly extends survival in recurrent ovarian cancer. Other strategies have focused on reducing adverse effects from cancer therapy without compromising cancer control. Among these are shortening the duration of adjuvant chemotherapy for stage III colorectal cancer. With improvements in cancer therapy, a 25% decline in cancer death rate has been achieved since its peak in 1991.\textsuperscript{188–190} For all tumor sites, a high prevalence of moderate to severe symptoms was experienced by 120,745 cancer patients during the first year after cancer diagnosis. In the 729,861 symptom surveys conducted between 2007 and 2014 in patients who survived at least 1 full year after cancer diagnosis, the most symptoms were documented in the first month, whereas elevated scores for nausea persisted up to 6 months after
diagnosis. On multivariable analysis, cancer site, younger age, higher comorbidities, female gender, lower income, and urban residence were significantly associated with a higher symptom burden. Consistent with other studies, greater symptom burden occurred in patients with respiratory and oropharyngeal cancers. Younger patients have a greater likelihood of receiving more aggressive therapies, an increased prevalence of advanced-stage cancers, and/or higher expectations for functioning and the resumption of their roles prior to the cancer diagnosis.  

Also in the first year after diagnosis, a 71% hospitalization rate was documented for 25,032 patients who were treated for advanced cancer between 2009 and 2012. Hospital admission was prompted through the emergency department in 64% of cases, and 16% of patients were hospitalized three or more times during the first year after cancer diagnosis. Readmission rates were significantly associated with minority status (race/ethnicity); public or no insurance; lower socioeconomic status; comorbidities; and pancreatic, non–small-cell lung, or colorectal cancers.

The goal of personalized medicine is to have systemic therapies selectively target tumor cells located in any site while sparing normal tissues/ organs from the toxicity of antineoplastic therapy. Significant advances have been accomplished in systemic therapies within the realm of precision medicine. These advances have resulted in two out of three cancer patients living at least 5 years after diagnosis, and an increased 10-year cancer survival rates to 64% in 2005 from 35% in 1975. From November 2016 through October 2017, the FDA approved 31 new therapies for more than 16 types of cancer. Adoptive cell immunotherapy allows genetic reprogramming of a patient’s own immune cells to find and attack cancer cells throughout the body. Chimeric antigen receptor (CAR) T-cell therapy has resulted in significant advances in pediatric acute lymphoblastic leukemia (ALL), and adult lymphoma and multiple myeloma.

The FDA approved the first adoptive cell immunotherapy in August 2017 for ALL. In May 2016, the FDA gave accelerated approval to a second CAR T-cell therapy, an immune checkpoint inhibitor for previously treated urothelial cancer that progressed despite platinum-based
Throughout 2017, the FDA approved four other immune checkpoint inhibitors. One checkpoint inhibitor, pembrolizumab, resulted in a 3-month survival improvement while the adverse effects were three times lower for pembrolizumab than the chemotherapy group (15% vs. 49%) in a major clinical trial. Based on these results, especially because two-thirds of patients are not eligible for cisplatin-based chemotherapy due to physical frailty, immunotherapy is now being considered as an initial treatment for advanced bladder cancer. In October 2017, an immune checkpoint inhibitor became the first cancer treatment to receive a tumor-agnostic indication. This accelerated FDA approval allows treatment of any type of solid tumor that has mismatch repair deficiency a defect that undermines the cell’s ability to repair DNA damage. Biomarkers ideally should temper the socioeconomic cost for administration of checkpoint inhibitors and other adoptive cell immunotherapies. Tumors with a large number of mutations are generally more susceptible to checkpoint inhibitors as mutations make more abnormal proteins (antigens) that the immune system recognizes as foreign.

Although more traditional systemic therapies continue to be routinely administered, advances continue within personalized medicine. More traditional chemotherapy administered for palliative effect is then displaced by a novel agent that not only may be less toxic but also offers hope to reverse the course of disease from palliative back to curative intent. The two issues that exist in palliative chemotherapy involve whether a meaningful improvement in quality and the length of life can be achieved and the socioeconomic cost.

Breakthrough designated cancer drugs receive faster FDA approval. Between 2012 and 2017, the FDA approved 58 new cancer drugs; 25 (43%) of these drugs were approved through breakthrough therapy designation. Breakthrough therapy-designated drugs were not more likely to act via a novel mechanism of action. The median time to first FDA approval was 5.2 years for breakthrough designation versus 7.1 years for the routine approval process. Rates of death and serious adverse events were also similar in FDA approval through breakthrough designation and routine process. Additionally, no statistically significant difference in median progression free survival was found between drugs approved
through the routine and the breakthrough designation (4 months vs. 8.6 months; \( P = .11 \)).

The issues of survival and quality of life will be borne out of expanded clinical experience with these novel agents. Although greater clinical experience may better define the indications for the agent, the same unwillingness to abandon hope for a cure will invariably be encountered. As was the experience when novel chemotherapeutic agents became available, patients would seek the hope offered by a newer chemotherapeutic regimen. The American Society of Clinical Oncology Value Framework and the European Society of Medical Oncology Magnitude of Clinical Benefit Scale evaluated the clinical benefits of novel anticancer drugs relative to increasing costs. Anticancer drugs from 42 phase III randomized controlled trials cited for clinical efficacy evidence in drug approvals between January 2006 and December 2015 were scored according to this value framework. Both monthly prices and incremental anticancer drug costs increased and were significantly associated with the year of approval, 9% and 21%, respectively. The mean incremental anticancer drug cost increased fivefold from $30,447 in 2006 to $161,141 in 2015; however, the clinical benefits of these drugs did not correlate with a proportional positive change.

There are many factors responsible for the limited efficacy of chemotherapy in these tumors. First, the cellular biology of these solid tumors that often produce pain is such that they have limited response to current drug regimens. Second, the size of the tumor is inversely related to the incidence of satisfactory drug penetration into the mass. As a general principle, the larger the mass, the poorer the cytotoxic response. Furthermore, given that these tumors generally do not exhibit long-term responses to first-line therapy, additional therapy with second- or third-line drug treatments often yields a minimal (usually less than primary therapy) response rate. Finally, in certain target sites (e.g., head and neck, pelvis), prior radical surgery and/or prior radiation therapy impair the vascular supply to the tumor bed, thus interfering with delivery of an effective drug concentration to the target site.

Because this group represents the most challenging to demonstrate objective response rates to chemotherapy, it is the ideal patient population
in which to demonstrate a purely palliative benefit of chemotherapy, represented by decreases in pain, dyspnea, and fatigue and increases in performance status, appetite, and weight gain. A few investigators have pursued these outcome measures with meaningful results. The initial FDA approval of gemcitabine was granted not by data showing its benefits on overall survival or objective response rate, but by improvements in pain control, weight gain, and performance status in patients with pancreatic cancer.

**CLINICAL APPLICATIONS**

Conventionally, efficacy of chemotherapy is defined by an objective decrease in the radiographic size of the tumor (usually by CT). A CR represents total disappearance of all observable disease for a minimum of 1 to 3 months, depending on the criteria used, whereas a PR represents a decrease in measurable tumor size by at least 50%. Overall response rate for a given regimen is the combination of CR + PR, and a significant response rate translates into an improved survival of responders compared with nonresponders. It also translates into relief of pain related to the tumor mass—although pain relief from chemotherapy has rarely been the endpoint of clinical trials.

**PALLIATIVE CHEMOTHERAPY**

The category that falls between an objective response and progressive disease, in which the tumor neither shrinks nor grows in the face of active anticancer therapy, is referred to as stable disease. Whether or not there is any pain-relieving benefit to the administration of chemotherapy in the setting of stable disease is undetermined. Although there is speculation about the role of chemotherapy in altering peripheral sensory nerve function, thereby producing analgesia as well as relieving pain by altering the “tumor-host milieu,” these hypotheses have been tested in limited trials. In the absence of empirically proven outcomes, clinical observations suggest that “systemically administered cytotoxic drugs do not relieve cancer pain in the absence of tumor regression.” Tumor regression is a function of responsiveness to a given chemotherapeutic regimen. Tumor variables that determine the course of chemotherapy and
prognosis for response rate include histologic type (squamous cell carcinoma, adenocarcinoma, germ cell, lymphoma, etc.), grade (high, intermediate, low), and the degree of differentiation (well differentiated, poorly differentiated).

In general, the more rapidly growing the tumor, the more frequent its cellular division; therefore, the cells are more potentially responsive to cytotoxic therapy: In these cases, intervention can lead to increased pain control, long-term survival, and, potentially, cure. Those rapidly growing tumors that are chemotherapy-resistant tend to be imminently fatal.

**LYMPHOMA**

Compared with other solid tumor types, Hodgkin and non-Hodgkin lymphomas (NHLs) tend to respond better than most to combination chemotherapy. For Hodgkin lymphoma, there are several active regimens, but the preferred treatment regimen of doxorubicin, bleomycin, vinblastine, and dacarbazine is highly active and produces a complete remission rate that varies from 98% for early-stage disease (overall survival of more than 93% at 6 years) to 82% for advanced stage disease (overall survival of 73% at 6 years). The therapeutic effect of this combination regimen is rapid, even in advanced cases, providing prompt pain relief in those patients who have pain (although this has never been a primary endpoint of clinical trials), with observed resolution of other symptoms and signs as well. In NHL, there is a larger variability based on histology, with high-grade NHL being significantly more responsive to therapy than low-grade types. For high-grade NHL, treatment with a variety of combination chemotherapy regimens (e.g., bleomycin, doxorubicin, cyclophosphamide, vincristine, and prednisone; cyclophosphamide, doxorubicin, vincristine, and prednisone; or others with antibody therapies with rituximab) produces a 79% event-free survival. Again, no studies of NHL have examined pain as a primary endpoint, although pain remits in concert with active disease.

**BREAST CANCER**

In moderately chemosensitive tumors, the results obtained with the various chemotherapeutic combinations are less favorable (30% to 60% response
rates), and in general, the therapeutic effect is slower in onset. Small-cell lung cancer, for example, tends to be quite aggressive, and combination chemotherapy regimens with cisplatin and etoposide or cyclophosphamide, doxorubicin, and vincristine can induce an objective response in approximately 60% of cases, with CR occurring in approximately 10%. Again, this and other studies have not attempted to quantify relief from pain or dyspnea in small-cell lung cancer.

The course of recurrent or metastatic breast cancer follows two dominant pathways. The hormone receptor–positive tumors tend to occur in older (postmenopausal) women and follow a more indolent course when treated with hormone therapy, with bone as the most common metastatic site. The hormone receptor–negative tumors tend to occur in younger (premenopausal) women and follow a more aggressive course, with visceral and soft tissue involvement that is usually responsive to chemotherapy. Conventional chemotherapy includes cyclophosphamide, methotrexate, and prednisone and has been shown to improve quality of life. Anthracycline-containing regimens have been shown to be superior to cyclophosphamide, methotrexate, and prednisone. Single agents that contain taxanes (docetaxel, paclitaxel, and protein-bound paclitaxel), capecitabine, gemcitabine, or vinorelbine have been shown to be as effective in improving survival and quality of life as combination chemotherapy in metastatic breast cancer.\textsuperscript{204–206} Trastuzumab, alone or in combination in human epidermal growth factor receptor 2 (HER2)/neu–positive patients, has been shown to increase survival. Yet again, it is noteworthy that given the prevalence of recurrent breast cancer, few studies have specifically addressed quality-of-life issues and that even fewer address symptomatic benefits of therapy.

A British study evaluating patients with advanced breast cancer who received first-line palliative chemotherapy (a variety of regimens) did have primary palliative (subjective patient-centered) outcomes that were assessed by using the Rotterdam Symptom Checklist. In this study, one-fourth of the patients (26%) felt better after having received chemotherapy, with statistically significant decreases in psychological distress, pain, and improvement in lack of energy and sense of tiredness. As might be expected, feeling better correlated with disease response (P = .03).\textsuperscript{206} 2493
HEAD AND NECK CANCER
Head and neck cancer is one of the most challenging disease sites to treat. Cisplatin and 5-fluorouracil (5-FU) make the tumor more responsive to radiotherapy, and this is the standard accepted multimodal regimen that has been shown to increase survival. In fact, studies have shown that combination chemotherapy with cisplatin and 5-FU, hydroxyurea and 5-FU, and taxanes like paclitaxel and cisplatin followed by radiation have all increased survival by 50% to 60%.207,208 Chemotherapy with a single agent like cisplatin or carboplatin followed by radiation is also being investigated.209 These aggressive regimens have potential toxicities and twice-a-day radiotherapy with concomitant chemotherapy have shown improved regional control, survival, and improved quality of life.210

OVARIAN CANCER
Finally, ovarian cancer is one of the more sensitive malignancies to cytotoxic chemotherapy. Combination regimens in which a platinum-based agent (cisplatin or carboplatin) is used achieve overall response rates of 60% to 80%. Newer agents, most notably the taxanes, also have significant activity in ovarian cancer, with overall response rates of 20% to 40%. The combination of carboplatin and paclitaxel has demonstrated superior response rates and has become the standard of care for ovarian cancer amenable to chemotherapy.211–212 Doyle et al.213 showed that although objective responses are low with palliative chemotherapy, active palliation with chemotherapy is associated with substantive improvement in patients’ emotional function and global quality of life. In 2016, the FDA approved a regimen of bevacizumab to standard platinum-based chemotherapy when the addition of bevacizumab significantly extended median time to progression of disease to 13.8 months from 10.4 months with chemotherapy alone. Although not statistically significant, overall survival was also longer with bevacizumab being 42 months versus 37 months, respectively. Severe adverse effects occurred in 96% of bevacizumab compared to 86% of the chemotherapy-alone group.188–190 The FDA approved a maintenance treatment in 2017 for ovarian cancer based on a clinical trial in which olaparib, a poly (adenosine diphosphate [ADP]-ribose) polymerase (PARP) inhibitor,
markedly slowed ovarian cancer progression of disease (19.1 months vs. 5.1 months).

**LUNG CANCER**
Non–small-cell lung cancer is the most prevalent cancer type, and combinations of chemotherapeutic drugs like vinorelbine, gemcitabine, docetaxel, and paclitaxel provide modest survival and probable quality-of-life benefit in a significant number of patients when contrasted with best supportive care.\(^{214–217}\) These agents show response rates in the 11% to 25% range when combined with platinum-based therapy. No study has examined the effects of therapy on pain or dyspnea, although a few have evaluated improvements in performance status and weight gain.\(^{217}\) However, oral topotecan has been shown to improve pain, dyspnea, sleep, and fatigue, as well as increased survival, in patients with recurrent small-cell lung cancer compared with best supportive care. Even when early palliative care is performed, patients with metastatic non–small-cell lung cancer receive similar number of chemotherapy regimens. The early palliative care group, however, had half the odds of receiving chemotherapy within 60 days of death. There was also a longer interval between the last dose of intravenous chemotherapy and death in the early palliative care group (median 64 days vs. 40.5 days) and a higher hospice care enrollments for more than 1 week (60% vs. 33.3%; \(P = .004\)).\(^{218}\)

**GASTROINTESTINAL CANCERS**
For gastrointestinal malignancies, the role of palliative chemotherapy is limited. The fluoropyrimidines (5-FU and its derivatives) are the conventional agents with demonstrated efficacy in gastrointestinal malignancies. 5-FU has resulted in disappointingly low response rates of approximately 20%.\(^{219}\) In a large study of more than 400 patients conducted by the North Central Cancer Treatment Group,\(^{220}\) 70% of patients who received 5-FU/low-dose leucovorin had improvements in performance status and weight gain; there was no assessment of pain as a primary endpoint. The combination of 5-FU and leucovorin with agents like oxaliplatin (FOLFOX) and irinotecan (FLOFIRI) have shown improvement in quality of life.\(^{219–223}\)
In pancreatic cancer, the approval of gemcitabine for pancreatic cancer was based on the palliative endpoint of “clinical benefit” over the conventional 5-FU therapy. In this study, clinical benefit was defined by a composite of pain, performance status, and weight gain. This was one of the first studies to directly assess the primary endpoint of pain via patient report of pain intensity together with analgesic consumption. Several recent systematic reviews have shown that gemcitabine-based combinations have shown improved survival as well as quality of life.

PROSTATE CANCER
Prostate cancer is yet another prevalent disease that is poorly responsive to conventional chemotherapy. There is more palliative endpoint evidence supporting the use of chemotherapy in prostate cancer than any other disease in part because it is a slow-growing tumor that tends to cause significant pain and disability for a prolonged period of time. The most widely discussed study is Tannock’s Canadian study that used mitoxantrone and prednisone for hormone-refractory metastatic prostate cancer where the primary endpoint was pain relief. In this study, pain relief was again defined differently from previous studies as a “2-point decrease in pain as assessed by a six-point pain scale . . . without an increase in analgesic medication and maintained for two consecutive evaluations at least 3 weeks apart.” They found that this chemotherapy combination produced a positive effect above the benefit of prednisone alone in 29% of patients, with a 50% decrease in analgesic requirements. Other studies suggest the positive impact of docetaxel-based chemotherapy in providing relief of pain in hormone-refractory metastatic prostate cancer. Androgen deprivation therapy (ADT) for metastatic prostate cancer plus docetaxel or abiraterone in newly diagnosed metastatic noncastrate prostate cancer offers a survival benefit as compared to ADT alone. The strongest evidence of benefit for docetaxel was for men with de novo metastatic disease or high-volume disease (defined as four or more bone metastases, one of more of which were outside the spine or pelvis and/or the presence of any visceral disease).
DECISION MAKING ABOUT CHEMOTHERAPY

The diagnosis of cancer is often quite traumatic for both the patient and the family. On the one hand, the administration of chemotherapy is, by definition, cytotoxic—to malignant cells as well as normal host cells. On the other hand, the risks of not treating the disease are also quite significant. Given the fact that pain is a prevalent feature of both early- and advanced-stage cancer—present in nearly 50% of patients with early-stage disease and in 70% to 90% of cases of advanced cancer—the challenge is to strike a balance between therapeutic and toxic (including fatal) effects of chemotherapy. Thus, it is imperative that an interdisciplinary team of clinicians with expertise in oncologic surgery, radiation therapy and medical oncology, nursing, palliative medicine, and pharmacology evaluate patients to determine the treatment plan that is likely to provide the greatest cumulative benefit for the patient. If, as ought to be the ideal, the patient is always to be kept at the center of the decision-making process, then studies that assess patient-centered outcomes (pain, dyspnea, fatigue, appetite, weight loss, performance status, anxiety, well-being, and other quality-of-life measures) for chemotherapy merit a higher priority. Newer targeted therapies need to be evaluated for benefits related to reduction of symptom burden from neoplastic disease. Although it is generally accepted that patients with a poor performance status do not usually benefit from systemic chemotherapy, it is not known whether the response to newer targeted agents will shift this paradigm.

An additional challenge for the medical oncologist is decision making if first-line chemotherapy fails to control the tumor. For some disease types, there is clear objective benefit from second-line therapy. For many, however, second-line therapy is more likely to lead to enhanced cumulative toxicities rather than objective tumor response.

Oncology patients have among the highest rates of hospitalization, especially near the end of life. Changes in reimbursement policies result in losses to hospital systems with unplanned readmissions within 60 days of hospital discharge. In one cancer institute, 6% of all discharged patients accounted for more than 40% of unplanned readmissions. The use of hospital resources included ICU stay, emergency department visits, overuse of chemotherapy, and under use of hospice care. Instituting an
interdisciplinary care team (ICT) was created to evaluate patients, on a bimonthly basis, with at least two unplanned hospital readmissions over the last 60 days. Over a 6-month period, 36 patients had 226 hospitalizations and 163 emergency department visits, resulting in an average number of hospitalizations of 1.08 per patient month (ppm); hospitalizations dropped to 0.23 ppm after implementation of the ICT. After the creation of the ICT, the average length of stay decreased from 7.17 to 4.06 days per admission, the average emergency department visits decreased from 0.58 to 0.34 ppm, and the average number of unplanned readmissions decreased from 0.43 to 0.13 ppm. Average time to death was 72 days, and time to death from the last exposure to chemotherapy was 58 days after institution of the ICT. Financial incentives for hospital systems have made a major impact on the aggressiveness of care at the end of life.\(^{230}\)

A retrospective analysis of the hospital stay, lasting at least 3 days, was conducted in 695 adult cancer patients who died in the hospital. Prior to hospital admission, 21% had received outpatient palliative care (OPC), 46% inpatient palliative care (IPC), and 33% no palliative care (NPC). Despite the differences in the care prior to hospital admission, no differences were identified in the care administered during the final admission; 11.2% of patients received radiation therapy, and 12.5% received antineoplastic therapy. In the last 3 days of life, imaging tests occurred in 50.1% patients; imaging tests were obtained in fewer palliative care patients (43.5% OPC; 47.3% IPC) than the 58.1% who received NPC. Radiation therapy was administered in 11.2%, and approximately 16% of all patients received chemotherapy within 14 days of death among the study groups. All patients received pain medications. Do-not-resuscitate orders were in place within 6 months before the final admission at a greater rate for OPC patients (22%) than for IPC (8%) and those with NPC (12%).\(^ {231}\)

A sensitive and thoughtful discussion with the patient and the family regarding the goals and priorities of care is needed. Emphasis must be placed on the ability to successfully manage the symptoms of progressive advanced disease with nonchemotherapeutic modalities when burdens are likely to outweigh benefits.
SIDE EFFECTS AND COMPLICATIONS
The toxicities and side effects of chemotherapeutic agents, such as nausea, are commonly known. Perhaps the most common painful sequela of chemotherapy administration is a toxic peripheral neuropathy manifested as painful paresthesias, hyporeflexia, and, less frequently, sensory or motor loss or autonomic dysfunction. The drugs most commonly associated with this complication are the plant alkaloids, especially vincristine; antimetabolites; the taxanes, especially paclitaxel; and platinum-based compounds like cisplatin; vinorelbine, procarbazine, and interferon. In some cases, the painful peripheral neuropathy not only limits the dosing of anticancer therapy but also significantly affects quality of life and can be more difficult to treat than the more common nociceptive pain syndromes associated with the disease.

Dermatologic complications can occur from extravasation of chemotherapeutic agents into the subcutaneous tissues. This is especially problematic with drugs like vinca alkaloids, anthracyclines, and taxanes that cause severe local pain and ulceration with progressive tissue destruction.

Another painful complication of cancer and its therapy is acute herpes zoster and postherpetic neuralgia, which occur with increased frequency in patients with cancer—especially in those receiving chemotherapy or immunosuppressive drugs. Lastly, although the palliative benefits of glucocorticoids on mood, pain (as an anti-inflammatory coanalgesic), and appetite are well-known, chronic steroid therapy can cause myopathy, as well as necrosis of the femoral and humeral heads. Furthermore, one should be aware of the fact that withdrawal of glucocorticoids can cause a sense of decreased well-being, with increased pain, decreased energy, and apathy.

Endocrine Therapy
Many types of tumors have been shown to respond to hormonal manipulation, which is achieved either by ablating endocrine glands or by administration of an exogenous hormone or hormone antagonist. The mechanism of action of these agents has been clarified by the
demonstration that receptors that bind with estrogen exist in the cytosol of normal and malignant cells. Hormones bind to receptors in the cytoplasm and sterically alter the shape of the receptive protein itself, which, after transport to the cell nucleus, interacts with DNA, and results in altered messenger RNA production and protein synthesis. After this interaction, cytoplasmic receptor concentration is restored and the cycle can be repeated. Estrogen receptors can be quantitated as 8S and 4S proteins. Primary tumors in humans have estrogen receptor values that range from 0 to almost 1,000 fmol/mg cytosol protein. Receptors also exist for progesterones and androgens, and receptors for corticosteroids have been identified in the cytosol of leukemic cells.

Hormonal ablation can be achieved by surgical means, as occurs with oophorectomy, adrenalectomy, and hypophysectomy; by irradiation of the ovaries or ablating the pituitary gland with the various radioactive compounds; by injecting alcohol; or by surgical extirpation. Medical adrenalectomy can be achieved by administering aminogluthethimide, a potent inhibitor of the conversion of cholesterol to pregnenolone in the adrenal gland. Hormone additive therapy is achieved by the administration of estrogens, progestins, androgens, antiestrogens, corticosteroids, and thyroid hormones. Such hormone changes can cause complex endocrine effects, such as pituitary inhibition of luteinizing hormone, follicle-stimulating hormone, and prolactin, as well as changes in endogenous steroid hormone production.\textsuperscript{199}

**ENDOCRINE THERAPY FOR RELIEF OF CANCER PAIN**

The first reports of the efficacy of hormonal therapy on relieving cancer pain were correlated with tumor regression. A significant number of other studies only reported the reduction in tumor volume without also assessing pain relief.

Two large clinical trials were conducted in 2016 in hormone receptor–positive early breast cancer patients with the aromatase inhibitor letrozole. Compared to the recommended standard length of therapy was 5 years, the clinical trials found that 10 years of letrozole reduced breast cancer recurrences or a new cancer in the opposite breast by one-third. Despite
these improvements in outcomes, longer hormonal therapy did not improve overall or disease-free survival in these trials. In 2017, the 5-year disease-free survival was improved to 83% when anastrozole was prescribed for 6 years after tamoxifen therapy.188–190

Bisphosphonates

Bisphosphonates have significantly reduced skeletal-related events (SREs) such as pathologic fracture, spinal cord compression, or the necessity of radiation or surgery to reduce the morbidity of bone metastases. Zoledronic acid (ZA), a third-generation aminobisphosphonate, reduces the risk of SREs by 40%; after an initial 9 to 12 monthly doses, ZA is then administered every 3 months. Denosumab, a human monoclonal antibody that inhibits osteoclasts by binding to the receptor activator of kappa B ligand, delays the onset of first and subsequent SREs more than ZA.236

The American Society of Clinical Oncology and Cancer Care Ontario guidelines indicate that breast cancer patients with bone metastases should be treated with bone modifying agents. Options include denosumab (120 mg subcutaneously every 4 weeks), pamidronate (90 mg intravenously every 3 to 4 weeks), or ZA (4 mg intravenously every 12 weeks or every 3 to 4 weeks). These agents are most effective in reducing the incidence of SRE and should not be used alone for bone pain.237

Summary

Sophisticated local and novel systemic therapeutic approaches are being developed to better localize or personalize treatment. In palliative radiotherapy, SRT (and to a lesser degree proton therapy) localizes radiation to the tumor, often allowing for repeat radiation near critical structures like the spinal cord. Novel systemic therapeutic approaches include adoptive cell immunotherapy. Using few high-dose radiation fractions, SRT is an accepted tool in palliative radiation therapy for specific indications, and single-fraction radiation therapy is now an accepted alternative to longer courses of palliative radiation. Although a sophisticated radiation technique is used to address a difficult clinical presentation, the palliative goals remain aligned. In contrast, novel
systemic therapies, like adoptive cell immunotherapy, continue to provide hope for curative intent even in advanced disease. Although the therapeutic mechanisms of adoptive cell immunotherapy are novel, the paradigm of curative intent for the patient, despite advanced disease, remains unchanged. Furthermore, these therapeutic innovations have substantial socioeconomic costs.

Despite the development of palliative care teams that become involved early in the course of cancer care, much futile therapy continues to be administered. Palliative care teams have had some success in reducing chemotherapy administration in the last 14 days of life, increasing hospice placement, and reducing hospital admissions and readmissions in the last 60 days of life. However, palliative care teams are not available within all health systems, and decisions regarding antineoplastic therapy remain largely unchanged.

Therapeutic decisions for cancer care become more difficult as the stage of cancer advances. These therapeutic decisions are largely based on the patient’s preferences and performance status, availability of novel therapies, and the availability of supportive care.

Overview of Childhood Cancer

EPIDEMIOLOGY

Worldwide, cancer is diagnosed in approximately 300,000 children under age 20 years each year, and childhood cancer contributes to 80,000 deaths per year. In the United States, almost 16,000 cases of cancer are diagnosed each year in children aged birth to 19 years, contributing to almost 2,000 deaths per year. As recently as the 1970s, a diagnosis of cancer during childhood was considered a uniformly fatal disease. However, through enrollment in clinical trials available through cooperative pediatric oncology groups, as well as advances in supportive care, 5-year overall survival rates in childhood cancer are now over 80% in the United States. The 12 major diagnostic categories of childhood cancer in The International Classification of Childhood Cancers, third edition (ICCC-3) include (1) leukemias and myeloproliferative and myelodysplastic diseases, (2) lymphomas, (3) central nervous system (CNS) neoplasms, (4) neuroblastoma and other peripheral nervous cell tumors, (5) retinoblastoma, (6) renal tumors, (7) hepatic tumors, (8) malignant bone tumors, (9) soft tissue and other extraosseous sarcomas (e.g., rhabdomyosarcoma), (10) germ cell tumors, (11) other malignant epithelial neoplasms and malignant melanomas (e.g., thyroid and nasopharyngeal carcinomas), and (12) other unspecified malignant neoplasms. Certain types of cancer are more common in specific age groups of children. For example, acute leukemias, neuroblastoma, and renal tumors are more common in the younger age groups (ages 2 to 6 years), whereas the malignant bone tumors and lymphomas are more common during the adolescent years.
TREATMENT
The dramatic improvements in overall survival in childhood cancer are due to better supportive care and use of aggressive, multimodal treatment strategies combining chemotherapy, radiation, surgery, and/or hematopoietic stem cell transplant (HSCT). In addition, protein kinase inhibitors, monoclonal antibodies, and other targeted therapies have become part of standard therapy in some diseases. Because the majority of pediatric cancer centers are participants in cooperative group clinical trials, children with cancer are often treated uniformly through the use of internationally available, standardized treatment protocols. There are “roadmaps” that are followed by the treating pediatric oncologists and communicated to the family and patient so that they know when to expect the next cycle of chemotherapy, including when the next invasive procedure can be anticipated to occur. As a result, there may be certain periods of higher anxiety, resulting in greater pain for pediatric cancer patients during the cancer treatment continuum as they anticipate the upcoming procedures. However, with careful planning, an effective pain management regimen can be developed and implemented.

SURVIVORSHIP
The end result of these aggressive treatment regimens for pediatric cancer patients is a success story for the 21st century. The current estimated survival rate for a pediatric cancer patient is 80%. The current number of survivors within the United States is over 370,000. However, despite these advances, there continues to be a high risk for the development of chronic health conditions (late effects) years after the cancer treatment is completed. Complications of treatment include risk for second malignant neoplasms, cardiac and/or pulmonary dysfunction, skeletal problems, and neurocognitive deficits. There is nearly a 75% risk of childhood cancer patients having a chronic health problem by 30 years postdiagnosis. As the population of childhood cancer survivors continues to grow, it is important to be familiar with the unique challenges faced both during and after completion of treatment for cancer during childhood.

Pain in Children: How Does This Differ from That in
Adults?
The model of pain for the adult population is a comprehensive one consisting not only of a physical domain but also psychological and social domains—the biopsychosocial model. In children, the biopsychosocial model of pain is more complex because the developmental level of the child needs to be considered. Childhood is a period in which there are complex and rapid neurodevelopmental changes occurring from birth to young adulthood. Children grow and develop through five stages of development: (1) infancy, (2) toddlerhood, (3) preschool period, (4) school-age period, and (5) adolescence. These levels of development are important because they directly impact the assessment and management of pain in children. For example, it was previously believed that newborns and infants could not experience pain because of immature neurologic systems and only as the child developed could pain be experienced. However, ongoing basic research has dispelled this myth, and newborns and infants can experience pain and mount a stress response to noxious stimuli. Furthermore, a noxious stimulus transmitted through neural afferent systems to a newborn brain may even be experienced as more painful than for an adult because the pain inhibitory system is not fully developed at birth.

INFANTS–PRESCHOOL
From birth through early childhood, a normal developmental assessment evaluates five main areas: gross motor skills, fine motor skills, language skills, personal/social skills, and cognitive skills. Changes occurring in these areas impact the pain assessment and emotional response of the child to the painful stimuli. For example, the language skills of a 2-year-old include a 50-word vocabulary and 2-word sentences. During this period, if the child is unable to effectively communicate his or her pain sensation and his or her pain is inadequately treated, there can be more fear and anxiety with each subsequent painful procedure. One year later, at 3 years of age, there is an expected 250-word vocabulary, 3-word sentences, and speech is intelligible to strangers 75% of the time. This child may be able to more effectively communicate with his or her parents and doctors and have a treatment for the pain initiated more promptly, a factor related to
these enhanced communication skills that can serve to decrease anxiety for future procedures.

**SCHOOL AGE–ADOLESCENCE**

A school-age child will have a progressive ability to effectively communicate with the health care team. In turn, the providers must clearly communicate with the child about their treatment plan in order to minimize the anxiety children can experience from medical interventions. During adolescence, normal development of increasing desire for autonomy necessitates direct communication by the health care team, not only with parents but also directly with the adolescent based on the adolescent’s desire for independent decision making (when possible). However, in all levels of normal development, the impact of illness can cause a pediatric patient to regress and become more dependent on his or her parents to support physical and emotional needs, with parents often providing the primary input to the health care team about children’s pain and effectiveness of pain management. When possible, it is always helpful for the health care team to also attempt to get the child or adolescent’s self-report of pain.

**Pediatric Cancer Pain**

The vast majority of children with cancer do not have a chronic medical condition at the time of diagnosis and therefore have not experienced chronic or recurrent episodic pain. Instead, they have mainly interfaced with the health care system for well-child checks with the associated immunization schedules and for acute, intermittent self-limiting infections or minor injuries. Thus, it is not surprising that the diagnosis and rapid initiation of treatment of cancer can overwhelm a child with fear and anxiety because of the number of invasive, painful medical procedures that are required, but for which the child is not psychologically prepared. In addition, acute pain associated with the first medical procedure at the time of diagnosis can set expectations of pain to be experienced by the child for all future procedures. Studies have demonstrated that even posttraumatic stress symptoms can be experienced by childhood cancer survivors due to memory recall of invasive procedures during treatment and that these
painful memories continue beyond the treatment into the survivorship period.8

**EPIDEMIOLOGY OF PEDIATRIC CANCER PAIN**

Pain is a prevalent symptom accompanying pediatric cancer. Many patients (49% to 62%) with pediatric cancer have pain as a presenting symptom at diagnosis, with many of these patients having pain as the sole presenting symptom of their cancer.9–11 Pain is often present for several months prior to diagnosis.9 Using surveys during treatment, Miser et al.12 found nonprocedural pain was prevalent for 54% of inpatients and 26% of outpatients in a single center. A national study in Germany by Zernikow et al.13 found 15%, 28%, 50%, and 58% of patients diagnosed with cancer to be in pain at time of, within 24 hours, within 7 days, or within 28 days of interview, respectively. This is corroborated by Fortier et al.14 who used a daily diary to show that 53.3% of children diagnosed with cancer had chronic or recurrent pain, with 40% of children requiring at least one dose of analgesic over the 14-day study period. Pain is more prevalent in pediatric inpatients with cancer versus outpatients (84% vs. 35%) and most prevalent in children with solid tumors (63%) versus leukemia (44%), lymphoma (27%), or CNS tumors (50%).15

In contrast to findings in adults, pain in children undergoing treatment for cancer was predominantly caused by antineoplastic treatments and procedures, rather than from the disease itself.10,11,13,16–18 In one study, 49% of children stated that treatment-related pain was the most severe problem, followed by 38% of children for procedure-related pain, and finally 13% for disease-related pain.10 Disease-related pain generally becomes less prevalent over time.9,11,12 The difference in etiology between adult and pediatric cancer pain reflects differing cancer diagnoses and treatment strategies for adult and pediatric cancers. Although pediatric cancers are often rapidly proliferating mesenchymal tumors or leukemia and thus cause pain at diagnosis, many are also responsive to an aggressive combination of intravenous and intrathecal chemotherapeutic agents, surgery, and/or radiation, which all can lead to painful therapy-related pain. In contrast, adult cancers are often slow-growing epithelial tumors which are often treated with less aggressive therapies.13
Increased pain prevalence is reported for certain groups of patients. Among children with acute lymphoblastic leukemia (ALL), pain is reported by the majority of patients throughout the first year of treatment, improving somewhat over time.\textsuperscript{19,20} In children with progressive, recurrent, or nonresponsive cancer, pain prevalence is 49\%, rising to 62\% in the last 12 weeks of life. Furthermore, high-distress pain prevalence in the same group of children is 39\%, rising to 58\% in the last 12 weeks of life.\textsuperscript{21} By the last month of life, other studies show pain prevalence at 82\%, with about half of all patients suffering “a great deal” or “a lot” from the pain.\textsuperscript{22}

**UNDEPARTMENT AND IMPACT OF PEDIATRIC CANCER PAIN**

Undertreatment of pain continues to be a concern in pediatric cancer, both in the inpatient setting\textsuperscript{23–25} and in the outpatient and home settings.\textsuperscript{14,19} Pain in these settings continues to be common, underrecognized, and undertreated. At the end of life, treatment of pain is often unsuccessful.\textsuperscript{22}

Barriers to adequate pain control in pediatrics include lack of pain documentation and assessment\textsuperscript{18,25,26} and clinical staff reluctance to prescribe or administer analgesics\textsuperscript{25} whether because of fear of addiction\textsuperscript{27} or inadequate pain management knowledge.\textsuperscript{27,28} Some clinicians hold the mistaken belief that infants and children are less sensitive to pain.\textsuperscript{27} Physicians have been found to underestimate children’s pain as reported by the patient or the parent.\textsuperscript{29} Other common misconceptions include beliefs that a significant percentage of children overreport pain, that increases in morphine dose beyond a certain amount will not produce increased pain relief, and that respiratory depression is likely to happen in patients who have received opioids for months.\textsuperscript{30–32} Breakthrough pain, defined as episodes of medium to severe pain on a background of otherwise controlled pain, can occur suddenly. It can last seconds to minutes, often too fast for many “as-needed” medications to work effectively.\textsuperscript{23}

In the home setting, barriers to adequate analgesia may include caregiver misconceptions regarding children’s pain, fears of side effects of analgesic use, as well as avoidance of analgesic use.\textsuperscript{33,34} Two studies in
different cultural contexts have found that many parents reported believing that a child always tells his or her parent when he or she is in pain.\textsuperscript{32,35}

In adolescents, patient attitudes may also act as barriers to effective treatment of pain. Similarly to adults, adolescents are concerned about addiction, development of tolerance, and analgesic side effects as well as losing their ability to monitor health-related bodily changes. Some also hold the fatalistic belief that cancer pain is unavoidable. Some attitudes are more uniquely seen in this age group and stem from developmental needs for autonomy and control, including concerns about how reporting pain may lead to undesirable tests and restrictions in social activities. They are also concerned about not being involved in treatment decisions. Thus, active listening is important when reviewing adolescents’ pain symptoms.\textsuperscript{36,37}

Finally, system-based barriers exist, including limits to access to opioids and accessibility of pain and palliative care specialists, especially for pediatric populations and resource-poor areas.\textsuperscript{38–40}

Pain, especially from medical procedures, leads to fear and anxiety.\textsuperscript{41} Younger children receiving medications to control pain prior to a procedure experienced not only less pain with each procedure but also had consistently lower pain scores for subsequent medical procedures.\textsuperscript{42} Procedure-related pain contributes to posttraumatic stress symptoms in survivorship.\textsuperscript{43} Pain with moderate to severe distress was associated with a significant worsening in total health-related quality of life (HRQOL) scores as well as scores in specific domains related to physical, emotional, and school HRQOL.\textsuperscript{44} Adolescents with cancer, especially those experiencing severe pain, were significantly hindered in pursuing their personal goals, which are important to adolescent needs and their normal developmental trajectories.\textsuperscript{45}

### Evaluation of Pediatric Cancer Pain

Pain is a complex and subjective experience. Multiple components of the nervous system are involved in pain transmission, processing, and modulation, including sensory neurons, spinal cord, somatosensory cortex, prefrontal cortex, insula, and anterior cingulate cortex.\textsuperscript{46} This is mirrored
by the multidimensional nature of pain associated with cancer, where the cancer pain experience is affected by the complex interplay of biologic, psychological, and sociocultural domains of illness.\textsuperscript{47} For example, many children with oral mucositis experience mouth and throat pain. This results in severe emotional turmoil for the children, psychological distress for the parents, cognitive dilemmas balancing eating and pain, oral care and discomfort, and an increased need for distraction and psychological support.\textsuperscript{48} Thus, we advocate for a biopsychosocial approach to the evaluation of pain in children with cancer. In addition, because of the complexities of the physical, psychological, sociocultural, and spiritual contributors to pain in any one patient, a comprehensive pain evaluation is ideally accomplished by a holistic evaluation and discussion among a multidisciplinary team including a pediatric pain specialist, pediatric oncologist, bedside nurse, social worker, psychologist, chaplain, child life specialists, and other rehabilitative and expressive art therapists, with the patient and family unit at the center.

**HISTORY AND PHYSICAL EXAM**

The importance of eliciting and listening to all details of the pain narrative of the pediatric patient with cancer is critical. Again, what is asked of the child and expected of the child is dependent on his or her developmental level. For the school-age child or adolescent, the pain assessment should occur early on, where there is the support of family, and in a nonthreatening environment. At tertiary care centers that care for large numbers of pediatric cancer patients, child life services are available and can serve as another resource to help elucidate a clear description of the pain narrative. For the infant or toddler, the health care provider is dependent on the parents’ narratives of the painful experience because they are the source of safety and communication for the young child.

Across the entire developmental continuum of pediatrics, the physical examination, including close observation of the child and the family dynamic, is critical to provide additional information about physical factors that contribute to the experience of pain. During the history and physical examination, it is also critical for the clinician to recognize and identify psychosocial factors, such as parental fear or anxiety, which can
also increase the suffering associated with pain for the pediatric patient with cancer.

**SENSORY EXPERIENCE—SELF-REPORT**

The evaluation of pain often begins with assessment of its sensory experience. The PQRST method is a useful method of assessing the dimensions of the pain sensory experience in many children.\(^{49,50}\) PQRST includes asking about Palliating/provoking factors, Quality descriptors of the pain, Radiation of the pain to other parts of the body, Site/symptoms/severity of the pain, and Timing/triggers. Different characteristics may suggest neuropathic pain versus nociceptive pain and may help narrow down sources of pain or may suggest different treatment modalities.

The most commonly evaluated sensory dimension is pain intensity, and several one-dimensional self-report scales are available. The Pieces of Hurt/Poker Chip Tool,\(^{51}\) Oucher,\(^{52}\) Faces Pain Scale–Revised,\(^{53}\) and the Visual Analogue Scale\(^{54}\) have been extensively validated and have been recommended by several systematic reviews\(^{55–57}\) as the best measures for clinical practice and research. These tools have been validated for a wide range of pediatric age groups—Pieces of Hurt for 3 to 18 years, Oucher for 3 to 12 years, Faces Pain Scale–Revised for 4 to 16 years, and the Visual Analogue Scale for at least 7 years and older. For children 8 years and older, the 11-point numerical rating (0 to 10) is recommended, when possible.\(^{58}\) Specific one-dimensional self-report tools are also available for pain location\(^{59,60}\) and to describe the temporal dimension of pain.\(^{61}\)

**SENSORY EXPERIENCE—OBSERVATION**

Observing a patient’s behaviors can be useful when self-report is not available or unreliable. In young children, facial expressions, body posture, cries, and inconsolability are commonly associated with acute pain. Observations of physiologic indices such as heart rate, oxygen saturation, or sweating can also be useful in acute pain and are sometimes used in behavior scales for critically ill patients.

These observations are reflected in observational pain intensity scales which can be employed in lieu or in addition to self-report scales. Patients
whose pain might need to be measured with an observational (i.e., behavioral) scale might be too young (e.g., below 4 years of age); too distressed; impaired in their cognitive or communication abilities; very restricted by bandages, surgical tape, mechanical ventilation, or paralyzing drugs; or whose self-report ratings are considered to be exaggerated, minimized, or unrealistic due to cognitive, emotional, or situational factors. A systematic review by von Baeyer and Spagrud\textsuperscript{62} recommends two scales for brief pain events and procedural pain (Face, Legs, Arms, Cry, and Consolability [FLACC]\textsuperscript{63} and Children’s Hospital of Eastern Ontario Pain Scale [CHEOPS]\textsuperscript{64}), one scale for postoperative pain in the hospital (FLACC), one scale for postoperative pain at home (Parents’ Postoperative Pain Measure [PPPM]\textsuperscript{65}), and one scale for critical care and ventilator patients (COMFORT Scale\textsuperscript{66}).

However, many of these behaviors and observations normalize as the body adapts to persistent pain, and thus, different tools and observations may need to be utilized for persistent pain. Verbal expressions of pain continue to be an important indicator; however, lack of interest in surroundings, assuming pain-relieving postures, slowness and paucity of movement, and wariness at being moved become more prominent with persisting pain in young toddlers.\textsuperscript{62} Recently, an observational scale incorporating the aforementioned observations was developed and validated specifically for persistent cancer pain in 2- to 6-year-olds (Hétero Evaluation Douleur Enfant [HEDEN]).\textsuperscript{67}

In adolescents, nonverbal cues to persistent pain can be more subtle. In addition to decreased activity, adolescents with chronic pain have been described as exhibiting irritability and moodiness, social withdrawal, and sometimes uncooperativeness with treatments and medications, especially as a way to rebel and exert some bodily control when in pain.\textsuperscript{50}

**EMOTIONAL AND COGNITIVE EXPERIENCE**

It is important to include emotional (affective) and cognitive (evaluative) measures when assessing children for pain. Affective measures reflect the emotional experience of pain. Evaluative measures reflect the child’s ability to cope with his or her pain.

Toddlers with cancer who experience pain display specific pain
behaviors but can also display psychomotor inertia and anxiety behaviors. Anxiety behaviors include tenseness, hostility, crying easily, and wariness at being moved. On the opposite end of pain expression is withdrawal or psychomotor inertia. Behaviors that suggest this include resignation (lack of resistance), withdrawal, lack of expression, lack of interest in surroundings, and slowness and paucity of movement. This behavioral pattern is sometimes labeled “learned helplessness,” “passive coping behavior,” and “sickness behavior, such as fatigue and malaise.” These depressive symptoms can be confused with actual depression, both for the observer as well as for the patient but may improve once pain is addressed.

There are several multidimensional tools that bring together both questions about pain sensory experience as well as affective or evaluative measures. One of these, the Adolescent and Pediatric Pain Tool (APPT), itself derived from the McGill Pain Questionnaire, has been validated in children 8 years and over and has been used in several studies of children with cancer. It measures pain intensity, location, quality descriptors, temporal descriptors, and the evaluative and affective dimensions of pain. Affective words include words such as awful, frightening, and suffocating. Evaluative words include words such as uncontrollable, horrible, and annoying.

**FUNCTIONAL AND QUALITY OF LIFE ASSESSMENT**

Pain is but one of the symptoms that children experience while going through cancer. Fatigue, nausea/vomiting, poor appetite, and depression and anxiety are some of the most common, besides pain. Symptoms often cluster and contribute toward overall decreases in HRQOL. For example, pain in children with cancer can often lead to decreased functioning and quality of life. As physical activity or play activities can be exacerbated by pain from cancer, many patients instinctively avoid activities, a factor that leads to deconditioning and loss of function. This and the presence of pain itself can lead to depressive symptoms. Sleep is also intuitively affected by pain, leading to fatigue.

The National Institutes of Health (NIH)-sponsored Patient-Reported Outcomes Measurement Information System (PROMIS) initiative has
developed a pain interference tool, evaluating the presence of psychological, social, and physical dysfunction secondary to pain. The questionnaire asks patients if pain has hindered their function in regard to sleeping, attention, doing schoolwork, standing, walking, running, being happy, or being angry. Data from PROMIS shows strong positive correlations between pain interference and fatigue and pain interference and depressive symptoms and a strong negative correlation between pain interference and physical functioning-mobility. Symptom cluster analyses show that pain in adolescents with cancer often co-occurs in the same patients as fatigue, sleep disturbance, and depression or with nausea and vomiting. Another cluster analysis study using PROMIS data in children with cancer showed that patients with high pain interference scores are more likely to also have high anxiety, depression, and fatigue scores.

Based on these data, clinicians should assess the effect of the child’s pain on their function in several different domains, including physical functioning and health; mood, coping, and psychological well-being; social and family relationships; and fatigue and sleep.

PAST PAIN-DIRECTED THERAPIES
Treatments for pain along with patient pain relief, functional improvement, and adverse effects should be noted in initial and ongoing evaluations of the patient. Past pain treatments, especially when associated with less than optimal control of pain, should be critically evaluated for appropriate medication or modality, dosing, route of administration, and both beneficial and adverse effects on pain and function. Common reasons for pain treatment failure include intolerable adverse effects, too long of a dosing interval, too small of a dose, or inappropriate route of administration. In addition, not all pain treatments are equally effective for each patient, and thus, it is helpful to know the history of what has been attempted in the past.

CANCER HISTORY—DIAGNOSIS
Understanding the patient’s cancer diagnosis, extent of disease, treatments, and prognosis is crucial to understanding the nature of pain that a patient
with cancer might experience. Cancer, even in children, is a diverse set of diagnoses affecting almost any organ system or part of the body, and even each tumor type can present differently in each child. A cancer history for the pain clinician should start with understanding the patient’s initial presentation and diagnosis. Some patients present asymptptomatically, perhaps with a routine blood test, whereas some patients go for months or years with symptoms, often painful, while undergoing different blood tests, imaging studies, and even different surgical interventions before a diagnosis of cancer is finally made. Some patients carry congenital syndrome diagnoses or have undergone procedures, such as organ transplant, which predispose to the development of different cancers. Each of these situations brings a different set of pain experiences and pain expectations for patients undergoing cancer treatments and survivors.

The location and extent of neoplastic disease is an important consideration. Common solid tumor sites in children and adolescents include the brain and spinal cord, peripheral nervous system, abdominal organs (e.g., Wilms tumor, neuroblastoma, hepatoblastoma, germ cell tumors, some rhabdomyosarcomas), the genitourinary systems (testicular and ovarian germ cell tumors, rhabdomyosarcoma), the extremities (bone and soft tissue sarcomas, Langerhans cell histiocytosis), mediastinum (lymphomas, leukemia, teratoma), and the head and neck (rhabdomyosarcoma, lymphomas, retinoblastoma, neuroblastoma, Langerhans cell histiocytosis). By no means is this a comprehensive list, and other rare diagnoses have been known to present in any organ system.

Although some patients will have been diagnosed with a tumor which is localized to a specific organ or body part, other patients will have tumors which have locally extended to adjacent organs and body regions. Some common pediatric cancers are disseminated by nature, such as the leukemias and many lymphomas. These hematologic malignancies can involve not only bone marrow, lymph nodes, spleen, and mediastinum but also extramedullary sites such as the brain and CNS, testes, bones, and even skin. Other patients will have metastatic disease. Sites of metastasis vary for each diagnosis, but common sites of metastasis include adjacent lymph nodes, brain and CNS, lungs, liver, and bones. Each site of involvement can result in a potentially different set of pain symptoms for
the patient.

**CANCER HISTORY—TREATMENTS**

Treatments vary considerably depending on the cancer diagnosis, location, extent, and other factors and bring along with them their own sets of pain and symptom experiences for each patient. The most common treatment plans for cancer in children include chemotherapy, surgery, and radiation. Radiation therapy, including external beam radiation, brachytherapy, and radioisotope therapy, and surgical resection have been mainstays of treatment for various pediatric tumors. Chemotherapy, in common usage, is often defined as any drug which works through the inhibition of mitosis and cell division to induce tumor cell death. Chemotherapy is commonly given orally, intravenously, intramuscularly, or intrathecally depending on the agent and treatment regimen.

Other drugs have also become part of the cancer armamentarium but work in other ways. Hormonal therapies, which are more common in adult cancers such as breast and prostate cancer, are less often used in pediatric cancers. Targeted therapies including monoclonal antibodies, small molecule inhibitors, and other immunotherapy agents, which have largely been developed for adult tumors, are becoming more and more frequently used in pediatric cancers as well. In addition, autologous or allogeneic hematopoietic stem cell infusions, sourced from bone marrow (“bone marrow transplant”), peripheral blood, or umbilical cord blood, can be used in different ways to replace a diseased hematopoietic system, rescue it from high-dose chemotherapy, and/or induce an immune response to a tumor (e.g., graft-versus-leukemia effect). Cellular therapies such as chimeric antigen receptor–T cell therapy build on the concept of graft-versus-tumor effect and have recently gained U.S. Food and Drug Administration (FDA) approval.79

Besides cancer-directed treatments, different supportive therapies are employed which can lead to pain. Stem cell factors such as granulocyte and granulocyte/monocyte colony-stimulating factors are used to decrease rates of febrile neutropenia and sepsis but can cause bone marrow expansion leading to pain. Medical devices and catheters are often placed to facilitate treatments. The most common of these include central venous
access catheters such as tunneled catheters, peripherally inserted central catheters, and implanted port catheters; feeding tubes such as nasogastric tubes and percutaneous gastrostomy tubes; and intraventricular devices such as ventriculoperitoneal shunts and Ommaya reservoirs. Even in the presence of a central venous access catheter, peripheral intravenous catheter placements are sometimes necessary for certain imaging procedures and treatments.

Additionally, adverse effects of different cancer therapies are common and important to help understand the patient’s cancer experience and identify possible sources of pain. Because of the cyclical nature of many treatment regimens, this knowledge can help the clinician anticipate possible pain for the patient in later cycles and plan appropriate pain preventive measures and treatments.

The patient’s prognosis and—critically—the patient and family’s understanding of prognosis and goals of treatment are also important considerations in evaluating pain in a patient with cancer. Treatment plans can be curative or palliative in intent, and it is important to elicit this intent in anticipating a patient’s pain experience. Whereas curative treatments weigh the promise of long-term cure against possible short-term symptoms and other adverse effects, palliative treatments prioritize the preservation of a patient’s quality of life.

**PAST MEDICAL, PSYCHIATRIC, SOCIAL, AND SPIRITUAL HISTORY**

Preexisting medical and psychiatric conditions are less common in children but play a role in their ability to cope, physically or psychologically, with cancer treatments. A patient and family’s social situation and spirituality may also play a role in the support systems available in coping with both disease diagnosis and pain and symptom experience.

**PROXY REPORTS**

Whether or not a pediatric patient is able to provide a good history of his or her pain, it can be helpful to elicit observations and history from parents and other caretakers. Often, proxy report is the only source of information
when patients are too young developmentally, in distress, or unwilling to provide this history. In addition, pediatric oncology patients are sometimes in the hospital so frequently, or for such an extended period of time, bedside nurses in oncology units and infusion centers will also have a longitudinal perspective on the patients and their current pain. On the other hand, the clinician needs to be mindful that proxy reports from parents sometimes differ from patient self-reports, especially when it comes to internalizing symptoms such as pain, fatigue, and emotional distress. Parental anxiety can also affect their report of their child’s pain.

INTEGRATING DATA IN EVALUATION OF THE WHOLE CHILD
Some of the literature of pain evaluation focuses on pain intensity scales, which have been necessary for quantitating pain for the purposes of research and quality improvement efforts. In reality, however, each clinician faced with a patient experiencing pain integrates multiple data points from various sources in evaluating each patient. As an example, although self-report pain scores have classically been the gold standard in pain intensity assessment, recent observations and criticisms have led to a reevaluation of this dogma. An isolated self-report pain score can have wide variability in meaning from patient to patient and can even be biased depending on situation, age, cognitive development, or experience. This leads to difficulty in translating overly simplistic pain scores directly into clinical decisions.

Instead, although pain is inherently a subjective experience and thus self-report is an important piece of information, bundled or hierarchical pain assessment approaches hint at ways to include other factors to inform clinical judgment. A bundled approach takes self-report, observation, proxy report, and other factors into account before making a global assessment of pain. One bundled approach, “CARES,” uses the following factors: Context (evaluating for likely sources of pain), Assess pain expression (including self-report and observation of pain behaviors and functional limitations from pain), Risk (balancing adverse effects of treatment with the clinical situation of the patient), Emotional factors (considering developmental and psychological factors), and Sociocultural
Hierarchical assessments take the bundled approach a step further, by arranging pain-modifying factors into a specified order. An example of this is a pain assessment guideline by Herr et al., developed for patients who cannot self-report pain reliably, including several groups which are often encountered in pediatric oncology—preverbal infants and toddlers, critically ill or unconscious patients, patients with intellectual disabilities, and some patients at the end of life. This particular hierarchical approach takes the following steps in order: (1) (attempt to) obtain self-report, (2) search for potential causes of pain, (3) observe patient behavior, (4) obtain proxy report, and (5) attempt an analgesic trial if pain behaviors continue despite providing for basic needs and comfort.

After consideration of all these factors, and a discussion with the child, caretakers, bedside providers, as well as the multidisciplinary team, a targeted treatment plan can then be developed. Reassessment after any analgesic trial is mandatory to further adjust the treatment plan to the patients’ needs.

INCORPORATING TECHNOLOGY INTO ASSESSMENT

Finally, it is worth mentioning that there has been work done to develop technologies to address barriers of inadequate assessment and documentation of pain and patient reluctance to report pain. Phone text messaging has been used to improve patient compliance with reporting pain intensity, duration, and pain-related disability. A smartphone application similarly has been shown to be feasible and perform consistently compared to traditional interviewer-administered questionnaires. The NIH PROMIS can be used on multiple platforms. Studies have shown its feasibility and cross-cultural validity for measuring functional mobility, pain interference, fatigue, depression, anxiety, peer relationships, and anger. Tablet applications not only improve patient reporting of pain and symptoms but can also incorporate basic cognitive and behavioral skills training through electronic games.

Etiologies of Cancer Pain
Pain in children with cancer is often classified into one of four etiologies: (1) cancer- or disease-related pain, (2) treatment-related pain, (3) procedure-related pain, and (4) pain from other etiologies.\(^\text{87}\)

**DISEASE-RELATED PAIN**

**Bone Marrow Infiltration**

The acute leukemias—ALL and acute myelogenous leukemia (AML)—are the most common diagnostic category of pediatric cancer.\(^\text{88}\) The rapid proliferation of leukemic blasts within the bone marrow commonly results in the experience of diffuse bone pain. The clinical presentation of the bone pain, however, is variable depending on the age of the patient. Toddlers may present with a limp or inability to walk. A school-age child who is able to provide a pain narrative may report diffuse, poorly localized, total-body pain. An adolescent patient may have back pain that he or she associates with a sports injury and may localize the pain to a specific area in a long bone. Other pediatric leukemias include chronic myeloid leukemia (CML) and juvenile myelomonocytic leukemia (JMML) and in some situations can also present with bone pain. Some solid tumors, such as neuroblastoma, can metastasize to the bone marrow and can also present as a limp or, alternatively, as localized pain to a specific bony area.

Primary treatment of the underlying oncologic process is usually the most effective way to alleviate the pain, sometimes working within days of starting treatment. In the interim, standing or sometimes continuous opioids may sometimes need to be used for pain control. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided as they can exacerbate the risk of bleeding in a patient whose bone marrow may not be able to produce as many platelets, a condition which will soon be exacerbated by undergoing myelosuppressive chemotherapy. Acetaminophen can be helpful but may sometimes mask fever, which in a neutropenic or functionally neutropenic child may signal septicemia.

**Brain and Spinal Tumors**

CNS tumors are the second most common cancer in children and the most common group of solid tumors diagnosed during childhood. Headache is one of the most common initial presenting signs of brain tumor in children.
In recent studies, 31% to 40% of children with a brain tumor had headache at symptom onset. At diagnosis, headache is a prominent feature in 33% to 62%. Headache is less common in children under the age of 3 years, likely because of both communication and expansile skull of the infant, and sometimes is noted as ear, face, or neck pain. Most commonly, headache is a result of mass effect of the brain tumor causing increased intracranial pressure. Other times, headache may be the result of a trigeminal or glossopharyngeal neuralgia caused by tumor compression of cranial nerves. To decrease the intracranial pressure and thereby treat the pain/headache for the child, different therapeutic approaches can be used.

For some brain tumors that are locally invasive without metastatic potential, such as low-grade gliomas (astrocytomas), complete surgical removal is the treatment of choice. For malignant brain tumors with metastatic potential, such as medulloblastoma, chemotherapy and radiation therapy are included in addition to the surgical treatment regimen. Not all primary resections of malignant brain tumors result in complete surgical removal of the tumor, so pain may persist due to residual disease. Often, the child will be started on a corticosteroid pulse pre- or postoperatively to decrease tumor- and surgery-associated cerebral edema. Temporary or permanent ventricular shunts or ventriculostomies are often used to alleviate intracranial pressure from the tumor and/or postoperative edema. If the child continues to have headache after surgical intervention, NSAIDs, such as ibuprofen, can be considered if there is no plan for chemotherapy and/or radiation therapy. A histamine H2-receptor antagonist is used to inhibit gastric acid production, especially with concurrent corticosteroids. Otherwise, strong opioid therapy is the treatment of choice.

Benzodiazepines, such as midazolam, can also be used indirectly for the treatment of pain due to CNS tumors even though this class of medications does not have direct analgesic effect. Their mechanism of action for the treatment of pain in children includes decrease in anxiety, decrease in muscle spasm that may occur postoperatively, and facilitation of night sleep. Postoperatively after the resection of the CNS tumor, the child may remain within the intensive care unit (ICU) because of the need for monitoring intracranial pressure. In this setting, benzodiazepines may be
used as a continuous infusion or with frequent bolus dosing so that agitation is minimized.\textsuperscript{94} Benzodiazepines are often used concomitantly with opioid analgesics in the ICU setting when significant postoperative pain is reported, observed, or expected. Antipsychotics, such as quetiapine, are also commonly used for agitation as are α-adrenergic agents such as clonidine.

**Visceral Pain**

The four major etiologies of visceral pain include (1) organ invasion with capsular wall stretching, (2) organ compression, (3) hollow organ obstruction (e.g., ureter or bowel), and (4) tumor regrowth within the organ or peritoneal cavity bleeding. In children, the abdominal tumors which are most commonly implicated in visceral pain are Wilms tumor (and other kidney tumors), neuroblastoma, abdominal germ cell tumors, rhabdomyosarcoma and other soft tissue sarcomas, lymphoma, and hepatic tumors (hepatoblastoma, hepatocellular carcinoma, sarcomas of the liver, and metastatic lesions of the liver). Although pain is a common complaint, many of these tumors may also present asymptptomatically after incidental palpation of a mass by the parent or pediatrician, or through other symptoms, such as with Wilms tumor. As with bone pain in leukemia, treatment with chemotherapy, radiation, or resection of the diseased organ or part of the organ can eventually lead to a decrease in the child’s pain. In the interim and in the postoperative period, opioids are the mainstay of treatment.

**Bone Tumors**

Primary malignant bone tumors, such as osteosarcoma or Ewing sarcoma, bone metastases from other malignancies, and Langerhans cell histiocytosis, and some benign tumors, such as giant cell tumor of the bone, can result in significant pain for the childhood cancer patient. Bone pain in cancer is a complex pain state involving nociceptive, neuropathic, and inflammatory elements.\textsuperscript{95} Bone pain from osteosarcoma, for example, is due to both destruction of normal trabecular bone pattern from direct tumor invasion in combination with intense soft tissue inflammation from the periosteal new bone formation. Thus, the pain can often be very severe.
and often requires the use of opioids. NSAIDs could also be considered in the prechemotherapy setting. After the start of chemotherapy, however, NSAIDs should be used with caution as chemotherapy-related myelosuppression, and resultant thrombocytopenia may put the patient at a higher risk for bleeding.

Primary treatment of the tumor often provides the longest lasting effects on tumor-related pain from bone tumors. For osteosarcoma and Ewing sarcoma, neoadjuvant chemotherapy, followed by surgical resection and/or radiation, are the common treatment approaches. A small reduction in the size of the tumor may be enough to bring relief to the patient. Metastatic bone lesions may sometimes be treated symptomatically with radiation therapy, surgical decompression, or systemic chemotherapy depending on the disease.

In adults, osteoclast inhibition—using a bisphosphonate or a receptor activator of nuclear factor kappa B (RANK)-ligand inhibitor—has been shown to decrease fractures, spinal cord compression, and need for surgery or radiation therapy in the setting of bone metastasis from solid tumors such as breast and prostate cancer. Symptomatically, both treatments can delay the progression of moderate-to-severe pain in these adult patients.

Studies in children are lacking. There are encouraging results for bisphosphonates in pain control for benign cartilage tumors, unresectable symptomatic benign bone tumors, and Langerhans cell histiocytosis. Newer agents, such as denosumab, a RANK-ligand inhibitor, have been shown to be useful for treatment of bone pain in giant cell tumor of the bone. Children’s Oncology Group studies on both zoledronic acid and denosumab (ClinicalTrials.gov identifier NCT20470091) in metastatic or recurrent osteosarcoma have been undertaken, although effect on pain was not an aim of either study. Bisphosphonates have also been well tolerated in the treatment of children with hypercalcemia of malignancy.

**PROCEDURE-RELATED PAIN**

A child undergoing cancer treatment will undergo many invasive, painful procedures. These include diagnostic or therapeutic procedures such as bone marrow biopsies, lumbar punctures (LPs), and surgery for tissue
biopsy or tumor removal; venipunctures and subcutaneous port access (puncture) for diagnostic testing and/or treatment administration; placement of feeding tubes and urinary catheters; and placement of tunneled, peripherally inserted, or subcutaneous implanted “port” central venous access catheters. Even dressing changes (for central lines, surgical wounds) and suture and staple removal are a source of pain and distress for patients.¹⁰⁴

Not only does a child newly diagnosed with cancer face many repeated painful stimuli but these pain-evoking procedures can also occur in a relatively short period of time (within a few days, weeks, or months). In addition to the physical pain that invasive procedures cause related to tissue damage by insertion of a needle or device through the skin and/or bone, the procedures themselves produce a great deal of psychological distress, including fear and anxiety.¹⁰⁵ This anxiety can result in a quick recall of the procedure that will impact future pain management for all future painful procedures. Children with ALL on current treatment protocols, for example, undergo LPs on a regular basis ranging from once or twice weekly during induction therapy to once every 3 months during maintenance therapy. The initial LPs that are done at time of diagnosis and for the initial induction treatment therefore set the stage for the pain anticipated and experienced for children during their 2 to 3 years of ongoing chemotherapy. Studies in leukemia patients have clearly demonstrated that children have accurate memories of their painful procedures. The more negative a memory a child had about a previous LP, the higher the likelihood of increasing distress related to future LPs.¹⁰⁶ Similar findings have been found for children undergoing other repeated painful procedures.¹⁰⁷,¹⁰⁸

There may also be specific groups of pediatric cancer patients that are at higher risk for distress due to painful, invasive procedures. Early studies have suggested that differences in reactions to painful stimuli can be attributed, at least in part, to a child’s temperament, including the dimensions of distractibility and persistence.¹⁰⁹–¹¹² Having a higher level of pain sensitivity (i.e., pain perception) is associated with greater anxiety and pain both prior to and during an LP procedure.¹¹³ In addition, the psychological stress and corresponding coping experienced by the parent
can affect the child’s coping responses to the painful stressor. It has been shown that mothers of childhood cancer survivors do experience posttraumatic stress symptoms well into the survivorship period years after their child was treated for cancer. Thus, given that a child is dependent on parents for both physical and emotional support throughout the cancer care continuum, a child can be at increased risk for distress due to pain if his or her caretaker is not able to soothe or provide a safe, consistent environment because of his or her own stress and maladaptive coping.

Topical and local therapies for pain control are important. More than 50% of children report pain during venipunctures or intravenous cannulation, making these procedures an important target for pain prevention and control. Topical anesthetics are attractive because of the effectiveness without need for intravenous access and relative lack of systemic side effects. Eutectic mixture of lidocaine and prilocaine (eutectic mixture of local anesthetics [EMLA]) has been standard practice for decreasing procedural pain in children, available both in cream and patch forms. A warm lidocaine and tetracaine patch has also been shown to be effective for facilitating first-time needle procedure success. If insufficient time is available to allow topical anesthetic creams to take effect, vapocoolant sprays may be helpful in decreasing pain and decreasing intravenous cannulation failures in children. If anxiety is a major factor, low-dose oral midazolam has been useful in reducing fear and distress in younger children undergoing needle procedures such as subcutaneous port access. High-dose acetaminophen or morphine did not have the same effect.

EMLA may also be useful by itself for LPs but only with those patients who undergo successful LP on their first attempt. When used along with sedation, EMLA is useful in decreasing propofol use during LP. When sedation is contraindicated, such as for patients with a large mediastinal mass with risk for airway compromise, topical and local anesthetic may be the only safe pain prevention strategy for these patients undergoing LP or bone marrow biopsy.

More and more pediatric oncology centers have instituted sedation and analgesia protocols for pediatric oncology procedures such as LPs and bone marrow biopsies and aspirations. Guidelines for pediatric procedural
sedation have been published. The desired level of sedation (e.g., anxiolysis vs. deep sedation vs. general anesthesia) depends on patient age and cognitive development and painfulness of the procedure, balanced with the risks of sedation (e.g., in setting of airway compression from a mediastinal mass). Level of sedation also depends on the need for immobility, as there is a risk of introducing leukemic cells from blood into the spinal fluid with traumatic LP during induction therapy for ALL. 

The addition of intravenous fentanyl to intravenous propofol reduces movement, propofol dose, recovery time, and hypotension and was preferred by families. Intravenous ketamine had a superior effect on procedural pain and hemodynamic stability in comparison with an opioid alone; however, ketamine/midazolam compared with propofol was associated with a longer recovery period. Adding low-dose oral midazolam does not affect pain, fear, or distress levels whether given with or without intravenous ketamine prior to procedures for hematologic disease.

A combination of these two approaches may be considered. Two studies showed the addition of ketamine (0.5 to 1 mg/kg) to fentanyl (1 µg/kg) and propofol (0.5 to 2 mg/kg induction followed by 0.5 to 1 mg/kg as needed) decreased propofol dose, rates of hypotension and hypoxia, and recovery time. Ketamine may indeed replace the opioid, as a combination of ketamine, and propofol may decrease incidence of respiratory compression compared to propofol and alfentanil.

Nitrous oxide (NO) may also be useful for pediatric procedural sedation, especially in children who might be willing to accept a mask, and for procedures which are not extremely painful. Delivery systems are being improved and are more available for procedural applications. Randomized controlled trials comparing other agents to NO are lacking, but a recent study showed utility of NO in an outpatient setting for LPs.

### Postlumbar Puncture Headache

Even with adequate analgesia and sedation, LPs can sometimes be associated with postlumbar puncture headaches (PLPHA). These are characteristically postural headaches—worse with upright posture and improved in the supine position—occur within 6 to 72 hours of a LP, and
last 3 to 15 days. The mechanism is thought to be from ongoing leak of cerebrospinal fluid through the puncture site resulting in low cerebrospinal fluid pressure and volume. The incidence of PLPHA is rare in younger children and peaks in the fourth or fifth decade of life. Preventive measures are mandatory. The most well-studied and recommended preventive measures include (1) using a needle no larger than 22 gauge, (2) using a pencil point rather than a cutting point needle, and (3) orienting the needle bevel to be parallel, rather than perpendicular, to the long axis of the spinal column. Position of the patient in bed rest for 6 to 24 hours after LP does not appear to reduce the incidence of PLPHA compared to lifting of activity limitations after 0 to 1 hour. Replacement of the stylette before withdrawal of the needle has also been recommended, but application to pediatric cancer is limited because of the administration of intrathecal chemotherapy.

Placement of an epidural blood patch is one of the few therapies for PLPHA which has enough evidence to support its benefit. Autologous blood is collected intravenously from the patient and injected into the epidural space near the site of the prior LP, working to tamponade the area of the previous dural puncture and facilitate sealing of the leak. Because autologous blood is used, this should be avoided if the patient has leukemia which is not yet in remission. Other therapies, such as intravenous or oral caffeine, intravenous or oral hydration, tramadol, acetaminophen, and ibuprofen, had either weak or no evidence supporting their use or lack of pediatric data.

Postoperative Pain
Surgical biopsy is often necessary for diagnosis, and resection of tumors is a mainstay of therapy for most solid tumors. In addition, tunneled and subcutaneous “port” central venous access catheters are often placed surgically. These procedures, and the pain associated with them, are a commonly distressing part of the cancer experience in children. For abdominal surgery, an oncologic approach often precludes laparoscopic resection, and this also increases pain and recovery time. Joint guidelines from the American Pain Society, American Society of Regional Anesthesia and Pain Medicine, and several committees within the
American Society of Anesthesiologists are available.\textsuperscript{146} Recommendations include the consideration of using multimodal analgesia, using medications which target multiple mechanisms of action in the peripheral and CNS; physical modalities such as transcutaneous electrical nerve stimulation; cognitive behavioral modalities; nonopioid analgesics and gabapentin, intravenous ketamine, and opioids including patient-controlled analgesia (PCA); peripheral regional anesthesia; and neuraxial analgesia for major thoracic and abdominal procedures. More about pediatric postoperative pain management can be found in Chapter 50.

**Phantom Limb Pain**

Amputation and limb-salvage procedures may be used as surgical approaches to achieve local control of a bone tumor, and each can result in a chronic pain syndrome coined phantom limb pain. Phantom limb pain is experienced when the pediatric patient continues to have pain appearing to come from where the affected amputated limb used to be. There are multiple possible etiologies for the occurrence of phantom limb pain that include possible damage to the nerve endings in the surgical residual limb with abnormal regrowth postoperatively leading to abnormal painful discharges to spinal cord and brain. There may also be abnormalities in the CNS response to the loss of limb in which there may be loss of inhibitory sensory input from the amputated limb. Phantom limb pain is often severe and very challenging to treat.

Systematic analyses of studies to effectively treat chronic postoperative phantom limb pain have not clearly demonstrated an effective treatment option in randomized controlled trials.\textsuperscript{147,148} Gabapentin and pregabalin, amitriptyline, ketamine infusion, and lidocaine infusion are some of the more commonly tested treatments. Central strategies, such as hypnotherapy, biofeedback, and acupuncture, aimed at altering metabolic activity in pain perception areas of the brain, such as the anterior cingulate cortical area, may be more effective than peripheral strategies or opioids (see Chapters 26 and 54). Mirror therapy, a nonpharmacologic therapy which aims to reverse postamputation maladaptive reorganization of the sensorimotor cortex, has been used to beneficial effect in the pediatric oncology population\textsuperscript{149}; however, systematic reviews including a broader
population of adults and children with different reasons for amputation show insufficient evidence of benefit for either mirror therapy or movement representation techniques.\textsuperscript{150,151}

**TREATMENT-RELATED PAIN**

**Bone Marrow Expansion**

Filgrastim and pegfilgrastim (versions of granulocyte colony-stimulating factor), and sargramostim (granulocyte-macrophage colony-stimulating factor) are often used subcutaneously during chemotherapy treatment to raise neutrophil counts and reduce the number of episodes of febrile neutropenia in between cycles of myelosuppressive chemotherapy or during bone marrow engraftment after an HSCT. Alternatively, higher doses can be used in patients to mobilize and boost recovery of hematopoietic stem and progenitor cells for use later in autologous stem cell rescue after high-dose chemotherapy. One major adverse effect of these agents is bone pain secondary to a combination of bone marrow expansion, peripheral nociceptor sensitization to nociceptive stimuli, modulation of immune function, and a direct effect on bone metabolism.\textsuperscript{152} A meta-analysis showed bone pain rates for filgrastim and its long-acting version, pegfilgrastim, to be similar, at around 25\% to 50\%.\textsuperscript{153} As patients receiving colony-stimulating factors to prevent febrile neutropenia are by definition at risk for neutropenia and thrombocytopenia, NSAIDs should be avoided as well as around-the-clock acetaminophen to prevent masking of fever. As-needed acetaminophen and low-dose oral opioids are sometimes necessary to help patients manage this pain.

**Mucositis**

Mucositis may occur when chemotherapy is given alone, but certain treatments such as head and neck radiation, as well as high-dose chemotherapy in the setting of HSCT, can worsen and prolong mucositis.\textsuperscript{154} After HSCT, there is often a longer period for stem cell recovery extending beyond the 7- to 10-day nadir occurring after chemotherapy exposure. The grading scale for describing the severity of oral mucositis established by the World Health Organization (WHO)
ranges from mild, grade I mucositis, in which the oral mucosa is red and tender, to severe, grade IV mucositis in which the patient is unable to eat and maintain his or her own nutrition. The severity of the mucositis often corresponds to the description of the severity of the pain by the patient. Grade I mucositis may only require bolus dosing of an opioid analgesic. In the high-dose chemotherapy and HSCT setting, however, mucositis pain often requires use of an opioid PCA given the chronicity of the pain (over a several week period) and the extensive tissue injury involving the entire gastrointestinal tract. This often precludes enteral analgesic therapies. An effective approach to PCA delivery of the opioid analgesic is to have a low basal rate that is augmented with demand dosing for breakthrough pain. If demand dosing usage is frequent, resulting in a lockout of demand dose administration, then an increase in the basal rate is warranted. These patients may require several weeks’ use of an opioid PCA because the pain from mucositis can be severe and occur over a prolonged time period while awaiting engraftment. However, when engraftment occurs and counts recover, the PCA can often be weaned off quickly. The caveat to this is that there may be withdrawal symptoms, including agitation and/or diarrhea, and a methadone taper should be considered.

Patients with head and neck cancers often will be treated with radiation to the head and neck area or concurrent chemoradiation and are thus at higher risk for severe oral mucositis in addition to other oral toxicities such as trismus, xerostomia, and taste loss caused by inclusion of the jaw, salivary glands, and tongue in radiation fields. These often present a major challenge to oromotor function, enteral nutrition management, and maintenance of quality of life. Mucosal erythema appears at around 10 Gy of radiation, with associated burning sensation and sensitivity to spicy foods. At 30 Gy, ulcers develop leading to opioid requirement and feeding difficulties, and then mucositis remains at its peak for at least 2 weeks following completion of radiation. Pain and symptoms of mucositis can persist for 8 weeks.

Guidelines for the prevention of mucositis in children have been developed by the Pediatric Oncology Group of Ontario. A similar guideline is available for adults and includes treatment options for
mucositis. Preventive measures with sufficient supportive evidence for both panel recommendations include oral cryotherapy, low-level light therapy (LLLT), and keratinocyte growth factor. Oral cryotherapy involves placing ice cubes or chips in the mouth continuously during a period of cytotoxic treatment, typically 30 to 60 minutes at a time, resulting in vasoconstriction in the oral mucosal surface and thus decreased exposure to chemotherapy. Cryotherapy significantly reduced severe oral mucositis in a pooled analysis of eight studies which reported on this outcome (RR 0.46, 95% confidence interval [CI] 0.30 to 0.71). There is, however, a lack of positive studies in children, and feasibility is limited to only chemotherapeutic agents with a short half-life given in a short infusion, as well as by the concern that ice may pose a risk of choking hazard in young children.

LLLT involves exposing oral mucosal tissues to a low-energy light source, which may have anti-inflammatory, wound-healing, and analgesic effects. Advantages include two studies which included children with positive results. Limitations for hospitals include acquiring LLLT machines and training. Overall severe mucositis was reduced (RR 0.37, 95% CI 0.20 to 0.67), as was severe pain (RR 0.26, 95% CI 0.18 to 0.37). Finally, keratinocyte growth factor (e.g., palifermin) is an epithelial growth factor that works partly by thickening the oral mucosa. Severe oral mucositis was reduced with keratinocyte growth factor as well (RR 0.81, 95% CI 0.67 to 0.97), which is given for several days before and after mucositis-inducing chemotherapy.

Other interventions, including filgrastim, glutamine, Traumeel S, topical vitamin E, chewing gum, oral chlorhexidine, sucralfate, and a preventive oral care protocol, were not effective in reducing mucositis. Additional recommendations from the adult guideline panel include PCA opioids for oral mucositis and benzydamine mouthwash in patients with head and neck cancer receiving moderate dose radiation therapy (up to 50 Gy) without concomitant chemotherapy. They also suggest transdermal fentanyl for oral mucositis due to high-dose chemotherapy, 2% morphine mouthwash for mucositis in patients receiving head and neck chemoradiation, 0.5% doxepin mouthwash for any oral mucositis, as well as systemic zinc supplementation for prevention of mucositis. Again,
studies in children are lacking so their use should be limited to selected
children and under expert guidance. Other topical treatments that have
been used include honey\textsuperscript{159} and aloe vera.\textsuperscript{160} Honey has been used in other
wound care settings to promote healing but requires irradiation to
neutralize botulinum toxin spores and other microbes which may
otherwise contraindicate their use in immunocompromised and very young
children,\textsuperscript{161} and further clinical trials would be needed to clarify its safety
in these populations.

**Neuropathic Pain**

Pediatric cancer patients can experience neuropathic pain for a variety of
reasons, including nerve invasion, inflammation of a nerve root due to the
malignancy or infectious process, and/or from cancer treatment side
effects. These etiologies include (1) chemotherapy-related peripheral
neuropathies, such as with vincristine neurotoxicity; (2) neural
compression or invasion by tumors, such as pelvic Ewing sarcomas; and
(3) infection related, such as herpes zoster reactivation due to immune
suppression. One common cause of chemotherapy-related peripheral
neuropathy is vincristine, a vinca alkaloid used as an effective cytotoxic
agent for many types of pediatric malignancies including leukemias,
lymphomas, and various solid tumors. Vincristine binds to tubulin and
inhibits microtubule formation and disrupts the formation of the mitotic
spindle, which is thought to be one of the mechanisms by which it causes
peripheral neuropathies, including jaw pain, leg pain, and abdominal
pain.\textsuperscript{162} In addition, direct injury of the nerve can occur with soft tissue
sarcomas arising in the pelvis, such as Ewing sarcoma or
rhabdomyosarcoma, and the child may present with complaints of
abdominal pain, lower extremity weakness, and/or bladder and bowel
dysfunction.

Assessment of chemotherapy-induced peripheral neuropathy is informed
not just by the painful aspect, or even the sensory symptoms, but also by
motor and autonomic symptoms; pin, vibration, and light touch sensation
by exam; motor exam; and deep tendon reflexes. These are included in the
pediatric Total Neuropathy Scale (TNS) and this can be included in the
pain assessment.\textsuperscript{163–165}
Besides vincristine, peripheral neuropathy is also associated with bortezomib, cisplatin, paclitaxel and other taxanes, and thalidomide. Calcineurin inhibitors, such as tacrolimus and cyclosporine, often used after allogeneic HSCT, may also be associated with peripheral neuropathy. Newer agents including dinutuximab (aka ch14.18), a chimeric, monoclonal anti-GD2 antibody approved in the immunotherapy of neuroblastoma, can also be associated with neuropathic pain, specifically alldynia. In the phase 3 trial which led to its approval, grade 3 or 4 neuropathic pain was reported in 52% of patients receiving the drug, typically occurring during the infusion and reported as abdominal pain, generalized pain, extremity pain, back pain, neuralgia, musculoskeletal chest pain, and/or arthralgia. Opioid analgesic premedication is usually given prior to start of the infusion, followed by continuous opioid infusion until 2 hours following the completion of the medication. One study describes the use of dexmedetomidine in combination with hydromorphone for pain management during dinutuximab. The pain is thought to be due to antibody binding to GD2 expressed on normal nerve cells. Another immunotherapy agent against neuroblastoma is being developed to avoid this adverse effect.

**PAIN FROM OTHER ETIOLOGIES**

**Infection**

Patients undergoing immunosuppressive therapies such as chemotherapy, or those with decreased immunologic reserve, such as patients with leukemia, are susceptible to a myriad of infectious complications, many of which can be painful and involve almost any part of the body. An evaluation of pain in a patient with cancer must include evaluation for bacterial, fungal, or viral infections based on the patient’s current level of immnosuppression. Treatment of the primary infection and resolution of neutropenia lead to improvement in pain. In the meantime, analgesic therapy may be needed.

Of particular interest are herpes simplex viruses (HSV-1 and HSV-2) and varicella zoster virus (VZV). Primary HSV-1 infection is often asymptomatic in immunocompetent hosts but can commonly manifest as painful vesicles in the mouth, throat, or other parts of the body. HSV-2 has
a tropism for the genital area. After primary infection, these viruses become latent in nerve cell nuclei. In immunocompromised hosts, however, primary infection can be disseminated, and reactivation of HSV and VZV infections is common and more severe, leading to substantial morbidity and in some cases mortality. HSV-1 seropositivity is also a strong risk factor for oral mucositis,\textsuperscript{171} with reactivation contributing to as much as half of oral mucositis episodes\textsuperscript{172} and greater mucositis severity\textsuperscript{173} in HSV-1–seropositive children undergoing myelosuppressive chemotherapy.

VZV reactivation, also known as (herpes) zoster, often presents with painful lesions within a dermatomal distribution and severe postherpetic neuralgia, but immunocompromised patients are also at risk for cutaneous or visceral dissemination, retinal necrosis, and mortality. Zoster affects children with cancer at much higher rates than the general population, but this is improving with varicella immunization.\textsuperscript{174,175}

HSV infections, and thus, a proportion of oral mucositis, can be treated and prevented with acyclovir.\textsuperscript{176} VZV reactivation in a patient with cancer should also be treated with antivirals (e.g., acyclovir); however, additional analgesic therapy with acetaminophen and/or opioids is often needed for the acute neuritis associated with zoster, depending on severity. Postherpetic neuralgia can nevertheless develop despite antiviral therapy,\textsuperscript{177} and persistent pain despite healed lesions can be treated with topical lidocaine or capsaicin on intact skin. Systemic therapy with gabapentinoids and tricyclic antidepressants may be considered to treat or attempt to prevent severe pain.\textsuperscript{178}

**Graft-versus-host Disease**

Because of the intensity of treatment involved, pediatric cancer patients requiring HSCT as part of their treatment are considered a high-risk group of patients for the development of acute and chronic pain. Cancer diagnoses that may require HSCT, either allogeneic or autologous, for curative therapy include ALL, AML, myelodysplastic syndrome, and neuroblastoma. Pediatric cancer patients who have received HSCT have unique risk factors for the development of acute pain, including mucositis, graft-versus-host disease (GVHD), and tissue erosive infectious...
complications.\textsuperscript{179} Thus, pain management is critical in the care of the HSCT patient and, if not treated adequately, can result in decreased quality of life.

GVHD is a unique complication of childhood cancer patients who undergo HSCT. GVHD occurs due to the host (recipient) cells appearing foreign to the engrafted hematopoietic stem cells. There are two forms of GVHD, consisting of acute and chronic GVHD. Acute GVHD occurs within the first 100 days of the HSCT, causing dermatitis, enteritis, and/or hepatitis. Acute GVHD can be clinically manifested by skin rash, right upper quadrant pain, and/or diarrhea and abdominal pain. The skin rash can range from mild erythema of the palms and soles of the feet to bullous desquamation in the severe form. Chronic GVHD typically occurs 100 days beyond the hematopoietic stem cell infusion and is thought to be an autoimmune process. Chronic GVHD primarily has skin manifestations that include scleroderma-type changes often accompanied by joint stiffness and immobility.

**Bone Complications of Therapy**

Pediatric cancer patients are at risk for decreased bone mineral density and painful and debilitating bone complications such as fractures and osteonecrosis. Risk factors which are commonly seen in patients treated for pediatric cancer include exposure to corticosteroids, methotrexate, skeletal radiation, hypogonadism and growth hormone deficiency from pituitary tumor or treatment, as well as long-term inactivity and suboptimal nutrition during treatment.\textsuperscript{180,181} Severe osteonecrosis and most fractures are treated with surgical intervention, but nonsurgical treatments under investigation for osteonecrosis have included bisphosphonates and hyperbaric oxygen therapy.\textsuperscript{182,183}

**PAIN IN SURVIVORSHIP**

As more children, adolescents, and young adults become long-term survivors of pediatric cancers, more is becoming known about their physical and mental health. Adult survivors of pediatric cancers are more likely to have chronic health conditions, some of them life threatening or painful.\textsuperscript{7} A significant percentage of adult survivors of pediatric cancer
also report poor physical or mental HRQOL. Thus, it is not surprising that survivors of childhood cancers are much more likely to report pain than their siblings and more likely to use prescription analgesics. Cancer-related or cancer treatment–related pain still affected 21% of cancer survivors in the study. Predictors of recent pain attributed to pediatric cancer or its treatment in these studies include lower household income, divorced/separated/widowed status, lower educational attainment, and primary cancer diagnosis of bone cancer or soft tissue sarcoma. Risk factors for having been diagnosed with any pain condition, including headache, included age less than 3 years at diagnosis, female gender, minority race, single marital status, lower income, and unemployment. Pain contributes negatively to quality of life in survivors. Survivors with pain were more likely to have comorbid internalizing and externalizing symptoms. Thus, it is important to screen for and address pain in childhood cancer survivors and also important to take measures during initial treatment to prevent or moderate development of pain sensitization.

Management of Pain

Just as the assessment of pain in a pediatric patient with cancer ideally involves a multidisciplinary team, a multidisciplinary approach is also ideally employed in the management of pain in these patients. Anticipation of expected painful effects of cancer and its treatment, education of the parent and child, and prevention of procedural and therapy-related pain are paramount to improving the patient’s cancer experience. A pain prevention plan could involve critically evaluating potentially painful procedures for their necessity. It is also important to consider procedural sedation if indicated and consolidating painful procedures under one sedation if possible. Similarly to the strategy of antiemetic prophylaxis for emetogenic cancer treatments, the different interventions detailed in the following text can also be used for prevention of pain when pain is expected. A comprehensive approach incorporates this anticipatory guidance and prevention as well as physical, psychological, and pharmacologic approaches to treatment of the various pain syndromes in children with cancer. Prevention of or minimizing pain will reduce the
likelihood of distressing pain memories that can impact future pain experiences.\(^{188}\)

**Pharmacologic Management of Cancer-Related Pain in Children**

In 2012, the WHO\(^{189}\) expanded guidelines on Cancer Pain Relief and Palliative Care in Children, now covering pharmacologic treatment of persisting pain in all children with medical illness with ongoing tissue damage or inflammation. The WHO now recommends a two-step approach to pharmacologic management of pain in this population. In this approach, acetaminophen (paracetamol) or an NSAID, such as ibuprofen, is given for mild pain, and strong opioids are given for moderate to severe pain. In previous guidelines, the WHO had recommended an intermediate step with weak opioids such as tramadol and codeine. However, because tramadol is generally not labeled for patients under 12 years, and codeine presents significant variability in response and toxicity related to CYP2D6 polymorphisms, this intermediate step has been removed from the pediatric recommendation. Several studies in adults\(^{190,191}\) and the European Association for Palliative Care guidelines for treatment of cancer pain\(^{192}\) are also supportive of this strategy.

Treatment of cancer-related pain in children should follow this two-step approach but with certain considerations. NSAIDs are known to cause temporary platelet dysfunction which can lead to an increased risk for bleeding. This may not be acceptable in the setting of bone marrow infiltration (such as with newly diagnosed leukemia) nor in the setting of bone marrow myelosuppression and resulting thrombocytopenia (such as with ongoing chemotherapy). In addition, prolonged NSAID use can result in renal injury, which can exacerbate cumulative renal insults from other chemotherapy and supportive care medications such as aminoglycosides. NSAIDs can also decrease renal clearance of toxic chemotherapy agents such as methotrexate.\(^{193}\) Finally, NSAIDs are associated with gastric and duodenal ulcers, especially in combination with corticosteroids.\(^{194}\) If given in combination with corticosteroids, a histamine H\(_2\) receptor antagonist or proton pump inhibitor may be required to prevent gastroduodenal
ulcerations and stomach discomfort.

For these reasons, acetaminophen is more commonly used than NSAIDs as a first-line treatment for mild pain in a child who has or is at risk of thrombocytopenia. This includes patients newly diagnosed with leukemia or other bone marrow infiltrating tumor as well as children undergoing chemotherapy. Acetaminophen is most effective at doses of 15 mg/kg every 6 hours.\textsuperscript{195} It is also now available in the intravenous formulation for children not able to tolerate oral medications, but it can be costly. Acetaminophen, however, has its own limits, especially in the setting of liver dysfunction or failure.

Moreover, acetaminophen and ibuprofen are both used for their antipyretic effects as well. This can complicate the treatment of pain in patients with neutropenia (absolute neutrophil count <500 cells/µL). Because fever may be the earliest and only sign of a severe infection in a neutropenic patient, scheduled acetaminophen or NSAIDs may theoretically pose a risk for delayed recognition of an infection which can lead to sepsis or death. For this reason, these medications are usually dosed as needed (“PRN”), and persisting pain is treated with scheduled opioids.

Lastly, it should be emphasized that the two-step strategy does not necessarily preclude use of strong opioids as first-line therapy for moderate to severe pain. A randomized trial testing nonopioid analgesics against strong opioids as first-line therapy for moderate to severe pain in “terminal” adult cancer patients showed that patients started on strong opioids had better pain relief, fewer changes in therapy, greater reduction in pain, and greater satisfaction with treatment, without serious adverse events.\textsuperscript{196}

The other principles advocated by WHO\textsuperscript{189} guidelines are to treat pain “at regular intervals,” “by the appropriate route,” and “to the individual child.”

- At regular intervals: Unless pain is truly intermittent or unpredictable, persisting pain should be treated at regular intervals, while monitoring for adverse effects, with the addition of “rescue doses” for intermittent and breakthrough pain.
- By appropriate route: Analgesia should be administered by the simplest, most effective, and least painful route. For most children,
oral analgesics are the route of choice; however, intravenous, rectal, and subcutaneous routes may be needed depending on the clinical situation. Of note, the rectal route is usually avoided in potentially immunocompromised children, including those receiving chemotherapy.

- To the individual child: Opioid analgesics should be titrated in collaboration with the patient to achieve the best possible analgesic effect with side effects acceptable to the patient.

**Overview of Opioid Analgesia in Children**

Strong opioids with the most evidence and clinical experience for pain in pediatric patients with cancer include morphine, hydromorphone, and fentanyl. Other important strong opioids with less data in pediatric cancer patients include oxycodone, methadone, and buprenorphine.

PCA with morphine, hydromorphone, or fentanyl is also an effective option for pediatric patients as young as 5 years of age, depending on their level of cognitive development.

There are several unique delivery systems of opioid analgesics which might prove useful in the pediatric cancer population to avoid the fear and pain associated with injections. Options for oral transmucosal delivery of fentanyl now include a lozenge/troche (Actiq), sublingual tablet (Abstral), buccal tablet (Fentora), soluble film (Onsolis), and a sublingual spray (Subsys). These preparations may even be more efficacious than oral morphine for breakthrough cancer pain.

Labeling, at this time, is limited to opioid-tolerant adult patients.

Another noninvasive method of opioid drug delivery includes the use of fentanyl or buprenorphine transdermal therapeutic systems (TTS). One practical advantage is that when the oral route of tablet, capsule, or liquid administration is contraindicated or not well tolerated by a child, the transdermal drug delivery method allows for an alternative route. There are emerging numbers of pharmacokinetic studies on the use of TTS in children. The data supporting the transdermal route over traditional morphine is minimal, but there are studies that demonstrate child and parent satisfaction with the TTS delivery system of fentanyl and
buprenorphine in both pain relief and quality of life in the pediatric palliative care setting.\textsuperscript{207,208}

It has been shown that in the pediatric cancer population, opioid monotherapy is the most effective method for treating moderate to severe pain.\textsuperscript{209} It is not effective, however, for all pediatric cancer patients due to various etiologies including opioid-induced tolerance and opioid-induced hyperalgesia.\textsuperscript{210} The analgesic response to any given opioid dose depends on the tolerance of the patient. An opioid-tolerant patient will require a higher dose for the same analgesic response when compared to the opioid-naive patient.

**ADVERSE EFFECTS**

Adverse effects of opioid analgesics, for both the opioid-naive as well as the opioid-tolerant patient, include somnolence, constipation, pruritus, nausea, vomiting, urinary retention, and sweating. Management of opioid-induced adverse effects is critical in pediatric patients with cancer. Constipation may already be a significant problem for the child prior to the use of opioids as certain types of chemotherapeutic agents, such as vincristine, can cause severe impaired gut peristalsis. This, combined with mucosal breakdown in an immunocompromised host, can lead to severe infectious complications and sepsis. When using high dose or prolonged courses of opioids for the treatment of CNS pain, the treatment plan must also include a bowel regimen to reduce the likelihood of constipation.

There are several different classes of medications that can be used to treat or prevent constipation including polyethylene glycol 3350 (often preferable because it is a tasteless and odorless powder that can be mixed with any liquid), senna (a stimulant laxative), docusate (a lubricating laxative), milk of magnesia (which contains magnesium hydroxide, an osmotic laxative), and/or mineral oil (a lubricant). Peripherally acting $\mu$-opioid receptor antagonists such as subcutaneous methylnaltrexone and oral naloxegol\textsuperscript{211} are approved for opioid-induced constipation not responsive to usual laxatives in adult noncancer patients, but they are often used off-label for cancer patients without known or suspected lesions in the intestinal wall.

Urinary retention may lead to hemorrhagic cystitis when combined with
oxazaphosphorines such as ifosfamide and cyclophosphamide, and strict intake and output parameters must be monitored while receiving these medications. Patients with cancer are also at higher risk for nausea and vomiting with concurrent chemotherapy. They are also at higher risk for somnolence because of polypharmacy with potentially sedating medications such as diphenhydramine and lorazepam used as antiemetic therapy.

Opioid rotation is commonly used as a means of optimizing analgesia while minimizing opioid-related adverse effects.

**DEPENDENCE AND ADDICTION**

There can also be barriers to the use of high dose or long-term use of opioid analgesia in children due to parents’ and health care providers’ concerns regarding the risk of dependence or addiction. Some of the more common symptoms of withdrawal in a child with physiologic opioid dependence include severe dysphoria, diarrhea, anxiety, restlessness, and chills and usually occur when the opioid analgesic is stopped abruptly. The symptoms observed in pediatric patients can vary from those observed in adults. For example, an infant can have a high-pitched cry and inability to be soothed with a pacifier, bottle, or swaddling. A toddler’s signs of withdrawal may include only diarrhea and temperature instability. Conversely, addiction is a complex behavior characterized by the compulsive use of a drug and psychological craving. Addiction is not commonly seen in the pediatric population but may be observed in the older adolescent who has complex psychosocial issues resulting in maladaptive coping to pain.

**TOLERANCE TO OPIOIDS**

Given that tolerance to opioid analgesics can limit their clinical effectiveness, various approaches can be used to prevent or reverse tolerance in children who require prolonged exposure to high-dose opioids. One proposed approach to prevent tolerance includes the use of N-methyl-D-aspartate (NMDA) antagonists concomitantly with the opioid. Methadone is a synthetic, long-acting opioid that has often been used for both its μ-opioid effect as well as its NMDA receptor antagonist effect,
which is thought to help prevent opioid tolerance. When managed by experienced clinicians, opioid rotation from other opioids to methadone in the face of opioid tolerance or unacceptable side effects can be safe and effective in cancer pain.\textsuperscript{213}

Ketamine has been studied and shown to have a role in mitigating opioid-induced tolerance in children and adolescents who experience cancer pain.\textsuperscript{214} Finkel et al.\textsuperscript{215} have used ketamine at lower doses than used for anesthetic purposes. Specifically, they used ketamine from 0.1 to 1.0 mg/kg/hour in patients who had signs of opioid tolerance or had severe side effects such as profound sedation. With this regimen, they found that adjuvant ketamine infusions used in combination with opioid analgesics (including morphine, methadone, and hydromorphone) resulted in improved pain control.

**“WEAK” OPIOID**

Tramadol is an atypical opioid that has a weak affinity for the $\mu$-opioid receptor as well as being a weak inhibitor of serotonin and noradrenaline reuptake. The advantage of tramadol is that it has negligible respiratory depression.\textsuperscript{216} It is hepatically metabolized and renally excreted, factors that must be taken into consideration when using this medication in the pediatric cancer patient because chemotherapy can result in both renal and hepatotoxicity. The active metabolite is O-desmethyltramadol (M1), and recent pharmacokinetic studies in children have demonstrated that it is possible to produce enough of the active metabolite to achieve adequate pain relief.\textsuperscript{217} Safe dosing regimens for children $\geq$12 months of age include 1 to 2 mg/kg per oral route of administration every 4 to 6 hours with a maximum dose of 8 mg/kg/day.\textsuperscript{218}

**ADJUVANT THERAPIES FOR NEUROPATHIC PAIN**

A review by Friedrichsdorf and Nugent\textsuperscript{219} acknowledges a lack of randomized clinical trial data about the management of neuropathic pain in children. There is evidence that NSAIDs (when not contraindicated), weak opioids, and strong opioids may be helpful in adults, and the authors suggest a stepwise approach including treatment of the underlying disease process, integrative/nonpharmacologic therapies, NSAIDs, and weak or
strong opioids before considering a tricyclic antidepressant (such as amitriptyline), a gabapentinoid (gabapentin or pregabalin), or a combination of a tricyclic and gabapentinoid. Because these medications often take time to reach therapeutic effect, the addition of ketamine or methadone for NMDA-receptor-channel blockade may be considered, or low-dose benzodiazepine, α-agonists such as dexmedetomidine or clonidine, and/or intravenous lidocaine. Localized pain can also be treated with a lidocaine 5% patch. Regional anesthesia can also be considered. Duloxetine is also a consideration in some patients based on its modest effectiveness in adult chemotherapy-induced peripheral neuropathic pain.220

Physical and Psychological Therapies for Pain in the Pediatric Cancer Patient

There are multiple nonpharmacologic therapies that can be employed for pain management in the pediatric cancer patient (Table 49.1). These include massage therapy, yoga, hypnotherapy, meditation, biofeedback, relaxation, spirituality, acupuncture, botanicals, physical therapy (PT), and energy therapies including the use of magnets. The definition of complementary and alternative medicine (CAM) was those interventions that are neither generally provided by US hospital clinics nor widely taught in medical school.221 More recently, there has been a concerted effort by the NIH and clinicians alike to consider these options as “integrative therapy.”222–224

2556
Thus, although these nontraditional pain treatments may not be familiar territory for physicians trained within the United States, there is an emerging body of literature discussing the state of the science of integrative therapy use in both adult and pediatric populations.\textsuperscript{225} In addition, the latest literature in medical education has documented a clear trend of higher usage rates of integrative therapies by anesthesia training programs across the United States.\textsuperscript{226} Thus, integrative interventions, including pharmacologic, psychologic, physical, and other therapies, should be considered in the treatment of pediatric cancer pain.

**ACUPUNCTURE**

Acupuncture consists of inserting fine needles into the skin’s surface, or using heat, pressure, or other stimulation in areas that correspond to specific points along “meridians” (i.e., energy channels within the body). These meridians in which the body’s life forces (spiritual, emotional, mental, and physical) flow can be out of balance and cause the physical sensations of pain, imbalance, and sickness. Insertion of the needles into specific points along meridians through the practice of acupuncture helps to restore the balance of forces within the body and thereby eliminate the pain by achieving a flow of energy or Qi (pronounced “chi”). Although the practice of acupuncture is more widely accepted within East Asian societies, the use of acupuncture for treatment of pain has been increasing across the United States.\textsuperscript{227,228} Currently, 46 US states and the District of Columbia require licensure for the practice of acupuncture. For those states that do not regulate the practice, the health care provider should ask for certification by the National Certification Commission for Acupuncture and Oriental Medicine (see Chapter 94).

There is a growing body of literature evaluating its effectiveness for alleviating pain.\textsuperscript{229,230} The available literature on the use and effectiveness of acupuncture in the treatment of pain in the pediatric population suggests it is an acceptable treatment modality for adolescents with chronic pain, as well as an effective modality for other common symptoms experienced by the childhood cancer patient, including headache, nausea, and vomiting.\textsuperscript{231–233} Nonetheless, acupuncture has not been widely disseminated into pain treatment regimens for the pediatric population.
One reason is preexisting beliefs by health care practitioners in the United States that children are afraid of needles, and thus, they do not make referrals for acupuncture. On the contrary, it has been shown that for those children who have been referred to acupuncture for various chronic pain syndromes, over two-thirds report that it was a positive experience and an effective modality for treatment of their pain. Acupuncture, therefore, can be considered as a possible adjuvant treatment modality for neuropathic pain in the pediatric cancer patient.

**BEHAVIORAL INTERVENTIONS**

A Cochrane review on psychological interventions in needle-related procedural pain supports distraction as an effective modality for decreasing self-reported pain. Distraction techniques include listening to music, watching cartoons, playing with a toy, nonprocedural talk, squeezing a rubber ball, using cards with questions on them, listening to stories via earphones, parental soothing, or a combination. Virtual reality is a specific type of distraction technique involving immersing the child in a virtual world using visual and auditory stimuli, with some positive results.

Cognitive-behavior therapies (CBTs) have also been extensively studied needle-related procedural pain and distress in children. Specific therapies included procedural preparation and information, relaxation, guided imagery, modeling, procedural rehearsal, coping skills teaching, parent coaching, and memory alteration techniques. A Cochrane review in 2006 found sufficient evidence supporting combined CBT; however, an update in 2013 had stricter inclusion criteria for included studies and no longer had sufficient data to support the benefit of CBT.

**HYPNOTHERAPY**

Hypnosis is a cognitive strategy that helps the child achieve a narrowed focus of attention, relax, and learn how to dissociate from the current sensory environment. Several groups in randomized controlled studies of children with cancer undergoing medical procedures have shown hypnotherapy to be effective in reducing procedure-related pain and anxiety. These are summarized in numerous reviews.
and Bioy provide a succinct review on the effectiveness of this technique, an understanding of the physiologic effect of hypnosis, and the practical application of its use to treat pain in children. For example, Rainville and colleagues have demonstrated, through the use of positive emission tomography (PET), changes in regional cerebral blood flow when hypnosis is used. In hypnotic states, there is increased blood flow to the occipital cortical areas. This increase in blood flow to the occipital region is thought to result in a reduction of inhibitory processes that occur normally during high levels of attention. Thus, hypnosis results in an acceptance of specific, altered sensations, thereby mediating changes in perception of the painful experience.

Several studies on the effect of hypnosis for symptom management in children, including the effect on pain perception, anxiety, and nausea/vomiting have been completed. Early studies demonstrated the feasibility of being able to hypnotize children. Subsequent studies by Zeltzer et al. have demonstrated the effectiveness of hypnosis in decreasing other symptoms experienced by pediatric cancer patients, including nausea. Studies have also demonstrated the effectiveness of hypnosis in decreasing pain and anxiety in children undergoing the invasive painful procedures of LPs and bone marrow biopsies. Thus, there continues to be increasing evidence of both the feasibility of administration and the effectiveness of hypnosis in the pediatric population, and it should be considered when a pediatric cancer patient is undergoing invasive, painful procedures. As the review paper by Wood and Bioy discusses, practical considerations of using hypnosis include the child’s age (as younger children are more responsive to the hypnosis when compared to adolescents), cognitive development, and therapeutic relationship with his or her provider.

**EXPRESSIVE ARTS THERAPIES**

Expressive or creative arts therapies include such disciplines as art therapy, music therapy, dance/movement therapy, drama therapy, and poetry therapy. Expressive arts therapists are trained, credentialed specialists who use an expressive art form in the context of psychotherapy, medicine, or rehabilitation. The therapist systematically assesses the
patient and tailors an interactive expressive art experience to the patient’s psychological needs through a therapeutic process. The expressive arts not only help to distract from the patient’s current illness and normalize the hospital or clinic environment but also use theoretical concepts to improve coping and manage distress. For example, Robb et al.\textsuperscript{251} studied a therapeutic music video intervention in adolescents and young adults which was grounded in motivational and developmental coping therapy to (1) provide predictability through clearly defined goals and structured, preferred music; (2) autonomy support through patient-directed choices about music, lyric writing, video content, and involvement of others; and (3) relationship building through a nonthreatening, creative activity to help patients explore, identify, and express what is important to them.

Expressive arts therapies, especially music therapy, have been shown to improve symptoms, such as anxiety, pain, and need for analgesics; lower heart rate, respiratory rate, and blood pressure; and improve quality of life and perceived social support.\textsuperscript{252} A small art therapy study using different techniques such as visual imagination, structured and free drawing, and medical play to promote coping behaviors helped improve patient cooperation with painful procedures.\textsuperscript{253} Integrating different creative arts therapies together may also be beneficial. A randomized study in pediatric brain tumor patients showed that creative arts therapies can help improve pain as well as nausea, anxiety, and mood.\textsuperscript{254}

**MASSAGE**

Massage is the practice of light body stroking or deep tissue stroking that is thought to work by increasing serotonin and reducing cortisol. The basic principle of massage is that when muscles are overworked, there is a release of waste products that accumulate in the area that can be relieved using the hands of the therapist to manipulate muscles and surrounding tissues. Massage therapy has been used as an adjuvant therapy in pain management with a number of studies demonstrating its effectiveness. For example, it has been shown that when massage therapy was used in addition to a standard pharmacologic regimen for postoperative pain management, the experimental group demonstrated decreased pain intensity, pain unpleasantness, and anxiety when compared to the control group.
group. Massage therapy is also a CAM modality that can be easily instituted at the bedside for the cancer patient. There are a few studies to date completed in the pediatric population on the use and effectiveness of massage therapy for cancer-related pain. For example, oncology and hematology inpatients who received a standardized massage therapy protocol experienced significant improvements in anxiety, emotional state, muscle soreness, discomfort, respiratory rate, and overall progress compared with a control group. Children assigned to massage therapy for 20 minutes prior to an LP or bone marrow procedure, in addition to topical EMLA and intravenous midazolam, had significantly decreased levels of pain and anxiety after the massage therapy compared to patients in a control group. In a study of children with ALL, a daily massage over a 1-month period was found to have an impact on the immune system as demonstrated by an increased white blood cell count as well as an improvement in children’s negative affect. Given the promising application of massage therapy to decrease pain in children, future research is warranted to evaluate the effectiveness of the healing powers of touch (i.e., massage) in a randomized controlled trial for pediatric cancer patients.

**BIOFEEDBACK**

Biofeedback involves measuring physiologic parameters, including blood pressure, heart rate, skin temperature, sweating, and muscle tension, and conveying the changes that occur while the child is learning breathing and imagery strategies to alter these bodily processes. This bodily feedback information can be provided through the use of computer-generated, audio-generated, or other forms of visual-generated systems with skin temperature or muscle contraction being the most commonly measured parameter. The basic concept of biofeedback is that by providing physiologic information to a patient who is usually unaware of these bodily processes, while also teaching the child cognitive and breathing strategies that alter these processes, the child can learn to reduce muscle tension and autonomic arousal, thereby reducing pain. For children, it provides proof that the mind can affect the body by being able to gain physiologic control of the part of the nervous system that is activated by
pain or stress.

Studies on the use of biofeedback have primarily been focused on adult patients, particularly those with headaches. Meta-analysis of this mind–body approach for the treatment of headache pain indicates that it is effective when used alone or in combination with other CAM modalities.\textsuperscript{260} Studies completed in pediatric patients again are limited in number, but those that have been completed also have focused on the treatment of pediatric migraine headache. Similar to the adult literature, meta-analysis on the use of biofeedback, as well as other behavioral methodologies to treat headache in children, demonstrates that it can be considered as an important adjunct to the pain treatment regimen.\textsuperscript{261} Given that there are minimal side effects and there is data suggesting its effectiveness, biofeedback can also be considered as another adjunctive therapy to pain management in the pediatric cancer patient. There is no license to practice biofeedback, although the majority of practitioners have other medical licensures, such as registered nursing (RN), PT, or marriage and family therapy (MFT). Hospitals and clinics with pediatric pain programs can often provide referral lists of biofeedback therapists.

**BOTANICALS**

The use of herbal or alternative medicines requires discussion in the treatment of cancer pain given the increasing frequency of use within the US population with or without data suggesting its effectiveness.\textsuperscript{262} The studies that have evaluated the use of herbal medicine in pediatric patients have been for the treatment of otalgia and have been completed outside the United States.\textsuperscript{263} One such study evaluating the use of the naturopathic ear drop, Otikon, concluded that it was as effective as anesthetic ear drops for acute otitis media associated with ear pain.\textsuperscript{264} Thus, given the paucity of studies documenting effectiveness of botanicals, this CAM option cannot be recommended in the treatment of pediatric cancer pain. The lesson that must be taken away, however, is that it is important for practitioners to ask if botanicals (including megavitamins and herbs) are being used by the parent to help treat their child’s pain because there may be drug interactions that may interfere with the cancer treatment regimen.
CANNABIS

Because of legalization efforts in several US states, Canada, and other countries, “medical” cannabis is becoming more available and in many different forms. Cannabis, including marijuana, is a psychoactive substance produced from the cannabis plant and often comprising multiple compounds, including plant-derived cannabinoids like tetrahydrocannabinol (THC) and cannabidiol (CBD). Synthetic cannabinoids have also been produced such as dronabinol, nabilone, and nabiximols spray. The use of cannabis, especially for pain, nausea, or even antitumor effects has generated significant interest in the public and among some patients with cancer and their families. In humans, cannabinoids bind endocannabinoid receptors CB$_1$, found in the brain and nervous system, and CB$_2$, found in the immune system. Some reviews have found improvement in cancer-related or other pain with certain preparations of cannabis. A review of medical cannabis in pediatric populations in many ways parallels the findings in adults in regard to chemotherapy-induced nausea/vomiting, seizures, and spasticity; however, data on pain, even neuropathic pain, in children is lacking. Short-term side effects such as increased heart rate and blood pressure are common and may limit its use in patients with heart disease. Side effects of THC include drowsiness and dizziness. Side effects of CBD include somnolence, diarrhea, and decreased appetite. Prolonged use in recreational users has been associated with mood, anxiety, and psychotic symptoms and disorders.

Because of the heterogeneity of its composition and the lack of regulation, a great deal of caution must be used in extrapolating results from controlled studies to what is available on the market. Immunocompromised patients should be warned against use of unregulated marijuana, especially smoked and vaporized forms, because of potential infectious complications such as invasive pulmonary aspergillosis. Data on effectiveness on pain in children with cancer are lacking, and effects of chronic cannabis use on the developing brain are concerning. Because of a lack of efficacy data and these safety concerns, pediatric societies have advocated for further research and urged caution in recommending cannabis to pediatric patients, acknowledging
that there may be a role in certain exceptional cases such as for children with life-limiting or severely debilitating conditions. Comprehensive discussion of potential benefits and risks and robust monitoring of safety and efficacy during treatment is necessary.

**MAGNETS**
The use of magnets to treat chronic pain is another modality that has been under investigation in adult populations. Interestingly, despite the lack of clear data documenting the effectiveness, one study documented that magnet use was the second most common nontraditional modality used by adult patients with arthritis, second only to the use of a chiropractor. The basic mechanism of magnet use is that they produce a type of energy—a magnetic field—that can affect pain sensation, although the exact mechanism by which pain reduction occurs has not been identified. There are various magnet products for use in health care including shoe insoles, shoe inserts, mattress pads, bandages, belts, pillows, bracelets, and headwear. Despite all of these various health care products, there are limited data documenting the effectiveness of this modality. A recent systematic review and meta-analysis of randomized trials demonstrated no significant difference in pain reduction. There may be a placebo effect for the patient who places a magnet on the body in the form of a bracelet or bandage. The only reports in the literature of magnets in pediatric populations refer to the dangers of magnet ingestions resulting in gastrointestinal injuries. Thus, the use of magnets to treat young pediatric cancer patients is another treatment modality that cannot be recommended at this point in time and may be associated with risk of ingestion by a young child.

**SPIRITUALITY/RELIGIOSITY**
Spirituality (i.e., religiosity) is an important domain that must be considered when conceptualizing the model of palliative care for children with pain. Spirituality is commonly used by cancer patients to cope with their diagnosis, aggressive treatment plans, and associated painful experiences. Spirituality has been shown to be an important coping mechanism for adult cancer patients. For example, it has been shown that
breast cancer patients who rate their spirituality as high have lower rates of depression, although no effect on pain ratings.\textsuperscript{279} Similarly, when mothers of childhood cancer patients were asked to rate their religiosity concomitantly with the measurement of depression using the Beck Depression Inventory-II, it was shown that those mothers who reported lower levels of religious beliefs and behaviors had higher rates of depressive symptoms.\textsuperscript{280} It has therefore been recommended that health care providers consider—when they have patients practicing prayer or prayer-like behaviors—to include a discussion on the benefit of this behavior at improving health through the mind–body connection.\textsuperscript{281} In addition, given that most major medical centers caring for children with cancer have access to a chaplain or spiritual support, consulting this service should be considered (where appropriate) when developing a pain management plan for the pediatric cancer patient.

**THERAPEUTIC YOGA**

Therapeutic yoga, including Iyengar yoga, has been used in children to reduce pain, anxiety, and correct health problems. Iyengar yoga, for example, uses poses (asanas) and breathing to correct body structure, enhance internal organ function, facilitate mindful awareness, and achieve a sense of mind–body–spiritual well-being. Studies conducted in adolescents have demonstrated the practice of yoga results in improvement of mood, a decrease in the stress hormones, and decreased pain and disability.\textsuperscript{282,283} There are no published randomized controlled trials of yoga therapy in pediatric oncology; however, several single-arm pilot studies suggest improvement in physical function, quality of life, functional mobility, flexibility, physical activity, energy, sleep, and mood and decreases in anxiety, nausea, and pain medication, as summarized in a recent review.\textsuperscript{284} In the practice of Iyengar yoga, a teacher who has studied for a minimum of 5 years teaches various poses to a child that can be beneficial in decreasing pain. For the pediatric cancer patient with unique needs, including an impaired immune system, private yoga lessons are preferred over group lessons, with therapeutic Iyengar yoga our preferred method of yoga because of extensive teacher training, the use of supportive props, and selection of specific poses based on the needs of the
Palliative Care for Children with Cancer

A chapter on pain management for children with cancer is not complete without highlighting the important topic of palliative care given that overall 20% of children will not be cured of their disease. The WHO’s definition of palliative care is “the active total care of patients whose disease is not responsive to curative treatment. Control of pain, other symptoms, and psychological, social, and spiritual problems is of paramount concern. The goal of palliative care is achievement of the best possible quality of life for patients and their families.”285 The “other symptoms” in addition to pain that can be experienced by the child without the option of curative therapy include fatigue, dyspnea, poor appetite, nausea, vomiting, constipation, and/or diarrhea.23 Thus, symptom control for children facing end of life is imperative. Studies have demonstrated that when the multidisciplinary approach of palliative care is employed, families and patients report improved satisfaction with their care, improved informed decision making, and a decrease in the number of emergency room visits and inpatient admissions.286

The American Academy of Pediatrics (AAP) has put forth a policy statement promoting the use of palliative care at the end of life for children with life-limiting disease. Their statement highlights that palliative care can improve the quality of life for terminal patients and their families through the treatment of symptoms and by addressing the psychological, social, or spiritual aspects of facing a noncurable disease.287 Despite this policy statement on the importance of the provision of palliative care services for children with life-threatening disease, there are barriers that currently exist and thereby impede its implementation across the US health care system. First, there can be differences in parents’ understanding of prognosis of their child’s illness when compared to their health care providers’ knowledge, a discrepancy that in turn can impact a parental-informed decision for end-of-life care, including pain management.288 Secondly, parents whose children have an incurable cancer diagnosis rate doctor–patient communication as the principal determinant of high-quality
physician care. Conversely, physicians’ care ratings depend on biomedical rather than doctor–patient relationship aspects of care.\textsuperscript{289} It is, therefore, critical for physicians caring for the dying child to listen to the concerns of the patient and the parent particularly for those related to descriptions of pain. By listening to a patient’s description of pain and thereby classifying the etiology of the pain one can determine the best therapeutic approach. By being aggressive with symptom management, the pain and suffering at the end of life for a terminal pediatric cancer can be minimized.\textsuperscript{290}

Pediatric palliative care requires evaluation and reevaluation of symptoms. In addition to the assessment of pain, the provider needs to assess for symptoms of fatigue, dyspnea, anxiety, nausea, and sleep patterns. There should also be the assessment of caretaker function and support because fatigue or anxiety in the primary caretaker can in turn affect the symptoms associated with pain manifested by the child. Treatment of other end-of-life symptoms, such as dyspnea, can require the use of opioids, especially morphine, to decrease the sensation of air hunger. If the child is heavily sedated and the family or caretaker has minimal awake time with the child, psychostimulants (e.g., methylphenidate, modafinil) can be used in the mornings to override some of the sedative side effects of high-dose opioids needed for pain. In addition, nondrug therapies, such as music therapy or hypnotherapy, can be used concurrently with pain medications. The pediatric palliative care model as described earlier can be delivered both in the inpatient setting as well as in the home if pediatric hospice services are available. In either setting, the goal of maximizing quality of life for the quantity of time that remains for a child without curative therapy should be emphasized. It should be noted that many clinicians now consider palliative care to begin with a serious diagnosis, such as cancer, even if the likelihood for cure is high, because even some children with lower risk cancers, like ALL in the young child, will die. Thus, a focus on maximizing quality of life and reducing distressing symptoms should be as important a focus in the child with cancer as is the aim for cure.\textsuperscript{291,292}

\textbf{Summary}
Although pediatric cancer statistics are currently at an all time high with an overall survival rate of 80%, cancer-related morbidity, including the risk for the development of significant acute and chronic pain, persists. Thus, a comprehensive approach to pain management in the pediatric cancer patient, especially through empowerment of the child through a mind–body therapeutic approach to their pain management, is critical. There are several pharmacologic treatments that can be used to treat the various types of pediatric cancer pain including opioid analgesia, NMDA antagonist agents, atypical opioid medications, tricyclic antidepressants, and anticonvulsants. Integration of nonpharmacologic modalities as an adjuvant or alternative to pharmacologic interventions is also important because there can be limitations in the traditional pharmacologic approach to pain, particularly for chronic pain syndromes. Although not all nonpharmacologic therapies have a long track record in the scientific literature regarding their effectiveness, it does not mean these options should be excluded from pain management consideration, but rather, a discussion with families of the strengths and limitations of such approaches is warranted.

In summary, the foundation to the pain evaluation and treatment plans for children with cancer is a focus on the whole child. The importance of eliciting and listening to all details of the pain narrative of the pediatric cancer patient is critical. Child self-report will be dependent on the developmental level of the child and child pain evaluation encompasses the parental role in the pain experience, a proxy reporter of the pain narrative. For both the child and the parents, the pain assessment should occur early on, in a nonthreatening environment, where the strong triad relationship between the pediatric cancer patient, the parent, and the health care provider can be an effective one. In this family-centered care approach, the common goal of alleviating the child’s pain can be achieved through education, empowerment, and the provision of mind–body therapeutics.

Nociception alerts the organism to potential or actual sources of harm. Nociceptive functions are active at birth, even in preterm neonates, and the experience of pain or pleasure has a powerful impact on learning and neurologic development.\textsuperscript{1} Fitzgerald and Walker,\textsuperscript{1} using neurobiologic studies in infant rats and psychophysical studies in infant humans, showed that the infant nervous system is in many respects hyperresponsive to noxious stimuli compared to the mature nervous system. Infant rats and humans withdraw their limbs from milder mechanical or thermal stimuli compared to older rats or humans. Infant rats and humans develop hyperalgesia following tissue injury, with evidence for spinal sensitization even in preterm neonates.

In the 1980s, there was a growing acceptance that peripheral and spinal mechanisms of nociception are active in preterm and term neonates. Controversy persisted regarding maturation of supraspinal mechanisms and regarding how to view pain as a conscious experience or suffering in neonates. Recent studies have examined correlates of brain activation using near-infrared spectroscopy, which is sensitive to regional changes in blood flow. A noxious stimulus to the heel (performed for clinically indicated blood sampling) evoked increased signal overlying the contralateral, but not ipsilateral, cerebral cortex, which has been interpreted as a specific pattern of activation not solely dependent on global changes in autonomic arousal and blood pressure. These and other lines of evidence suggest that “painful stimulation reaches the brain” in neonates, although they do not per se establish the nature of pain viewed as
conscious experience or suffering in neonates. Additional discussion follows later in the chapter regarding potential consequences of either untreated pain or pain treatment in critically ill neonates.\(^1\)

Care of infants and children with acute pain has changed considerably over the past several decades, and available evidence suggests that undertreatment of acute pain has become less prevalent in economically developed countries over this time period.\(^2\) Changes in practice appear to be the combined result of a series of developments in basic research, clinical trials, and advocacy by parents as well as by clinicians, as listed in Table 50.1.

Pain Assessment in Infants and Children

Assessing pain in infants and children is a fundamental but challenging aspect of pediatric care. Uniform assessment of pain should be part of the standard of care for hospitals and clinics caring for children. Typical adult pain measures are not applicable to preverbal and young children. Infants and very young children are dependent on adult caregivers to adequately interpret their behavior and other signs in determining whether they have pain. Methods of measuring pain in preverbal patients and toddlers (ages 2 and 3 years) generally involve combinations of behavioral observation, such as facial expression, crying, and physiologic parameters. Preschool-age and early school-age children (ages 3 years or 4 to 8 years) are generally able to give some degree of self-report and pain scales in this age
group incorporate self-report measures. In the younger group (ages 3 to 4 years), pain may be only be expressed in a binary way (i.e., either present or not present), but by early school age (ages 5 to 6 years), children are generally able to communicate a variety of pain levels. Fear and anxiety in children may complicate pain assessment and, in some cases, leads them to either overrate or underrate pain. For this reason, many behavioral scales are taken to be measures of “distress,” which combines pain, fear, and anxiety. For example, a 2-year-old child fearful of having a relatively painless ear examination may appear to have extreme pain based on behavioral measures. A 7-year-old child may deny pain because of the fear of having to receive a “shot” if he admits to having pain. Valid and reliable pain measures have been developed for children based on developmental levels reflecting a child’s ability to communicate and understand concepts of pain. In general, behavioral measures tend to underrate persistent pain relative to self-report.

Pain assessment in infants, neonates, and premature infants is especially challenging. Previously, infants were not thought to be fully capable of experiencing pain, which led in part to inadequate efforts to treat pain in infants. Numerous studies have examined the response of neonates and preterm infants to pain and have shown various response patterns including changes in stress hormones levels; observed behavioral responses; and alterations in heart rate, heart rate variability, oxygen saturation, and other physiologic responses. Studies have shown that neonates who are subjected to heel lancing for blood sampling consistently swipe the foot being lanced with the unaffected foot, indicating that neonates have the ability to localize to the site of pain. Other data have shown that hospitalized infants display graded responses of heart rate, oxygen saturation, mean arterial pressure, and behavioral state with varying degrees of pain intensity, indicating that infants have the ability to distinguish severity of pain. Pain assessment scales for infants are typically composite pain scores consisting of behavioral parameters such as facial grimacing, posture, and crying combined with more objective data such as heart rate, blood pressure, and oxygen saturation. Pain ratings may be erroneous in critically ill infants because sepsis, hypotension, respiratory failure, and other conditions will change many of the
physiologic and behavioral parameters in composite pain scales. The CRIES; Face, Legs, Activity, Cry, and Consolability (FLACC) scales; and the Premature Infant Pain Profile have been validated for infants and premature infants.\textsuperscript{11–13}

Concrete thinking and stages of cognitive and language development of preschool-age children can present difficulties in pain assessment. Many toddlers when ill, hospitalized, or confronted with strangers refuse to cooperate with self-report or formal testing of pain. Involving parents or other familiar caregivers in the assessment of pain for toddlers can provide useful information. Studies comparing parents’ to clinicians’ pain ratings are inconsistent with some showing good agreement but others showing disparities.\textsuperscript{14}

The Children’s Hospital of Eastern Ontario Pain Scale (CHEOPS) and the Behavioral Observational Pain Scale (BOPS) have been validated for assessing postoperative pain in toddlers and young children.\textsuperscript{15,16} The FLACC scale is a very widely used scale involving five items, each scored from 0 to 2 to give a composite score ranging from 0 to 10.\textsuperscript{17} The FLACC scale has become widely used because it is quick and versatile and its components appear reasonable for a wide range of patient groups, including infants and older patients with developmental disabilities.\textsuperscript{13,17–21} A recent review does find evidence to support its use in children aged 2 months to 7 years for postoperative pain as well as in children from ages 4 to 10 years who have cognitive impairment.\textsuperscript{21}

Several validated self-report pain scores have been developed for children 4 years and older, including photos or drawings of faces where numerical anchors signify gradations of pain and a slide rule device where increasing color intensity indicates increasing pain intensity.\textsuperscript{22} Young children are able to differentiate pain intensity when presented with facial expressions, although more than five choices of facial expressions interfere with the child’s ability to reliably indicate pain.\textsuperscript{23} Most older school-age children and adolescents have the cognitive and emotional maturity to use adult numerical visual analogue scales; nevertheless, pain, illness, hospitalization, and separation from parents cause some older children and teenagers to regress emotionally, making scales used for younger children, such as faces scale, more applicable. There has been considerable dispute
regarding relative merits of different presentations of face-type scales; however, the most widely accepted and validated face-based scale is the Bieri Faces Pain Scale-Revised.\textsuperscript{23,24}

### Analgesic Pharmacology in Infants and Children

Age-related differences in analgesic pharmacology are explained by a combination of pharmacokinetic and pharmacodynamics factors that vary with development. Neonates and young children have delayed maturation of hepatic enzymes involved in the metabolism of analgesics such as opioids and amide local anesthetics, increasing the risk of drug accumulation and toxicity.\textsuperscript{25} For example, ester-type local anesthetics are metabolized by pseudocholinesterase. Young infants have significantly less of this enzyme compared to the adult population; therefore, clearance can be decreased and the effect of the local anesthetic is prolonged. Most neonates and young infants will have considerable maturation of the hepatic enzyme systems involved in biotransformation and conjugation by the age of 6 months, although enzyme maturation rates can vary considerably.\textsuperscript{26} Neonates and young infants have decreased plasma concentrations of albumin and $\alpha_1$ acid glycoprotein, which leads to decreased protein binding and greater concentrations of unbound, pharmacologically active drug.\textsuperscript{27} Neonates also have reduced glomerular filtration rates in the first few weeks of life resulting in slower elimination of many drugs and many active metabolites of drugs that have undergone hepatic metabolism which are excreted via the kidneys. A number of specific age-related differences in pharmacokinetics and in drug actions and risks are detailed with each drug class in the following text.

### Nonopioid Analgesics

Nonopioid analgesics traditionally refer to aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and selective cyclooxygenase (COX) inhibitors. More recently, evidence of analgesic efficacy in adjuvant medications such as gabapentin and pregabalin have expanded the choices of nonopioid analgesics. Several new entities, such as the G
protein-related receptor agonists, will provide other nontraditional opioid receptor mediated analgesic choices. Many of the NSAID analgesics were thought of as primarily peripherally active agents; however, analgesia does occur from a combination of peripheral as well as central actions, involving mechanisms in the spinal cord and brain, especially with activation of microglia. Nonopioid analgesics are often first-line drugs used for mild to moderate pain in infants and children because they do not produce respiratory effects and are generally nonsedating.

**ONTOGENY OF PROSTANOID BIOSYNTHESIS AND CYCLO-OXYGENASES**

A variety of prostanoids are produced during fetal life, and COX inhibition can alter essential functions, including patency of the ductus arteriosus. Recent studies by Ririe and coworkers in infant rats suggest that COX-mediated processes in spinal microglia are quite immature at birth. These studies raise the question of whether commonly used analgesics acting on COX isoforms might be ineffective in infants due to this delayed maturation of a prominent site of action.

**ASPIRIN AND OTHER SALICYLATES**

The use of aspirin in children has diminished significantly, largely due to its association with Reye syndrome. The elimination of aspirin is greatly reduced in infants. In our practice, aspirin is almost never prescribed as an analgesic; its use is confined to situations in which antiplatelet actions are required.

**ACETAMINOPHEN**

Acetaminophen is the most commonly used analgesic in pediatrics and has been safely used in children of all ages. It is typically used for mild to moderate pain, fever, and can be combined with opioids to provide additional analgesic effect and decreased opioid use. The mechanisms underlying acetaminophen’s analgesic and antipyretic actions remain controversial. Multiple central targets of acetaminophen’s actions have been described, including COX isoenzyme (type 3 as well as type 2) inhibition, endogenous cannabinoid receptors, and nitric oxide pathways.
Clinically, acetaminophen, by itself, appears to produce minimal gastropathy, minimal effect on platelet function, and much milder anti-inflammatory actions compared to NSAIDs. Acetaminophen, combined with NSAIDs, can produce additional analgesic benefits, with synergism in some models. The elimination of acetaminophen is primarily through glucuronidation and sulfation and elimination rates are similar among infants, children, and adults. Various formulations are available with different concentrations in the United States, although there has been a recent attempt at standardization of dose formulations. Inadvertent dosing errors have led to reports of fulminant hepatic failure among infants and children. Typical oral dosing is 10 to 15 mg/kg per dose. The maximum daily dosing is 40 mg/kg/day for premature infants and 75 mg/kg/day for term infants and children. Rectal dosing can be used for children who are unable to tolerate oral dosing, although absorption of rectal dosing can be variable. Maximal concentration after rectal dosing occurs at approximately 2 to 3 hours. Typical rectal dosing is 30 to 45 mg/kg initially, followed by 20 mg/kg every 6 hours. In 2010, the U.S. Food and Drug Administration (FDA) approved the use of intravenous acetaminophen. Peak plasma concentration is reached in 15 minutes following infusion and data show improved pain control with use of the intravenous, with opioid sparing effect. There is a role for use of the intravenous form in children who are both nothing by mouth (NPO) and nothing by rectum (NPR), as well as situations where children are NPO alone, given that rectal dosing can lead to discomfort, fear, or anxiety in children beyond infancy.

**NONSTEROIDAL ANTI-INFLAMMATORY DRUGS**

NSAIDs are commonly used for mild to moderate pain and for fever control in children. They are often combined with opioids to augment analgesic efficacy and potentially reduce opioid use and opioid side effects. The use of several NSAIDs in postsurgical patients has been shown to reduce opioid use by approximately 30% to 40%. NSAIDs produce their anti-inflammatory effect by reversibly inhibiting COX-1 and COX-2 isoforms and inhibiting the conversion of arachidonic acid to prostanoids. The clearance of ibuprofen, ketorolac, and several
other NSAIDs is more rapid in toddlers and preschool children compared to adults.\textsuperscript{41}

Based on epidemiologic studies and pooled data from clinical trials, NSAIDs have a generally good safety margin in children and infants from roughly age 6 months onward, particularly with short-term use. There are limited safety data on the use of NSAIDs among neonates and young infants. In certain situations, one can consider NSAID use, such as ketorolac, in infants under 6 months, if the risk of using alternate analgesics is felt to be greater than use of an NSAID.\textsuperscript{42,43} Indomethacin has been used for closure of patent ductus arteriosus in neonates. Elimination of indomethacin is slower in neonates and has the associated risk of hyponatremia and renal toxicity in this age group.\textsuperscript{44} The incidence of NSAID side effects is quite low in children, when administered for postoperative pain relief. A large-scale study in children administered short-term use of ibuprofen showed a very low overall risk of severe side effects.\textsuperscript{45} The risks of renal and hepatic toxicities are increased in states of decreased renal and hepatic blood flow, such as with significant surgical blood loss or shock. Much of the safety data for long-term use of NSAIDs in children is based on experience in treating juvenile rheumatoid arthritis (JRA).\textsuperscript{46} Long-term use is associated with a higher incidence of mild gastrointestinal distress, but significant gastropathy and gastrointestinal bleeding in children is less common when compared to adults.

Although NSAIDs inhibit platelet aggregation and can prolong bleeding time, clinically significant bleeding is uncommon in healthy children. The use of NSAIDS after tonsillectomy procedures remains somewhat controversial. Children requiring tonsillectomy often have obstructive sleep apnea and are at increased risk of hypoventilation and apnea with opioids, making nonopioid analgesics an attractive alternative. Nausea and vomiting are also common after tonsillectomy, and opioids exacerbate these problems. Life-threatening bleeding can occur after tonsillectomy in the immediate postoperative period and approximately 7 days postoperatively after the patient has been discharged from the hospital.

Two meta-analyses came to different conclusions about the safety of NSAIDs in tonsillectomy. One found no significant increase in bleeding, whereas the other reported a threefold increase in bleeding episodes of
sufficient severity to require reoperation. A more recent retrospective chart review did support the findings that postoperative use of ibuprofen did increase posttonsillectomy bleeding. It is less clear if single dosing of ketorolac during the perioperative period increases the risk of postoperative bleeding in this population. A recent meta-analysis does not show increased risk of posttonsillectomy hemorrhage in children with perioperative ketorolac use. Despite these concerns, NSAIDs remain commonly used in the posttonsillectomy population worldwide at many institutions both perioperatively and in the postoperative healing period.

An additional concern with NSAID use is impaired bone healing after orthopedic surgeries that involve osteoclast activation and new bone formation. In vitro studies, animal models, and some case-control studies in adults suggest a higher incidence of impaired bone healing and nonunion with NSAID use. However, compared to adults, children are less likely to have impairment of bone formation with similar orthopedic procedures. Even in major procedures such as posterior spinal fusion for scoliosis, perioperative use of NSAIDS appears to be safe and not to result in a higher incidence of nonunion. For surgeries with lower risk of nonunion, or for selected patients with greater than average risks or side effects from opioids, judicious use of NSAIDs for brief time periods should be considered.

Selective COX-2 inhibitors have the advantage of lower incidence of gastrointestinal symptoms and decreased effect on platelet function compared to traditional NSAIDs in adult patients. The risk of nephropathy with selective COX-2 inhibitors is similar to that of traditional NSAIDs. Anti-inflammatory and analgesic effects of COX-2 inhibitors are also similar to those of traditional NSAIDs. COX-2 inhibitors have been associated with cardiovascular complications in adults, with both short- and long-term use. Rofecoxib and valdecoxib have been withdrawn from the market in response to these reports of cardiovascular complications in adults. The cardiovascular risk of COX-2 inhibitors in infants and children remains unclear. The use of COX-2 inhibitors may be considered in children with JRA who experience good analgesia with traditional NSAIDs, but who have significant gastrointestinal symptoms, or in children with bleeding disorders, such as hemophilia or thrombocytopenia,
to achieve analgesia with less risk of bleeding than with traditional NSAIDs. Studies of COX-2 inhibitors for analgesia after tonsillectomy are mixed. One study found better analgesia with ibuprofen compared to placebo.\textsuperscript{54} One double-blind randomized controlled trial (RCT) found benefit to use of celecoxib in the posttonsillectomy population with a modest decrease in pain scores in addition to decreased use of acetaminophen.\textsuperscript{55} Some studies suggest that COX-2 inhibitors might be less likely to interfere with active bone formation. Please see Table 50.2 for dosing guidelines of common nonopioid analgesics.

NOTE: Dosing guidelines listed herein refer to children > 1 year of age. Maximum dose acetaminophen: 75 mg/kg/day. Further modifications in dosing are required for use of these agents in term and preterm neonates and in infants. Modifications are detailed in the text. IV, intravenous; PO, orally.

**KETAMINE**

Ketamine is increasingly used in both acute and chronic pain, especially in the postoperative period. Ketamine has anti-N-methyl-D-aspartate (NMDA) activity, which acts to decrease wind-up, central sensitization, opioid-induced hyperalgesia, and opioid tolerance. Multiple studies in the adult population have shown that ketamine has not only opioid-sparing effects but also analgesic and antihyperalgesic effects.\textsuperscript{56} Literature supporting the use of ketamine in the perioperative period in children is not as clear. A 2016 meta-analysis of perioperative ketamine use in children did not find that ketamine beneficial in decreasing the amount of opioids used postoperatively.\textsuperscript{57} Although the meta-analysis was not
favorable, individual studies favor the use of ketamine in the postoperative period. This study showed decreased opioid use and lower pain scores following Nuss procedure in the group that received ketamine in addition to fentanyl.\textsuperscript{58} One study published in 2016 did not find that low-dose ketamine postoperatively in posterior fusion spine surgery in children decreased opioid use postoperatively.\textsuperscript{59} This particular study also did not find benefit in preventing long-term postoperative pain, although the incidence of persistent postoperative pain in this demographic is not clearly known. It is reasonable to consider use of ketamine in children, particularly in those with difficult to control pain or a history of chronic opioid use. The data for use in adults is well-established and thus is an area that can be further explored in pediatrics.

**ANTICONVULSANTS**

The use of anticonvulsants in chronic pain is well established; however, their use in acute pain, especially in children, is not as well established. There is evidence to support perioperative use of gabapentin for spine surgery in children. A study published in 2010 did show benefit to perioperative use of gabapentin 15 mg/kg prior to posterior spine fusion.\textsuperscript{60} Gabapentin (continued at 5 mg/kg three times a day for a total of 5 days) decreased opioid requirements and postoperative pain scores only in the first 48 hours after surgery. Therefore, some clinicians only provide a preoperative oral loading dose. Valproic acid is another anticonvulsant that finds limited use in the acute treatment of pediatric migraine with one study finding approximately 50% of patients receiving significant relief from their headache.\textsuperscript{61} There is some evidence to support its efficacy in the treatment of acute migraine; however, the studies are few and also complicated by the fact that valproic acid was not the first-line treatment; thus, other medications, treatments, and factors likely played a role in the reported relief.\textsuperscript{62}

**Opioids**

Opioids are among the most widely used analgesics for treating moderate to severe pain in infants and children. As with adults, they are extremely
useful but require careful patient selection, titrated dosing, and active
treatment of side effects.

**ONTGENY OF OPIOID ACTIONS**

The ontogeny of opioid actions has been studied in human clinical trials, in
case series, and in a number of infant animal models. Infant animal models
have provided useful information, although there are marked differences
among species in opioid actions. There are age-related differences in
analgesia and side effects involving pharmacokinetic and
pharmacodynamics differences. Opioids (except for remifentanil) have
prolonged actions in neonates and infants due to immature hepatic enzyme
systems and immature renal excretion of active metabolites. Effects of
hepatic and renal dysfunction on opioid clearance are discussed in a
separate section in the following text. Additional factors that influence
opioid pharmacokinetics include developmental changes in expression of
P-glycoproteins, both in the gastrointestinal tract and in the blood–brain
barrier, and changes in protein binding.

Pharmacodynamic studies of opioids in neonates and younger infants
have examined analgesia and side effects, with a major emphasis on
measures of respiratory depression. These studies are made difficult by a
number of factors, including the imprecision inherent in observational pain
measures in neonates, on the state dependence of behavioral responses, on
the confounding effects of critical illness on measures, and on the
variability of painful stimuli. Major sites of opioid actions, including the
periaqueductal grey matter and descending pathways of the dorsolateral
funiculus, appear immature in infant rats. Conversely, opioids
administered systemically or via the epidural route show strong analgesic
responses in infant rats at developmental stages corresponding to preterm
neonates. In human studies, there are mixed results with use of opioids in
studies of procedural pain in neonates, and studies randomly assigning
ventilated neonates to receive morphine infusions versus placebo infusions
(with both groups receiving morphine for painful procedures) have not
shown clear advantages in the morphine infusion groups.63,64

Children who are at particular risk for respiratory depressant effects of
opioids include those with tonsillar hypertrophy, obstructive sleep apnea,
certain neurologic conditions, and craniofacial abnormalities as well as neonates and young infants. Neonates and infants, particularly premature infants, have an increased risk of apnea and hypoventilation in response to opioids on a pharmacodynamic as well as pharmacokinetic basis. Careful dosing, cardiorespiratory monitoring, and close nursing observation are warranted for neonates and younger infants receiving opioids.

CODEINE
Codeine is an opioid previously used widely to treat mild to moderate pain. It is available as an elixir in pill and parenteral forms. Although it has seen a declining use for pain, it remains commonly used in cough suppressant formulations. For reasons to be detailed in the following text, our opinion is that codeine is in general a suboptimal choice as an analgesic in children in most settings, and we recommend against its use. Codeine is a prodrug extensively metabolized in the liver. It is demethylated to morphine, which accounts for the analgesic effect. A study of children undergoing surgery, receiving a fairly large dose of codeine, found that roughly one-third of the subjects generated undetectable blood concentrations of morphine, which would result in no discernible analgesic effect. Conversely, there are genotypes associated with ultrarapid metabolism of codeine to morphine. In these subjects, standard recommended codeine doses can produce apnea. Standard dosing is 0.5 to 1 mg/kg every 4 hours. Dose escalation beyond this range appears to generate a higher incidence of side effects, particularly nausea and vomiting. In standard doses, codeine is a very weak analgesic. Studies in adult patients comparing efficacy of codeine to ibuprofen have shown that 30 to 45 mg codeine has less analgesic effect than 600 mg of ibuprofen. Because of the relatively high incidence of the impaired inability to demethylate codeine and higher incidence of side effects, other oral opioids such as oxycodone, morphine, hydromorphone, and hydrocodone are preferred. Intramuscular (IM) codeine has the double disadvantage of being a weak and inconsistent analgesic delivered by a noxious route.

Codeine is often dispensed in combination with acetaminophen to increase efficacy. When prescribing codeine combined with acetaminophen, care is required to avoid inadvertent administration of
toxic doses of acetaminophen, particularly when increased dosages are prescribed for pain or when patients are taking other over-the-counter preparations containing acetaminophen. Codeine is also commonly prescribed as an antitussive.

As of 2013, the FDA has issued a new contraindication for the use of codeine to treat pain or cough in children younger than 12 years as well as a warning against its use the 12- to 18-year-old age group of children who have sleep apnea and/or are obese.\textsuperscript{69}

**TRAMADOL**

Tramadol has both opioid and nonopioid properties. It exists in a racemic mixture where the positive enantiomer has opioid and serotoninergic properties and its negative enantiomer exerts noradrenergic reuptake properties.\textsuperscript{70} Like codeine, it is metabolized to O-desmethyltramadol by the P450 isoenzyme CYP2D6. It exerts its analgesic effect via the \( \mu \)-opioid as well as acting as a serotonin and norepinephrine reuptake inhibitor. In the United States, it is available only in the oral form. In other countries, it is also available in an intravenous preparation. Although not approved for use in children under the age of 12 years, it is widely used for postoperative pain as well as acute pain in children.\textsuperscript{71}

Tramadol is also associated with many reports of toxicity in children. Overall, the incidence of these adverse reactions is low, but they do occur. Toxicity for tramadol, like opioids, not only can result in respiratory depression but can also result in seizures.

As of 2017, the FDA has issued new black box contraindication for the use of tramadol to treat pain or cough in children less than 12 years of age. They have also included a contraindication to the use of tramadol in children undergoing tonsillectomy and/or adenoidectomy in patients under the age of 18 years. In addition to these contraindications, a new warning against the of tramadol in the 12- to 18-year-old age group in children with sleep apnea or who are obese is also in place. These were put in place after the recognition of the implications of genetic variability in P450 2D6 metabolism and the potential for life-threatening reactions.\textsuperscript{72}

**OXYCODONE**
Oxycodone can be used for moderate pain in doses of 0.05 to 0.1 mg/kg every 4 hours and for moderate to severe pain in starting doses of 0.1 to 0.2 mg/kg every 4 hours in infants and children >1 year of age. Less information regarding the use of oxycodone in neonates and small infants is available. Recent review and modeling suggests the use of lower doses in preterm neonate and small infants starting as low as 0.035 mg/kg and increasing to 0.065 mg/kg in term neonates.73,74 Although historically prescribed in smaller doses, oxycodone dosing can be escalated as needed much like any of the so-called strong opioids. Oxycodone is generally well tolerated by children either alone or in combination with acetaminophen. Our impression is that it is associated with fewer side effects than codeine when used to treat moderate to severe pain. Oxycodone is metabolized in the liver to oxymorphone, which is metabolically active.75 Because oxymorphone is eliminated by the kidneys, it can accumulate in patients with renal failure. Oxycodone is commonly used in children postoperatively when transitioning from parenteral opioids to oral opioids in preparation for discharge.

A sustained-release preparation of oxycodone (OxyContin) is available for use in the treatment of chronic pain and was approved use in children age 11 to 16 years in 2015. Recently, the trend at our institution is away from the use of long-acting oxycodone for postoperative pain. It has a bioavailability of approximately 60% and reaches peak analgesic effect after 60 to 90 minutes.76

**MORPHINE**

Morphine is often the first-line opioid chosen for parenteral use in children. It has a long track record in pediatrics; it has received extensive pharmacologic study at all age groups; it is inexpensive; and it can be administered via oral, sublingual, intravenous, subcutaneous, rectal, and neuraxial routes.

The duration of morphine’s clinical effects are related in a complex manner to distribution into and out of the central nervous system, hepatic metabolism, and excretion of active metabolites, including morphine 6-glucuronide. Morphine primarily undergoes glucuronidation by the UDP glucuronosyltransferase (UGT) pathway in the liver to morphine-3-
glucuronide, which has predominantly excitatory actions, and morphine-6-glucuronide, which has analgesic, sedative, and respiratory depressant actions more potent than morphine.\textsuperscript{77} Because morphine-6-glucuronide is renally eliminated, it can accumulate in patients with renal failure, producing delayed sedation and hypoventilation. In addition, accumulation of morphine 3-glucuronide can contribute to delirium, agitation, and seizures. The elimination half-life of morphine in older children and adults is approximately 3 to 4 hours. The elimination half-life is approximately 7 hours in full-term newborns and even longer in premature infants.\textsuperscript{78,79} Long-acting preparations of morphine, such as MS Contin or KADIAN, are typically used for children with sickle cell pain, cancer pain, and other types of chronic pain.

Dosing of morphine in children, as with all opioids, should be titrated to effect and individualized based on severity of pain, underlying medical conditions, age, side effects, and weight. See Table 50.3 for dosing guidelines for oral and parenteral morphine.

</table>

NOTE: Doses are for patients over 6 months of age. In infants under 6 months, initial per kilogram doses should begin at roughly 25% of the per kilogram doses recommended here. Higher doses are often required for patients receiving mechanical ventilation. All doses are approximate and should be adjusted according to clinical circumstances. Recommendations are adapted from previous summary tables, including those of a consensus statement from the World Health Organization and the International Association for the Study of Pain.\(^a\)

\(^a\)Methadone requires additional vigilance because it can accumulate and produce delayed sedation. If sedation occurs, doses should be withheld until sedation resolves. Thereafter, doses should be substantially reduced, the interval between doses should be extended to 3 to 12 hours, or both. Electrocardiogram (ECG) for QT interval required.

\(^b\)The use of meperidine should generally be avoided. Can consider use for postoperative shivering. NA, not applicable; NR, not recommended.

**HYDROMORPHONE**

Hydromorphone is a commonly used opioid for acute pain management in children for both parenteral and oral use. Like morphine, it is used in
children for patient-controlled analgesia (PCA), continuous infusions, oral
dosing, intermittent intravenous boluses, and epidural analgesia.
Hydromorphone can provide effective analgesia in children with cancer
pain and mucositis. In steady-state dosing, hydromorphone is 5 to 6 times
more potent than morphine when given intravenously in children.\(^\text{80}\)

Although hydromorphone is commonly prescribed to patients with renal
insufficiency, this practice is not evidence-based. Hydromorphone is
metabolized primarily to hydromorphone-3-glucuronide (H3G) and, to a
much lesser extent, hydromorphone-6-glucuronide (H6G) through UGT
pathways.\(^\text{81}\) These glucuronides can also accumulate in patients with renal
insufficiency. Information on metabolism of hydromorphone in neonates
and young infants is very sparse.

**METHADONE**

Methadone is a long-acting opioid with a slow elimination and prolonged
duration of analgesia.\(^\text{82,83}\) The elimination half-life is highly variable,
rangeing from 6 to 30 hours. Methadone has a high oral bioavailability of
70% to 100%. Due to these unique properties, methadone is convenient to
use as a prolonged duration opioid. Intermittent intravenous dosing at
prolonged intervals (e.g., every 4, 6, or 8 hours) can provide a basal level
of analgesia similar to that achieved by continuous infusions or frequent
intravenous boluses of other opioids.\(^\text{84}\)

Methadone is available as an elixir and is often used in place of
sustained-release opioid preparations to treat chronic pain in young
children or in children unable to swallow pills. Conversely, methadone
requires careful titration and vigilance to avoid overdosage, both because
of extreme pharmacokinetic variability and for pharmacodynamic reasons
detailed in the following text.

Methadone is prepared as a racemic mixture of levo (l-) and dextro (d-)
isomers. The l-isomer acts as a \(\mu\)-receptor agonist; the d-isomer acts as an
antagonist at the NMDA receptor in the brain and spinal cord. Antagonism
at the NMDA receptors results in analgesia and reduced hyperalgesia as
well as partially reversing tolerance to opioids.\(^\text{85}\)

The NMDA antagonism of methadone is also a rationale for its use in
the treatment of neuropathic pain. The combined \(\mu\)-agonist and NMDA
antagonist actions of methadone result in incomplete cross tolerance. Thus, the dose conversion ratios between methadone and morphine and other μ-opioids are different for opioid-naive versus opioid-tolerant patients. For opioid-naive patients, the average daily intravenous methadone requirement is roughly one-third of the corresponding intravenous morphine requirement; however, average daily methadone requirements for opioid-tolerant patients may be as little as 10% to 15% of the total daily morphine dosing. This is particularly relevant when converting morphine to methadone for children with advanced cancer and when weaning nonventilated infants and children following prolonged opioid therapy, especially following intensive care. Careful titration and frequent patient assessment for respiratory depression is warranted in dosing methadone. When anticipating long-term methadone use, either when weaning from a long-term opioid infusion, the opioid-dependent infant, or in cancer-related pain, care should be taken during initial titration of methadone given its long and variable half-life. It is generally our practice to increase methadone no more frequently than every 2 to 3 days. For patients showing signs of oversedation or respiratory depression, it is often necessary to hold multiple doses of methadone because of its prolonged duration of action. In our practice, we also use methadone intraoperatively during certain procedures such as posterior-spinal fusion or Nuss bar placement. We do not routinely manage acute pain with methadone given other available alternatives.

FENTANYL
Fentanyl has a rapid onset and brief duration of action after single-dose administration, and it is often used for brief painful procedures in children, such as lumbar punctures, bone marrow aspirations, fracture reductions, and dressing changes. Fentanyl is also used for PCA in children with acute and chronic pain and in highly selected situations as a transdermal patch for children with cancer-related chronic pain. Fentanyl primarily undergoes glucuronidation in the liver to inactive metabolites, making it a preferred opioid for patients with renal or liver failure. Fentanyl is 50 to 100 times more potent than morphine with single-dose administration and roughly 20 to 50 times more potent with
The action of fentanyl after single-dose administration is terminated by rapid redistribution; however, after prolonged infusion or repeated boluses, the termination of fentanyl effect is determined more by elimination than redistribution and results in a prolonged duration of action. In addition, pharmacokinetics of fentanyl are easily altered in small infants, as hepatic blood flow is affected during surgery. Continuous infusions or repeated boluses in neonates can cause a particularly prolonged effect. Rapid administration is associated with glottic and chest wall rigidity, which can be especially pronounced in neonates and young infants. Neuromuscular blockade and assisted ventilation are usually necessary for treatment, particularly in neonates and young infants. Naloxone may sometimes be effective in reversing fentanyl-induced rigidity, but this action is not reliable.

For brief painful procedures, incremental doses of fentanyl at 0.5 to 1 µg/kg every 1 to 3 minutes usually provide effective analgesia. Cardiorespiratory monitoring and immediate availability of airway equipment and personal skilled in airway management are necessary. Oral transmucosal fentanyl has also been used for brief painful procedures in children and for breakthrough cancer pain. The oral transmucosal dose is partially absorbed across the buccal mucosa and partially swallowed; overall, the bioavailability is approximately 50%. It is generally well tolerated by children, although almost 90% of children experience facial pruritus. Additionally, the peak analgesic effect after a standard 15 µg/kg dose is 20 minutes, which may be limiting for some procedures. Another option is the use of intranasal fentanyl, which is particularly beneficial in patients who do not have established intravenous access. Dosing of intranasal fentanyl is higher than intravenous, at 1.5 µg/kg. Intranasal fentanyl may be used in a variety of acute pain situations including sickle cell crisis, limb injuries, and during general anesthesia for myringotomy.

Transdermal fentanyl is used in children with cancer pain and other forms of chronic pain requiring regular opioid dosing. It is indicated in a small subgroup of children who are unable to swallow pills, who have limited intravenous access, or who have experienced side effects with a number of other opioids. Approximately 12 to 24 hours are necessary to achieve steady-state plasma levels after applying the transdermal fentanyl.
patch, and it is therefore not indicated for acute fluctuations in pain intensity. Additional short-acting opioids are necessary to treat breakthrough pain. Transdermal fentanyl is indicated for opioid-tolerant patients who have relatively constant pain. Serious and lethal adverse events have been reported among opioid-naive patients who were treated with transdermal fentanyl for acute postsurgical pain. There has been a series of manufacturing problems that have led to inconsistent delivery for some batches of transdermal fentanyl. We emphasize here that transdermal fentanyl is not recommended for opioid-naive patients under any circumstances.

**MEPERIDINE**

Meperidine is a synthetic opioid roughly one-tenth the potency of morphine when administered intravenously. It has some anticholinergic actions and is metabolized to normeperidine, which can cause seizures, hallucinations, and agitation, particularly with repeated dosing. Metabolism in infants is quite variable. Life-threatening reactions can occur with the use of meperidine in patients taking monoamine oxidase inhibitors, leading to hyperreflexia, seizures, hemodynamic instability, and death.

Meperidine does have the unique property in subanalgesic doses of treating rigors associated with blood product transfusions or shivering following general anesthesia. Because of the serious adverse effects of meperidine and because it offers no particular advantage for pain control, its use should be limited to the treatment of rigors or shivering.

**Opioid Administration in Infants and Children**

As in adult patients, there are several means for systemic opioid delivery in pediatric patients. The choice of which method depends to a certain extent on available resources, coexisting medical conditions, types of pain, patients’ mobility, and other factors.

Regardless of method of opioid delivery, protocols for safe opioid administration should be in place to detect excess sedation, signs of respiratory depression, and impending respiratory failure. Protocols should
include regular nursing assessments, documentation of vital signs and levels sedation, and, where appropriate, use of electronic cardiorespiratory monitoring that should include pulse oximetry. Patients who should be considered for cardiorespiratory monitoring include infants who are younger than 6 months, infants who have a history of apnea and bradycardia, or prematurity, and opioid-naive children who require a continuous opioid infusion. Children at increased risk for airway obstruction while receiving opioids such as those with tonsillar hypertrophy and obstructive sleep apnea or children with craniofacial abnormalities should also be considered for cardiorespiratory monitoring. There is considerable variation in practices regarding methods to detect and prevent opioid-induced respiratory depression. It is our general practice to use continuous pulse oximetry for children who are utilizing continuous opioids, PCA, or parent-/nurse-controlled analgesia (PNCA). Many recommendations are based on reasonable extrapolation from physiologic considerations. Nevertheless, evidence to quantify the risk reduction from specific forms of monitoring is quite sparse.

INTERMITTENT INTRAVENOUS BOLUS DOSING

In clinical care areas other than the intensive care units or the postanesthesia care units, in our institution, most intermittent bolus dosing of opioids are administered as an infusion over 20 minutes rather than “intravenous push.” Although a slow administration is thought of as a somewhat safer method of intermittent dosing, careful monitoring and repeated patient assessments remain important during and after the opioid infusion. Intermittent systemic boluses cause wide fluctuations in plasma opioids concentrations. Patients therefore experience probably few side effects but increased pain just prior to their next bolus opioid dose. After the dose is administered, patients experience pain relief, but often with excessive side effects, as the plasma opioid concentration reaches supratherapeutic levels. Regular, intermittent dosing of opioids can result in dose stacking, especially if the opioids are ordered around the clock. As each next dose is administered, the prior dose has not fully cleared the plasma and the remaining plasma concentration can ramp up with each successive dose. At some point, the next bolus results in a toxic peak level,
which in the frail opioid-naive patient can result in significant cardiorespiratory compromise. To avoid wide variations in plasma concentrations with resultant fluctuations in analgesia and side effects, continuous infusions and PCA are commonly used.

**CONTINUOUS OPIOID INFUSIONS**

Continuous opioid infusions offer the advantage of providing steady-state plasma levels and result in good analgesia in infants and children who experience relatively constant levels of pain intensity. Additional intermittent boluses are necessary for periods of increased pain, such as endotracheal tube suctioning or chest physiotherapy. Recommended starting infusion rates have been adjusted for age based on both pharmacokinetic considerations, on studies of respiratory responses, and on clinical outcome studies. Starting infusion rates for morphine have been recommended as around 0.025 to 0.030 mg/kg/hour for children and infants >6 months of age, with reductions to 0.015 mg/kg/hour from 1 to 6 months, ranging down to 0.005 mg/kg/hour for preterm neonates at 32 weeks postconception. These recommendations should be taken as population averages; individual rates should be adjusted according to clinical conditions, expected intensity of painful stimuli, and behavioral and physiologic signs.

**PATIENT-, NURSE-, AND PARENT-CONTROLLED ANALGESIA**

PCA is widely used among pediatric centers for variety of acute painful conditions such as cancer pain, sickle cell pain from vasoocclusive crises, trauma, and acute postoperative pain. Most children 8 years of age and older have the cognitive ability to understand cause and effect relationships of pushing the PCA button and obtaining pain relief. In rare cases, experienced children younger than 6 to 8 years, who have had long-standing pain, are able to use PCA. For most children younger than 6 to 8 years, PCA has a higher failure rate in part because of the inability to understand the causal connection between button-pressing and delivery of medication to provide pain relief. However, nurse-controlled analgesia (NCA) or PNCA has been shown to provide effective analgesia with good
patient, parent, and caregiver satisfaction in younger children. PNCA is also used for children with cognitive and physical limitations who are unable to use the PCA. In our hospital, PNCA is the most common method of systemic opioid administration following major surgery in infants and in children with cognitive or physical limitations to self-administration. At our institution, we have also adopted the use of PNCA in our neonatal population. In this population, we recommend starting your opioid dose lower at 10 µg/kg.

Commonly used opioids for PCA/NCA are morphine, hydromorphone, and fentanyl. Use of a basal infusion along with PCA boluses has been a subject of controversy and some controlled studies in adults and children. In some studies, a basal infusion improves pain scores, patient satisfaction, and the quality of nighttime sleep. In other studies, a basal infusion increased surrogate measures of hypoventilation, including brief respiratory pauses. Our view is that the recommendations regarding addition of a basal infusion depend on patient medical conditions and risk factors, on psychological factors, on expected intensity of painful stimuli, and on history of previous opioid use. For example, a basal infusion may be omitted for children who have received a regional block intraoperatively, for children with increased respiratory risks, or for those undergoing surgical procedures expected to be only moderately, but not severely, painful. Conversely, we generally include a basal infusion for patients who are opioid-tolerant or for procedures expected to cause severe pain. For those undergoing very painful operations, such as scoliosis surgery, open lateral thoracotomy, or major hip surgery, we generally maintain a basal infusion at least through the first postoperative night.

Parent-controlled analgesia is widely accepted for use among children with advanced cancer or children in palliative care. There have been several serious adverse events reported, including apnea and death with the use of parent-controlled analgesia in children with risk factors and with insufficient protocols for patient observation and education on proper use. Our view is that parent-controlled analgesia for opioid-naive children should be restricted to institutions which have formal programs for parent education, protocols for frequent assessments by nurses, and protocols for cardiorespiratory. Please see Tables 50.4 and 50.5 for PCA dosing.

### TREATMENT OF OPIOID SIDE EFFECTS

Opioids are alike in that all produce similar side effects including nausea, vomiting, constipation, pruritus, urinary retention, respiratory depression, and sedation. In some cases, severe side effects are as distressing to children as pain. Although children may have particular side effects with individual opioids, there are few data to suggest that side effects differ greatly among the more commonly used opioids. Kehlet<sup>101</sup> and others have argued for multimodal approaches to postoperative analgesia that emphasize opioid-sparing, in part because of the detrimental impact of opioid side effects on the course of postoperative recovery.

There is an important role for standardized protocols for treatment of opioid side effects and for rapid institution of therapy for many patients. Nevertheless, along with prompt intervention, there is a role for clinical assessment and for consideration of a differential diagnosis. Two examples illustrate this point: (1) A patient may not only be itching due to opioids but could also have itching as part of an allergic response to a variety of other medications or physiologic processes and (2) a patient with advanced cancer, worsening back pain, and increasing opioid dosing may have urinary retention due to the opioid, but urinary retention could also be a result of other factors.
harbinger of impending compression of the spinal cord or caudal equina. Clinicians need to balance prompt intervention with consideration of alternative diagnoses underlying these symptoms.

Opioid side effects occur by actions at both peripheral and central sites. For example, opioid-induced nausea and vomiting involves activation of receptors in the brainstem as well as in the gastrointestinal tract. Similarly, some opioids may produce itching by peripheral histamine release, but the observation of profound itching with very small doses of intrathecal morphine supports the view that a predominant mechanism of opioid-induced itching is neurogenic and central, involving an imbalance of afferent signaling and neurotransmission in the spinal dorsal horn and nucleus caudalis. Local hives or itching at a site of opioid injection does not imply an allergic response.

Traditionally, treatment of opioid side effects has emphasized antagonists at nonopioid receptors; that is, use of antagonists of dopamine or serotonin receptors for treatment of nausea and vomiting or antihistamines for treatment of itching. These drugs may generate their own side effects, including extra pyramidal reactions from dopamine antagonists (phenothiazines, butyrophenones, metoclopramide); headache from serotonin antagonists (ondansetron, granisetron); and sedation, constipation, and urinary retention from antihistamines (diphenhydramine, hydroxyzine). Extrapyramidal reactions from dopamine antagonists may be treated prophylactically or as needed with antihistamines or central muscarinic anticholinergics. In our experience, extrapyramidal reactions may be misdiagnosed by some clinicians as seizures. Even among patients who do not have overt extrapyramidal signs, occasional patients report extreme dysphoria following administration of these agents. Dopamine antagonists and serotonin antagonists are partially effective in treatment of opioid-induced nausea and vomiting, but the numbers-needed-to-treat (NNTs) are higher than commonly believed by clinicians. The evidence for effectiveness of antihistamines in the treatment of opioid-induced itching is quite weak.

There is a growing body of evidence supporting treating opioid side effects, especially nausea and vomiting and itching, at least in inpatients postoperatively, by ultra-low-dose infusions of opioid antagonists such as
naloxone. Low-dose naloxone infusions are not simply reversing opioid actions altogether, rather they are exploiting a differential dose response for reversing side effects versus reversing analgesia, in part due to differential binding to opioid receptors coupled to G-stimulatory versus G-inhibitory proteins. We could not identify studies that would guide low-dose naloxone infusions for side effect treatment in highly opioid-tolerant patients, although a preliminary report in patients with sickle cell disease suggested that a slightly higher naloxone infusion rate of 1 µg/kg/hour might be recommended. At our institution, we routinely use doses between 0.5 and 2 µg/kg/hour with 1 µg/kg/hour being the most prevalent dosing. Nalbuphine is widely used for treatment of opioid-induced itching and nausea, although one pediatric study showed no benefit compared to placebo.

Methylnaltrexone is a quaternized opioid antagonist that has access to the area postrema (which lacks a blood–brain barrier), but which is excluded from prominent sites of central analgesic action, such as the periaqueductal grey matter. Recent reports show methylnaltrexone to be beneficial to children and adolescents with opioid-induced constipation. Alvimopan is an enterally constrained opioid antagonist that blocks opioid actions in the gastrointestinal tract, with minimal uptake in the portal vein and efficient first-pass hepatic clearance of the small quantities that do reach the liver. Available evidence suggests that these two approaches hold promise for more effective treatment of opioid side effects, including nausea, vomiting, constipation, and other forms of postoperative gastrointestinal dysfunction.

Constipation is commonly seen in patients requiring opioids even for short-term use. It is such a prevalent side effect of opioids that one should employ a proactive approach of prescribing laxatives (polypropylene glycol, senna, bisacodyl, docusate) for patients expected to require more than just few doses of opioids. Please see Table 50.6 for management of common opioid side effects in children.

| TABLE 50.6 Management of Common Opioid Side Effects |
|-----------------------------|-----------------|------------------|
| **Side Effect** | **Comments** | **Drug Dosage** |
| Nausea | Consider switching to different opioid. | Ondansetron 10–30 kg: 1–2 mg intravenously q8h |

2609
Use antiemetics.
Exclude other processes (e.g., bowel obstruction).

>30 kg: 2–4 mg intravenously q8h
Naloxone infusion 0.25–1 µg/kg/h
Metoclopramide 0.1–0.2 mg/kg PO/intravenously q6h

Exclusion of other processes (e.g., bowel obstruction).
Naloxone infusion 0.25–1 µg/kg/h
Metoclopramide 0.1–0.2 mg/kg PO/intravenously q6h

Pruritus
Exclude other causes (e.g., drug allergy).
Consider switching to different opioid.
Use antipruritics.

>30 kg: 0.1 mg/kg per dose intravenously q6h
Nalbuphine 0.1 mg/kg per dose intravenously q6h
Naloxone infusion 0.25–2 µg/kg/h
Diphenhydramine 0.25–0.5 mg/kg PO/intravenously q6h

Sedation
Add nonsedating analgesic (e.g., ketorolac, acetaminophen) and reduce opioid dose.
Consider switching to different opioid.

Methylphenidate 0.05–0.2 mg/kg PO bid (morning and midday dosing)\textsuperscript{a}
Dextroamphetamine 5–10 mg every day\textsuperscript{a}

Constipation
Regular use of stimulant and stool softener laxatives

>30 kg: 10–40 mg PO daily
Docusate
Child: 10–40 mg PO daily
Adults: 50–200 mg PO daily
Dulcolax
Child: 5 mg PO/PR daily
Adult: 10 mg PO/PR daily
Methylnaltrexone, alvimopan dosing is extrapolated from adults

\textsuperscript{a}Generally, only for use when long-term opioids are appropriate such as in cancer pain.

bid, twice a day; PO, orally; PR, rectally.

LOCAL ANESTHETICS AND REGIONAL ANESTHESIA IN INFANTS AND CHILDREN

Local anesthetics are widely used for a range of indications in infants and children, including topical analgesia for needle procedures, cutaneous infiltration for minor procedures, wound infiltration for surgery, peripheral and plexus blocks, and epidural and spinal anesthesia and analgesia. Work over the past 30 years has examined pharmacokinetics, safety, and clinical outcomes of local anesthesia in infants and children.

Pharmacokinetic information is available for many of the commonly used local anesthetics. Amino amides, including lidocaine, bupivacaine, and ropivacaine, have reduced clearance in neonates and younger infants due to immaturity of hepatic metabolism.\textsuperscript{a} In the case of lidocaine, the predominant hepatic metabolite, MEGX, can accumulate in neonates, with a resultant risk of seizures. The amino ester chloroprocaine is rapidly metabolized by plasma esterases even in neonates and may be useful if prolonged infusions are required in neonates.\textsuperscript{b}

\textsuperscript{a}Generally, only for use when long-term opioids are appropriate such as in cancer pain.

\textsuperscript{b}Generally, only for use when long-term opioids are appropriate such as in cancer pain.
CUTANEOUS ANALGESIA

Needle procedures are a prominent source of acute distress for infants and children. A number of local anesthetic formulations can produce good analgesia for superficial needle procedures. Several approaches can accelerate transfer across the skin, including eutectic mixtures, heating elements, iontophoresis, and jet injection. Selection among approaches may depend, in part, on local availability, cost, desired onset time, and impact of vasodilatation or vasoconstriction on the planned procedures.\textsuperscript{111,112} A convenient jet injector device, the JTip has greatly facilitated the placement of intravenous lines, blood sampling, and skin preparation before a variety of procedures. It is easy to use, well-tolerated, and fast acting.\textsuperscript{113,114}

WOUND INFILTRATION

Infiltration of the layers of surgical wounds is a simple approach to providing postoperative analgesia. This may be accomplished by one-time infiltration before wound closure or by placement of wound catheters for prolonged infusions of local anesthetics. Liposomal bupivacaine is now available, making it possible to have analgesia for 24 to 48 hours following infiltration. Although not approved for use in pediatrics at this time, it is available at some major pediatric centers and can be considered for use in older children and adults. Further study is needed before recommending its use in infants and younger children.

Epidural Analgesia in Infants and Children

Epidural analgesia has widespread use in infants and children for postoperative pain management and can be considered in selected cases for children with cancer pain and for certain chronic pain conditions such as complex regional pain syndrome. Although epidural infusions can provide outstanding analgesia for children, they require specific expertise both in the techniques of placement and in management, and in our view, they should not be undertaken without a system of pediatric-specific management protocols.

A unique difference between adults and children concerns the fact that
most pediatric regional anesthesia, including epidural analgesia, is performed after induction of general anesthesia or sedation because many children will not tolerate having needle procedures while awake. Although the safety track record of placement of epidural needles and catheters has been good, there remained some controversy regarding the risk–benefit ratio. However, recent large reports from the Pediatric Regional Anesthesia Network (PRAN) have confirmed the safety and efficacy of a sleep block placement.

Placing a lumbar epidural catheter in an anesthetized child is generally considered to be safe among experienced pediatric anesthesia providers. As an alternative to direct thoracic needle placement in infants, a common technique is to advance an epidural catheter from the caudal space to the desired surgical dermatome. Several studies have shown success in placing thoracic epidural catheters in infants using this technique. Because neonates and infants have an increased risk of amide local anesthetic toxicity, proper placement of the epidural catheter tip is crucial in order to provide optimal analgesia while minimizing safe local anesthetic infusion rates.

For anesthetized patients who are receiving direct thoracic placement or for cephalad advancement of catheters to thoracic levels from the caudal route, our own strong personal preference is to encourage some method of objective confirmation of positioning whenever possible. Three methods can be used in different situations: (1) electrical nerve stimulation using Tsui’s technique; (2) radiographic confirmation, especially using fluoroscopy with radiopaque wire reinforced catheters and/or small amounts of water-soluble contrast material; and (3) ultrasound. Confirming the location of intended caudal-to-thoracic epidural catheter tip placement is strongly recommended because failure rates as high as 30% have been reported using a “blind” technique. As described by Tsui, electrical stimulation employs a saline-filled, wire-wrapped catheter, with twitches seen at the myotomal level of the catheter tip in a current range generally between 2 and 15 mA. This technique also confirms that a catheter is not subarachnoid (in which case, bilateral twitches in a broad distribution are seen at a current <0.5 to 1 mA) and not threaded out a nerve root foramen (in which case, unilateral twitches in a narrow
distribution may be seen at a current <1.5 mA).

Confirming location of the epidural catheter tip in infants can be accomplished by obtaining a chest radiograph after injecting a small volume of radiopaque dye or through the use of a radiopaque epidural catheter which can easily be seen on plain chest radiograph or fluoroscopy. An additional method of confirming epidural catheter tip location is to advance the catheter from the caudal space under direct visualization using fluoroscopy.

Ultrasound guidance can be used in guiding and confirming placement of epidural catheters in neonates and younger infants, although this technique requires two operators and significant experience in ultrasound techniques. Neuraxial structures such as ligamentum flavum, dura, and epidural space as well as depth from skin to epidural space can be clearly visualized using ultrasound in part because of incomplete ossification of the vertebrae in neonates and younger infants.  

**DRUGS AND DRUG DOSING USED FOR EPIDURAL ANALGESIA**

Continuous epidural analgesia in infants and children generally consists of dilute solutions of local anesthetics combined with fentanyl, morphine, hydromorphone, or an α₂ agonists such as clonidine.

Bupivacaine and ropivacaine are the most commonly used amide local anesthetics for epidural analgesia because they have long duration of action with slightly greater selectivity of sensory block compared to motor block. Pharmacokinetic studies of bupivacaine in children over the age of 6 months have reported good safety for infusion rates of bupivacaine of below 0.4 mg/kg/hour with plasma bupivacaine levels in a safe range of <2 to 3 µg/mL. Neonates have reduced clearance of bupivacaine. Pharmacokinetic studies in neonates receiving continuous bupivacaine infusions have shown a continuous rise in plasma bupivacaine levels after the first 48 hours.

As a result of various pharmacokinetic studies, we use a maximum dose of 0.4 mg/kg/hour of bupivacaine for continuous epidural infusions in children over the age of 6 months. For children less than 4 to 6 months of age, we restrict the dose of bupivacaine to 0.2 mg/kg/hour. Because of the
limitations in dosing of bupivacaine in young infants, it is reasonable to use adjuvants to epidural infusions which will have a synergistic effect with bupivacaine such as opioids and clonidine in order to maximize analgesia.

Ropivacaine is a long-acting amide local anesthetic, shown in adults, to have less central nervous system and cardiac toxicity and slightly more sensory selectivity when compared to bupivacaine. Due to this increased safety profile, ropivacaine is seeing increased use and becoming standard at many institutions such as ours. Pharmacokinetic studies in infants and children receiving single boluses of epidural ropivacaine show that, as with bupivacaine, clearances for ropivacaine are reduced in infants. In different studies, clearances for ropivacaine have ranged from around 4 to 8.5 mL/min/kg with generally lower values in younger infants. Data to support a less extensive motor block for ropivacaine have been mixed. Overall, infusion rates of 0.4 mg/kg/hour in older infants and children and 0.2 to 0.3 mg/kg/hour in neonates and younger infants appear quite safe. It is plausible that slightly higher rates than these will be shown to be safe as well.\(^{123–125}\)

Chloroprocaine is used as an alternative to amide local anesthetics for continuous epidural infusions in neonates and very young infants to avoid the limitations of reduced clearance of amide local anesthetics and to safely permit sufficient epidural infusion rates for optimal analgesia. Even in neonates, chloroprocaine is rapidly metabolized with an elimination half-life of less than 6 minutes, making it an attractive choice for continuous epidural infusions in neonates. Studies of continuous epidural chloroprocaine infusions in term and preterm infants have shown good sensory blockade with no signs of neurotoxicity.\(^{110,126}\)

Compared to infusions of ropivacaine or bupivacaine, higher weight-scaled infusion rates of chloroprocaine are required to achieve similar degrees of blockade. For preterm and term infants, 1.5% chloroprocaine can be infused at about 0.5 mL/kg/hour for midthoracic epidural catheters and 0.6 to 0.7 mL/kg/hour for lumbar and lower thoracic catheters. Even for neonates, additives may improve analgesia, but at roughly one-tenth the concentrations recommended earlier for infusions in older children with bupivacaine or ropivacaine. For example, fentanyl at a concentration...
of 0.2 µg/mL and clonidine at a concentration of 0.04 µg/mL might be considered as adjuvants.

Chloroprocaine may be used to test previously placed epidural catheters as a second loading dose. The rationale for using chloroprocaine rather than lidocaine or other amide local anesthetics for a second loading dose is based on the concern that because most patients will have had intraoperative infusions of amide local anesthetics, additional amide local anesthetics as a bolus test dose may cause serum amide local anesthetic levels to reach toxic levels. Injecting approximately 0.5 mL/kg of 3% chloroprocaine (up to a maximum total dose of around 18 mL for patients >50 kg) incrementally into the epidural catheter should result in some evidence of sensory and motor block, thereby confirming position of the catheter in the epidural space. Alternatively, lidocaine in the 0.75% to 1.5% range can also be employed. Both of these local anesthetics have relatively rapid onset to facilitate diagnosis of a working or misplaced catheter. If the patient is tachycardic or hypertensive due to pain, these parameters generally improve within 5 to 10 minutes if the catheter is in an epidural location covering the surgical field. Once proper position of the epidural catheter has been confirmed, then good analgesia should be able to be obtained through the adjustment of appropriate epidural solutions and infusion rates.

Neuraxially administered opioids have a synergistic analgesic effect when combined with local anesthetics. Due to the hydrophilic property of hydromorphone, there is a slight preference to using hydromorphone for postoperative analgesia for more extensive surgical procedures involving several dermatomes. However, due to more rostral spread of hydromorphone, the risk of respiratory depression is greater. Specific data point to no better analgesia but slightly more pruritus when morphine or hydromorphone are compared for epidural administration. All neuraxially administered opioids can cause side effects including nausea, vomiting, urinary retention, pruritus, sedation, respiratory depression, and constipation. Nausea, vomiting, and other side effects from epidural opioids are treated similarly to those seen from parenteral opioids. Low-dose naloxone infusions significantly reduce opioid side effects without reversing opioid-induced analgesia.
Clonidine is often added to epidural local anesthetic infusions to enhance analgesia without increasing nausea, vomiting, pruritus, or respiratory depression. Studies of combinations of epidural clonidine with local anesthetics in children have shown a low side effect profile.\textsuperscript{129,130}

Controlled trials of single-dose caudal administration of clonidine with bupivacaine have shown variable prolongation of analgesia by approximately 50% to 75% than epidural bupivacaine alone. Pharmacokinetic studies of single-dose epidural clonidine in children show wide variation in plasma concentration as well as wide variation in the time for clonidine absorption from the epidural space. Other studies have not shown significant prolongation of single-shot caudal analgesia with clonidine doses as high as 2 µg/kg.\textsuperscript{131}

Although some clinicians perform single-shot caudal blocks routinely with clonidine doses in the range of 2 µg/kg, our view is that this dose frequently results in prolonged sedation, especially if other sedatives or systemic opioids are administered as well. Our practice for children 1 year of age and older is to use 0.5 to 1 µg/kg, to a maximum of 15 µg as a single bolus for caudal blocks and roughly 0.12 to 0.16 µg/kg/hour (0.3 to 0.4 mL/kg/hour of a solution containing 0.4 µg/mL) added to continuous epidural local anesthetic infusions (except for neonates, where lower doses and concentrations are used, as noted in the preceding text). Please see Table 50.7 for recommended doses for epidural infusions.

\textsuperscript{b}Rarely used

Table 50.7 Recommended Epidural Infusion Rates
NOTE: Solutions containing hydrophilic opioids such as hydromorphone may pose a higher risk for delayed respiratory depression, so appropriate frequency of observation and continuous electronic monitoring is recommended. Higher concentrations of opioids may be considered for selected patients who are opioid-tolerant. Patient-controlled epidural anesthesia (PCEA) doses if used should be 1/4 to 1/6 the basal rate. Hourly maximums: opioid (µg/kg/h): morphine, 3–5; hydromorphone, 1.5–2.5; fentanyl, 0.1–0.5; ropivacaine, 0.4 mg/kg/h, 0.2 mg/kg/h in newborns/neonates.

Infusion rates and solutions should be modified according to clinical circumstances. Little information is available on how best to adjust these rates based on degrees of prematurity.

Weight scaled infusion rates should plateau at values recommended for patients weighing around 45 kg, such as maximum infusion rates for larger patients should rarely exceed 15 mL/h.

In infants <6 months of age, we recommend using fentanyl at 1 µg/mL.

We recommend frequent (every 4 hour) assessment of the epidural site by the nursing staff and twice-daily inspection by the pain management team. Catheter depth should be noted with care, as the catheter can migrate either inward or outward. A small study suggests that this movement is more common in children <40 kg compared to large children and adults. Assessing the site for potential signs of infection, such as tenderness, erythema, or abnormal discharge, should also be part of frequent monitoring. Care should also be taken when using adherence substances such as Mastisol to secure the epidural occlusive dressing, as there are reports of contact dermatitis with use of these agents.

Peripheral Nerve Blocks in Children

Peripheral nerve blocks provide reliable and safe postoperative pain management. A report by the French-Language Society of Pediatric Anesthesiologists showed that among 24,000 regional blocks in children, the complication rate for peripheral nerve block was 0 in 1,000. The PRAN database also showed the safety of peripheral nerve blocks in a cohort of 13,725 patients. In 455 upper extremity blocks, the complication rate was 2%, no complications in 556 head and neck blocks, and a complication rate of 1% in 2,307 lower extremity blocks. In a retrospective review of 226 continuous peripheral nerve blocks in children over a 4-year period, no major adverse events were noted. A recent
study using the PRAN database also demonstrated the safety of 2,074 continuous peripheral nerve block catheters with a complication rate of 12.1% with no incidences of deep infection, persistent neurologic deficits or systemic local anesthetic toxicity.\textsuperscript{136}

A general trend in clinical trials of peripheral nerve blockade is the observation of very good analgesia with a very low side effect profile that compares favorably to either systemic opioids or epidural infusions. In a randomized trial comparing popliteal block versus epidural analgesia for foot and ankle surgery, popliteal block results in superior analgesia with reduced incidences of nausea, vomiting, and urinary retention.\textsuperscript{137}

A recent review shows that the use of ultrasound improves both the success rate of the block and improves the duration of the block.\textsuperscript{138} Advantages of ultrasound guidance include direct visualization of nerves and other structures such as arteries which may reduce the likelihood of intraneural or intravascular injection and direct visualization of local anesthetic spread. Combining the use of ultrasound with peripheral nerve stimulation is sometimes used when advancing catheters for continuous use to further confirm catheter placement. The addition of clonidine to peripheral nerve blocks in children has been shown to significantly increase duration of sensory blockade by approximately 4 hours; however, the incidence of motor blockade was also significantly increased.\textsuperscript{139}

Like epidural anesthesia, the placement of peripheral nerve block may require general anesthesia or deep sedation for most younger children. Motivated older children and adolescents will often require only minimal sedation. It is often helpful to apply a topical anesthetic, such as via a JTip, to the anticipated needle insertion site to minimize pain from needle insertion. It is our practice to perform the majority of neuraxial and peripheral nerve blocks under general sedation. Indications for using peripheral nerve blocks as the sole anesthetic technique include risk of malignant hyperthermia, risk of postoperative apnea, and patient preference.

Recommendations regarding dosing of local anesthetics for peripheral nerve block in children vary among authors. Where immediate onset is required, one group has recommended 0.5 mL/kg of a mixture of 1% lidocaine with 1:200,000 epinephrine and 0.5% ropivacaine. Several
groups employ continuous perineural infusions with 0.1 to 0.15 mL/kg/hour of ropivacaine in a concentration range between 0.1% and 0.2%. As with epidural anesthesia, use of $\alpha_2$ adrenergic agonists (e.g., clonidine) as adjuncts can be considered. Clonidine has been found to increase time to first use of supplemental analgesia as well as fewer doses of analgesia needed in first 24 hours following surgery at least when lower concentrations of ropivacaine or bupivacaine are used.\textsuperscript{140} It is unclear if this remains true with higher concentrations, such as 0.2% or 0.25% of ropivacaine and bupivacaine respectively.

**SUPRACLAVICULAR**

A supraclavicular block is applicable to all surgeries of the upper extremity excluding shoulder surgery. Placement of a continuous catheter technique can be used in the treatment of refractory complex regional pain syndrome in children.\textsuperscript{141} Supraclavicular block has been successfully used as the sole anesthetic for children younger than 12 years of age undergoing closed reduction of arm fractures.\textsuperscript{142}

The trunks of the brachial plexus are located between the anterior and medial scalene muscles in the interscalene groove. Using ultrasound guidance, the first rib and subclavian artery should be located, with the pleura located just beneath the first rib. The anterior and middle scalene muscles are then located as they insert onto the first rib cephalad to the subclavian artery. The brachial plexus is located between the anterior and middle scalene muscles and superficial and lateral to the subclavian artery. Under direct ultrasound visualization, the needle is inserted from a lateral to medial direction toward the plexus, with particular attention to avoiding directing the needle medial to the anterior scalene muscles or caudally beneath the first rib to prevent pneumothorax. Only a single injection is required due to the close proximity of the trunks of the plexus in this region. If using a continuous catheter technique, we typically recommend tunneling supraclavicular catheters, particularly for patients requiring aggressive postoperative physical therapy and for catheters of longer duration such as in the treatment of complex regional pain syndrome.

**INFRACLAVICULAR**

2619
Infraclavicular block is indicated for all distal upper extremity surgeries such as syndactyly repair and repairs of open forearm fractures. In the infraclavicular region, the plexus is located posterior to the pectoralis major and minor. The cords of the brachial plexus are located medial, lateral, and posterior to the axillary artery. Under direct ultrasound visualization, with the ultrasound probe medial and caudal to the coracoid process, the pectoralis muscles and the axillary artery and vein should be identified. The axillary vein is located caudal to the axillary artery. The needle is inserted under direct ultrasound visualization and advanced laterally; once the sheath surrounding the plexus is reached, spread of local anesthetic should be visualized spreading to the cords of the plexus.

**SCIATIC NERVE BLOCK**

The sciatic nerve block is useful in providing analgesia for a variety of surgical procedures of the lower leg or foot, for painful physical therapy following surgery, and for treatment of complex regional pain syndrome affecting the lower leg or foot. The latter study showed excellent pain relief and excellent rehabilitation with no adverse events using a continuous infusion of 0.2% ropivacaine at 0.1 mL/kg/hour for 96 hours. In the study of foot and ankle surgery by Dadure et al., the children with continuous popliteal nerve blocks received a continuous infusion of 0.2% ropivacaine at 0.1 mL/kg/hour, and a 100% satisfaction rate was reported.

Studies in adult patients comparing continuous sciatic nerve block with PCA have shown superior analgesia; reduced morphine use; and reduced frequency of nausea, vomiting, and sedation for adult patients with continuous popliteal sciatic catheters. Two commonly used approaches for sciatic nerve block in children are the subgluteal approach and the popliteal approach. A single-injection technique is indicated after relatively minor surgery when postoperative pain is expected to be mild and of short duration. A continuous catheter technique will provide prolonged analgesia after more extensive surgical procedures.

**Sciatic-Subgluteal Approach**

Because patients will need to be positioned in the prone position for a
subgluteal approach to a sciatic nerve block, younger children will require
general anesthesia for placement. Cooperative older children and
adolescents can often tolerate the procedure in a prone procedure with
sedation. The technique described in the following text uses ultrasound
guidance with peripheral nerve stimulation for further confirmation. With
the patient in a prone position, ultrasound is used to locate the sciatic
nerve; a line marking the midpoint between the ischial tuberosity and the
greater trochanter can be useful in estimating position of the sciatic nerve.
Under visualization, an insulated 17G stimulating needle is advanced
approximately 1 to 2 cm below the midpoint mark and is directed medially
and superiorly. Initially, twitching of the gluteal muscles can be observed
but will disappear as the needle advanced further. Dorsi- and plantar-
flexion of foot is observed with stimulation of the sciatic nerve. A 20G
stimulating catheter is advanced approximately 3 cm beyond the tip of the
needle; angling the needle slightly caudally may facilitate advancing the
catheter. Further nerve stimulation of the catheter confirms proper catheter
placement.146

**Popliteal Approach**

Block of the sciatic nerve can also be achieved at the level of the popliteal
fossa. The sciatic nerve divides into the tibial and common peroneal nerves
in the popliteal fossa; proximal to the popliteal fossa crease. For this block,
patients can be positioned either prone or supine with the hip and knee
flexed. Our general preference is to use the prone approach when catheter
placement is being considered because it makes it easier to maintain
sterility and to perform tunneling of the catheter. Ultrasound is used to
locate the structures in the popliteal fossa; the popliteal artery and vein are
located deep and proximal to the sciatic nerve. The course of the sciatic
nerve should be seen and the point at which the sciatic nerve bifurcates
should be located. The tendon of the biceps femoris is located laterally,
and the tendons of the semimembranosus and semitendinosus muscles are
located medially. Ultrasound viewing and needle advancement can be
performed using several approaches, including an in-plane approach, with
the needle advancing in a lateral-to-medial direction, or an out of plane
approach, with the needle advancing in a sagittal direction. Injection of
local anesthetic should show local anesthetic spread around the tibial and common peroneal nerves.146

**FEMORAL BLOCK**
A femoral nerve block provides effective analgesia for knee surgery, for surgery on the anterior thigh such as a muscle biopsy, and for femur surgery or fractures. It will also provide analgesia to the medial lower extremity below the knee by blocking the saphenous nerve. Compared to PCA morphine and epidural analgesia, continuous femoral nerve block provides more effective analgesia with fewer side effects. Results indicate that using ultrasound guidance produced prolonged duration of sensory blockade with less volume of local anesthetic compared to using nerve stimulation. The typical landmarks for a femoral nerve block are the inguinal crease and the femoral arterial pulse. The femoral nerve is located lateral and deep to the femoral artery as it courses below the inguinal ligament. With the patient positioned in a supine position, ultrasound is used to locate the position of the femoral vein, artery, and nerve in the inguinal crease. Under ultrasound visualization, an insulated block needle is inserted just lateral to the arterial pulse and directed slightly cephalad. Proper placement of the needle should be seen on ultrasound, positioned alongside the femoral nerve. Nerve stimulation is an alternative method to confirm proper placement of the needle. With proper needle placement, twitching of the quadriceps and patella should be seen. Quadriceps movement alone without signs of patellar movement is due to stimulation of the sartorius muscle and does not confirm proper needle placement. If the femoral nerve is not readily located, it will be necessary to redirect the needle slightly laterally. When placing a catheter for continuous femoral block, the needle is angled slightly more cephalad and the catheter is advanced. If using nerve stimulation, twitching of the quadriceps and patella will indicate correct catheter placement. Infection rates for continuous femoral catheters appear to be low when used for short-term use. In a study examining bacterial colonization and infection rates in continuous femoral catheters, 57% of catheters had positive bacterial colonization with *Staphylococcus epidermidis* as the most common organism. However, there were no septic complications or serious
infections for catheters in place for 48 hours.\textsuperscript{147}

Recent study of femoral nerve blocks in the pediatric population found that use of ropivacaine 0.5\% was superior to ropivacaine 0.2\% or bupivacaine 0.25\%, leading to decreased opioid use and earlier hospital discharge.\textsuperscript{148}

**TRANSVERSUS ABDOMINIS PLANE BLOCK**

Transversus abdominis plane (TAP) block is a technique where local anesthetic is injected between the transversus abdominis and the internal oblique muscles. This is generally easily visualized with the use of ultrasonography. Recently, it has been gaining increasing popularity for use in pediatrics. The block may be performed as a single shot or as a continuous infusion. Applications for use include procedures such as inguinal hernia repair or other abdominal surgery.\textsuperscript{149} A study using the PRAN database looked at the safety of 1,994 children receiving TAP blocks and found the upper incidence of overall complications was 0.3\% and these complications did not require any further interventions and were considered minor.\textsuperscript{150} Although caudal epidural blockade may provide superior pain relief, the TAP can be considered as it is less invasive and also does not cause lower extremity motor weakness.

**Painful Conditions in Pediatric Hospital Care**

**CANCER PAIN**

Infants and children with cancer experience pain from cancer treatment such as painful mucositis, postamputation pain, and peripheral neuropathies as well as from tumor spread causing bone pain, neuropathic pain, or headaches from raised intracranial pressure. Repeated painful needles procedures, such as bone marrow biopsies and lumbar punctures, are a great source of pain and distress. Several surveys have shown that as successful chemotherapeutic protocols, radiation therapy and surgical techniques have advanced, cancer treatment and painful procedures account for greater sources of cancer pain in infants and children.\textsuperscript{151}

Frequent diagnostic and painful procedures are common for infants and children with cancer. For minor needle procedures such as intravenous line
insertions and assessing implanted vascular access ports, topical analgesia should be routinely used. A number of approaches to cutaneous analgesia have been used, including local anesthetic creams or patches, with or without physical methods to accelerate transit of drug across the stratum corneum. Cognitive-behavioral interventions such as hypnosis and other relaxation techniques have also been shown to be effective for procedural pain. Children can also apply these techniques to nausea, headaches, and other symptoms. Conscious sedation or general anesthesia is typically used for more invasive needle procedures such as bone marrow biopsies and lumbar punctures. Safe sedation protocols have been developed by the American Academy of Pediatrics and are widely used by pediatric oncologists and other pediatric subspecialists for procedural sedation. Pediatric anesthesiologists are consulted for patients with risk factors that place them at increased risk for conscious sedation, for patients who fail conscious sedation, or for more invasive procedures such as central line insertions.

Mucositis is a common side effect in children receiving chemotherapy or radiation; it is especially severe and prolonged with bone marrow transplantation. Initially, pain from mucositis is often treated with topical agents, although evidence for efficacy in the prevention and treatment of mucositis has been mixed. Opioids are used for pain that persists despite topical agents. Data supports the safety and efficacy of opioid infusions and PCA for the treatment of mucositis.\textsuperscript{80,152} Because many children with mucositis will require opioids for weeks, our practice is to eventually administer approximately 60% of the total daily opioid dose as a basal rate in order to provide sustained analgesia. NCA is used for young children.

Although a majority of children have resolution of the cancer pain after initial chemotherapy induction protocols, some children will continue to experience visceral, somatic, and neuropathic pain due to tumor invasion of solid organs, bone, nerves, and plexuses. Opioids are provided by the oral route whenever feasible. It is common practice to use a long-acting opioid, either methadone elixir or tablets or capsules of a sustained-release preparation of morphine, hydromorphone, or oxycodone, along with short-acting opioids for rescue or breakthrough pain. Currently, methadone is the most widely available long-acting opioid available as an elixir formulation.
When using methadone in the cancer population, it is essential to be aware of the risk of increased QTc from other agents or due to possibility of increased serum methadone levels. Some patients with rapidly escalating pain or patients unable to tolerate oral opioids may require opioids via parenteral routes, including intravenous and subcutaneous routes. Some acute breakthrough pain can be managed with transmucosal fentanyl. Continuous infusions and PCA or NCA allow rapid titration for escalating pain as well. In the setting of neuropathic cancer pain, we frequently prescribe anticonvulsants and antidepressants largely by extrapolation from adult practice. Opioids and other sedating medications may contribute to fatigue, somnolence, sleep disturbance, and depressed mood, but they may exist even in children not receiving opioids or sedatives. Along with treating specific or remediable causes of these symptoms, our common practice, again extrapolated from adult clinical trials, is to consider a trial of a stimulant such as methylphenidate.

A subgroup of children with cancer pain will have persistent pain despite massive dose escalation. Many of these children will have unremitting neuropathic pain associated with tumor extension to the epidural space, onto a plexus or along the course of major nerves. One approach to persistent pain in this setting is to add a low-dose ketamine infusion. At rates below 0.2 mg/kg/hour, dysphoria and dissociation are relatively uncommon. Oral ketamine has been used as well, with a provisional dose ratio of about 3:1 compared to intravenous dosing in steady state. In selected cases of refractory pain, our practice is to use regional anesthetic techniques, and most commonly in this setting, we favor implanted intrathecal ports with the catheter generally advanced to the dorsal horn level appropriate to the patient’s location of greatest pain. Note that for tumors predominantly in the pelvis, lumbar spine, or lower extremities, this implies having the catheter tip advanced up to around T11. The choice of drugs for these infusions must be individualized based on the nature of the patient’s pain and quality of life issues, including considerations of weakness, bowel and bladder dysfunction, and sedation. In the majority of cases, we have found it necessary to include small doses of local anesthetics along with opioids, and in some cases, we have included other additives such as clonidine or
ketamine. There is a small subgroup of children for whom it appears that the most feasible option for achieving relief of pain, distress, or terminal dyspnea is to provide sedation, using a range of agents, including benzodiazepines, barbiturates, or other drugs.\textsuperscript{156}

**PAIN ASSOCIATED WITH SICKLE CELL VASOOCCLUSIVE EPISODES**

Pain is a common consequence of sickle cell disease due to acute vasoocclusive episodes as well as pain from compression fractures, avascular necrosis, acute cholecystitis, splenic sequestration, and stroke. Painful vasoocclusive episodes are the most common cause of pain in children with sickle cell disease and can occur in children as young as 6 months of age as fetal hemoglobin and its protection against vasoocclusive crises decreases. Children can demonstrate a range of severity and frequency of vasoocclusive episodes, from occasional episodes managed at home with oral analgesics to baseline daily pain with frequent exacerbations requiring numerous hospitalizations and systemic opioids administration. PCA is commonly used for severe pain in hospitalized patients, along with NSAIDs, hydration, red blood cell transfusion, and supplemental oxygen. Larger opioid boluses may be necessary than are typically used for postoperative pain management for patients with extreme pain or for patients who are opioid-tolerant.\textsuperscript{157} Often basal infusions are necessary, particularly at night to permit periods of uninterrupted sleep. Published case series indicate that even with generous PCA parameters, pain scores remain high for a high percentage of patients.\textsuperscript{158} Recent data has shown promising results for subanesthetic dosing of ketamine in patients with sickle cell disease.

**CHILDREN WITH TRAUMA**

General sound principles of analgesic management should be applied to the care of children with the vast variety of traumatic injuries. Application of appropriate nerve blocks, central blocks, when possible, can facilitate recovery from the child’s injuries. In addition, many injured children are fully able to take oral analgesics, avoiding the necessity of intravenous access or, even, continued stay in the hospital, once their pain is
successfully managed.

**CHILDREN WITH DEVELOPMENTAL DISABILITIES**

Children with cognitive and developmental disabilities such as cerebral palsy and neurodegenerative disorders present unique challenges in assessing and managing pain. Many children with disabilities experience daily pain associated with muscle spasms, hip dislocation, and other musculoskeletal pains and undergo frequent painful invasive procedures such as scoliosis repair, tendon releases, and surgical treatment of gastroesophageal reflux. Children may have little or no cognitive deficits but significant motor and communication impairments, making pain assessment especially difficult. Often, parents and caretakers are able to distinguish subtle behavioral signs indicating pain. A number of pain assessment tools such as the FLACC tool and the Non-communicating Children’s Pain Checklist have been used for children with cognitive and developmental disabilities. In comparing several pain assessment tools for children with cognitive limitations, physicians and nurses rated the FLACC as having higher clinical utility.\(^ {159} \)

Other children with severe cognitive impairment will have persistent agitation and screaming without a clear etiology and are admitted to the hospital for diagnostic evaluation and therapeutic trials. Patients should be evaluated for treatable causes of pain such as fractures, hip dislocations, esophagitis, and constipation. In some cases where no underlying cause can be eventually identified, therapeutic trials of anticonvulsants and antispasmodics may provide relief.\(^ {160} \)

**Conclusions**

Evidence is available to support safe and effective treatment of acute pain in infants, children, and adolescents in the majority of circumstances. Analgesic pharmacology has received extensive study in pediatrics over the past several decades. Individual analgesics often provide incomplete relief in standard doses, and there is a rationale for analgesic combinations and multimodal analgesia in many situations. Opioids can provide good analgesia at all ages, but with a spectrum of side effects that require active
treatment, and with specific requirements for observation and monitoring according to age and patient condition–related risk factors. Techniques have been developed for neuraxial and peripheral regional anesthesia at all ages. There is a growing emphasis on ultrasound, nerve stimulation, selective use of fluoroscopy, and other approaches to provide objective confirmation of needle and/or catheter positioning. Pediatric acute pain management, whether by an acute pain service or by other delivery models, can be improved by system-wide approaches that emphasize systematic assessment of pain and other symptoms, communication, clinician education, clarification of responsibilities, and protocols for analgesic administration, side effect management, and monitoring.

Acute pain is the normal and predictable neurophysiologic response to noxious mechanical, thermal, or chemical stimuli; is generally time-limited; and resolves with the cessation of the noxious stimuli. The etiology, often, is known or understood. It is typically associated with invasive procedures, trauma, or medical diseases. The pain sensation is usually limited to the area of trauma or damage or the area that immediately surrounds it. Perhaps most importantly, the painful sensations associated with such an injury are expected to resolve over time when adequate wound healing has occurred. In contrast, chronic pain persists beyond either the course of an acute injury or illness or its expected time for healing and repair. Acute pain states can then be further divided by duration, etiology, mechanism, intensity, and/or symptoms. In this chapter, acute pain is discussed using postsurgical or postprocedural and posttraumatic pain as models.

A revolution in the management of acute pain has occurred over the past few decades. Widespread recognition of the undertreatment of acute pain by clinicians, economists, and health policy experts has led to the development of a national clinical practice guideline for acute pain management by the Agency for Healthcare Quality and Research (formerly the Agency for Health Care Policy and Research) of the U.S. Department of Health and Human Services. This landmark document includes acknowledgment of the historic inadequacies in perioperative pain management, importance of good pain control, need for accountability for adequate provision of perioperative analgesia by health care institutions, and a statement on the need for involvement of specialists in appropriate cases. In addition, several professional societies and regulatory agencies, including the American Society of
Anesthesiologists\textsuperscript{1,2} and The Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]), have developed acute pain management standards\textsuperscript{3} or clinical practice guidelines for acute pain management in hospitalized patients.\textsuperscript{4} With the recent surge of opioid misuse and abuse in the United States, there has been increased focus on the influence of these pain assessment standards on opioid prescribing.\textsuperscript{4} Although the incorrect interpretation of these standards by prescribers likely has a role in the increased use of opioids in the acute care setting, it is unlikely that it was a primary driver of the escalation in outpatient opioid prescribing. More likely causes of the increased use of opioid medications in the outpatient setting were the best intentions and overly simplistic advice of prominent physicians,\textsuperscript{5} the incorrect interpretation of medical literature,\textsuperscript{6} generalization from small uncontrolled studies,\textsuperscript{7} and the intentional misuse of this same literature for financial gain by the manufacturers of the medications\textsuperscript{8}.

With their knowledge of and familiarity with pharmacology, various regional techniques, and the neurobiology of nociception, perioperative physicians such as anesthesiologists are continually on the forefront of clinical and research advances in acute pain, especially acute postoperative pain management, and have traditionally been leaders in the development of acute postoperative pain services, application of evidence-based practice to acute postoperative pain, and creation of innovative approaches to acute pain management. The effective treatment of acute pain (including postprocedural pain) needs to involve a multidisciplinary approach like that which has evolved in the treatment of chronic pain. Programs such as the enhanced recovery after surgery (ERAS) pathways that are evidence-based and multidisciplinary have demonstrated great success in the management of postoperative pain and overall patient recovery.

\textbf{Acute and Chronic Effects of Acute Pain}

Uncontrolled acute pain may produce a range of detrimental acute and chronic effects. Attenuation of periprocedural pathophysiology that occurs during a procedure or surgery through reduction of nociceptive input into the central nervous system (CNS) and optimization of periprocedural
analgesia may decrease complications, facilitate the patient’s recovery during the immediate postprocedural period,\textsuperscript{9} reduce the length of stay,\textsuperscript{10} and after discharge from the hospital.

The perioperative period is associated with a variety of pathophysiologic responses that may be initiated or maintained by peripheral nociceptive input. Although these responses may have had a beneficial purpose in nature, the same response to the modern-day surgery may be harmful. Uncontrolled perioperative pain may therefore be considered a major morbidity for the patient. Furthermore, attenuation of postprocedural or acute medical pain may decrease perioperative morbidity and mortality.\textsuperscript{11}

The transmission of pain stimuli from the periphery to the spinal cord and supraspinally results in the neuroendocrine stress response. The dominant neuroendocrine response to pain involves hypothalamic–pituitary–adrenocortical and sympathoadrenal interaction, resulting in increased sympathetic tone; increased catecholamine and catabolic hormone secretion including cortisol, adrenocorticotropic hormone, antidiuretic hormone, glucagon, aldosterone, renin, and angiotensin II; and decreased secretion of anabolic hormones. The outcome of these changes includes sodium and water retention and increased levels of blood glucose, free fatty acids, ketone bodies, and lactate. A hypermetabolic, catabolic state results as metabolism and oxygen consumption are increased, and metabolic substrates are mobilized from storage depots. The negative nitrogen balance and protein catabolism may impede the patient’s recovery and contribute to morbidity or mortality. Sympathetic activation may increase myocardial oxygen consumption and decrease myocardial oxygen supply, which may be important in the development of myocardial ischemia and infarction.\textsuperscript{11,12} Sympathetic activation may also delay return of postprocedural gastrointestinal motility that may develop into an ileus.

Postprocedural acute pain may initiate several detrimental spinal reflex pathways. Respiratory function can be markedly diminished, especially with acute pain involving the upper abdomen, flank, and/or thorax. Reflex inhibition of phrenic nerve activity is an important component of this decreased pulmonary function.\textsuperscript{11,12} However, control of acute pain is also important because patients with poor pain control may have poor
inspiratory effort, have an inadequate cough, and be more likely to develop pulmonary complications.\textsuperscript{11}

Neurobiology of Acute Pain

The neurobiology of pain is extremely complex, with redundancy and plasticity such that there is no “final common pathway” for the process of nociception. However, understanding the neurobiology of pain is crucial when contemplating which nociceptive processes to target in the treatment of acute pain. Identification of new molecular and cellular processes involved in the process of nociception has increased the number of potential targets for analgesic therapies.

PRIMARY AFFERENTS AND PERIPHERAL NERVE NEUROTRANSMITTERS

A variety of mechanical, thermal, or chemical stimuli can result in the sensation of pain. Information about these painful or noxious stimuli is carried to higher brain centers by receptors and neurons that are distinct from those that carry innocuous somatic sensory information. This topic is covered at length in Chapters 3 and 4. In brief, small-diameter A\textdelta and C fibers primarily transmit nociceptive information, but subsets of A\textdelta and C fibers are thermo receptors that transmit nonpainful cold and warm information, respectively.\textsuperscript{13} Neurotransmission by the A\textdelta and C fibers is performed by numerous peptides and amino acids. Substance P (SP) was the first peptide to be defined as specific to the small diameter primary afferents and is released by noxious thermal, mechanical, and chemical stimulation of the periphery.\textsuperscript{14–16} Exogenous application of SP into the spinal cord of rats results in dorsal horn neuronal activation\textsuperscript{17} and behavioral responses consistent with pain.\textsuperscript{18} Neurokinin-1 (NK-1), the receptor for SP, is found on superficial and deep neurons in the dorsal horn of the spinal cord consistent with their role in pain transmission.\textsuperscript{19} Other peptides present in the small diameter afferents include calcitonin growth-related protein (CGRP), galanin, vasoactive intestinal polypeptide (VIP), and somatostatin (SST); however, their role in the modulation of nociceptive transmission is less well understood. In addition to these
peptides, the excitatory amino acid glutamate is also present within small
diameter primary afferents, released by noxious stimulation\(^\text{20}\) and activates
the second-order dorsal horn neurons.\(^\text{21}\) The effects of glutamate are
predominantly mediated by three receptor classes: alpha-amino-3-
hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate, N-methyl-
D-aspartate (NMDA), and metabotropic glutamate receptors (mGluR).
AMPA receptors are found on postsynaptic neurons predominantly within
the superficial dorsal horn.\(^\text{22}\) NMDA receptors are found both pre- and
postsynaptically (i.e., on nociceptive primary afferents and apposing
second-order neurons within the superficial and deep dorsal horn).\(^\text{23}\)
mGluR are predominantly found postsynaptically on the cell body and
dendrites of dorsal horns neurons.

The primary afferent’s presynaptic nerve terminal in the dorsal horn of
the spinal cord represents a site for a therapeutic intervention. Primary
afferent fibers transmit the pain signal to the spinal cord and possess
numerous receptor systems that can reduce this transmission by reducing
transmitter release such as the \(\alpha_2\)-adrenergic, glycinergic, serotonergic,
opioidergic, and GABAergic receptors\(^\text{24–26}\) as well as ion channels
sensitive to local anesthetics and anticonvulsants including voltage-gated
calcium, sodium, and potassium channels.

**SPINAL CORD AND SUPRASPINAL STRUCTURES**
Aδ and C fiber neurons synapse primarily within laminae I, II, and V of
the dorsal horn of the spinal cord. These primary afferents release
neurotransmitters and neuropeptides that activate the second-order
projection neurons of the spinal cord. Pain transmission through the spinal
cord may be modulated by an endogenous descending pain inhibitory
system and may be influenced by exogenously administered medications.
The primary components of this descending pain inhibition system are the
“triad” of the periaqueductal gray (PAG), the rostral ventromedial medulla
(RVM), and the dorsal lateral pontine tegmentum (DLPT), which includes
the locus coeruleus (LC) and the A7 nuclei. The PAG is an important site
to produce analgesia following systemic administration of opioids. The
endogenous opioid [Met\(^5\)]enkephalin is present within this nucleus,\(^\text{27}\) and
opioid receptors of each subtype are present in this region.\(^\text{28}\) The PAG
provides dense projections to the RVM and brainstem noradrenergic nuclei LC and A7. Although each of these regions has direct projections to the spinal cord, it has been proposed that their projections to the RVM are important components in the modulation of pain by these regions. The RVM can function as a relay nucleus in the production of antinociception by more rostral midbrain structures (PAG), but it also has a primary role in the suppression of nociceptive transmission at the level of the spinal cord. The suppression of nociceptive reflex behavior is thought to be mediated by the axons of RVM neurons that descend within the dorsolateral funiculus and terminate bilaterally in laminae I, II, V, VI, and VII of the spinal cord. Anatomical studies have shown these axons terminate coincident with spinothalamic tract cells and interneurons of the dorsal horn that are related to pain transmission. Consistent with the anatomical terminations of the RVM axons, physiologic studies have shown that stimulation of the RVM results in the inhibition of a population of pain-specific neurons within the dorsal horn. Spinally projecting neurons of the RVM possess numerous neurotransmitters including serotonin, enkephalin, γ-aminobutyric acid (GABA), glutamate, and SP. The DLPT contains all of the noradrenergic neurons that project to the RVM and the spinal cord. In animal models, electrical stimulation of the DLPT sites produces analgesia and the analgesia produced by the activation of these nuclei is mediated by the α2 adrenergic receptor. The pain physician can pharmacologically manipulate each of these neurotransmitter systems to modulate pain transmission throughout the CNS.

Prevention

PREVENTIVE ANALGESIA

The development of central and/or peripheral sensitization after traumatic injury or surgical incision can result in the amplification of acute pain. Preventing the establishment of altered central processing by analgesic treatment may, in the short term, result in the reduction of postprocedural or traumatic pain and accelerated recovery. In the long term, the benefits may include a reduction in the development of chronic pain and an
improvement in the patient’s quality of recovery and satisfaction. Although experimental animal studies convincingly confirm the ability of preventive analgesia to decrease postinjury pain, the results of clinical trials are mixed.\textsuperscript{44–46}

The precise definition of preventive analgesia is a controversy in this area of medicine and contributes to the question of whether preemptive analgesia is clinically relevant. Definitions of “preventive analgesia” include (1) any attempt to give medications prior to surgical incision, (2) administration of medications during the intraoperative or intraprocedural period, or (3) administration of medications during the intraoperative and postoperative period.\textsuperscript{47} The first two definitions describe an exclusive preemptive approach and are relatively narrow and may contribute to the lack of a detectable effect of in clinical trials. For this text, preemptive analgesia is defined as an analgesic intervention started before the noxious stimulus arises to block peripheral and central pain transmission. This preemptive intervention is possible, primarily, in the context of surgical intervention; ideally, one in which the patient has no or minimal pain prior to the intervention. “Preventive analgesia” encompasses all three. It includes an attempt to block pain transmission prior to the injury (incision), during the noxious insult (surgery itself), and following the injury and throughout the recovery period. Unfortunately, few trials have examined the concept of preventive analgesia in a rigorous fashion. Preemptive analgesia abiding by the first one of the aforementioned three definitions has been loosely examined, although some argue that the timing of the intervention\textsuperscript{44–46} may not be as clinically important as other aspects of preemptive analgesia including intensity and duration of the intervention. In the purest definition of preemptive analgesia, an intervention such as preoperative administration of gabapentin\textsuperscript{48} is not necessarily preemptive if the blockade of nociceptive transmission from the periphery to central sites is incomplete or insufficient such that the development of peripheral or central sensitization would not be prevented. Incisional and inflammatory injuries are important in initiating and maintaining both peripheral and central sensitization. Confining the definition of preemptive analgesia to only the immediately preoperative or intraoperative (incisional) period may not be clinically relevant or
appropriate because the inflammatory response may last well into the postoperative period and continue to maintain this sensitization. Other methodologic and study design issues also may complicate the question of whether preemptive analgesia is clinically relevant. A variety of agents and techniques\textsuperscript{44–46} have been used to study preemptive analgesia. Using the broader definition of preventive analgesia that covers the preoperative, the intraoperative, and postoperative periods, the combination of experimental data and positive clinical trials strongly suggests that preventive analgesia is a clinically relevant phenomenon. Maximal clinical benefit is observed when there is complete blockade of noxious stimuli with extension of this blockade into the postoperative period. Recent preclinical and clinical studies provide substantial evidence that central sensitization and persistent pain after surgical incision is predominantly maintained by the incoming barrage of sensitized peripheral pain fibers throughout the perioperative period.\textsuperscript{49} By preventing central sensitization and the peripheral input maintaining it, preventive analgesia along with intensive multimodal analgesic interventions could theoretically reduce acute postprocedure pain/hyperalgesia and chronic pain after surgery or trauma.\textsuperscript{50} In a systematic review of clinical trials examining preemptive or preventive analgesic approaches, Katz and McCartney\textsuperscript{51} reported an analgesic benefit of preventive analgesia but no such benefit with the strictly preemptive strategy.

Treatment Methods

Many options are available for the treatment of acute pain, including systemic (i.e., opioid and nonopioid adjuvant) analgesics and regional (i.e., neuraxial and peripheral) analgesic techniques. By considering patients’ preferences and an individualized assessment of the risks and benefits of each treatment modality, the clinician can optimize the analgesic regimen for each patient. Essential aspects for postoperative monitoring for patients receiving various postoperative analgesic treatment methods are listed in Table 51.1.

| TABLE 51.1 Monitoring and Documentation of Postoperative | 2644 |
## Analgesia

### Analgesic Medication

- Name, concentration, and dose of drug
- Settings of PCA device: demand dose, lockout interval, continuous infusion
- Limits set (e.g., 1-h limits on dose administered)
- Supplemental or breakthrough analgesics

### Routine Monitoring

- Amount of drug administered including number of unsuccessful and successful doses
- Vital signs: temperature, heart rate, blood pressure, respiratory rate, 0–10 pain score
- Analgesia
- Pain at rest and with activity, percent pain relief
- Use of breakthrough medication

### Common Side Effects

- Cardiovascular: hypotension, bradycardia, or tachycardia
- Pulmonary: respiratory rate
- Gastrointestinal: nausea and vomiting, pruritus, urinary retention
- Neurologic: motor and sensory function, level of sedation

### Instructions Provided

- Treatment of side effects
- Parameters for triggering notification of covering physician
- Contact information should be provided (24 h/7 d per week) if problems occur
- Emergency analgesic treatment if PCA device fails

---

*Postoperative analgesia includes systemic opioids and regional analgesic techniques. This list incorporates some of the important elements of preprinted orders, documentation, and intravenous PCA and epidural analgesia daily care described in the American Society of Anesthesiologists Practice Guidelines for Acute Pain Management.*

CNS, central nervous system; PCA, patient-controlled analgesia.

### SYSTEMIC ANALGESIC TECHNIQUES

#### Opioids

Opioid analgesics are the gold standard treatments for postprocedural, traumatic and acute medical pain. These agents generally exert their analgesic effects through μ-opioid receptors in the CNS and the periphery following an inflammatory injury, including surgical incision. A theoretical advantage of full agonist opioid analgesics is that there is no analgesic ceiling. Another advantage is that opioids may be administered multiple routes including subcutaneous, transcutaneous, transmucosal, and intramuscular (IM) routes. Opioids also may be administered at specific anatomic sites such as the intrathecal (subarachnoid) or epidural space (see...
“Single-Dose Neuraxial Opioids” and “Continuous Epidural Analgesia” sections in the following text). Unfortunately, the effectiveness of opioids is limited by side effects including nausea, vomiting, sedation, or, the most concerning, respiratory depression. The repetitive use of opioids may induce the development of tolerance.

The most common routes of systemic opioid analgesic administration in the acute pain setting are oral, intravenous (IV), and IM. Commonly, parenteral administration of medications is necessary in the acute pain setting because the patient is unable to tolerate oral intake. Possible parenteral routes of administration include IV, IM, transdermal, and iontophoretic/transdermal (ITD). The treatment of moderate to severe acute pain often requires rapid and reliable onset of analgesia. To achieve this, the preferred medication route has traditionally been IV or IM. The development of ITD fentanyl and the validation of its efficacy in postoperative patients may expand the parenteral administration possibilities but do pose a risk of misuse and diversion. Traditional transdermal fentanyl is not ideal for the use in the acute pain setting because of its slow onset of analgesia and less predictable absorption and pharmacokinetics in the postoperative recovery period. The full analgesic benefit of this medication can be up to 24 to 36 hours after application to the skin. The other important criterion for acute pain management includes reliable and predictable analgesia. Unfortunately, there is wide intersubject and intrasubject variability in serum concentration and analgesic response after systemically administered opioids in the treatment of postoperative pain. The IM route of administration may result in a wider variability than the IV route and therefore may be a less ideal alternative. However, because it possesses a rapid onset time, it may be the best alternative to those who do not have immediate IV access.

The transition from parenteral to oral administration of opioids usually occurs after the patient can tolerate oral intake and his or her pain has been stabilized with parenteral opioids. The conversion from IV or IM medications can be performed by converting the parenteral opioid into the 24-hour “parenteral morphine equivalents” (PME) and converting this into the oral equivalent of the short- and long-acting opioid of choice. The division of long-acting versus short-acting medications is highly dependent
on the patient, the nature of the pain, the diurnal variation of the pain, but a
general rule is 50% of the daily requirement can be provided as a sustained
preparation and 50% as an immediate release breakthrough preparation.
Numerous “standard” tables exist for these conversions that are based on
pharmacokinetic data and physician experience. Other sources of
conversion tables or calculators are available including Washington State
Agency Medical Directors’ Group Calculator, the Hopkins Opioid
Program, and on mobile applications from the Centers for Disease
Control and Prevention or in tabular form (Tables 51.2 and 51.3).

**NOTE:** Equianalgesic doses are approximate and are intended to serve only as an estimate of opioid
requirements. Actual doses may vary, in part because of wide interpatient variability in response
to opioids. Doses should be individualized and gradually titrated to effect.

a Not recommended due to allelic variation of CYP2D6 leading to unpredictable, slow to ultrarapid,
metabolism.
b Not recommended for acute postoperative pain management.
c Methadone conversion is dependent on starting dose of morphine equivalent secondary to atypical
pharmacokinetics and dynamics and is not recommended for acute pain management.

Tramadol
Tramadol is a synthetic opioid that exhibits weak µ-agonist activity and inhibits reuptake of norepinephrine and serotonin. Although tramadol exerts its analgesic effects primarily through central mechanisms, it may exhibit peripheral local anesthetic properties.58 Tramadol is effective for treating moderate postoperative pain and comparable in analgesic efficacy to aspirin (650 mg) and acetaminophen (1,000 mg) (Table 51.4). The advantages of tramadol for mild to moderate acute pain treatment include the relative lack of respiratory depression, major organ toxicity, or depression of gastrointestinal motility, and it has a low potential for abuse.59 Common side effects with an overall incidence ranging from 1.6% to 6.1% include dizziness, drowsiness, sweating, nausea, vomiting, dry mouth, and headache.60 It is metabolized in the cytochrome P450 system via CYP2D6 and CYP3A4. It is, therefore, subject to the same risk of variable metabolism as codeine due to genetic differences in the CYP2D6 alleles. As a result of the CYP3A4 metabolism, it should be used with caution in patients with seizures or increased intracranial pressure and in those taking monoamine oxidase inhibitors or serotonin reuptake inhibitors, including most antidepressants.61

Nonsteroidal Anti-inflammatory Agents
Nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin, ibuprofen, and naproxen exert their analgesic effect through the inhibition of the cyclooxygenase (COX) and synthesis of prostaglandins (PG). COX enzymes and PGs are important inflammatory mediators and may play an important role in the generation and maintenance of peripheral and central sensitization. Nonselective NSAIDs inhibit both COX-1 and COX-2 enzymes and thereby decrease the production of prostaglandin E2 (PGE2) and other PGs derived from arachidonic acid. PGs act at peripheral as well
as central sites to alter nociceptive thresholds.\textsuperscript{61} For example, administration of PGE\textsubscript{2} directly into the hind paw\textsuperscript{62} or onto the spinal cord\textsuperscript{63} of animals produces peripheral edema and hyperalgesia. Several studies have highlighted the importance of a peripheral site of action for NSAIDs. Administration in the periphery of monoclonal antibodies to PGE\textsubscript{2} is associated with a decrease in paw edema and hyperalgesia.\textsuperscript{64} More recently, studies have highlighted a central component for NSAID action. In the spinal cord, PGE\textsubscript{2} can act presynaptically to increase the release of glutamate from primary afferent C fibers\textsuperscript{63,65} and postsynaptically to directly excite dorsal horn neurons by activation of nonselective cation currents.\textsuperscript{66} Both effects promote the development and maintenance of central sensitization and enhanced pain states. The systemic administration of NSAIDs reduces inflammation and the behavioral correlate of central/peripheral sensitization and hyperalgesia.\textsuperscript{67}

NSAIDs provide effective analgesia for mild to moderate acute pain and are a useful supplement to opioids for treatment of moderate to severe pain. The NSAID may provide some opioid-sparing properties through an additive or synergistic analgesic effect. NSAIDs such as ketorolac, which can be administered either orally or parenterally, are considered an integral part of a multimodal analgesic regimen by producing analgesia through different mechanisms than opioids or local anesthetics. As with opioids, NSAIDs by themselves do not appear to have a significant impact on mortality or major morbidity when compared to other analgesic agents. However, NSAIDs may improve analgesia and patient-oriented outcomes (e.g., satisfaction and quality of life) in part by reducing opioid analgesic requirements, decreasing opioid-related side effects, and facilitating patient recovery.\textsuperscript{68,69} When given in addition to systemic opioids, NSAIDs will improve postoperative analgesia and reduce opioid requirements by up to 50\%, which may reduce some opioid-related side effects including nausea and sedation. However, not all studies note a decrease in opioid-related side effects with concurrent NSAID use.\textsuperscript{70}

An analgesic benefit of aspirin over placebo has been shown for the 650-mg and 1,000-mg doses (see Table 51.4). The number of patients needed to treat for at least a 50\% reduction in pain (number needed to treat [NNT]) was 4.4 (4.0 to 4.9) and 4.0 (3.2 to 5.4), respectively. Single-dose
aspirin (650 mg) produced significantly more drowsiness and gastric irritation than placebo, with a number needed to harm (NNH) of 28 (19 to 51) and 38 (22 to 174), respectively. The authors also found that the type of pain model, pain measurement, sample size, quality of study design, and study duration had no significant impact on the results.\textsuperscript{71} Similar NNT were obtained for naproxen 400 to 500 mg in postoperative patients.\textsuperscript{72,73} The COX-2 selective inhibitor, celecoxib, when given at 200 mg has an NNT of 4.5 when compared to placebo in postoperative patients.\textsuperscript{74} Neither naproxen nor celecoxib were associated with an increase in adverse events.

CI, confidence interval; NNT, number needed to treat.

\textsuperscript{a}NNT in this case refers to the number of patients who must be treated to obtain more than 50% pain relief for moderate to severe postoperative pain. NNT conveys statistical and clinical significance, is useful to compare treatment efficacy for different interventions, and summarizes treatment effects in a clinically relevant way. A lower mean NNT implies greater analgesic efficacy in this example.

NSAIDs will affect osteoblastic and clastic activity in animal studies,\textsuperscript{75} and whether NSAIDs inhibit bone healing clinically is not certain. The quality of the available literature is suboptimal, but several systematic reviews have been conducted. In one meta-analysis of case-control and
cohort studies,\textsuperscript{76} a significant association between lower quality studies and higher reported odds ratios for nonunion was observed; however, there was no increased risk of nonunion with NSAIDs when only the highest quality studies were utilized. In another meta-analysis,\textsuperscript{77} short-time (<14 days) exposure to NSAIDs in lower/normal doses were not associated with disunion after spinal fusion but exposure to higher dose ketorolac was associated with an increased risk of nonunion.

Acetaminophen is commonly used for acute pain management as an alternative to NSAIDs, but its site of action at the molecular level is still controversial and not well defined. There are, however, some lines of evidence supporting its role in the inhibition of COX. Acetaminophen has been demonstrated to inhibit a variant of COX-2 enzymes in vivo\textsuperscript{78} and be similar to the COX-2 selective inhibitors: It inhibits prostaglandin synthesis in intact cells at low concentrations of added arachidonic acid further suggesting that it may inhibit COX-2 function.\textsuperscript{79} It has also been suggested that the molecular target of acetaminophen is a splice variant of COX-1, named as COX-3,\textsuperscript{80} but its low expression level and activity suggests that this selective interaction is unlikely to be clinically relevant.\textsuperscript{81} This suggests that acetaminophen inhibits COX-2 activity in vivo and that its analgesic effect may be a function of decreased peripheral PGE\textsubscript{2} synthesis in addition to centrally mediated analgesic effects of acetaminophen on descending serotonergic pathways.\textsuperscript{82}

Acetaminophen is very effective in the treatment of acute pain, especially that of postprocedural pain. The number of patients needed to treat for at least a 50% reduction in pain over 4 to 6 hours (NNT) for 1,000 mg of acetaminophen is 4.4, which is similar to that of 650 mg of aspirin or 100 mg of ibuprofen.\textsuperscript{83} However, it was less effective than higher dose ibuprofen (400 mg) or diclofenac (50 mg) with NNTs of 2.3 and 2.4, respectively. Fortunately, acetaminophen is rarely associated with adverse effects in the short term; however, it is associated with hepatotoxicity after chronic use or overdose. In countries, outside of the United States, IV propacetamol, the prodrug of acetaminophen or acetaminophen itself is administered to postoperative patients who are not able to tolerate oral analgesics. In clinical trials conducted in patients with moderate to severe pain after orthopedic and gynecologic surgery, the analgesic efficacy of
propacetamol was similar to that of NSAIDs.\textsuperscript{84,85} Although providing fast and significant pain relief as well as a significant opioid-sparing effect,\textsuperscript{84–86} it is not associated with the increased incidence of nausea, vomiting, and respiratory depression observed with opioids or the deleterious gastrointestinal, hematologic, cardiovascular, and renal effects associated with NSAIDs and selective COX-2 inhibitors. Lack of inhibition of COX-1 peripherally by acetaminophen may explain its favorable safety effect.\textsuperscript{87} These results have been replicated with IV acetaminophen in patients recovering from major orthopedic surgery.\textsuperscript{88} In the patient who is able to tolerate oral acetaminophen and has normal gastrointestinal absorption, there is likely minimal additional benefit of IV acetaminophen over the oral equivalent.

**Excitatory Amino Acids**

The excitatory amino acid neurotransmitter, glutamate, has a central role in the transmission of nociceptive signals from the periphery to the supraspinal structures and in the modulation of those signals in brainstem and spinal cord through descending bulbospinal tracts. The NMDA receptor, in particular, has been shown to have a crucial role in the development of persistent pain states including neuropathic pain.\textsuperscript{89} Although this receptor represents an obvious target to produce analgesia, pharmacologic antagonism has met with little clinical success. IV administration of the NMDA antagonist ketamine produced a reduction in neuropathic pain; however, this came at the cost of high incidence of side effects.\textsuperscript{90} Ketamine has had better results in the treatment of cancer pain as both a direct analgesic and by improving opioid-based analgesia.\textsuperscript{91,92} Clinical trials of dextromethorphan and memantine have failed to show any beneficial effect when compared to placebo.\textsuperscript{93,94} The role of NMDA antagonists in acute postprocedural or posttraumatic pain has met with less disappointing but somewhat mixed results. In one study, the addition of a single low-dose ketamine (0.25 mg/kg) administration to postoperative pain management with morphine was not found to be beneficial.\textsuperscript{95} However, the use of low-dose (subanesthetic doses) infusions of ketamine has been successfully used to reduce morphine requirements, need for rescue analgesia and pain scores in patients recovering from abdominal
surgery, spine, orthopedic surgery, and trauma. In a recent meta-analysis, the inclusion of ketamine to a postoperative analgesic regimen improved pain relief and resulted in lower opioid requirement without adding adverse events.

### Anticonvulsants

Anticonvulsants, including gabapentin, carbamazepine, lamotrigine, and pregabalin, have traditionally used for the treatment of chronic neuropathic conditions. Gabapentin is an anticonvulsant that was developed as a spasmolytic and adjunct for the treatment of generalized or partial epileptic seizures resistant to conventional therapies. Although it was originally designed as a structural analog of the inhibitory neurotransmitter GABA, it does not bind to GABA receptors, and the mechanism of action of this class of drugs is not fully understood. It is likely that its analgesic effects result from an action at the α2δ1 accessory unit of voltage-dependent Ca2+ channels for which it has substantial affinity and which are upregulated in the dorsal root ganglia and spinal cord after peripheral nerve injury as can be produced by surgical incision. Gabapentin may produce analgesia by binding to and inhibiting presynaptic voltage-dependent Ca2+ channels, decreasing calcium influx and thereby inhibiting the release of neurotransmitters including glutamate from the primary afferent nerve fibers that synapse on and activate pain responsive neurons in the spinal cord.

In clinical studies, several open-label single-center and multicenter, double-blind trials established that gabapentin was also effective for the treatment of chronic pain conditions, including postherpetic neuralgia, diabetic neuropathy, central pain, phantom pain, malignant pain, trigeminal neuralgia, and HIV-related neuropathy, which may be difficult to treat with more conventional therapies. The role of gabapentin in the treatment of acute pain is more controversial. Although in animal and human models of acute pain the administration of gabapentin or pregabalin produces no analgesia, when it is administered prior to a variety of surgical procedures, patients report decreased pain and decreased opioid use postoperatively. Gilron et al. showed synergism between gabapentin and morphine in patients suffering from neuropathic pain. This
synergistic effect may have played a role in the decreased pain scores of those receiving gabapentin because concomitant opioids were routinely administered in the postoperative period. Pregabalin and gabapentin have not been found to be effective in the treatment of acute chemotherapy-induced pain. Pregabalin was not found to have a benefit in the treatment of acute sciatica pain. Therefore, with the exception of the well-documented effectiveness of carbamazepine in the treatment of the acute exacerbation of trigeminal neuralgia, there is no evidence for the effectiveness of anticonvulsants in the treatment of acute pain not related to an operation or trauma.

α-Adrenergic Medications

α-Adrenergic receptors are widely distributed throughout the CNS and peripheral nervous system (PNS). The $\alpha_1$ receptors play an essential role in the regulation of vascular tone but no significant role in nociception. Activation of $\alpha_2$ receptors produces analgesia. They are linked to an inhibitory G protein on the presynaptic terminus of Aδ and C fibers and are activated by descending noradrenergic tracts from the brainstem LC and A7, which hyperpolarizes the primary afferent and reduces afferent transmitter release and pain transmission. However, depending on the $\alpha_2$ receptor subtype 2a, 2b, or 2c, different physiologic consequences may occur. The $\alpha_{2b}$ subtype produces hemodynamic responses (hypotension), whereas the $\alpha_{2a}$ receptor is responsible analgesia. Clonidine is the prototypic $\alpha_2$ agonist used for analgesia, although it has substantial hemodynamic side effects because of its lack of absolute $\alpha$ subtype selectivity. A newer agent, dexmedetomidine, is a more selective $\alpha_2$ receptor agonist that is analgesic and sedating with fewer cardiovascular effects.

In experimental models of acute transient pain, systemically administered clonidine had no analgesic benefit. In studies of postoperative patients, IV clonidine has been found to augment the local anesthetic block of the psoas compartment for hip surgery. However, the benefit was short lived and provided approximately 7 hours of additional analgesia. Preoperative and perioperative administration of
Systemic clonidine has been found to have a very modest analgesic (and anxiolytic) effect following abdominal hysterectomy.\textsuperscript{125,126} Perioperative use of systemic clonidine has been found to reduce overall opioid requirements following spinal surgery when given as a bolus of 3 µg/kg and followed by an infusion of 0.3 µg/kg/hour; however, modest changes in blood pressure and heart were also noted.\textsuperscript{127}

Dexmedetomidine, although more selective for \(\alpha_2\) receptors and more subtype selective (\(\alpha_{2A}\)), does not produce significant analgesia in human experimental models of acute heat or electrical pain at doses that produce modest to severe sedation.\textsuperscript{128} In one study, dexmedetomidine infusion reduced healthy volunteer’s cold pressor–induced pain by 30\% at doses that produced sedation and memory loss but did not produce hemodynamic perturbations.\textsuperscript{121} Preoperative administration of dexmedetomidine reduced postoperative opioid consumption but had no effect on postprocedure pain scores or recovery time.\textsuperscript{129} Perioperative administration reduces opioid requirements after thoracotomy\textsuperscript{130} and tubal ligation\textsuperscript{131} but resulted in significant sedation and heart rate instability in some patients.

**Steroids**

Glucocorticoids are commonly used as prophylaxis for postoperative nausea and vomiting, but these agents may also produce an analgesic effect. Glucocorticoids may reduce acute pain in a variety of mechanisms including a reduction in inflammation and tissue damage. A recent meta-analysis examined the analgesic efficacy of a single perioperative dose of dexamethasone. Patients who received dexamethasone had lower pain scores, used less opioids, required less rescue analgesia for intolerable pain, had longer time to first dose of analgesic, and had shorter stays in the postanesthesia care unit.\textsuperscript{132} There was no increase in infection or delayed wound healing with dexamethasone despite the finding that but blood glucose levels were higher 24 hours postoperatively. On the other hand, another meta-analysis in thyroidectomy patients\textsuperscript{133} found that a single preoperative dose of dexamethasone did not decrease the incidence and severity of pain postoperatively. A meta-analysis of studies examining the addition of dexamethasone (4 to 10 mg) to local anesthetics for peripheral nerve blocks noted a faster onset of action and significant increase in the
duration of analgesia with the addition of dexamethasone compared with local anesthetic solutions alone.\textsuperscript{134}

**Serotonergic Medications**

Serotonergic receptors found in the spinal dorsal horn have a complex relationship to the modulation of nociceptive transmission. Three of the subtypes of serotonergic receptors play a role in nociceptive transmission, 5-HT\textsubscript{1} and 5-HT\textsubscript{2} hyperpolarize neurons within the dorsal horn and inhibit pain transmission, whereas 5-HT\textsubscript{4} receptors depolarize dorsal horn neurons and augment the transmission of nociceptive information.\textsuperscript{135} Presynaptic terminals of descending neurons from the RVM appear to oppose 5-HT\textsubscript{1} and 5-HT\textsubscript{2} receptors of primary afferents and interneurons in the spinal cord producing a reduction in pain like behavior in animals following activation of the RVM. Unfortunately, no subtype-specific serotonergic agonists are available for human use for analgesia. Interestingly, a recent study found that activation of the 5-HT\textsubscript{4} receptor in the brainstem eliminates the respiratory depression associated with administration the opioid fentanyl,\textsuperscript{136} thus having an indirect but very beneficial effect on the treatment of pain.

The only clinically available serotonergic agonists or indirect serotonergic agonists consist of the selective serotonin reuptake inhibitors (SSRIs) that are primarily used for the treatment of depression and anxiety disorders. Unfortunately, the data regarding the use of SSRIs in acute pain are lacking or negative. The lack of clinical studies assessing the analgesic value of this class is likely due to the lack of analgesic benefit of this class of drugs in the treatment of chronic pain.\textsuperscript{137}

**NONSELECTIVE NORADRENERGIC AND SEROTONINERGIC MEDICATIONS**

Although the group of nonselective noradrenergic and serotonergic reuptake inhibitor medications, the tricyclic antidepressants (TCAs), does not carry a U.S. Food and Drug Administration indication for pain, they are a mainstay of treatment of a variety of neuropathic and nonneuropathic chronic pain states. TCAs suppress nociceptive transmission independent of their effects on depressed affect in the psychological domain. The exact
mechanism of analgesic action remains unclear. As a class of agents, TCAs act to inhibit the reuptake and destruction or storage of biogenic amines including norepinephrine and serotonin. One possible mechanism is the accentuation of the descending serotoninergic and noradrenergic bulbospinal pathways on the spinal cord dorsal horn, by acting locally on 5-HT\textsubscript{1}, 5-HT\textsubscript{2}, and \(\alpha_2\) receptors. Interestingly, SSRIs have little if any analgesic potential\textsuperscript{138}; yet, the TCAs with the greatest pain relieving effects have their greatest inhibition of serotonin reuptake.\textsuperscript{139} Alternate mechanisms including histamine receptor blockade,\textsuperscript{140} calcium channel blockade,\textsuperscript{141} antagonism of the NMDA receptor,\textsuperscript{142} anti-inflammatory effects,\textsuperscript{143} and blockade of sodium channels\textsuperscript{144} have been suggested.

The results for TCAs in experimental models of acute pain are somewhat mixed. The secondary amine, desipramine, which has the greatest norepinephrine reuptake inhibitor selectivity, has no effect on pain scores in a capsaicin-induced mechanical allodynia model.\textsuperscript{145} In contrast, imipramine the tertiary amine precursor to desipramine produced a reduction in pain resulting from noxious stimulation of the nasal mucosa.\textsuperscript{146} A single study found that the administration of the tertiary tricyclic amine, amitriptyline, during the acute stage of herpes zoster decreased the prevalence of postherpetic neuralgia.\textsuperscript{147} TCAs have not been found to be effective in the treatment of postoperative pain.\textsuperscript{148–150}

The role of the selective serotonin and norepinephrine reuptake inhibitors, duloxetine and venlafaxine, has not been fully elucidated. Like the TCAs, these drugs have been used successfully to treat chronic pain conditions. However, in the acute postoperative setting, the results are mixed. A recent randomized controlled trial (RCT) examining the perioperative administration of duloxetine found a decrease in postoperative pain and opioid consumption following spine surgery\textsuperscript{151} and hysterectomy,\textsuperscript{152} however was ineffective following knee arthroplasty.\textsuperscript{153} Another selective serotonin-norepinephrine reuptake inhibitor (SSNRI), venlafaxine has similarly mixed results for postoperative pain.\textsuperscript{154} The atypical antidepressant bupropion has not been investigated in trials of acute pain; however, it is not effective in the treatment of mechanical chronic back pain.\textsuperscript{155}
INTRANESSIVE PATIENT-CONTROLLED ANALGESIA

Various factors, including the interpatient and intrapatient variability in analgesic needs, variability in serum drug levels (especially with IM injections), and administrative delays, may contribute to inadequate postoperative analgesia. There may be difficulty in compensating for these factors with the use of a traditional PRN analgesic regimen. By circumventing some of these issues, IV patient-controlled analgesia (IVPCA) optimizes delivery of analgesic opioids and minimizes the effects of pharmacokinetic variability among individual patients. IVPCA is based on the premise that a negative feedback loop exists, when pain is experienced, analgesic medication is self-administered, and when pain is reduced, there are no further demands. When the negative feedback loop is violated, excessive sedation or respiratory depression may occur.\(^\text{156}\)

Although some equipment-related malfunctions have been reported, the PCA device itself is relatively free of problems, and most problems related to PCA use result from user or operator errors.\(^\text{156}\)

A PCA device can be programmed for several variables, including the demand (bolus) dose, lockout interval, and background infusion (Table 51.5). The optimal demand or bolus dose is integral to IVPCA analgesic efficacy because an insufficient demand dose may result in inadequate analgesia, whereas an excessive demand dose may result in a higher incidence of undesirable side effects such as respiratory depression.\(^\text{157}\)

Although the optimal demand dose is uncertain, available data suggest that the optimal demand dose for morphine is 1 mg and that for fentanyl is 40 µg for opioid-naive patients; however, the actual dose for fentanyl is often less in clinical practice.\(^\text{156,157}\) The lockout interval may also affect the analgesic efficacy of IVPCA and is a safety feature of IVPCA. Although the optimal lockout interval is unknown, most intervals range from 5 to 10 minutes, and varying the interval within this range appears to have no effect on analgesia or side effects.\(^\text{156}\) Most PCA devices allow the addition of a continuous or background infusion in addition to the demand dose. Initially, routine use of a background infusion was thought to confer certain advantages, including improved analgesia especially during sleep; however, subsequent trials failed to demonstrate any analgesic benefits of a background infusion in opioid-naive patients.\(^\text{158}\) Although the routine
use of continuous or background infusions in IVPCA in adult opioid-naive patients is not recommended, there may be a role for use of a background infusion for opioid-tolerant or pediatric patients. A Cochrane database meta-analysis revealed that IVPCA (compared to PRN opioids) provided significantly greater analgesia and patient satisfaction; however, patients who had IVPCA used more opioids with a higher incidence of pruritus but no difference in the incidence of other adverse events compared to PRN opioids.\textsuperscript{159}

<sup>a</sup> All doses are for adult patients. The anesthesiologist should proceed with titrated intravenous loading doses if necessary to establish initial analgesia. Individual patient’s requirements vary widely, with smaller doses typically given for elderly or compromised patients. Continuous infusions are not initially recommended for opioid-naive adult patients. NMDA, N-methyl-d-aspartate.

The incidence of opioid-related adverse events from IVPCA does not appear to differ significantly from that administered intravenously,
intramuscularly, or subcutaneously. The rate of respiratory depression associated with IVPCA is low (<0.5%) and does not appear to be higher than that with systemic or neuraxial opioids. Factors that may be associated with occurrence of respiratory depression with IVPCA include use of a background infusion, advanced age, concomitant administration of sedative or hypnotic agents, and coexisting pulmonary disease such as sleep apnea.

**REGIONAL ANALGESIC TECHNIQUES**

A variety of neuraxial and peripheral regional analgesic techniques may be employed for the effective treatment of acute pain. Many of these techniques were initially developed for the management of acute postoperative pain; however, their application is appropriate for the treatment of any severe acute pain. In general, epidural and peripheral techniques when local anesthetics are used can provide superior analgesia compared with systemic opioids, and use of these techniques may even reduce morbidity and mortality in the postoperative population. However, there are risks associated with the use of these techniques, and a risk versus benefit analysis of these techniques should be performed on an individual basis to determine the appropriateness of neuraxial or peripheral regional techniques for each patient, especially in light of some of the controversies about the use of these techniques in the presence of anticoagulation.

**Single-Dose Neuraxial Opioids**

A single dose of opioid may provide significant analgesia when administered as a sole or adjuvant analgesic agent when administered intrathecally or epidurally. One of the most important factors in determining the clinical pharmacology for an opioid is its degree of lipid solubility. Once inside the cerebrospinal fluid (CSF) through direct intrathecal injection or gradual migration from the epidural space, hydrophilic opioids (i.e., morphine and hydromorphone) tend to remain within the CSF and produce a delayed but longer duration of analgesia along with a generally higher incidence of side effects due to its cephalad spread. Neuraxial administration of lipophilic opioids, such as fentanyl and
sufentanil, tends to provide rapid onset of analgesia, and the rapid
clearance from the CSF may limit cephalad spread and development of
certain side effects such as delayed respiratory depression but not
pruritus. The site of analgesic action for hydrophilic opioids is
overwhelmingly spinal, but the primary site of action (spinal vs. systemic)
for single-dose neuraxial lipophilic opioids is not as certain.

The differences in pharmacokinetics between lipophilic and hydrophilic
opioids may influence the choice of opioid to optimize analgesia and
minimize side effects for a clinical situation. Single-dose intrathecal
administration of a lipophilic opioid may be useful in situations (e.g.,
ambulatory surgical patients) in which rapid analgesic onset (minutes)
combined with a moderate duration of action (<4 hours) and minimal risk
of respiratory depression is needed. Single-dose hydrophilic opioid
administration provides effective postoperative analgesia and may be
useful in patients monitored on an inpatient basis for which a longer
duration of analgesia would be beneficial.

Single-dose epidural administration of lipophilic and hydrophilic
opioids is used to provide analgesia, with considerations generally like
those discussed with single-dose intrathecal administration of opioids. A
single bolus of epidural fentanyl may be administered to provide rapid
postoperative analgesia; however, diluting the epidural dose of fentanyl
(typically 50 to 100 µg) in at least 10 mL of preservative-free normal
saline is suggested to decrease the onset and prolong the duration of
analgesia, possibly as a result of an increase in the initial spread and
diffusion of the lipophilic opioid. Single-dose epidural morphine is
effective for postoperative analgesia and may decrease postoperative
patient morbidity in selected patients. Use of a single-dose
hydrophilic opioid may be especially helpful in providing postoperative
epidural analgesia when the epidural catheter’s location is not congruent
with the surgical incision (e.g., lumbar epidural catheter for thoracic
surgery). Lower doses of epidural morphine may be required for elderly
patients and thoracic catheter sites. Commonly used dosages for intrathecal
and epidural administration of neuraxial opioids are provided in Table
51.6.

NOTE: Doses are approximate and based on the use of the neuraxial opioid alone. No continuous intrathecal infusions are provided. Lower doses may be effective when administered to elderly patients. Units vary across medications for single dose (µg vs. mg) and continuous infusions (µg/h vs. mg/h).

An extended-release formulation of (single-dose) epidural morphine (DepoDur) encapsulated within liposomes resulting in up to 48 hours of analgesia is available. The greatest benefit of liposomal morphine is its extended-release formulation and the prolonged duration of effect that may be important with the increasing use of long-acting low molecular weight heparin medications for postoperative patients for thrombosis prophylaxis. Liposomal morphine exhibits not only a dose-dependent increase in analgesia but, unfortunately, also a dose-dependent increase in adverse events including respiratory depression. This formulation is used infrequently, and therefore, no long-term data have been developed looking at patient outcomes including overall adverse event rates or any reduction in thrombosis rates as compared to traditional epidural catheter-based long-term management. As with traditional single-dose neuraxial opioids, clinicians should provide a lower dose of liposomal extended-release morphine in the elderly or those with decreased physiologic reserve or coexisting diseases, and liposomal extended-release morphine has not been approved for use in pediatric patients.

**Continuous Epidural Analgesia**

Analgesia delivered through an indwelling epidural catheter is a generally safe and effective method for management of acute pain. Postoperative
Epidural analgesia can provide superior analgesia compared with systemic opioids.\textsuperscript{171}

Epidural Medications
Epidural infusions of local anesthetic alone may be used for postoperative analgesia, but in general, they are not as effective in controlling pain as local anesthetic–opioid epidural analgesic combinations.\textsuperscript{171} The rationale for using local anesthetic only epidural infusions has been to avoid the side effects of epidural opioids. Traditionally, this practice has resulted in inadequate analgesia and relatively high incidence of motor block and hypotension although utilizing lower concentration of local anesthetics may ameliorate some of the negative effects.

Opioids may be used alone for postoperative epidural infusions in order to avoid the motor block or hypotension from local anesthetic–induced sympathetic blockade.\textsuperscript{170} This advantage might be desirable in patients following abdominal aortic aneurysm operations as well as surgery with large fluid shifts in patients with significant cardiac or cerebrovascular disease. There are differences between continuous epidural infusions (CEIs) of lipophilic (e.g., fentanyl, sufentanil) and hydrophilic (e.g., morphine, hydromorphone) opioids. The analgesic site of action (spinal vs. systemic) for CEIs of lipophilic opioids is not clear, although several randomized clinical trials suggest that it is systemic\textsuperscript{172} because there were no differences in plasma concentrations, side effects, or pain scores between those who received IV or epidural infusions of fentanyl. Although some data suggest a benefit from epidural of lipophilic opioids when compared to IV administration,\textsuperscript{173} the overall advantage of administering CEIs of lipophilic opioids alone is marginal at best. Hydrophilic opioids are quite different because of their relative lack of diffusion into the systemic circulation; the primary site of their analgesic action is spinal.\textsuperscript{172} Hydrophilic opioids can distribute throughout the CSF; therefore, the continuous infusion of these opioids may be especially useful for providing postoperative analgesia when the site of catheter insertion is not congruent with the site of surgery. CEIs of hydrophilic opioids provide superior analgesia compared with traditional PRN administration of systemic opioids.\textsuperscript{174}
The combination of local anesthetics and opioids in a CEI may have advantages over infusions using a local anesthetic or opioid alone. Compared with a local anesthetic or opioid alone, a local anesthetic–opioid combination provides superior postoperative analgesia including improved dynamic pain relief, limits regression of sensory block, and possibly decreases the dose of local anesthetic administered, although the incidence of side effects may or may not be diminished. CEI of a local anesthetic–opioid combination also provides superior analgesia compared with IVPCA with opioids. It is unclear whether the analgesic effect of the local anesthetic and opioid in the epidural analgesia is additive or synergistic. Experimental studies demonstrate a synergistic effect between local anesthetics and opioids; however, clinical trials suggest an additive effect and the lack of improvement in side effects when used in combination supports the clinical experimental data.

The choice of local anesthetic for CEIs varies. In general, bupivacaine or ropivacaine over lidocaine is chosen because of the differential and preferential clinical sensory blockade with minimal impairment of motor function. The concentrations used for postoperative epidural analgesia (≤0.125% bupivacaine or ≤0.2% ropivacaine) are lower than those used for intraoperative anesthesia. The choice of opioid also varies, although many clinicians choose to use a lipophilic opioid (fentanyl, 2 to 5 µg/mL, or sufentanil, 0.5 to 1 µg/mL) to allow for rapid titration of analgesia. However, the use of the lipophilic opioid may just provide greater analgesia than local anesthetics alone; it is not clear whether use of these highly permeable medications does not simply provide a stable systemic concentration of opioid. The use of a hydrophilic opioid (morphine, 0.05 to 0.1 mg/mL, or hydromorphone, 0.01 to 0.05 mg/mL) as part of a local anesthetic–opioid epidural analgesic regimen is more consistent with the goal of spinal delivery of opioid and also provides effective postoperative analgesia.

A variety of adjuvant medications may be added to epidural infusions to enhance analgesia while minimizing side effects, but none has gained widespread acceptance. Two of the more studied adjuvants are clonidine and epinephrine. Clonidine mediates its analgesic effects primarily through its action at α₂ receptors in the spinal cord, and the epidural dose typically
used ranges from 5 to 20 µg per hour. The clinical application of clonidine is limited by its side effects: hypotension, bradycardia, and sedation. Hypotension and bradycardia are both dose-dependent. Epinephrine may improve epidural analgesia, can increase sensory block, and is generally administered at a concentration of 2 to 5 µg/mL, but it is also associated with a worsened motor block. Epidural epinephrine added to local anesthetics is also associated with longer stage 2 labor and decrease Apgar scores in parturient. Epidural administration of NMDA antagonists, such as ketamine, has been performed on a limited basis. Lauretti et al. found no analgesic benefit when ketamine was added to the clonidine epidural infusion following orthopedic surgery. This contrasts with another trial showing a preemptive analgesic benefit of epidural ketamine prior to a thoracotomy incision. The theoretical explanation for the latter result is that ketamine attenuates the development of central sensitization and might potentiate the analgesic effect of epidural opioids. The caveat to this is that the safety of neuraxial ketamine infusions is controversial and may result in neuronal apoptosis and is therefore should not be used. Further safety and analgesic data are needed to justify its use.

Side Effects of Neuraxial Analgesic Drugs
Many medication-related (opioid and local anesthetic) side effects can occur with use of postoperative epidural analgesia. However, before automatically ascribing the cause to the epidural analgesic regimen, it is important to first consider other causes of the most common adverse effects of epidural analgesia; namely, hypotension, respiratory insufficiency/depression. These can include low intravascular volume, bleeding, and low cardiac output for hypotension and cerebrovascular accident, pulmonary edema, and evolving sepsis. Standing orders and nursing protocols for analgesic regimens, neurologic, hemodynamic, and respiratory monitoring; treatment of side effects; and physician notification about critical parameters should be standard for all patients receiving neuraxial and other types of postoperative analgesia.

Local anesthetics used in an epidural analgesic regimen may block sympathetic fibers and contribute to postoperative hypotension. Although
the incidence of postoperative hypotension with postoperative epidural analgesia may be as high as approximately 7%, the average is closer to 0.7% to 3%. Strategies to treat noncritical hypotension due to epidural analgesia include decreasing the overall dose of local anesthetic administered, or use of opioid-alone epidural because it is unlikely that neuraxial opioid alone would contribute to postoperative hypotension. Use of local anesthetics for postoperative epidural analgesia may also contribute to lower extremity motor block in approximately 2% to 3% of patients, and this may contribute to development of pressure sores in the heels. A lower concentration of local anesthetics and catheter-incision congruent placement of epidural catheters for abdominal or thoracic procedures may decrease the incidence of motor block. Although motor block resolves in most cases after stopping the epidural infusion for approximately 2 hours, persistent or increasing motor block needs to be promptly evaluated, and spinal hematoma, spinal abscess, and intrathecal catheter migration should be considered as part of the differential diagnosis.

Nausea and vomiting associated with neuraxial administration of a single-dose opioid occurs in approximately 20% to 50% of patients, and the cumulative incidence among those receiving continuous infusions of opioids may be as high as 45% to 80%. Clinical and experimental data suggest that the incidence of neuraxial opioid–related nausea and vomiting is dose-dependent. Nausea and vomiting from neuraxial opioids may be related to the cephalad migration of opioid within the CSF to the area postrema in the medulla. Use of fentanyl alone or in combination with a local anesthetic in an epidural infusion is associated with a lower incidence of nausea and vomiting compared with infusions using morphine. A variety of agents have been successfully used to treat neuraxial opioid–induced nausea and vomiting, including naloxone, droperidol, metoclopramide, dexamethasone, and transdermal scopolamine.

Pruritus is one of the most common side effects of epidural or intrathecal administration of opioids, with an incidence of approximately 60% compared with about 15% to 18% for epidural local anesthetic administration or systemic opioids. Although the cause of neuraxial opioid–induced pruritus is uncertain, it does not appear to be associated
with peripheral histamine release but may be related to central activation of an “itch center” in the medulla or opioid receptors in the trigeminal nucleus or nerve roots with cephalad migration of the opioid or through the activation of a separate population of primary afferents that mediate nonhistamine itch. It is unclear whether the incidence of neuraxial opioid–related pruritus is dose-dependent because a quantitative systematic review suggests no evidence of a relationship, whereas other clinical and experimental studies indicate a significant correlation. Use of an epidural infusion of fentanyl alone or as part of a local anesthetic–opioid combination appears to be generally associated with a lower incidence of pruritus compared with morphine. A variety of agents have been evaluated for the prevention and treatment of opioid-induced pruritus. IV naloxone, naltrexone, nalbuphine, and droperidol appear to be efficacious for the pharmacologic control of opioid-induced pruritus. Although pruritus is a common side effect, it often mild, it is relatively easy to treat.

Neuraxial opioids used in appropriate doses are not associated with a higher incidence of respiratory depression than that seen with systemic administration of opioids. The incidence of respiratory depression associated with neuraxial administration of opioids is dose-dependent and typically ranges from 0.1% to 0.9%. The incidence of respiratory depression with continuous infusions of epidural opioids appears to be no greater than that seen after systemic opioid administration. Although some institutions require patients with CEIs of hydrophilic opioids to receive monitoring in an intensive care unit setting, many large-scale trials have demonstrated the relative safety (incidence of respiratory depression <0.9%) of this technique on regular hospital wards. Neuraxial lipophilic opioids are thought to cause less delayed respiratory depression than hydrophilic opioids, although administration of lipophilic opioids may be associated with significant, early respiratory depression. Delayed respiratory depression is primarily associated with the cephalad spread of the hydrophilic opioids, which typically occurs within 12 hours after injection. Risks factors for respiratory depression with neuraxial opioids include increasing dose, increasing age, concomitant use of systemic opioids or sedatives, and possibly prolonged or extensive surgery,
presence of comorbidities, and thoracic surgery.\textsuperscript{202} Treatment with naloxone and airway management, if necessary, is effective in 0.1- to 0.4-mg increments; however, the clinical duration of action is relatively short compared with the respiratory-depressant effect of neuraxial opioids, and a continuous infusion of naloxone (0.5 to 5 µg/kg/hour) may be needed.\textsuperscript{203}

Urinary retention associated with neuraxial administration of opioids is the result of an interaction with the opioid receptors in the spinal cord that decreases the detrusor muscle’s strength of contraction.\textsuperscript{189} The incidence of urinary retention seems to be higher with neuraxially administered opioids than that given systemically. Urinary retention does not appear to depend on opioid dose and may be treated with the use of low-dose naloxone, although at the risk of reversing the analgesic effects.\textsuperscript{203} Epidural administration of local anesthetics is also associated with urinary retention, with a reported rate of approximately 10\% to 30\%.\textsuperscript{204} Higher epidural infusion rates of local anesthetics (with a greater extent of sensory block and higher incidence of motor block) may be associated with a higher incidence of urinary retention.\textsuperscript{205}

Patient-Controlled Epidural Analgesia

Epidural analgesia can be delivered as a fixed rate or continuous infusion (CEI) or through a patient-controlled device (patient-controlled epidural analgesia [PCEA]) has become more common. Like IVPCA, PCEA allows for individualization of postoperative analgesic requirements and may have several advantages over CEI, including lower drug use and greater patient satisfaction.\textsuperscript{206} PCEA also provides superior analgesia compared with IVPCA. PCEA is a safe and effective technique for acute analgesia in hospitalized. Observational data from two series of more than 1,000 patients each reveal that more than 90\% of patients with PCEA receive adequate analgesia, with a median pain score of 1 (of a possible 10) at rest and 4 with activity.\textsuperscript{186,207} Incidences of side effects are 1.8\% to 16.7\% for pruritus, 3.8\% to 14.8\% for nausea, 13.2\% for sedation, 4.3\% to 6.8\% for hypotension, 0.1\% to 2\% for motor block, and 0.2\% to 0.3\% for respiratory depression.\textsuperscript{186,207} These rates are comparable to those reported with CEI, with an incidence of 10.2\% to 22\% for pruritus, 3.1\% to 22\% for nausea, 7.4\% for sedation, 0.7\% to 6.6\% for hypotension, 3\% for motor
block, and 0.1% to 1.6% for respiratory depression. The optimal PCEA analgesic solution and delivery parameters are unclear. Use of a continuous or background infusion in addition to the demand dose is more common with PCEA than with IVPCA and may provide analgesia superior to the use of a demand dose alone.

In general, most acute pain specialists are gravitating toward a variety of low-concentration local anesthetic–opioid combinations (Table 51.7) in an attempt to improve analgesia while minimizing side effects.

NOTE: Patient-controlled epidural analgesic regimens commonly used at the Johns Hopkins Hospital.
Use of perioperative epidural anesthesia and analgesia, especially with a local anesthetic–based analgesic solution, can attenuate the pathophysiologic response to surgery and may be associated with a reduction in mortality and morbidity compared with analgesia with systemic (opioid) agents.\textsuperscript{11,12} A meta-analysis of randomized data (141 trials enrolling 9,559 subjects) demonstrated that perioperative use of neuraxial anesthesia and analgesia versus general anesthesia and systemic opioids reduced overall mortality (primarily in orthopedic patients) by approximately 30\%.\textsuperscript{210} In a Medicare database analysis of 68,000 surgical patients, postoperative epidural-based analgesia was associated with a decrease in overall mortality.\textsuperscript{211} Furthermore, use of epidural analgesia can decrease the incidence of postoperative gastrointestinal, pulmonary, and possibly cardiac complications.\textsuperscript{11,12} By inhibiting sympathetic outflow, decreasing the total opioid dose, and attenuating a spinal reflex inhibition of the gastrointestinal tract,\textsuperscript{11} postoperative thoracic epidural analgesia can facilitate return of gastrointestinal motility without contributing to bowel dehiscence.\textsuperscript{212} Randomized clinical trials demonstrate that use of postoperative thoracic epidural analgesia with a local anesthetic–based analgesic solution allows earlier return of gastrointestinal function and fulfillment of discharge criteria.

The benefits of perioperative epidural analgesia (compared with systemic opioid analgesia) on morbidity and mortality is best summarized in a meta-analysis in adults having surgery under general anesthesia.\textsuperscript{213} A total of 125 trials (9,044 patients) were examined and patients who received epidural analgesia had a significantly lower risk of death (3.1\% vs. 4.9\%; odds ratio, 0.60; 95\% confidence interval, 0.39 to 0.93) and also decreased risk of atrial fibrillation, supraventricular tachycardia, deep vein thrombosis, respiratory depression, atelectasis, pneumonia, gastrointestinal ileus, and postoperative nausea and vomiting.

The ability of postoperative epidural analgesia to attenuate postoperative pathophysiology and improve outcomes also depends on the type of drugs used (opioids vs. local anesthetics). Maximal attenuation of perioperative pathophysiology occurs with use of a local anesthetic–based epidural analgesic solution. The use of a local anesthetic–based or local anesthetic/opioid combination versus opioid-alone analgesic solution is
associated with an earlier recovery of gastrointestinal motility after abdominal surgery and less frequent occurrence of pulmonary complications. Epidural analgesia is not a generic entity because different catheter locations and analgesic regimens may differentially affect perioperative morbidity.

Risks of Epidural Analgesia
The benefits of perioperative epidural anesthesia-analgesia must be weighed against the risks of this technique. Risks and benefits should be evaluated for each patient. There are complications associated with placement of an epidural catheter, with several risks associated with indwelling epidural catheters including epidural hematoma and abscess should be discussed in the context of postprocedure and/or acute pain management with epidural analgesia. The concurrent use of anticoagulants and of neuraxial anesthesia and analgesia has always been a relatively controversial issue but has been highlighted over the past decade with the increased incidence of spinal hematomas after the introduction of low molecular weight heparin in North America in 1993. Different types and classes of anticoagulants have different pharmacokinetic properties that affect the timing of neuraxial catheter or needle insertion and catheter removal. Despite several observational and retrospective studies investigating the incidence of spinal hematoma in the setting of various anticoagulants and neuraxial techniques, there is no definitive conclusion regarding the absolute safety of neuraxial anesthesia and anticoagulation. The American Society of Regional Anesthesia and Pain Medicine (ASRA) lists a series of consensus statements based on the available literature for administration (insertion and removal) of neuraxial techniques in the presence of various anticoagulants, including oral anticoagulants (warfarin), antiplatelet agents, fibrinolytics-thrombolytics, standard unfractionated heparin, and low molecular weight heparin. The ASRA consensus statements include the concepts that the timing of neuraxial needle or catheter insertion or removal should reflect the pharmacokinetic properties of the specific anticoagulant, that frequent neurologic monitoring is essential, that concurrent use of multiple anticoagulants may increase the risk of bleeding, and that the analgesic regimen should be tailored to facilitate neurologic monitoring, which may be continued in
some cases for 24 hours after epidural catheter removal. An updated version of the ASRA consensus statements on neuraxial anesthesia and anticoagulation can be found on their Web site, and some of these statements address the newer anticoagulants. Anticoagulation risk associated with indwelling spinal cord stimulator leads, which could be considered an approximation of indwelling epidural catheters, has been addressed in a recent guideline.

Infection associated with postoperative epidural analgesia may result from exogenous or endogenous sources. Serious infections such as epidural abscess and meningitis associated with epidural analgesic are rare (<1 in 1,000, <1 in 50,000, respectively). Epidural infections are associated with many sources of the bacteria including needle contamination, catheter contamination, epidural medication contamination, lack of the use of in-line bacterial filters, duration of catheter implantation, and patient predisposing factors for infection. The use of epidural analgesia in the general surgical population with a typical duration of postoperative catheterization (approximately 2 to 4 days) is generally not associated with epidural abscess formation. A trial of postoperative epidural analgesia (mean catheterization of 6.3 days) in more than 4,000 surgical cancer patients did not reveal any abscesses. Even though serious infectious complications appear to be rare after short-term (<4 days) epidural infusions, there may be a relatively higher incidence of superficial inflammation or cellulitis (4% to 14%) and even higher rate of catheter colonization (20% to 35%), with the proportion of positive cultures increasing with the duration of catheterization; however, catheter colonization rate may not be a good predictor of epidural space infection.

PERIPHERAL REGIONAL ANALGESIA
The use of peripheral regional analgesic techniques as a single injection or continuous infusion can provide superior analgesia for acute pain when compared with systemic opioids and may even result in improvement in various outcomes. A variety of wound infiltration and peripheral regional techniques (e.g., brachial plexus, lumbar plexus, femoral, sciatic-popliteal, and scalp nerve blocks) can be used to provide postprocedural
and acute analgesia. Peripheral nerve regional analgesic techniques may have several advantages over systemic opioids including superior analgesia and decrease in opioid-related side effects and over neuraxial techniques including decreased risk of epidural hematoma formation. A one-time injection of local anesthetic for peripheral regional techniques may be used primarily for intraoperative anesthesia or as an adjunct for postprocedure analgesia but can be used for acute traumatic pain management such as long bone fractures or rib fractures. Compared with placebo, peripheral nerve blocks with local anesthetics provide superior analgesia and are associated with decreased opioid use, decreased opioid-related side effects, and improvement in patient satisfaction.

The duration of postoperative analgesia resulting from the local anesthetic in the peripheral nerve block varies but may last up to 24 hours after injection. Continuous infusions of local anesthetics can be administered through peripheral nerve catheters. The use of continuous infusions or patient-controlled peripheral analgesia results in superior analgesia decreased opioid-related side effects, and greater patient satisfaction in comparison with systemic opioids. Unfortunately, the optimal parameters including the local anesthetic, the medication concentration, the inclusion of opioid or other adjuvant medications, or continuous versus PCA versus intermittent boluses for peripheral analgesia have not been determined.

Several nonepidural regional analgesic techniques can be used for management of postoperative thoracic pain, including paravertebral and intercostal blocks, interpleural (intrapleural) analgesia, and cryoanalgesia. The most promising technique appears to be the thoracic paravertebral block, which has been used for thoracic, breast, and upper abdominal surgery and for treatment of rib fracture pain. The possible sites of analgesia for the thoracic paravertebral block include direct somatic nerve, sympathetic nerve, and epidural blockade. The thoracic paravertebral block can be administered as a single injection or continuous infusion through a catheter may provide equal or superior analgesia compared with thoracic epidural analgesia and is a valuable alternative to thoracic epidural analgesia. The analgesic efficacy of interpleural analgesia is controversial. In a meta-analysis of RCTs examining interpleural
analgesia, no difference was observed between interpleural analgesia and placebo injections. Interpleural analgesia appears to be inferior to epidural and paravertebral analgesia for postoperative pain control, preservation of lung function after thoracotomy, and reduction of postoperative pulmonary complications.\textsuperscript{224} Intercostal blocks may provide short-term postoperative analgesia and may be repeated postoperatively; however, the incidence of pneumothorax increases with each intercostal nerve blocked (1.4% per nerve, with an overall incidence of 8.7% per patient).\textsuperscript{225} Like interpleural analgesia, intercostal blocks do not reduce the incidence of pulmonary complications postoperatively compared to epidural analgesia. Cryoanalgesia can be used for postoperative analgesia after thoracotomy but, like interpleural analgesia and intercostal blocks, does not appear to provide any analgesic advantage over epidural analgesia and is not effective for other types of postoperative pain.\textsuperscript{226}

**Intra-articular Analgesia**

Local peripheral administration of opioids including intra-articular injections after knee procedures may provide analgesia for up to 24 hours after surgery.\textsuperscript{227} Peripheral opioid receptors are found on the peripheral terminals of primary afferent nerves and are upregulated during inflammation of peripheral tissues.\textsuperscript{52} The results of the several randomized clinical trials investigating this topic are summarized.\textsuperscript{227} Use of a higher dose of intra-articular morphine (5 mg vs. 1 mg) results in superior analgesia; however, there may be no advantage in the degree of analgesia provided between intra-articular and systemic opioids. The systemic absorption and action of intra-articular morphine injection have not yet been excluded. Intra-articular injection of local anesthetics may provide a limited duration of postoperative analgesia, but the clinical benefit from intra-articular local anesthetics injections is unclear.\textsuperscript{228} Liposomal bupivacaine, a new formulation, is now available and is approved for surgical wound infiltration. This preparation has been promoted to surgeons to reduce the need for regional anesthetic techniques, improve postoperative ambulation, and recovery. Unfortunately, the evidence from independent trials (nonmanufacturer supported trials) has not found additional benefit of this preparation over nonliposomal (standard)
bupivacaine. In an analysis of cost efficacy, liposomal bupivacaine was found to be equally effective and significantly more expensive.

ENHANCED RECOVERY AFTER SURGERY PATHWAYS

ERAS pathways are perioperative care programs whose main goals are to improve patient recovery through research, education, and implementation of evidence-based practice. Compared to traditional care, ERAS pathways have been associated with a decrease length of stay, decreased pulmonary/cardiac complications and urinary tract infections, although there may not be any improvement in mortality or readmission rate. Use of ERAS pathways have also been associated with decreases in rate of surgical site infections and even possibly cancer recurrence for oncologic surgical patients. ERAS pathways have been established for many surgical procedures including colon resection, cystectomy, pancreatoduodenectomy, and liver surgery.

The recent increased interest in these pathways provides many opportunities for pain management clinicians, as one of the key cornerstones of any ERAS pathway is the control of perioperative pain while minimizing analgesic-related side effects. Uncontrolled postoperative pain results in detrimental physiologic effects (e.g., delayed gastrointestinal function, decreased respiratory activity), which may delay patient recovery. The delivery of postoperative pain management in ERAS patients’ needs to be tailored to facilitate patient recovery and clinicians must carefully choose from a variety of analgesic agents/techniques for the treatment of postoperative pain in ERAS patients such that the physiologic and pharmacologic benefits are maximized and side effects minimized to facilitate patient recovery and return to baseline function.

For any ERAS pathway, one of the primary pain management goals is to deliver a multimodal analgesic regimen incorporating many nonopioid analgesic agents/techniques to minimize the use of and side effects from opioids.

Multimodal analgesia commonly generally refers to use of mostly nonopioid analgesics/techniques to maximize analgesia while minimizing opioid-related side effects and may include a combination of interventional
analgesic techniques (e.g., epidural catheter or peripheral nerve catheter analgesia) and systemic pharmacologic therapies (e.g., NSAID, acetaminophen, gabapentinoids). Postprocedural or posttraumatic pain is best managed through a multimodal approach. The use of regional anesthesia and analgesia is an integral part of the multimodal strategy because of the superior analgesia and physiologic benefits conferred by these techniques.

**Analgesia in Special Populations**

This chapter provides a general approach to the principles and practice of acute pain management, but this approach may not be applicable to certain populations that may have unique anatomic, physiologic, pharmacologic, affective, and cognitive issues. The management of acute pain should be tailored to the specific needs of a population. Although each topic by itself could merit a separate chapter in some textbooks, the general principles and essence of the issues associated with each population are outlined, and references are made to other more extensive sources.

**WAR TRAUMA**

The treatment of traumatic battlefield pain is largely a function of the type and acuity of injury, stability of the patient, level of treatment (Table 51.8), availability of resources, and patient diagnosis. The chain of casualty evacuation is built on levels or echelons of care, which were developed in World War II to facilitate the rapid evacuation of wounded soldiers based on their medical condition and needs. To maximize efficiency and ensure the continued availability of resources, health care providers at each level provide no more care than that which is necessary to either return the soldier to duty or safely evacuate the casualty to the next highest level. For first-level treatment, pain management consists of NSAIDs or acetaminophen, which some units dispense to individual soldiers as part of “wound packs.” COX-2 inhibitors possess the advantage of having minimal inhibitory effects on platelet function, which can prolong bleeding. One concern about NSAIDs is the possible increased incidence of renal failure in dehydrated and hypovolemic soldiers, but this risk is
mitigated by the young age, and lack of concomitant medical problems and medication usage in most deployed soldiers. Acetaminophen may be marginally safer than NSAIDs but is generally less effective as an analgesic.\textsuperscript{239} Historically, morphine was the standard opioid analgesic used for battlefield pain control, having been first administered orally in the War of 1812 and parenterally in the US Civil War. During recent conflicts, the US military has widely incorporated Tactical Combat Casualty Care guidelines that include the suggested analgesic management of battlefield wounded service members. Patients who are injured with mild to moderate pain are administered acetaminophen and meloxicam. However, patients with more severe injuries not suffering from hemodynamic shock or respiratory depression may additionally receive oral transmucosal fentanyl citrate (OTFC) 800 µg. The pharmacokinetics of transmucosal delivery are comparable to that of IM administration, with therapeutic blood levels being reached within 10 to 15 minutes, and peak plasma concentration occurring about 20 minutes after administration.\textsuperscript{240} Approximately 25% of OTFC is absorbed via the oral mucosa, with another 25% being slowly absorbed through the gastrointestinal tract.\textsuperscript{240} The pharmacokinetics of OTFC appears to be independent of age, unaffected by multiple-dose regimens, and less prone to hemodynamic variations,\textsuperscript{241,242} which may make it an ideal drug for battlefield analgesia. In a study by Wedmore et al.,\textsuperscript{243} records of 286 battlefield wounded over a 7-year span who received OTFC were reviewed. Significant reductions in numerical rating scores were reported with only one soldier experiencing respiratory depression. For patients suffering from hemodynamic shock, respiratory depression, or inadequate analgesia from OTFC, ketamine 20 mg IV/intraosseous (IO) may be administered every 20 minutes with reassessment for benefit and untoward side effects. Morphine remains an alternative to OTFC in patients where IV access has been established. Other rapidly acting analgesics that may someday be used in lieu of parenteral opioids include intranasal butorphanol, intranasal ketamine, and fentanyl buccal tablets.

VA, Veteran’s Affairs.

Second-level medical treatment facilities include mobile field surgical teams and forward surgical teams (FST), whose providers include surgeons, anesthetists, and nurses. The primary functions of FSTs are resuscitation and stabilization, with the typical duration of stay being measured in hours. Pain control at this echelon of care generally involves oral opioid and nonopioid analgesics, and IV opioids, which can be safely monitored by nurses and other personnel trained in postanesthesia recovery. PCA may be used at these facilities as resources dictate but is often unavailable. During recent conflicts, the capability to conduct regional anesthetic techniques such as single injection peripheral nerve blocks has tremendously grown with the increasing presence of ultrasound technology with FSTs.

Care at third-level military treatment facilities includes intensive care
units and medical wards, which may administer continuous infusions of opioid and nonopioid (e.g., ketamine and epidural infusions of local anesthetics) analgesics for acute and subacute injuries. When pain management–trained anesthesiologists have been deployed to a combat support hospitals (CSH), more advanced interventions such as sympathetic and paravertebral blocks have been performed. Peripheral and neuraxial catheters are aggressively pursued for intermediate-term pain control directly following injury and during transport (Table 51.9). In addition to providing safe and titratable pain relief, peripheral nerve catheters can be used for anesthesia in patients requiring repeat surgery or wound débridement. With proper maintenance and monitoring, tunneled peripheral nerve catheters can be reliably used for up to 3 weeks after placement. The limitations of peripheral nerve catheters at CSH include shortage of personnel, speed of exodus, infection risk, and concerns about compartment syndrome.

In summary, pain management in the operational setting is fraught with a unique set of challenges almost unimaginable in civilian pain treatment facilities. Because of wide variations in medical resources and personnel, there is no “optimal” pain treatment for war injuries. Instead, treatment should be individually tailored based on a patient’s injury, hemodynamic condition, available resources, and the ability to monitor treatment response. In modern warfare, the most common cause of soldier attrition is not battle-related injury but rather acute and recurrent non–battle-related injuries like those encountered in civilian pain treatment facilities and primary care offices. Recent evidence suggests that high return-to-unit rates can be obtained by the deployment of aggressive pain management...
AMBULATORY SURGICAL PATIENTS
The percentage of surgical procedures being performed on an outpatient basis continues to increase. There is an increase in the number of outpatient surgical procedures and in the complexity of operations being performed and comorbidities of the surgical outpatients. Optimizing treatment of postoperative and postdischarge pain is especially important in patients undergoing outpatient surgery because inadequate control of postoperative pain is one of the leading causes of prolonged stays or readmission after outpatient surgery.247 Although there has been much effort to minimize symptoms such as pain and nausea in the postanesthesia care unit and subsequent (phase II) recovery area to facilitate discharge after outpatient surgery, increasing data suggest that postdischarge pain is common and may interfere with patients’ recovery and the overall health-related costs of outpatient surgery.248,249 Despite the advances in surgical techniques that minimize surgical trauma and postoperative pain, the incidence of moderate to severe postdischarge pain is still approximately 25% to 35%250 and can be especially troublesome for certain patients, such as those undergoing tubal ligation and orthopedic procedures.251 After discharge, poorly controlled nausea and vomiting may interfere with the intake of oral analgesics. In light of these considerations, the traditional reliance on opioid analgesia may not be appropriate for patients undergoing ambulatory surgery because of the opioid-related side effects that may delay hospital discharge and postdischarge recovery after outpatient surgery. A multimodal or “balanced” analgesic approach using a combination of opioid and nonopioid analgesic adjuvant medications including NSAIDs or acetaminophen and local anesthetics wound infiltration or regional anesthetic techniques may be more appropriate in this surgical population. The use of local anesthetics has decreased postoperative pain, and the drugs can be administered as peripheral nerve blocks, tissue infiltration, wound instillation, or topical analgesics. Similar results have been achieved using systemic NSAIDs and acetaminophen.

Although multimodal analgesia may be especially effective in the immediate postoperative period, not all the options may be routinely
available after the patient is discharged to home. For example, use of local anesthetics in peripheral nerve blocks, tissue infiltration, or wound instillation may be effective in the immediate postoperative period; however, a single dose of local anesthetic rarely provides more than 24 hours of analgesia. Realistically, most outpatients rely on a combination of short-acting analgesics including an opioid and acetaminophen or NSAID for postoperative pain control after hospital discharge. Routine use of acetaminophen, especially when an NSAID is added to the regimen, is recommended to maximize postoperative analgesia, although it is important to remember that when acetaminophen is used as a coanalgesic agent in combination products this limits the number of combination analgesic tablets that the patient may consume because of liver toxicity. The future of postoperative pain control in ambulatory surgical patients may include postdischarge (home) use of continuous infusion of local anesthetic solutions or even use of long-acting, “sustained-release” local anesthetics or opioids.

**ELDERLY PATIENTS**

The elderly population, which is expected to increase by 33% over the next two decades, accounts for approximately 12.5% of the total US population and 38% of all health care spending (approximately 5% of the US gross domestic product). There are changes in the physiology, pharmacodynamics, pharmacokinetics, and processing of nociceptive information that may influence the effectiveness of postoperative pain control in the elderly. There may be communication, affective, cognitive, social, and ideologic barriers to effective postoperative pain control in this group. The elderly generally have decreased physiologic reserves and increased comorbidities compared with younger counterparts, which may result in a higher incidence of postoperative complications such as postoperative delirium, especially in the presence of severe or uncontrolled postoperative pain.

There is a clinically significant reduction in the intensity of pain perception or symptoms with increasing age. For instance, silent myocardial ischemia is more common in the elderly, who may instead present with other angina equivalents. Experimental studies demonstrate a
decrease in Aδ and C fiber nociceptive function, delay in central sensitization, increase in pain thresholds, and decrease in sensitivity to low-intensity noxious stimuli. However, elderly patients may have an increased response to higher intensity noxious stimuli, decreased pain tolerance, and decreased descending modulation (i.e., serotonin and noradrenergic), which may contribute to the relatively high incidence of chronic pain in elderly patients. Despite the methodologic issues in available studies evaluating age-related differences in the perception of pain, there appears to be a clinically relevant decrease in pain perception with increasing age. However, this should not be interpreted that elderly patients experience less pain than younger patients when they do report the presence of pain.

The physiologic and pharmacokinetic effects of aging on acute pain management are complex, and the clinical implications include the slow titration of opioids that produces longer circulation times, smaller total doses because of increased sensitivity, and expectation of a longer duration of action due to reduced clearance. In general, analgesic requirements decrease with increasing age. Age has been shown to be the best predictor for postoperative requirements of intravenously and neuraxially administered morphine. Similar to that seen in younger patients, there is large interpatient variability in postoperative analgesic requirements. Use of IVPCA in the elderly is appropriate to compensate for the wide interpatient variability, although postoperative titration of IV morphine can also allow successful and safe administration to elderly patients. Age per se is not an impediment to effective postprocedure or acute pain use of IVPCA or PCEA. Use of postoperative epidural analgesia for elderly patients, especially in those with decreased physiologic reserves, may attenuate perioperative pathophysiology and is reported to improve postoperative outcomes such as facilitating return of gastrointestinal function after abdominal surgery, decreasing the incidence of myocardial ischemia, lowering pain scores, and decreasing pulmonary complications.

Postoperative pain management in the elderly may be especially challenging because of some of the affective, cognitive, social, and ideologic barriers. Health care providers treating geriatric patients tend to have an unfounded level of fear of complications associated with treating
perioperative pain as reflected by the inadequate treatment of pain in elderly patients, even relative to younger patients.\textsuperscript{257} Elderly patients may also contribute to inadequate pain control by their own reluctance to report pain or take opioid medications. Elderly patients have a higher incidence of affective or cognitive impairments such as depression or dementia that may interfere with effective pain management.\textsuperscript{257} One of the most devastating complications in the elderly surgical patient is postoperative delirium, which is associated with increased mortality rates and longer hospital stays.\textsuperscript{260} The cause of postoperative delirium is unknown, although it is believed to result from an imbalance of neurotransmitters, particularly acetylcholine and serotonin, in the presence of decreased neurophysiologic reserve and inflammatory mediators.\textsuperscript{261,262} Although the cause of postoperative delirium is multifactorial, uncontrolled postoperative pain may be an important contributor to its development.\textsuperscript{263} Higher pain scores predict a decline in mental status and an increased risk of delirium.\textsuperscript{264} A multimodal analgesic approach may be useful in elderly patients but must be used with caution because adverse drug reactions in the elderly increase as the number of medications administered increases. Although the benefits of intraoperative regional anesthetic techniques on postoperative cognitive function are unclear, the postoperative or acute pain use of epidural analgesia may diminish postoperative or pain-related delirium in part through superior analgesia and a decrease in pulmonary complications.

**OPIOID-TOLERANT PATIENTS**

Postprocedural or acute pain may be difficult to manage in the opioid-tolerant patient because the standard approaches used for assessment and therapy in opioid-naive patients is inadequate for opioid-tolerant patients. Although opioid-tolerant patients typically require higher doses of analgesic medications in the immediate postprocedure period, many health care providers still do not provide adequate postprocedural pain relief, in part because of the fear of addiction or medication-related side effects. In dealing with patients with chronic opioid use, health care providers often mistakenly interchange several pharmacologic terms (i.e., tolerance, physical dependence, and addiction), a practice that may contribute to
misunderstanding and inappropriate treatment decisions.

Tolerance refers to the pharmacologic property of an opioid in which an increasing amount is needed to maintain a given level of analgesia. Physical dependence is another pharmacologic property of opioids characterized by the occurrence of a withdrawal syndrome on abrupt discontinuation of the opioid or administration of an opioid antagonist. Tolerance and physical dependence are pharmacologic properties of opioids and not synonymous with the aberrant psychological state or behaviors associated with substance use disorder (SUD, formerly addiction), a chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm. The exaggerated fear of addiction contributes to the undertreatment of postprocedural and acute pain by health care providers; however, the data suggest that there is minimal risk of iatrogenic addiction with in-hospital or brief use of opioids for pain control in outpatients who do not have a prior history of addiction. Several principles for pain assessment and treatment can be applied in the postprocedural or acute pain opioid-tolerant patient. The physician should expect high self-reported pain scores; base treatment decisions on objective pain assessment (e.g., ability to deep breathe, cough, ambulate) in conjunction with patients’ self-reported pain scores; and recognize the need to identify and treat two major problems, maintenance of a baseline (home) opioid requirement and control of incisional/procedural/acute pain. It is also appropriate to recognize that opioid detoxification is usually not an appropriate goal in this period of acute postprocedural recovery. Likewise, several general strategies can be employed for the treatment of postprocedural or acute pain in the opioid-tolerant patient. The physician can create a treatment plan early and discuss it with the patient, procedural team, and nursing staff; replace the patient’s baseline opioid requirements; anticipate an increase in postprocedural analgesic requirements; maximize the use of adjuvant drugs; consider use of regional analgesic techniques; and plan for the transition to an oral regimen. Although chronic pain patients are not synonymous with opioid-tolerant patients, many of these patients are opioid-tolerant, and the same general principles and strategies may be applied to chronic pain patients who are opioid-tolerant.
Recognizing and treating nonnociceptive sources of distress may be especially important for chronic pain patients. Although there is no specific threshold or time frame for when a patient becomes opioid-tolerant, after an opioid-tolerant patient is identified, a strategy for acute pain control should be created and discussed with the patient. This may include anticipation or arrangement for a longer than normal length of hospital stay, consultation with the anesthesiology or pain service, and confirmation of the patient’s daily opioid intake to facilitate calculation of the patient’s basal or maintenance opioid requirement in the hospitalized period. Administration of a PRN analgesic regimen alone for opioid-tolerant patients is highly discouraged because replacing the basal opioid requirement in the acute period can optimize pain relief and possibly prevent opioid withdrawal. Basal opioid requirements can be administered systemically (typically intravenously or transdermally) until the patient can tolerate an oral analgesic regimen.\textsuperscript{156} For example, 50\% to 100\% of the patient’s baseline opioid requirement can be administered as a continuous infusion as part of an IVPCA regimen, with a demand dose to cover the additional incisional pain. Conversion tables (see Tables 51.2 and 51.3) may facilitate equianalgesic conversion of opioids; however, these tables provide only estimations to assist health care providers in initiating opioid titration.\textsuperscript{268} Opioid-tolerant patients generally require increased postoperative analgesic levels, including a larger demand dose.\textsuperscript{267} Patients may require frequent adjustment (e.g., two to three times each day) of the IVPCA demand dose or continuous infusion, depending on the analgesic requirements. There is individual variability in response to different opioids, and if a decision is made to switch opioids, the choice of opioid may not as important as using an equianalgesic dose. Patients may experience different side effects with different opioids, and rotating to another opioid may be reasonable if the patient is not tolerating the first opioid.\textsuperscript{269} Adjuvant agents such as NSAIDs should be administered on a regularly scheduled basis to optimize analgesic efficacy and possibly provide an opioid-sparing effect. Use of regional analgesic techniques with neuraxial opioids may provide excellent analgesia in opioid-tolerant patients while preventing withdrawal symptoms.\textsuperscript{270} After the patient is tolerating oral intake, the conversion from IV opioids to a form of oral or
transdermal administration that would be more suitable for discharge to home may be initiated. Opioid-tolerant patients typically can be converted to a combination of a regularly administered, controlled-release formulation of opioid such as sustained-release morphine or transdermal fentanyl and a short-acting, immediate-release opioid on a PRN basis. Although the conversion of IV opioid to an oral or transdermal form can be accomplished over a period of 1 to 2 days in opioid-tolerant patients, this process may take several days in extremely difficult cases. Converting from an IV to oral or transdermal form of opioid is not an exact science, and available conversion tables can serve only as a rough guide because of significant interpatient and intrapatient variability in the sensitivity to opioids, lack of complete cross-tolerance between opioids which may lead to greater than anticipated potency of a new opioid, and changes in the levels of pain, which may rapidly decrease in the immediate postoperative period. Opioid tolerance also takes a slightly different form in those patients receiving the partial µ-opioid agonist, buprenorphine, for with medication assisted SUD therapy or chronic pain. It has broad interpatient variability in pharmacologic half-life that can range for 24 to 60 hours while having a high affinity for but low intrinsic activity at the µ-opioid receptor. Therefore, patients presenting for surgery who receive buprenorphine may not have the expected analgesic response to full agonist opioids such as morphine and the time to a usual response may be unpredictable. It has been recommended that patients on buprenorphine presenting on the day of surgery have their buprenorphine maintained throughout the perioperative period. If advance notice is given (greater than 3 days), patients can be weaned from buprenorphine prior to surgery. It is recommended that these patients be considered high-risk for difficulty in postoperative pain and recovery; therefore, all nonopioid techniques and medications should be used as appropriate. Patients with an opioid use disorder will also represent a unique challenge for the perspective of opioid tolerance, venous access, infection risk, and patient expectation of appropriate pain care. In these patients, a discussion with the surgeon should stress the importance of nonopioid management including surgical and anesthetic techniques associated with lower postoperative pain as well as a postoperative management plan. Techniques including lidocaine or
Ketamine infusion can be considered as a component of the postoperative pain management plan. There should also be a recognition that the postoperative period may also coincide with opioid (or polysubstance) withdrawal and may need to be addressed. An addiction medicine or addiction psychiatry consultation, if available, is likely to be beneficial for comanagement.

A more challenging, yet durable, approach to the opioid-tolerant patient will involve a presurgical prehabilitation program in which the oral morphine equivalent dosage is reduced prior to the surgical procedure. This approach would involve the coordination of multiple clinicians including anesthesiologists or pain physician/anesthesiologists in perioperative clinics, pain physicians, and the primary surgeon. Recent evidence has shown that preoperative use of moderate to high dose opioids (above the opioid-tolerant threshold of 60 mg of morphine equivalents) is associated with increased length of stay, higher readmission rates, and greater health care expenditures. Therefore, this prehabilitative approach to opioids could result in improved patient outcomes and reduction in health care cost. This approach warrants future studies.

**OBESITY, OBSTRUCTIVE SLEEP APNEA, AND SLEEP**

Patients with obesity and obstructive sleep apnea (OSA) may be at higher risk for postoperative complications. Obesity and OSA are separate disease states, but there is some association between the two, because OSA occurs in a relatively higher percentage of obese than nonobese patients. Although some data suggest that epidural analgesia may decrease postoperative complications in the obese patient, the optimal postoperative analgesic and monitoring regimen for patients with OSA is not clear. Data suggest that sleep is disrupted in the immediate postoperative period and may influence postoperative morbidity and patient-oriented outcomes.

Obesity is defined as a body mass index (BMI) of more than 30 kg/m², with morbid and supermorbid obesity defined as a BMI of more than 35 kg/m² and 55 kg/m², respectively. The prevalence of obesity has increased to include approximately 22.5% of the US population. Although obese patients do not necessarily have OSA, obesity is the most important
physical characteristic associated with OSA. Approximately 60% to 90% of OSA patients are obese, and at least 5% of morbidly obese patients have OSA, which is defined as more than five episodes per hour of cessation of airflow for more than 10 seconds despite continued ventilatory effort.\cite{271} It is estimated that approximately 4% of men and 2% of women (18 million Americans overall) have OSA and that up to 95% of persons with OSA are underdiagnosed.\cite{271} Patients with OSA are generally at higher risk for chronic cognitive impairment, pulmonary hypertension, cardiomyopathy, systemic hypertension, and possibly for myocardial infarction.\cite{274,275} The pathophysiology of airflow obstruction is related primarily to upper airway pharyngeal collapse, including the retropalatal, retroglossal, and retroepiglottic pharynx, during sleep, especially during rapid eye movement (REM) sleep.\cite{271} During these obstructive episodes, OSA patients may exhibit hypoxia, bradyarrhythmias or tachyarrhythmias, myocardial ischemia, abrupt decreases in left ventricular stroke volume and cardiac output, or increases in pulmonary and systemic blood pressure.\cite{275} Based on our understanding of the pathophysiology of OSA, it is easy to see how acute pain management can be difficult in this population. Patients with OSA are at higher risk for respiratory arrest.\cite{276} Use of sedative doses of benzodiazepines and opioids may result in frequent hypoxemia and apnea, which may be especially dangerous in the OSA patient.\cite{276} Avoiding respiratory depressants by optimizing use of NSAIDs and epidural analgesia with a local anesthetic–based regimen may attenuate the risk for respiratory depression and arrest because the use of epidural and systemic opioids is associated with sudden postoperative respiratory arrest.\cite{277}

The American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea created guidelines that include acute pain management in patients with OSA.\cite{278} Although the consultants acknowledged that the conclusions regarding postoperative analgesic options were based on insufficient literature evaluating the effects of various analgesic techniques, the presence of equivocal literature regarding the use of epidural opioids compared with IM or IV opioids in reducing respiratory depression, and insufficient literature regarding the addition of a basal infusion to systemic patient-controlled opioids, the
consultants nevertheless recommended that regional techniques rather than systemic opioids should be used in an attempt to reduce the likelihood of adverse outcomes in patients at increased perioperative risk from OSA. In addition, the consultants recommended the exclusion of opioids from neuraxial postoperative analgesia to reduce perioperative risk, and the use of NSAIDs to reduce adverse outcomes through their opioid-sparing effect. The consultants were equivocal regarding whether avoiding a basal infusion of opioids in patients with OSA reduces the likelihood of adverse outcomes. Unfortunately, there is a paucity of randomized clinical trial data to provide definitive high-quality evidence-based recommendations in the provision of postoperative analgesia for OSA patients.

**Gender or Sex Differences in Analgesia**

A large body of data has been collected in the past 20 years concerning differences between the sexes in response to pain, including pain thresholds, and in the tolerance and response to acute pain treatment. However, the exact differences as well as their relevance are far from clear. According to the International Association for the Study of Pain (IASP), “Pain is an unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage.” This definition does not differentiate between “pain” as a woman experiences it from “pain” as a man experiences it, and thus, fundamental questions remain.

Females report more severe pain, more frequent bouts of pain, more anatomically diffuse, and longer lasting pain than males with similar disease processes, even when male- and female-specific disorders including male urologic and female gynecologic pain are excluded from the analysis. Females have a higher prevalence of pain related to musculoskeletal or to visceral origin as well as pain related to autoimmune disease (Table 51.10). Substantial amounts of the accumulated data rely heavily on the subjective signs of the pain experience. These are highly influenced by sociocultural variables that have little to do with a biologic difference of pain threshold or perception between women and men. An inherent reporting bias exists in the epidemiologic research related to the
incidence of pain in the sexes. Females are more likely to visit a physician and are more likely to report pain as a symptom than males\cite{280,281} reviewed in\cite{282} which can therefore lead to an overestimation of the differences between the sexes.

In a meta-analysis of studies examining sex differences in pain response in healthy subjects less than 60 years old, the authors found women report higher pain severity at lower thresholds and have less tolerance to noxious stimulation than males.\textsuperscript{283} In a large multicenter trial, Rolke and colleagues\textsuperscript{254} used quantitative sensory testing (QST) to determine sensory detection thresholds and pain thresholds for thermal and mechanical noxious stimuli. Females had lower pain thresholds, with the greatest disparities for sex differences found for heat pain threshold, followed by cold pain and pain to blunt pressure.

Many other physiologic, sociocultural, and psychological variables have been identified as contributing to the differences between the two sexes about pain. One factor includes the endpoint being examined, such as pain threshold versus pain tolerance.\textsuperscript{283–285} Pool and colleagues\textsuperscript{286} showed that pain tolerance is highly malleable and strongly influenced by the subject’s “gender” norms. Males who are highly identified with the “male” role tolerate higher levels of noxious stimuli, but those males who do not have this belief tolerate noxious stimuli at the same level as females. The age of the subject also modifies the pain threshold. Advancing age is positively associated with pain threshold.\textsuperscript{253,254} Pickering and colleagues\textsuperscript{285} found that the difference in score between males and females decreased with advancing age. The significant sex difference seen in thermal and mechanical threshold and in tolerance in younger volunteers became nonsignificant in volunteers greater than 40 years old.

As discussed earlier, the sex difference in humans is neither a universal nor a large effect. Furthermore, no difference between sexes is found in at least one-third of the published studies, and effect sizes are often in the small to moderate range.\textsuperscript{283} Other investigators have sought objective measures of pain as a result of the numerous factors that have been shown to influence and in some cases abolish the pain threshold and tolerance differences between the sexes. Paulson and colleagues\textsuperscript{284} used positron emission tomography (PET) to investigate regional brain activation after a
painful somatic thermal stimulus in healthy normal volunteer male and female subjects. They reported that females had significantly greater activation of the contralateral prefrontal cortex, the contralateral insula, and the thalamus compared to males suggesting sexual dimorphism in response to pain. Unfortunately, this study reflected a difference in brain activation that was more likely the result of different pain intensities rather than a true sex difference. In a later study also using PET technology, the pain intensity was matched between the sexes and the results were the opposite of the earlier study—males had greater activation than females. Finally, a study using matched pain intensity and functional magnetic resonance imaging (fMRI) showed no sex-based difference in brain activation. Other PET studies have described sex differences in responses to visceral pain from rectal balloon distension, although principally with chronic visceral pain patients. However, the differences reported were predominantly in the direction of greater activation in men. These studies were replicated using fMRI with similar results of a male predominance of neuronal activation in pain-related areas of the brain.

Pain thresholds in humans vary by internal factors such as sex, gender, female menstrual phase, and psychological variables including catastrophizing, anxiety, and depression. External factors also affect the outcome including testing environment, sex, and gender of the examiner and the modality of the noxious stimuli. In the largest study assessing the role of sex on pain thresholds using multiple modalities, it was found that females had lower pain thresholds in thermal and mechanical pain testing. Unfortunately, this subjective difference has not been consistently supported by other confirmatory techniques including PET or fMRI brain imaging. Awareness of the possible differences between males and females in response to pain is the only clinical application of the present data with no guidance for situations.

Unlike the abundance of literature addressing the question of drug-induced sex differences in experimental pain in rodents, the human literature is not as voluminous. Many in the literature address the response to μ-opioid receptor agonists and the remainder addresses κ-opioid receptor agonists. There has not been testing of other clinically available
medications on humans in models of experimental pain. In multiple studies, either no difference\textsuperscript{291–293} was noted between sexes or females had a significantly greater response to the medication.\textsuperscript{294–296} Although initial studies attributed the difference to pharmacokinetic differences,\textsuperscript{297} the metabolism of morphine to morphine-6-glucuronide (M6G), more recent work by Romberg and colleagues\textsuperscript{292} demonstrate that no sex differences exist in M6G concentrations. To further exclude pharmacokinetic explanations for the sex differences, the same investigative group subsequently published findings using the potent synthetic \(\mu\)-opioid receptor agonist alfentanil. The subject’s response to alfentanil did not differ based on his or her sex.\textsuperscript{298}

The human response to \(\kappa\)-opioid receptor agonists is somewhat variable. In a postsurgical model of pain, females had a greater analgesic response to \(\kappa\) agonist-antagonist medications including pentazocine, nalbuphine, and butorphanol.\textsuperscript{299–301} However, in experimental models of pain, either no difference between males and females was noted\textsuperscript{302} or males had an increased sensitivity to the medications.\textsuperscript{303} Mogil and colleagues\textsuperscript{303} suggest that the increased responsiveness to \(\kappa\)-opioid receptors agonists may be related to the absence of the MC1r gene. In an elegant study, this group studied women with fair skin and red hair who often have a functional reduction in MC1r. The women with a genetically proven loss of function polymorphisms experienced an accentuated analgesic response to pentazocine. Their analgesic response was indistinguishable from the male subjects in the study.\textsuperscript{303} This finding has led to the proposal that the MC1r gene product acts as an antiopioid and therefore when removed unmasks the true \(\kappa\)-opioid effect. This enhanced effect would be inconsistent with the finding that females have an increased response to \(\kappa\)-opioid receptor agonists in clinical models of pain (e.g., postoperative) because fair-skinned red-headed females represent only a minority of women in general. Unfortunately, it does not explain the lack of difference or the greater analgesic response of females to \(\mu\) opioids in clinical and experimental models or \(\kappa\) opioids in experimental models of pain.

Unfortunately, the data regarding opioid analgesics garnered from human trials is not sufficient to guide clinical practice. The studies, so far, do not justify the conclusion that males or females have a greater
responsiveness to μ or κ opioid receptor agonists, and therefore, they should continue to receive similar acute pain management until more definitive studies are conducted.

**Inpatient Pain Services**

Although dedicated individuals can improve postoperative pain control for a few patients, more comprehensive interdisciplinary pain services developed specifically to treat this problem can address the needs for all patients within an institution. The organizational aspects of such comprehensive services are considerable. With skills in regional anesthetic techniques and knowledge of the neurobiology of nociception and the pharmacology of analgesics and local anesthetics, anesthesiologists have been leaders in postoperative pain relief and development of inpatient pain services.

Although there are several models for the development of inpatient pain services, the key organizational aspects are similar. Development and maintenance of inpatient pain services require a commitment and financial support at the national and local level. In the United States, because there are financial burdens associated with the establishment of an acute pain service, high-volume or larger hospitals are more likely have acute pain services and have access to more high-tech analgesic techniques such as epidural analgesia. Whether inpatient pain services improve outcomes is unclear. Two systematic reviews have examined the impact of acute pain services on patients outcomes, and although systematic reviews suggest that the introduction of acute pain services is associated with a decrease in pain scores, the effect of acute pain services on the incidence of analgesic-related side effects such as nausea and vomiting, satisfaction, and overall costs or cost reductions are uncertain. Despite the direct costs (e.g., personnel, equipment, medication) associated with managing a pain service, there is no available properly conducted pharmacoeconomic study to examine the cost-effectiveness of a pain service. Use of postoperative epidural analgesia in the context of pain services may decrease the cost of patient care through shorter intensive care unit stays and a decreased rate of complications.
Long-term Impact of Acute Pain

Chronic postsurgical pain (CPSP) is a largely unrecognized problem which may occur in 10% to 50% of postoperative patients (depending on type of surgery) with 2% to 10% of these patients experiencing severe CPSP. Poorly controlled acute postoperative pain or acute pain in general may be an important predictive factor in the development of chronic pain. Increasing experimental and clinical evidence suggests that the transition from acute to chronic pain occurs very quickly and that long-term behavioral and neurobiologic changes occur much earlier than previously anticipated. CPSP is relatively common after procedures such as limb amputation (30% to 83%), thoracotomy (22% to 67%), sternotomy (27%), breast surgery (11% to 57%), and gallbladder surgery (up to 56%). Although studies suggest that the severity of acute postoperative pain may be an important predictor in the development of CPSP, a causal relationship between severity of acute postoperative pain and subsequent CPSP has not been definitively established and other factors may be more important in predicting the development of CPSP.

Control of acute pain may improve long-term recovery or patient-oriented outcomes including quality of life or return of function. Patients whose pain is controlled in the early postoperative period (especially with use of continuous epidural or peripheral catheter techniques) may be able to actively participate in postoperative rehabilitation, which may improve short- and long-term recovery after surgery. In a recent study, a multimodal approach to acute analgesia using either epidural or spinal analgesia reduced the patient’s area of hyperalgesia and allodynia in the acute phase and diminished the long-term pain as well. Another study examined the showed that acute postoperative pain was an important risk factor for the development of chronic pain. Optimizing treatment of acute postoperative pain can improve health-related quality of life (HRQL). Postsurgical chronic pain that develops as a result of poor acute pain control can interfere with patients’ activities of daily living and reduce a person to a less functional status.

In addition to CPSP, long-term opioid use following surgery has emerged as a significant public health concern. One source of confusion
relates to the definition of persistent opioid use after surgery as studies have commonly used time points from 90 days up to 1 year postoperatively. Although large retrospective studies have suggested a low 1-year incidence of opioid use (0.4% to 1.4%), only a certain subset of surgeries was examined. Different surgical types such as lumbar fusion or femur fixation have been characterized by rates of 27.9% to 85% or 36% for opioid therapy 1 year following surgery, respectively. Patient factors such as preoperative opioid use, depression, preoperative hypnotic use, and catastrophization have also been linked to persistent postsurgical opioid use. Other patient risk factors (e.g., age, anxiety, pain at surgical site) have predicted persistent postsurgical opioid use in some populations but not others. Future work must focus on surgery and population specific risk indices to account for the unique nociceptive and biopsychosocial variables that occur across surgical subtypes.

Acute pain management has become a focus of the health care system and an important ethical responsibility of the medical profession. Although opioids have been the primary analgesic agents used for treating moderate and severe pain after surgery for past few decades, aggressive multimodal analgesic interventions utilizing primary a combination of nonopioid analgesic agents and techniques have become widely used during the perioperative period. Maximum benefit occurs when pain interventions are extended into the postoperative phase.¹

Multimodal analgesia involves the administration of different agents that exert their effects via different analgesic mechanisms and act synergistically at different sites in the nervous system, thereby providing superior analgesia with fewer side effects. Multimodal analgesia can include regional analgesia with local anesthetics, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and opioids.²

Perioperative neuraxial and peripheral analgesia provide superior analgesia than do that from systemic opioids. Continuous analgesic techniques have the advantage of decreasing adverse perioperative pathophysiology and improving patient outcomes, including major morbidity.³,⁴ This chapter focuses on regional anesthesia techniques, including central neuraxial, truncal, and peripheral perineural analgesia, for acute postoperative pain management. Indications, techniques, mechanisms of action, side effects, and complications are described.

Continuous Epidural Analgesia
THORACIC EPIDURAL ANALGESIA
Thoracic epidural analgesia (TEA) is commonly used for the treatment of pain after upper abdominal/thoracic procedures and rib fractures. TEA is often used intraoperatively as an adjunct to general anesthesia and in the postoperative period for many upper abdominal and thoracic procedures (Table 52.1). Its use in video-assisted thoracic surgery and laparoscopic procedures is less common and may be recommended only for high-risk patients. The use of TEA offers superior analgesia compared with that from systemic opioids.\textsuperscript{5} Postoperative use of continuous epidural analgesia is associated with improved patient morbidity as it is associated with decreases in pulmonary,\textsuperscript{6–9} cardiovascular,\textsuperscript{6,7,9,10} and gastrointestinal\textsuperscript{11,12} complications in high-risk patients and after high-risk procedures. It also may improve outcomes in patients with multiple rib fractures.\textsuperscript{13}

GI, gastrointestinal; VATS, video-assisted thoracic surgery.

Many factors affect the overall outcomes of continuous epidural analgesia. Among them are the congruency of epidural catheter location and surgical incision, the type of analgesic regimen used, and whether the epidural is used as part of a multimodal approach.\(^{14,15}\) When compared with the systemic administration of opioids, local anesthetic-based epidural regimens provide superior analgesia and may decrease opioid-related side effects; epidural infusion of opioids alone may be used to avoid hypotension when sympathetic blockade is a concern.

The role of high TEA in cardiac surgery with cardiopulmonary bypass and in off-pump coronary artery bypass surgery remains controversial. It might improve distribution of coronary blood flow,\(^{16}\) reduce the incidence of supraventricular tachycardia,\(^{17}\) and decrease surgical stress response.\(^{18}\) Some studies found no difference in the rates of mortality and myocardial infarction when compared with those of traditional opioids,\(^{6}\) but others showed significant reduction in postoperative pulmonary and cardiac arrhythmias while improving pain scores, especially with off-pump procedures.\(^{19}\)

A recent randomized control study of 600 patients undergoing elective cardiac surgery both on and off pump\(^{20}\) reported no difference in 30-day mortality and morbidity, no difference in intensive care unit (ICU) stay or length of hospital stay, and no difference in quality of life at 30-day follow-up. Until there are more conclusive outcome data, the role of TEA
remains controversial.

**BLOCK TECHNIQUE: EPIDURAL**

Epidural blockade may be performed with the patient in the sitting or lateral position through a midline or paramedian approach. With the midline approach, the epidural needle is oriented in the same plane as the spinous processes, with slight cephalad orientation toward the interlaminar space. After subcutaneous injection of local anesthetic at the needle insertion site, the epidural needle is directed through the skin wheal from the local anesthetic and slowly advanced through the supraspinous and interspinous ligaments to enter the ligamentum flavum. The practitioner inserts a syringe containing air or saline which may include a small air bubble. Upon entering the epidural space, the practitioner will feel a sudden, significant loss of resistance to plunger displacement. A 20-gauge radiopaque catheter with 1-cm graduation is passed through the epidural needle. The catheter is generally advanced 3 to 5 cm beyond the needle tip into the epidural space. The needle is then withdrawn over the catheter and the catheter secured to the patient’s back. After a test dose of 3 mL of a local anesthetic with 1:200,000 epinephrine is injected, the patient is observed for signs and symptoms of intrathecal (IT) or intravascular injection. The local anesthetic should be administered in 3- to 5-mL increments, ideally with intermittent aspiration to assess for accidental IT or intravascular placement, until the appropriate total dose is given.

Alternatively, a paramedian-lateral or paramedian-lateral oblique approach to the epidural space may be used. For this approach, the epidural needle insertion site is approximately one fingerbreadth lateral to the insertion site of the midline approach. The epidural needle is directed with slight cephalomedial orientation to allow the needle to bypass the supraspinous and interspinous ligaments as it is advanced to enter the triangular-shaped ligamentum flavum. Once the needle enters the ligamentum flavum, the loss-of-resistance technique is used to enter the epidural space at the midline. Although the paramedian approach may be used for both lumbar and thoracic epidurals, it is extremely advantageous in the midthoracic vertebrae (T4–T10) where the steep angle of the spinous processes limits midline access to the interlaminar foramen.
Postoperative epidural analgesia may be delivered as a fixed continuous infusion or as patient-controlled epidural analgesia (PCEA). Based on the principles of patient-controlled analgesia (PCA), PCEA allows individualization of postoperative analgesic requirements, reduces drug use, improves patient satisfaction, and provides superior analgesia.\textsuperscript{21,22} The drug chosen for epidural analgesia is usually a local anesthetic with a long duration of action. It should exhibit preferential clinical sensory blockade and cause only minimal impairment of motor function.\textsuperscript{23} A lipophilic opioid (e.g., fentanyl or sufentanil) or hydrophilic opioid (e.g., morphine or hydromorphone) may be added for postoperative analgesia to allow relatively rapid titration of analgesia and densening of the block.\textsuperscript{24} Even though clonidine and epinephrine are potentially useful adjuvants, neither is widely used clinically in adults. Clonidine may enhance postoperative analgesia by activating the descending noradrenergic pathway; however, its clinical usefulness is typically limited by the presence of hypotension, bradycardia, and sedation.\textsuperscript{25,26} Epinephrine has been shown to improve epidural analgesia and increase sensory block in the postoperative setting.\textsuperscript{27}

Subarachnoid/Intrathecal Analgesia

Spinal analgesia may offer postoperative analgesia through additives like IT opioids for multiple procedures, including obstetric and gynecologic procedures; genitourinary procedures; orthopedic procedures of the lower extremity; and abdominal, vascular, spine, thoracic, and cardiac surgery. IT additives, including fentanyl, sufentanil, morphine, hydromorphone, and clonidine are discussed in the following text.

**TECHNIQUE**

Subarachnoid block may be performed with the patient in the sitting, lateral, or prone position through a midline or paramedian approach. After the patient is positioned, the appropriate interspace is identified, prepped, and draped in sterile fashion. Local anesthetic is infiltrated at the needle insertion site. The introducer needle is placed midline and advanced in the midline plane with slight cephalad angulation through the supraspinous
ligament and into the interspinous ligament. The depth to the subarachnoid space must be anticipated to avoid inadvertent dural puncture with the introducer needle in thin patients. The spinal needle is then advanced through the introducer while the introducer is stabilized with the nondominant hand. As the needle passes through the ligamentum flavum, an increase in resistance is appreciated, followed by a loss of resistance, with a characteristic “pop” indicating penetration of the dura and entry into the subarachnoid space. The spinal needle stylet is removed, and free cerebrospinal fluid (CSF) flow is confirmed through the needle. If free CSF flow is not visualized, the hub of the needle may be rotated 90 degrees, followed by slight advancement of the needle if necessary. If CSF free flow is unable to be confirmed, the needle is slowly withdrawn in slight increments, with 90-degree rotation at each increment to allow for free CSF flow. Upon obtaining free flow of CSF, the dorsal aspect of the nondominant hand is firmly placed against the patient’s back with the index finger and thumb stabilizing the spinal needle hub for injection. The syringe with local anesthetic and additive is attached to the spinal needle hub and injected with the dominant hand. If redirection of the spinal needle is necessary secondary to bone contact, paresthesia, or failure to obtain CSF, the anatomy should be reevaluated and the introducer repositioned as necessary at the same or a new level. If a paresthesia is encountered at any time, needle advancement or injection should be stopped and resolution of paresthesia confirmed before and during subsequent advancement and or injection.

The paramedian-lateral and paramedian-lateral oblique approaches offer alternatives to the midline approach in patients with narrow interspinous spaces for both subarachnoid and epidural blocks. For the paramedian-lateral approach, the spinal introducer insertion site is approximately one fingerbreadth lateral to the insertion site of the midline approach. The introducer is oriented with slight medial and cephalad direction to allow the spinal needle to bypass the supraspinous and interspinous ligaments, pass through the triangular-shaped ligamentum flavum, and enter the subarachnoid space at the midline.

In the paramedian-lateral oblique approach, the caudad spinous process of the desired interspace is identified. The needle is inserted approximately
one fingerbreadth lateral to this point and directed with cephalomedial orientation to bypass the supraspinous and interspinous ligaments, pass through the triangular-shaped ligamentum flavum, and enter the subarachnoid space at the midline. Alternatively, the needle is initially oriented perpendicular to the skin in all planes and advanced with the intent to contact lamina. Upon contact with lamina, the needle is walked off the superior edge of the lamina and advanced through the ligamentum flavum to enter the subarachnoid space.

**CLINICAL SUBARACHNOID ANALGESIA**

**Opioids**

Highly lipophilic, short-acting opioids, such as fentanyl, can be added to local anesthetics to improve short-term analgesia for inpatient or outpatient procedures.\(^{28-30}\) The addition of 10 µg fentanyl to bupivacaine 0.5% (hyperbaric) significantly improves the quality and duration of analgesia, with no further advantage occurring if the dose is increased up to 40 µg.\(^{31}\) Hydrophilic opioids, however, provide extended postoperative analgesia in the inpatient setting. Data from two meta-analyses that investigated the use of IT morphine in surgical patients suggest that use of IT morphine (0.05 to 0.2 mg) for surgical procedures will decrease pain scores and systemic opioid requirement after surgery.\(^{32,33}\) Dose–response trials have shown that low doses of hydrophilic opioids maximize postoperative analgesia with a lower incidence of side effects. For example, Cole et al.\(^{34}\) reported that 0.3 mg of IT morphine significantly reduces pain and PCA requirements compared to those of placebo after knee arthroplasty, with no significant difference in hypoxemia and apnea between groups. For opioid-tolerant patients, higher doses are probably acceptable, whereas doses of less than 0.3 mg may be ideal for opioid-naive individuals.\(^{35}\) IT opioids have been used for cardiac surgery with improved analgesia; however, concerns with bleeding complications in patients who are receiving heparin and demonstrations of prolonged extubation times may have limited their use. Alhashemi et al.\(^{36}\) showed that 250 µg is the optimal dose of IT morphine to provide significant postoperative analgesia without delaying tracheal extubation after coronary artery bypass graft surgery. IT opioid combinations provide better analgesia than systemic opioids in
patients undergoing vascular and thoracic procedures. Compared to those
who received intravenous (IV) PCA morphine, patients who received a
mixture of either 20 µg of sufentanil with 0.2 mg of morphine, or 50 µg of
sufentanil with 0.5 mg of morphine, have improved pain control with
minimal side effects other than an increased frequency of urinary
retention.\textsuperscript{9,37} Although epidural analgesia with local anesthetics and
opioids is likely superior to IT opioids in decreasing pulmonary
complications after thoracotomy,\textsuperscript{38} IT opioids may be a good alternative to
epidural analgesia when an epidural catheter cannot be used.

Clonidine
Studies have shown that IT clonidine at doses from 15 to 150 µg improves
postoperative analgesia while minimizing side effects. Adding concurrent
administration of 25 to 75 µg clonidine with 250 µg morphine to a
bupivacaine spinal anesthetic decreased 24-hour IV morphine
consumption and improved 24-hour visual analog scale (VAS) scores as
compared to adding 250 µg IT morphine alone to bupivacaine spinal
anesthetic.\textsuperscript{39–41}

Combined Spinal and Epidural
The combined spinal epidural (CSE) technique offers the advantage of
both spinal and epidural techniques. CSE provides rapid-onset surgical
anesthesia,\textsuperscript{42,43} the ability to titrate to the desired sensory level and
duration, and the ability to deliver postoperative analgesia through the
epidural catheter.

The CSE technique is widely used in obstetric anesthesia and analgesia.
In labor analgesia, CSE provides quick onset of pain relief while
maintaining ambulation ability. Studies have shown great benefit of using
small opioid doses (e.g., 10 to 15 µg of IT fentanyl\textsuperscript{44}) while adding a small
dose of isobaric bupivacaine,\textsuperscript{45} ropivacaine, or levobupivacaine.\textsuperscript{46,47} CSE
may be associated with reduced duration of the first stage of labor in
primiparous mothers\textsuperscript{48} but does not shorten total labor time compared to
conventional epidural analgesia.\textsuperscript{49}

Another advantage of using this technique is that small doses of the
spinal anesthetic can be used and the risk of a high spinal block and prolonged hypotension\textsuperscript{50,51} can be avoided in patients who are already hypovolemic. Potential challenges associated with CSE are the inability to properly test the epidural catheter, increased incidence of catheter migration to the IT space, and enhanced spread of the spinal local anesthetic.\textsuperscript{52}

**TECHNIQUE OF COMBINED SPINAL EPIDURAL**

**Needle through Needle Technique**

Neuraxial techniques in general can be performed with the patient in either a lateral or sitting position. The CSE technique is typically performed with patients sitting. It should be noted that during needle insertion, the distance from skin to epidural space is greater when patients are in the lateral position than when they are in the sitting position. After the epidural needle is inserted, a loss of resistance to plunger displacement indicates entrance into the epidural space. At that point, the plunger is carefully removed and a spinal needle is passed through the epidural needle until the characteristic “pop” is felt, indicating penetration of the dura and entry into the subarachnoid space. After free CSF flow is confirmed, the dorsal aspect of the nondominant hand is firmly placed against the patient’s back, with the index finger and thumb stabilizing the hub for injection. Local anesthetic with additive is injected, and the spinal needle is withdrawn. A 20-gauge radiopaque catheter with 1-cm graduation is passed through the epidural needle. The catheter is advanced 4 to 5 cm beyond the needle tip into the epidural space. The needle is then withdrawn over the catheter, and the catheter secured to the patient’s back. Prior to dosing, a test dose should be administered through the catheter.

**Separate Needles Techniques**

**Two-needle, two interspace techniques:** CSE could be carried out with two separate needles, one spinal and one epidural, with either the same interspace\textsuperscript{53,54} or two different interspaces.\textsuperscript{55–57} With the same-interspace technique, the epidural catheter will be placed first to allow proper testing before spinal anesthesia. This testing is mainly to decrease risks of IT or intravascular catheter migration. This technique carries the risk of
shearing\textsuperscript{58,59} the epidural catheter with the introduction of the spinal needle. In the different-interspaces technique, the practitioner places the spinal needle but does not inject local anesthetic. He or she then places the epidural catheter and tests it at a different interspace before administering the spinal dose. This technique allows testing of the epidural catheter while avoiding shirring of the catheter.

Regardless of which step is taken first, these techniques carry a disadvantage of taking longer to perform and requiring two separate injections. When the needle through needle (NTN) and separate needles techniques (SNT) have been compared,\textsuperscript{60,61} some have reported better success and lower failure rate with SNT but greater patient acceptance, less discomfort, and quicker procedure time with the NTN.

**COMPLICATIONS AND CHALLENGES WITH COMBINED SPINAL EPIDURAL**

Spinal migration of the epidural catheter and IT administration of epidural drugs are more likely to occur with the NTN technique.\textsuperscript{62–64} Regardless of the technique used, all epidural medications should be administered in small incremental doses while the patient’s hemodynamics are closely monitored.

Failure of the spinal block is a possibility and depends on the provider’s experience. Failures occur mainly as a result of the spinal needle being too short,\textsuperscript{65} failure to puncture the dura with a small-caliber spinal needle,\textsuperscript{66} and diverging from the midline.\textsuperscript{67} Additionally, delay while placing the epidural catheter\textsuperscript{68} might affect the density and level of the spinal block.

Another complication from CSE is possible nerve damage from needle or catheter trauma that occurs when the practitioner places an epidural in a patient who has received spinal anesthesia. Although this is a rare complication, the absence of sensation after spinal anesthesia may prevent identification of paresthesia that would alert anesthesiologists to needle misplacement.

**Contraindications of Neuraxial Techniques**

Although complications of neuraxial analgesia are extremely rare, they can
be very serious. Among those complications are neuraxial hematoma, abscess, and permanent nerve injuries. Evaluation of the risks and benefits of neuraxial analgesia is always helpful and should be based on the patient’s comorbidities and risk factors.

**SEPSIS, FEVER, AND VIRAL INFECTIONS**
Infectious complications of neuraxial techniques are extremely rare, and data are insufficient to determine whether epidural analgesia should or should not be initiated in septic patients. The possibility of introducing blood-borne pathogens into the neuraxial space is a very valid concern for many practitioners. Regional anesthesia in the presence of low-grade fever should be based on an individual risk–benefit analysis. Antibiotics should be used before initiating the block, and the practitioner should use strict aseptic techniques during postprocedure monitoring to detect any signs of central nervous system (CNS) infection.

The CNS is affected early in the course of HIV infection, and there is no evidence that epidural placements or an epidural blood patch for treatment of postdural puncture headache (PDPH) causes any additional spread of the virus to the CNS. It is advisable to obtain thorough documentation of any neurologic deficit before attempting a neuraxial technique in these patients. Studies have shown no reported incidence of CNS infection with neuraxial blocks in patients with recurrent herpes simplex infection. However, a neuraxial block or catheter is contraindicated in the presence of active herpes zoster at the site of injection. Complications such as aseptic meningitis and encephalitis might develop from spread of the virus to the CNS.

**COAGULOPATHY, THROMBOCYTOPENIA, AND BLEEDING DISORDERS**
Neuraxial techniques are contraindicated if the patient refuses it and in those with severe coagulopathy and disseminated intravascular coagulation (DIC). DIC can result from severe trauma, sepsis, amniotic fluid embolism, massive transfusion, and placental abruption, among many other diseases. Initiating an epidural in the presence of coagulopathy is an absolute contraindication, but keeping an epidural in the presence of
coagulopathy is controversial. The epidural should be removed only after normal coagulation is restored. Epidural catheter removal could be as traumatic as placement, and the same precautions should be applied.\textsuperscript{74}

Anticoagulants should be held in a timely fashion before initiation or removal of an epidural catheter. Placement of an epidural catheter is considered a relative contraindication in the presence of some bleeding disorders like hemophilia and von Willebrand disease, but it is considered safe after factor levels and partial thromboplastin time have reached normal values.

Thrombocytopenia is another relative contraindication to neuraxial anesthesia. Currently, no guidelines exist for a platelet count below which epidural placement is contraindicated. Some clinicians feel comfortable with a platelet count of 80,000, whereas others will go as low as 70,000.\textsuperscript{75} The etiology of thrombocytopenia, the patient’s bleeding status, and the trend in platelet count must be taken into consideration before placement of an epidural catheter. One can obtain a thromboelastography (TEG) to assist in determining whether to place an epidural or not. Ultimately, the decision is based on the risks and benefits for the individual patient.

**CENTRAL NERVOUS SYSTEM DISORDERS**

In the past, neuraxial blockade was contraindicated in patients with preexisting CNS disease, including multiple sclerosis (MS). However, a recent retrospective study\textsuperscript{76} of 35 patients with MS showed no evidence of MS relapse after neuraxial block. It is reasonable to use low concentrations and low volumes of local anesthetics in these patients and thoroughly document any preexisting neurologic deficits before initiating a neuraxial block. A thorough informed consent should be given to the patient explaining the possibility of MS symptom aggravation.\textsuperscript{77}

The risk of neurologic complication during a neuraxial technique is higher in anesthetized patients because they cannot respond to pain or paresthesia during needle placement.\textsuperscript{78} The risk of neurologic complications is minimal during placement of a lumbar epidural in anesthetized patients,\textsuperscript{79} and it is uncertain whether the risk might be higher with thoracic epidural. Previous back surgery and back pain are not considered contraindications for neuraxial techniques. In a large
A retrospective study of patients with a history of spinal stenosis, peripheral neuropathy, or lumbar radiculopathy, these conditions did not affect the efficacy or complications of neuraxial techniques. The practitioner should discuss an informed thorough consent with the patient and explain the increased risk of technical difficulties, dural puncture, and unsuccessful block.

**Analgesic Adjuvants for Central and Peripheral Analgesia**

**INTRODUCTION**

Nociceptive pathways in the central and peripheral nervous systems are very complex and not easily blocked by one drug type or one technique. The use of agonists at inhibitory receptors and antagonists at excitatory receptors in the pain pathways allows a “multimodal” approach with optimization of pain control and reduction of adverse effects.

Neuraxial drugs such as opioids selectively decrease nociceptive afferent input from A\(\delta\) and C fibers without affecting dorsal root axons or somatosensory-evoked potentials. Opioid receptors in the ventral medial medullary reticular formation may be involved in activation of noradrenergic pathways. Additionally, a descending inhibitory pathway projecting through the dorsolateral funiculus may reinforce other analgesic mechanisms. The advantages of neuraxial opioids lay in the absence of sympathetic blockade and postural hypotension, providing for potentially easier ambulation of patients.

The last few decades have witnessed important advances in the knowledge of nociceptive transmission from the peripheral nervous system to the CNS. A number of drugs have been tested, and some have proven clinically useful when added to local anesthetics for central and peripheral nerve block (PNB). These drugs, known as analgesic adjuvants, include opioids, dexamethasone, and \(\alpha_2\) agonists. They may have benefit if applied in the peripheral nervous system. Some adjuvants added to local anesthetics might speed their onset, prolong their effect, or reduce total required dose. Adjuncts are also used to enhance analgesia while minimizing side effects.
NEURAXIAL OPIOIDS

Opioids are classified by their lipophilic property. Lipophilic opioids (e.g., sufentanil and fentanyl) tend to provide a fast onset and short duration of analgesia as a result of rapid clearance from the CSF. Hydrophilic opioids (e.g., hydromorphone and morphine) remain within the CSF after neuraxial administration and produce a delayed but long duration of analgesia. They also tend to cause a higher incidence of side effects because of CSF spread. Hydrophilic opioids provide analgesia primarily via a spinal mechanism, whereas lipophilic opioids provide analgesia via either a spinal or systemic mechanism. Single-shot neuraxial administration of a lipophilic opioid is appropriate for short-duration analgesia, and single-shot neuraxial administration of a hydrophilic opioid is appropriate for longer duration analgesia.

Neuraxial opioids are associated with side effects that could affect patients’ quality of recovery. Side effects include nausea and vomiting in up to 50% of patients and pruritus in up to 60%, as opposed to 15% to 18% for PCEA with local anesthetic or systemic opioids. Other adverse effects include urinary retention in up to 80% of patients and early or delayed respiratory depression in 0.2% to 1.9%. These side effects are not limited to any specific opioid, and it is not clear whether their incidence is dose dependent. PCEA with combined local anesthetic and neuraxial opioids results in a low incidence of respiratory depression that varies from 0.07% to 0.4%, thus making PCEA relatively safe to use in an unmonitored hospital setting. It is essential that the dose of neuraxial opioid be reduced when used in elderly patients.

PERINEURAL OPIOIDS

Some systematic reviews found little evidence for the benefit of adding opioids to local anesthetics in peripheral nerve blockade. Preliminary results suggest that buprenorphine and tramadol are the two opioid agonists that have demonstrated analgesic efficacy when administered perineurally. Buprenorphine is a partial µ-receptor agonist with a very high receptor affinity compared with that of fentanyl or morphine. In addition, it has intermediate lipid solubility, which allows it to cross the neural membrane. Buprenorphine was found to
markedly increase the duration of analgesia when added to mepivacaine and tetracaine for axillary blocks, with no significant increase in adverse effects. Similar results were found when a 100-mg dose of tramadol was used as an adjuvant to mepivacaine in axillary brachial plexus block. One study reported an increased duration of motor and sensory blockade in the axillary tramadol group that significantly (P < .01) outlasted both IV and placebo groups.

**PERINEURAL CLONIDINE AND DEXMEDETOMIDINE**

Clonidine, an α₂ agonist with some α₁-stimulatory effects, is traditionally used as an antihypertensive agent but for many years has been noted to have sedative and analgesic effects. α₂ Receptors exist in the dorsal horn of the spinal cord, and their stimulation produces analgesic effects by inhibiting the presynaptic release of excitatory transmitters, including substance P and glutamate. IT clonidine mediates analgesia by increasing acetylcholine levels. Clonidine injected close to peripheral nerves with or without local anesthetic drugs appears to mediate analgesia in a number of ways. Clonidine has local anesthetic properties and has a pharmacokinetic effect on local anesthetic redistribution mediated by a vasoconstrictor effect at the α₁-receptor.

Many studies have examined the effect of clonidine on local anesthetics in PNB. There is good evidence from these studies that clonidine in doses up to 1.5 µg/kg prolongs sensory block and analgesia when administered with local anesthetics for PNB. Some studies have compared clonidine added to PNB to systemic clonidine. Clonidine added to the axillary brachial plexus block delayed the onset of pain twofold compared with subcutaneous clonidine injections, without producing adverse effects.

A meta-analysis by Pöpping and colleagues estimated that clonidine prolonged postoperative analgesia, sensory block, and motor block by 122, 74, and 141 minutes, respectively. Clonidine also increased the probability of hypotension (odds ratio [OR], 3.61), fainting (OR, 5.07), sedation (OR, 2.28), and bradycardia (OR, 3.09).

Ifield et al. have demonstrated in two studies that the addition of clonidine to continuous PNBs is not beneficial. It failed to reduce pain scores or oral analgesic use after upper extremity surgery.
Dexmedetomidine is selective for the $\alpha_2$ receptor and at present is mainly studied as a sedative agent in ICUs. Dexmedetomidine may be expected to produce not only more profound analgesia but also greater adverse effects because of the selectivity of action.\textsuperscript{119}

**PERINEURAL DEXAMETHASONE**

Dexamethasone is a potent synthetic corticosteroid with approximately 7 times the anti-inflammatory potency of prednisolone.\textsuperscript{120} The half-life is approximately 36 to 54 hours in the perioperative setting. The effectiveness of dexamethasone as a postoperative antiemetic (4 to 10 mg IV) has been confirmed by many randomized controlled trials.\textsuperscript{121} In a recent meta-analysis that included 2,751 patients,\textsuperscript{122} the analgesic effects of a single IV dose of dexamethasone was found to be very modest up to 24 hours postinjection.

Corticosteroids administered via perineural application are thought to exert their effect by several mechanisms, including attenuating the release of inflammatory mediators, reducing ectopic neuronal discharge, and inhibiting potassium channel–mediated discharge of nociceptive C fibers.\textsuperscript{123–125} It is widely believed that dexamethasone improves the quality and duration of peripheral nerve blockade when administered in conjunction with local anesthetics. The U.S. Food and Drug Administration (FDA), however, has not approved dexamethasone for perineural administration.

Multiple studies have assessed the effects of using dexamethasone (4 to 10 mg) with local anesthetic for PNBs.\textsuperscript{126–131} Dexamethasone was shown to prolong analgesia or sensory/motor block from approximately 50% to 75% beyond that of nerve blocks with local anesthetic alone. Nevertheless, some concerns have been raised over complications related to dexamethasone, such as effects on blood glucose and neurotoxicity. However, in several studies, a single dose of dexamethasone, whether administered perineurally or systemically, did not increase blood glucose to a clinically significant degree,\textsuperscript{132–134} and IT administration did not produce neurotoxicity.\textsuperscript{135}

Adjuvants have been added to local anesthetic for single perineural analgesia in an attempt to improve analgesia quality, spare local anesthetic
consumption, and minimize motor block. To date, clinical benefits such as improving pain have been found for adding adjuncts to continuous PNBs. No additive medications are currently approved for continuous perineural administration, and some additives that have been reported in clinical trials have undesirable side effects.

Transversus Abdominis Plane Block, Ilioinguinal Iliohypogastric Block, Rectus Sheath Block

Innervation of the anterolateral abdominal wall arises from the anterior rami of spinal nerves T7–L1. These include the intercostal nerves (T7–T11), the subcostal nerve (T12), and the iliohypogastric and ilioinguinal nerves (L1). The anterior divisions of T7–T11 continue from the intercostal space to enter the abdominal wall between the internal oblique and transversus abdominis muscles until they reach the rectus abdominis, which they perforate and supply, ending as anterior cutaneous branches supplying the skin of the front of the abdomen. Midway in their course, they pierce the external oblique muscle giving off the lateral cutaneous branch, which divides into anterior and posterior branches that supply the external oblique muscle and latissimus dorsi respectively.

TRANSVERSUS ABDOMINIS PLANE BLOCK

It may play a role in postsurgical pain control. Transversus abdominis plane (TAP) blocks may improve analgesia in patients undergoing laparotomy for colorectal surgery, laparoscopic cholecystectomy, and open and laparoscopic appendectomy. Blocks can be achieved by using anatomic landmarks or by ultrasound-guided techniques. The aim of a TAP block is to deposit local anesthetic in the plane between the internal oblique and transversus abdominis muscles, targeting the spinal nerves in this plane. The innervation to abdominal skin, muscles, and parietal peritoneum will be interrupted. If surgery traverses the peritoneal cavity, dull visceral pain (from spasm or inflammation following surgical insult) will still be experienced.

Landmark Technique
The landmark technique for performing a TAP block advocates a single entry point, the triangle of Petit, to access a number of abdominal wall nerves.\textsuperscript{145} The lumbar triangle of Petit is situated between the lower costal margin and the iliac crest. It is bound anteriorly by the external oblique muscle and posteriorly by the latissimus dorsi. This TAP technique relies on feeling double pops as the needle traverses the external oblique and internal oblique muscles. A blunt needle will make the loss of resistance more appreciable.

**Ultrasound-Guided Transversus Abdominis Plane**

Ultrasound guidance for the TAP block can help the practitioner localize and deposit the local anesthetic and thereby improve accuracy.\textsuperscript{146} The ultrasound probe is placed in a transverse plane to the lateral abdominal wall in the midaxillary line, between the lower costal margin and the iliac crest (Figs. 52.1 and 52.2). The local anesthetic is deposited in the correct neurovascular plane between the transverse abdominis and internal oblique muscles. If prolonged analgesia is required beyond the duration of a single shot of local anesthetic, a catheter can be introduced into the TAP through a Tuohy needle. After opening up the plane with 2 mL of saline, the practitioner introduces the catheter approximately 3 cm beyond the needle tip. The position is verified by injecting a local anesthetic bolus (20 mL). An infusion of a dilute local anesthetic is started at a rate of 7 to 10 mL per hour.

There has been controversy in the literature regarding the spread and level of block achieved with a single TAP injection. Early studies showed a T7–L1 spread after a single posterior injection, making the block suitable for midline abdominal incisions.\textsuperscript{147} Other studies, however, failed to demonstrate a spread cephalad to T10, making it more suited for lower abdominal surgery.\textsuperscript{148} It is reasonable to expect a good analgesic effect in the region between T10 and L1 after a single posterior injection. Augmentation with a subcostal injection will help attain a higher block up to T7. The subcostal TAP is a modification of the original technique in which the ultrasound probe is placed just beneath the costal margin and parallel to it (see Fig. 52.1). The needle is then introduced from the lateral side of the rectus muscle in plane of the ultrasound beam, and 10 mL of
local anesthetic is injected into the TAP to extend the analgesia provided by the posterior TAP block above the umbilicus.

Reported complications include intraperitoneal injection or hemorrhage, transient femoral nerve palsy, and local anesthetic toxicity.\textsuperscript{149–151} One case report has been published of intrahepatic injection with blind technique.\textsuperscript{152} Local anesthetic toxicity could also result from the large volumes required to perform this block, especially if it is done bilaterally. As with any regional technique, careful aspiration will help avoid intravascular injections.

**ILIHYPOGASTRIC AND ILIOINGUINAL BLOCK**

The iliohypogastric nerve (L1) divides between the internal oblique and transversus abdominis near the iliac crest into lateral and anterior cutaneous branches, the former supplying part of the skin of the gluteal region and the latter supplying the hypogastric region. The ilioinguinal nerve (L1) communicates with the iliohypogastric nerve between the
internal oblique and transversus abdominis near the anterior part of the iliac crest. It supplies the upper and medial part of the thigh and part of the skin covering the genitalia.

This block is indicated for any lower abdominal surgery, including appendectomy, hernia repair, cesarean section, abdominal hysterectomy, and prostatectomy. Efficacy in laparoscopic surgery has also been demonstrated. Bilateral blocks can be administered for midline incisions or laparoscopic surgery. The needle is introduced in plane of the ultrasound probe directly under the probe and advanced until it reaches the plane between the internal oblique and transversus abdominis muscles (see Figs. 52.1 and 52.3).

**RECTUS SHEATH BLOCK**
Local anesthetic deposition bilaterally within the posterior rectus sheath provides dense and predictable analgesia over the middle anterior wall from the xiphoid process to the symphysis pubis, as shown in Figures 52.1 and 52.4. It is used for surgery with midline (or paramedian) abdominal incision. Rectus sheath block does not provide analgesia for the lateral abdomen, but it will provide somatic pain relief for abdominal wall structures superficial to the peritoneum. Patients with rectus sheath catheters typically exhibit low pain scores and low opiate requirements.\textsuperscript{157,158}

Bilateral rectus sheath block might be helpful after emergency laparotomy. This patient group may have sepsis, coagulopathy, and hemodynamic instability. Administering an epidural postoperatively is usually not possible owing to positioning difficulty and safety concerns regarding placement of epidurals in unconscious patients.

**Peripheral Nerve Blocks and Catheters**

PNBs are an integral part of a postoperative multimodal analgesic regimen.\textsuperscript{159} Use of regional anesthesia techniques have been associated with postanesthesia care unit (PACU) phase 1 bypass, fewer unplanned hospital admissions, and lower hospital costs.\textsuperscript{160} These techniques improve analgesia and reduce the amount of IV analgesics required, thus decreasing opioid-related side effects.\textsuperscript{161–163} Some of the benefits of single-injection nerve blocks are limited by the duration of action of the local anesthetic used.
Peripheral nerve catheters (PNCs) offer the possibility of extending the effects of the nerve block. Continuous peripheral nerve blockade (CPNB) provides postoperative analgesia equivalent to that of epidural techniques and may be associated with higher patient satisfaction, improved side-effect profile, and fewer complications than epidurals.\textsuperscript{162,164} Strong evidence suggests that continuous perineural blockade provides superior analgesia compared to opioids for all catheter locations while reducing opioid consumption and opioid-related side effects.\textsuperscript{4} The use of CPNB decreases the time to readiness for discharge of inpatients and allows for more aggressive rehabilitation in the postoperative period.\textsuperscript{165} In the case of continuous interscalene nerve block for arthroscopic rotator cuff repair, its analgesic effects have been shown to extend into postoperative day 7.\textsuperscript{166}

The use of CPNB may allow surgical procedures that traditionally required hospital admission to be performed in an outpatient setting without a significant increase in complications.\textsuperscript{167} CPNB may be provided after discharge with a portable infusion pump, affording patients the possibility to convalesce in the comfort of their home while reducing inpatient costs.\textsuperscript{168} Shorter inpatient stays may also have other benefits, such as lower morbidity related to nosocomial infections or medical error.\textsuperscript{169} Complications associated with home CPNB are uncommon, the most common being block failure resulting from catheter dislodgment. Other potential complications include infection, pulmonary-related side effects as local anesthetic infusions may affect the phrenic nerve, systemic local anesthetic toxicity, and patient falls.\textsuperscript{170} Patient selection plays a key role in the success of ambulatory CPNB, and although the optimal method and frequency of patient monitoring remains to be established, daily phone calls seem to be a widely accepted method. A retrospective review of 1,059 ambulatory supraclavicular and popliteal catheters placed over a 2-year period and infused over a mean duration of 5 days failed to reveal an increased incidence of complications.\textsuperscript{171}

Among the different techniques for performing PNBs, ultrasound-guided regional anesthesia (UGRA) is becoming the method of choice. Compared with nerve stimulation, UGRA has been shown to provide a faster onset of blockade, better success rate, fewer needle passes with associated faster block performance, less patient discomfort, and greater
patient satisfaction.\textsuperscript{172–174} Additionally, there is level Ib evidence for a grade A recommendation that UGRA improves success of sensory block and decreases local anesthetic requirements.\textsuperscript{175} Interscalene catheters placed under UGRA after shoulder surgery were shown to be more effective in the first 24 hours than neurostimulation.\textsuperscript{176} Based on large prospective series, the complication rate does not seem to differ between UGRA and neurostimulation.\textsuperscript{177,178}

\section*{Interscalene Block}

\subsection*{INDICATIONS}

The interscalene block (ISB) is usually performed for surgical procedures involving the shoulder and upper arm. The brachial plexus is targeted at the trunk level; however, it commonly results in sparing blockade of the inferior trunk (C8–T1), making it less suitable for elbow, forearm, and hand procedures. ISB causes concomitant block of the phrenic nerve because of its close proximity, particularly at the cricoid cartilage level. At this level, the plexus and phrenic nerve are 2 to 4 mm apart. This distance increases progressively in a caudad direction.\textsuperscript{179} Horner syndrome and recurrent laryngeal nerve block resulting in hoarseness can occur. Relative contraindications to ISB include respiratory failure, contralateral phrenic nerve lesion, and contralateral recurrent laryngeal nerve lesion. The plexus can be accessed at the interscalene groove through a lateral approach or a cervical paravertebral approach.\textsuperscript{180,181}

\subsection*{LANDMARKS}

The brachial plexus is formed mainly by the anterior rami of the spinal nerves C5–T1. These nerves coalesce into three trunks (superior, middle, inferior), which emerge through the interscalene groove between the anterior and middle scalene muscles.

\subsection*{TECHNIQUES}

\subsubsection*{Nerve Stimulation}

At the level of the cricoid cartilage, the interscalene groove can be palpated behind the posterior border of the sternocleidomastoid muscle.
(SCM). The stimulating needle is introduced in a cephalocaudal and slightly medial direction. Adequate needle placement is identified by the presence of motor response to stimulation between 0.2 and 0.5 mA in the deltoid, triceps and biceps, forearm, or hand muscles. Contraction of the diaphragm or neck musculature indicates anterior placement of the needle tip, whereas contraction of the trapezius muscle indicates posterior placement.

**Ultrasound Guidance**

The practitioner places the high-frequency ultrasound probe transversally at the C6 (cricoid) level and slides it laterally while observing the internal jugular, carotid artery, and SCM superficially. As the posterior border of the SCM is visualized, the anterior and middle interscalene muscles appear deep to the SCM, with the trunks of the brachial plexus emerging between them as round hypoechoic structures. Alternatively, the probe can be placed in the supraclavicular fossa, where the divisions of the brachial plexus are visualized posterior and lateral to the subclavian artery and above the first rib. The practitioner then slides the probe in a cephalad direction, observing the divisions converge into trunks at the interscalene level. The needle can be advanced in plane lateromedially, allowing for visualization of the entire needle shaft and tip (Figs. 52.5 and 52.6). Alternatively, the needle can be introduced out of plane to the ultrasound beam, resulting in a dot in the ultrasound image when the tip of the needle crosses the beam.

FIGURE 52.6  **Left:** In-plane approach of interscalene block. **Right:** Ultrasound image of in-plane approach of interscalene nerve block. Green, local anesthetic; yellow, C5–C7 nerve roots. AS, anterior scalene; MS, middle scalene; SCM, sternocleidomastoid muscle. (Reproduced with permission from Ouanes et al. [here](http://anesthesiology.hopkinsmedicine.org/international-obstetric-and-regional-anesthesia/). Accessed July 18, 2018.)

**CLINICAL EFFECTS**

Single-injection ISB for shoulder arthroscopies may be associated with fewer side effects and fewer and shorter hospital admissions than that seen with general anesthesia. In the ambulatory setting, ISB results in decreased postanesthesia unit stay and fewer unplanned hospital admissions for pain, sedation, and nausea. ISB is effective at reducing the demand for IV PCA-delivered opioids and associated adverse effects after shoulder surgery. Abdallah et al. concluded in a recent meta-analysis that single-injection ISB provides effective analgesia for up to 8 hours postoperatively, whereas the opioid-sparing profile and lower adverse effects are limited to the first 12 and 24 postoperative hours respectively. In contrast to these findings, good evidence indicates that continuous ISB provides better analgesia, greater patient satisfaction, and fewer side effects than IV opioid PCA.

In a comparison of single-injection to continuous ISB for arthroscopic rotator cuff repair, Malik et al. concluded that continuous ISB for 3 days provides better analgesia than single-injection ISB and is associated with less opioid consumption and better sleep patterns. Such benefits may extend through the first postoperative week. A retrospective review of continuous ISB performed for shoulder surgery revealed similar effects on analgesia and reduction of opioid requirements in the PACU, although these benefits were not associated with enhancing fast-track capability. In contrast, a recent prospective randomized clinical trial comparing
single-injection ISB to general anesthesia alone for shoulder arthroscopy showed significantly faster postoperative recovery time with ISB. Continuous ISB with an indwelling catheter facilitates early physical therapy and enhances postoperative patient rehabilitation. Better functional outcomes stemming from superior analgesia and early mobilization have also been described in patients receiving ISB for proximal humerus fracture repair.

ISB should be considered with caution in patients with underlying severe pulmonary morbidity. Continuous ISB does not significantly prolong the duration of unilateral phrenic paresis compared to that with single injection ISB. A clinical comparison of patients randomized to anterior and posterior approaches to ISB did not show a difference in incidence of phrenic nerve block. Ghodki et al. found a higher incidence of hemidiaphragmatic paresis, as assessed by ultrasonographic evaluation and pulmonary function tests, when ISB was performed with peripheral nerve stimulation than when it was performed with ultrasound guidance. Extrrafascial injection (4 mm lateral to the brachial plexus sheath) has also been reported to reduce the incidence of hemidiaphragmatic paresis compared to that with conventional intrafascial injection (between C5 and C6 within the interscalene groove) while resulting in similar analgesia. Maga et al. reported that faster onset was the only advantage of injection inside the brachial plexus sheath over injection outside the sheath. There was no statistically significant difference in sensory blockade after 10 minutes, but injection inside the sheath resulted in a higher incidence of transient paresthesia.

**Supraclavicular Block**

**INDICATIONS**
The supraclavicular nerve block (SCB) targets the brachial plexus at the trunks/divisions level. It has been used for surgical procedures involving the shoulder, arm, forearm, and hand. It can be performed as a single injection or with a continuous infusion through a catheter. The supraclavicular approach has a high incidence of success in blocking the ulnar and musculocutaneous nerves, which are commonly missed with
interscalene and axillary blocks, respectively. Therefore, the SCB has a broader spectrum of applications for both surgical anesthesia and postoperative analgesia.

**LANDMARKS**

At the supraclavicular level, the brachial plexus is composed of the anterior and posterior divisions of the three trunks. It is surrounded by its own fascia and located superior and lateral in relation to the subclavian artery, between the clavicle and the first rib.

**ULTRASOUND TECHNIQUE**

With the patient’s head turned to the contralateral side of the block, the ultrasound probe is placed on the supraclavicular fossa, yielding a cross-sectional image of the brachial plexus and subclavian artery. The plexus is confirmed to lie superior and lateral to the artery. The optimal view is obtained when the first rib appears as a hyperechoic structure with its corresponding acoustic shadow just inferior to the subclavian artery and the brachial plexus. In this view, excessive advancement of the block needle should encounter the first rib, thereby reducing the risk of pneumothorax. The needle is introduced in plane from the lateral end of the ultrasound probe (Figs. 52.7 and 52.8).

CLINICAL EFFECTS
A duration of sensory block of up to 17 hours has been described after SCB.\textsuperscript{200} A recent randomized controlled trial of patients undergoing open rotator cuff repair found that continuous SCB provided analgesia in the 24-hour postoperative period equivalent to that of continuous ISB while reducing the incidence of hemidiaphragmatic paresis.\textsuperscript{201} Similar results were reported when these two block modalities were compared for arthroscopic shoulder surgery.\textsuperscript{202} SCB has been reported to cause hemidiaphragmatic paresis in approximately one-third of cases.\textsuperscript{203} Therefore, it should be chosen carefully for patients with significant respiratory comorbidities.

Studies have shown no significant advantages of using a double-injection technique over a single-injection technique for the SCB under ultrasound guidance.\textsuperscript{204,205} However, Arab et al.\textsuperscript{206} found that although a triple-injection technique was associated with a longer performance time than a single-injection, it provided a more successful nerve blockade in the first 20 minutes. There was no difference in the success of surgical anesthesia between the two groups at 30 minutes. Subfascial injection of the local anesthetic (deep to the brachial plexus sheath) under ultrasound guidance resulted in a faster onset of surgical blockade and longer duration of postoperative analgesia than did an extrafascial injection (superficial to the sheath).\textsuperscript{207}

Over the past decade, the application of ultrasound to SCB has reduced the probability of complications, including pneumothorax, Horner syndrome, phrenic nerve palsy (50% to 70% incidence), and local
anesthetic systemic toxicity. Ultrasound also allows a faster onset time of the sensory blockade, prolongs duration, and reduces the local anesthetic dose. Because of the proximity of the pleura to the supraclavicular fossa, pneumothorax can be a significant complication of the SCB. The incidence of pneumothorax was described to be as high as 6.1% when SCB was performed without ultrasound guidance. A prospective observational study of 6,366 ultrasound-guided SCBs found a pneumothorax incidence of 0.06%, suggesting that ultrasound decreases the incidence of this complication. A 5-year retrospective study confirmed the extremely low pneumothorax complication rate, including when SCB was performed by residents-in-training under direct faculty supervision. These findings suggest that ultrasound guidance has a significance in reducing pneumothorax complications.

The incidence of phrenic nerve palsy after SCB is 50% to 70%. The use of ultrasonography, by virtue of reducing the volume of local anesthetic required for an effective block, has not been associated with hemidiaphragmatic paresis with volumes of 20 mL. A recent prospective review of outcomes in upper limb surgery reinforced the efficacy and safety of ultrasound-guided SCB, with reported patient satisfaction in 96.7% of cases.

Infraclavicular Block

INDICATIONS
The infraclavicular nerve block (ICB) targets the brachial plexus at the level of the cords and provides adequate analgesia or anesthesia of the elbow, forearm, and hand. The block can be performed as a single injection or continuously via a catheter. The infraclavicular approach is particularly well suited for continuous blockade. The pectoralis muscles aid in anchoring the catheter in place, which, in conjunction with the limited range of motion of the infraclavicular area, helps to minimize unintended catheter migration.

LANDMARKS
At the infraclavicular level, the brachial plexus is composed of three cords
(medial, lateral, and posterior). These cords are named in accordance to their position relative to the axillary artery at the level of the pectoralis minor muscle (Pmm). However, there is significant individual variation in the position of the cords around the artery (Fig. 52.9). The level at which the block is performed is approximately 2 cm medial and 2 cm caudad to the coracoid process.

**FIGURE 52.9** Infraclavicular block. Variations in cord position relative to the axillary artery. L, lateral cord; M, medial cord; P, posterior cord. (Reprinted with permission of the American Society of Regional Anesthesia and Pain Medicine.)

**TECHNIQUE**

The patient is positioned with the head turned to the contralateral side of the arm to be blocked, which is abducted and externally rotated at approximately 90 degrees. This maneuver causes the plexus to become more superficial and displaces the clavicle cephalad. The needle can then be introduced further away from the ultrasound probe at a smaller angle, thereby allowing better needle visualization (Fig. 52.10). The transducer is placed perpendicular to the clavicle in the deltopectoral groove. At this level, the pulsatile axillary artery and compressible axillary vein are visualized in cross-section deep to the Pmm (Fig. 52.11). The needle is
introduced from the superior end of the transducer and advanced in plane to the ultrasound beam. The initial injection point is deep to the axillary artery, between the artery and the posterior cord (see Fig. 52.10). Injection at this point usually results in medial spread around the artery toward the medial cord. As the needle is withdrawn, local anesthetic is injected to bathe the lateral cord. It may be necessary to redirect the needle over the artery to a point between the artery and vein to ensure proper blockade of the medial cord.

Accessed July 18, 2018.)

**CLINICAL EFFECTS**

The ICB has been shown to offer faster recovery, cause fewer adverse
events, and provide better analgesia than general anesthesia with local wound infiltration.\textsuperscript{214} A systematic review that compared ICB to other brachial plexus blocks confirmed that ICB posed a lower likelihood of tourniquet-related pain and provided more reliable blockade of the musculocutaneous nerve than did axillary block.\textsuperscript{215} Ilfend et al.\textsuperscript{216} reported improved analgesia, decreased opioid use, decreased incidence of related side effects, fewer sleep disturbances, and greater patient satisfaction when continuous ICB was used for outpatients after upper extremity orthopedic surgery. An observational cohort study demonstrated a high success rate of single-injection ultrasound-guided ICB regardless of the operator’s expertise.\textsuperscript{217} In a randomized comparison study, continuous ICB provided superior analgesia to that of supraclavicular continuous block on the first postoperative day. Patients in the ICB group also required fewer oral analgesics for breakthrough pain in the first 18 to 24 postoperative hours.\textsuperscript{218}

**Axillary Block**

**INDICATIONS**

The brachial plexus block at the axillary level targets terminal branches of the brachial plexus (ulnar, median, radial, and musculocutaneous nerves). The axillary sheath at this level is often discontinuous. At this level, the risk of pneumothorax or phrenic nerve palsy is negligible. Its low incidence of complications has made it a popular choice for elbow, forearm, wrist, and hand procedures.\textsuperscript{219} A catheter can be placed at this level for continuous blockade. However, owing to the mobility of the axillary area and more superficial location of the plexus at this level, the catheter can be easily dislodged. This site may also be more susceptible to infection when an indwelling catheter is used.

**LANDMARKS**

At the axillary level, the neurovascular sheath contains the axillary artery surrounded by the radial, median, and ulnar nerves. Outside of this sheath are the intercostobrachial, axillary, and musculocutaneous nerves.
TECHNIQUES

Nerve Stimulation
The patient is positioned supine with the head turned to the contralateral side and the arm to be blocked abducted and externally rotated. The axillary artery is palpated in the axilla and stabilized with two fingers. The stimulating needle is introduced superior to it at a 30- to 45-degree angle to the skin. Finger flexion and/or thumb opposition indicate adequate needle placement. The needle should be adjusted so that muscle contraction is lost less than 0.5 mA prior to injection of local anesthetic.

At the axillary level, the musculocutaneous nerve has typically branched off the neurovascular bundle and travels within the coracobrachialis muscle. If musculocutaneous nerve block is required, a second injection is necessary. The coracobrachialis muscle is palpated underneath the biceps at the midhumeral level. The stimulating needle is introduced and its position adjusted until biceps contraction is elicited. Care must be taken not to introduce the needle into the biceps muscle itself, which could result in direct stimulation and contraction of the muscle but a failed block.

Transarterial Technique
If accidental puncture of the axillary artery occurs during the neurostimulation technique, evidenced by aspiration of blood, the needle should be advanced until blood is no longer aspirated. At this location, behind the artery, two-thirds of the local anesthetic is injected. The needle is then retracted slowly and the tip placed back inside the artery. When no blood is aspirated, the needle tip is located anterior to the axillary artery, and the remaining third of the local anesthetic is injected. Compression of the artery for a few minutes is advised to reduce the incidence of a hematoma.

Ultrasound Guidance
The patient is positioned as described earlier for the neurostimulation technique. The ultrasound probe is placed at the axillary level perpendicular to the forearm. The probe position is adjusted until a cross-sectional image of the axillary artery is obtained (Fig. 52.12). The axilla is a highly vascularized space, and releasing pressure from the probe
typically exposes several axillary veins in the vicinity of the artery. The radial, median, and ulnar nerves are identified around the axillary artery as hyperechoic structures. There is significant individual variation in the position of the nerves relative to the artery. However, the radial nerve most often lies posterior to the artery, with the ulnar nerve being medial and the median nerve anterior to the axillary artery. Sequential scanning proximally and distally will reveal the trajectory of the musculocutaneous nerve and help identify it as a hypoechoic structure with a hyperechoic rim. Proximally, it lies closer to the axillary neurovascular bundle. When scanning distally, the practitioner can trace the nerve travelling toward the coracobrachialis muscle, lying between it and the biceps muscle.

The needle can be advanced from the lateral end of the probe in plane, and the needle position adjusted to allow local anesthetic spread around each nerve (Fig. 52.13).
**CLINICAL EFFECTS**

Axillary brachial plexus block has been shown to provide several advantages over general anesthesia for outpatient hand surgery, including the ability to fast-track patients to phase 2, resulting in shorter PACU stays, better pain control, reduced opioid consumption prior to discharge, and lower incidence of nausea/vomiting.\(^{220}\) The use of ultrasound guidance with axillary brachial plexus block has been associated with increased success rate, shorter time to onset of anesthesia, and reduced time to perform the block.\(^{221}\) When studying novice practitioners, however, Barrington et al.\(^{222}\) were unable to demonstrate any differences between ultrasound guidance and nerve stimulator techniques. A prospective review of axillary brachial plexus block-associated complications that included over 27,000 procedures confirmed the extremely safe profile of this block, with an overall incidence of postoperative neurologic symptoms of 0.37 per 10,000.\(^{219}\)

**Suprascapular and Axillary Nerve Block**

**INDICATIONS**

Innervation to the shoulder joint from the brachial plexus is primarily carried out by the suprascapular and axillary nerves. In fact, the suprascapular nerve accounts for 70% of the sensory innervation of the shoulder.\(^{223}\) Thus, the suprascapular nerve block (SSNB) has been widely used for analgesia in procedures involving the shoulder, particularly when an interscalene nerve block may be contraindicated (e.g., with severe pulmonary disease).

**LANDMARKS**

The suprascapular nerve emerges as a branch of the superior trunk and courses through the supraspinous groove toward the shoulder. The axillary nerve is a branch of the posterior cord.

**ULTRASOUND TECHNIQUE**

Positioning the ultrasound probe along the long axis of the supraspinous fossa (Fig. 52.14) enables visualization of the greater suprascapular notch.
The suprascapular nerve and artery may also be visualized although not consistently. The needle is introduced in plane in a medial-to-lateral direction, and local anesthetic is deposited on the lateral aspect of the fossa, underneath the supraspinatus muscle (Fig. 52.15).

**Axillary Nerve Block**

The ultrasound probe is placed over the posterior surface of the humerus along its short axis, allowing visualization of the axillary artery and nerve in their short axis. Local anesthetic is deposited adjacent to the axillary artery on the posterior surface of the humerus (Fig. 52.16).

**FIGURE 52.14** Suprascapular nerve block. **Left:** Ultrasound image for the suprascapular anatomy. **Right:** Ultrasound image with anatomy labeled. m., muscle; n., nerve. **CLINICAL EFFECTS**

SSNB is effective for providing analgesia in the postoperative period after shoulder surgery. The combination of SSNB and axillary nerve block (ANB) provides superior analgesia and higher patient satisfaction after arthroscopic rotator cuff repair than SSNB alone. SSNB and ANB combined with IV PCA has also proven to be a better analgesic choice than SSNB plus IV PCA, or IV PCA alone. Dhir et al. reported differences between the analgesic profile of SSNB combined with ANB and the profile of ISB. In their prospective randomized study, SSNB in combination with ANB provided better pain relief for patients at rest, with fewer side effects, whereas ISB was associated with better analgesia in the first 6 postoperative days. This difference in analgesic profile is consistent with a prior study by Pitombo et al. who also described a significantly lower degree of motor blockade with the combination of SSNB and ANB. Combining ISB with SSNB provides superior analgesia to ISB alone within 48 hours after arthroscopic rotator cuff repair.

**Brachial Plexus Terminal Branch Blocks at the Elbow and Below**

**INDICATIONS**

Blockade of the terminal branches of the brachial plexus at the elbow can
offer certain advantages over more proximal blocks. It allows the possibility of selectively blocking a specific sensory distribution of the hand while preserving motor function of the proximal upper limb. Distal blocks may cause more patient discomfort if multiple nerves are blocked, as they usually require a separate injection for each nerve. The nerve paths at this level are further restricted by surrounding muscular structures, potentially making these locations more susceptible to nerve injury associated with compression ischemia.

**TECHNIQUES**

**Nerve Stimulation**

The median nerve can be blocked by introducing the stimulating needle 2 cm above the elbow and 2 cm medial to the point at which the brachial artery is palpated. Needle position is adjusted to obtain the corresponding motor response (forearm pronation, flexion of second and third digits, thumb opposition), and then, 5 mL of local anesthetic is injected.

The ulnar nerve runs in the canal between the olecranon and the medial epicondyle. This canal is narrow and superficial, making the nerve at this point susceptible to lesion from direct needle trauma or increased pressure from the injectate.

Consequently, the block is performed 1 to 2 cm proximal to this canal. The elicited motor response includes flexion of the fourth and fifth digits and wrist flexion toward the ulnar side.

To block the radial nerve at the elbow, the practitioner palpates the biceps tendon 1 to 2 cm proximal to the elbow and introduces the stimulating needle lateral to it. Radial nerve stimulation should elicit extension of the hand and forearm as well as forearm supination.

**Ultrasound Guidance**

The individual nerves can be blocked at various locations. At the elbow, proximal forearm and midforearm are described (Fig. 52.17).
Median Nerve Block
The median nerve can be block at various locations. The patient is positioned supine with the arm abducted and forearm supinated. The nerve can be visualized in the A position medial to the brachial artery (see Figs. 52.17 and 52.18) as well as in the B and C positions of Figure 52.17 (see also Figs. 52.19 and 52.20).
Ulnar Nerve Block
With the patient supine and the arm straight and supinated, the ultrasound probe is placed over the ulnar artery at the wrist and traced proximally. The ulnar nerve can be seen medial to the artery. Eventually, the ultrasound probe is moved further away to rest in between the flexor carpi ulnaris and flexor digitorum profundus (see Figs. 52.17, 52.19, and 52.21). \(^{230}\)
Radial Nerve Block

The patient is positioned supine with the arm abducted and forearm supinated. The radial nerve is visualized lying adjacent to the radius bone. It is flanked by the pronator teres muscle medially and by the brachioradialis muscle, the extensor carpi ulnaris longus muscle, and supinator muscle laterally (see Figs. 52.20 and 52.22).

CLINICAL EFFECTS
For most outpatient hand and wrist bone surgeries, an effective anesthetic and analgesic plan includes selective distal blocks with long-acting local anesthetics without vasoconstrictors like epinephrine and a concomitant axillary block with short-acting local anesthetic. This combination allows for muscle function preservation in the proximal upper limb. The presence of motor block in the affected limb in the immediate postoperative period has been associated with lower patient satisfaction. A prospective study that compared proximal brachial plexus blocks to terminal branch blocks performed at the level of the forearm for hand surgery found no differences in adequacy as a primary anesthetic, postoperative pain scores, or opioid consumption. However, terminal branch blocks at the level of the elbow will not prevent tourniquet pain in an unsedated patient because upper arm cutaneous innervation is supplied by the medial cutaneous nerve, musculocutaneous nerve, posterior cutaneous nerve, and intercostobrachial nerve.

Paravertebral Nerve Block

**INDICATIONS AND LANDMARKS**

Paravertebral nerve blocks (PVBs) provide anesthesia and analgesia to the thorax and abdomen. They have been successfully described for breast surgery, thoracotomy, thoracoscopy, nephrectomy, hip surgery, cardiac surgery, and lung transplant surgery. The goal of the PVB is to deposit local anesthetic in the paravertebral space adjacent to the vertebral bodies, where spinal nerves emerge from the spinal canal and bifurcate into the ventral and dorsal rami. This space is delineated medially by the vertebral bodies and discs and the intervertebral foramina; anterolateral by the parietal pleura at the thoracic levels or iliopsoas muscle; and posterolateral by the ribs, transverse processes, and intercostal spaces. The epidural space is a continuous space in the craniocaudal dimension. Therefore, local anesthetic injected at one level will spread to adjacent levels. Contralateral spread occurs in approximately 10% of cases. PVBs can be performed with single-injection or continuous techniques.

**TECHNIQUES**

2755
Landmark Technique
The patient is positioned sitting up with the neck and back flexed. The spinous processes are identified and marked. Additional marks are made 2.5 cm laterally from the spinous process on the side intended to block, which will correspond with the transverse process (Fig. 52.23). The needle is introduced at the lateral mark, perpendicular to the skin, until contact is made with the transverse process. Contact occurs at a depth of 2 to 4 cm, depending on the body habitus of the patient. If the transverse process is not encountered at 4 cm, the needle is redirected cephalad or caudad. Continuing to advance without prior contact with the transverse process carries the risk of pleural puncture. Regardless of body habitus, the paravertebral space is typically located 1 cm beyond the transverse process at the thoracic levels, or 0.5 cm at the lumbar levels because the transverse processes are thinner in this area. After contacting the transverse process, the needle is redirected caudad, walked off the transverse process, and advanced 1 cm (0.5 in the lumbar area) into the paravertebral space. It may be possible to feel a loss of resistance as the needle is advanced through the superior costotransverse ligament at the thoracic levels. However, this sensation can be very subtle and difficult to appreciate.

![Thoracic paravertebral block landmarks.](image)

Ultrasound Technique
Transverse Approach
The ultrasound probe is placed transversally over the midline at the level intended to block (Figs. 52.24 and 52.25). The acoustic shadow of the spinous process is identified, along with the transverse process and
costotransverse joint. The probe is then moved cephalad or caudad over the intercostal space, which allows for visualization of the pleura. The needle is introduced in plane and the local anesthetic deposited at the corner formed by the transverse process and pleura.235,239

**Parasagittal Approach**

The ultrasound probe is placed longitudinally 5 to 10 cm lateral to midline. At this level, the ribs are visualized in their short axis as curved structures with an acoustic shadow and the parietal pleura underneath. The probe is then slid medially and scanned over the level of the transverse processes, which appear as more square osseous structures. A slight tilt of the probe laterally will improve visualization of the pleura. The needle can be advanced in plane or out of plane into the paravertebral space ([Figs. 52.26 and 52.27](#)).240 Injection of local anesthetic causes depression of the
parietal pleura and spread to the adjacent levels.

**CONTRAINDICATIONS**
In addition to the general contraindications for PNBs, empyema and tumor invading the paravertebral space are specific for PVB. The same considerations for coagulopathy and neuraxial anesthesia apply to PVB.

**CLINICAL EFFECTS**
PVBs are effective in providing analgesia after breast cancer surgery and have been shown to decrease pain scores and mean opioid consumption up to 72% both intraoperatively and postoperatively,\(^{235}\) decrease opioid-
related side effects, shorten hospitalization, and possibly decrease chronic postsurgical pain at 6 months. Some of these benefits might be greatest in patients undergoing bilateral mastectomies with simultaneous breast reconstruction. However, many of these benefits have been replicated in studies involving post-mastectomy breast reconstructions. Multilevel PVB is associated with better postoperative pain control with movement as well as decreased analgesic consumption. During infusion, continuous PVB has the additional benefit of improving analgesia and decreasing functional deficit, compared with single-injection techniques. A recent study reported that PVB provided effective postoperative analgesia after thoracotomy, albeit inferior to that of epidurals. However, two recent meta-analyses found no difference in pain analgesic efficacy and reported that PVB was associated with less hypotension, nausea and vomiting, and urinary retention than epidurals were.

Nerve Blocks of the Lumbar Plexus

**INDICATIONS AND LANDMARKS**

The lumbar plexus (LP) is formed within the psoas muscle from the anterior rami of T12–L4. The branches of LP are the iliohypogastric (T12–L1), ilioinguinal (L1), genitofemoral (L1–L2), lateral femoral cutaneous (L2–L3), femoral (L2–L4), and obturator nerves (L2–L4) (Fig. 52.28). Of these, the femoral, lateral femoral cutaneous, and obturator nerves are most important for lower extremity surgery.
The LP block, also known as the psoas compartment block, was first described in 1976 by Chayen et al.\textsuperscript{248} It is a deep block of the LP, and the local anesthetic is deposited within the body of the psoas muscle. At the L4 level, it is thought to be the most consistent approach to block the entire LP with a single injection; however, it consistently provides anesthesia or analgesia in the distributions of the femoral, lateral femoral cutaneous, and the obturator nerves.\textsuperscript{249}

**TECHNIQUES**

**Landmark Technique**

There are two common methods of landmark-based nerve stimulation-assisted LP block.

For both techniques, the patient is placed in the lateral decubitus position with the operative side up (Fig. 52.29). Both mark palpated anatomy. In the first approach, the practitioner palpates the iliac crests and follows an imaginary line to the spinous processes of the lumbar spine to approximately the L4 spinous process. An insulated needle is inserted 4 cm lateral to the spinous process perpendicular to the skin and advanced...
until a quadriceps twitch is elicited or until bone is contacted. When the needle contacts bone, it is redirected off the bone either cephalad or caudad and advanced approximately 2 cm until quadriceps stimulation is obtained with current between 0.5 and 1 mA. If quadriceps stimulation is not elicited and no bony contact is made, the practitioner should reassess the landmarks.

**FIGURE 52.29** Landmark approaches to lumbar plexus (psoas compartment) block. PSIS, posterior superior iliac spine. (Reproduced with permission from Jeng CL, Rosenblatt MA. Lower extremity nerve blocks: Techniques. In: UpToDate, Post TW [Ed], UpToDate, Waltham, MA. [Accessed on September 13, 2018.] Copyright © 2018 UpToDate, Inc. For more information visit www.uptodate.com.)

The second commonly described landmark technique follows the same nerve stimulation principles with slightly modified landmarks (see Fig. 52.29). A line is drawn between the two iliac crests and another is drawn connecting the lumbar spinous processes. A third line is drawn through the posterior inferior iliac spine. Finally, a line is drawn perpendicular to the other lines at the level of L4 and divided into thirds. The needle is inserted 1 cm cephalad to this line at the point of the lateral third marking.
Several descriptions of various techniques for the psoas compartment blocks have been described in the literature.\textsuperscript{250–252} All rely on bony contact with the transverse process as a guide to depth of needle placement. Chayen et al.\textsuperscript{248} estimated the distance from the skin to the LP to be 8 cm in men (range, 6 to 10 cm) and 7 cm in women (range, 5 to 9 cm) based on CT images obtained in their patients. They found the depth of the LP from the transverse process to be consistently less than 2 cm. This relationship of transverse process to the LP was found to be independent of body mass index or gender. Thus, contact with the transverse process provides a consistent landmark to guide the user and help avoid very deep penetration.\textsuperscript{248}

**Ultrasound Guidance**

Several descriptions of various techniques have been published for the use of ultrasound to guide peripheral blocks and sonoanatomy of the LP.\textsuperscript{253,254} Using ultrasound guidance for the LP block is still challenging owing to the depth of the nerve and presence of the “acoustic shadow” formed by the transverse processes.\textsuperscript{255,256} In clinical practice, ultrasound can be used for preprocedural scanning or for real-time guidance in combination with nerve stimulation.

With the patient in a lateral decubitus position, a curved array, low-frequency ultrasound is placed parasagittal at the lumbosacral junction. With the sacrum identified, the practitioner counts the transverse process of each vertebra cephalad until L2, L3, and L4 are identified. The longitudinal sonogram exhibits an acoustic shadow of the transverse processes produced, or what Karmakar et al.\textsuperscript{253} call the trident sign because of its similarity to the trident (Fig. 52.30). They describe visualizing the roots of the LP within the psoas muscle in 60% of their patients. The needle is inserted from the caudal end of the probe and advanced through the space between the transverse processes of L3 and L4 into the posterior part of the psoas muscle. The needle takes a very steep angle in the plane view.\textsuperscript{254} After negative aspiration, local anesthetic is injected, and its spread is observed within the muscle.
FIGURE 52.30 Longitudinal sonogram. Note the hyperechoic transverse processes with their acoustic shadow that produces the trident sign. The psoas muscle is seen in the acoustic window between the transverse processes and is recognized by its typical striated appearance. Part of the lumbar plexus is also seen as a hyperechoic shadow in the posterior part of the psoas muscle between the transverse processes of L3 (TPL3) and L4 (TPL4) vertebrae. The inset shows the orientation of the ultrasound transducer and the direction in which the needle is introduced (long axis) during an ultrasound-guided lumbar plexus block. TPL2, transverse process of L2 vertebra.

COMPLICATIONS

Unlike most other PNBs described, the American Society of Regional Anesthesia and Pain Medicine (ASRA) recommends that anticoagulation guidelines for neuraxial blocks be followed when performing an LP block because of its deep nature.257

This block has the highest incidence of complications among PNBs, although the estimated rate of complication is low overall.249 The most common complication is neuraxial spread leading to bilateral block. Epidural spread is more common than total spinal.247,249,258,259 Epidural spread after LP block has been reported with an incidence range from 27%260 to 50%.178 Cases of cardiac arrest after LP block have been reported in patients who were found to have high dermatomal block
Other complications include injury to surrounding structures, including renal hematoma, pneumocele, total spinal anesthesia, and unintended intra-abdominal and intervertebral penetration. Vascular injury can lead to retroperitoneal hematoma, which can go unnoticed for some time and lead to serious complications. Dolan pointed out in a letter to the editor that ultrasound LP allows for visualization of the distribution of local anesthetic in real time and may translate to fewer complications.

To ensure the proper position of the needle during psoas compartment block and avoid excessive needle insertion, it is recommended that the transverse process be intentionally sought during the landmark approach.

**CLINICAL EFFECTS**

The LP block is usually used as a supplement to general anesthesia for pain control after lower extremity surgery. It may also be used as an alternative to neuraxial analgesia as a primary anesthetic to minimize the chance of sympathectomy and bilateral lower extremity block. However, if anesthesia of the lower leg or posterior thigh is required for the procedure, the sacral nerve roots must be blocked separately. LP block has been described as useful for hip and knee surgery. The posterior approach provides analgesia to the lateral portions of the hip and knee joints. In a prospective, randomized, blinded clinical trial that compared stimulating catheters and nonstimulating catheters for LP block, Cappelleri et al. found that the minimum effective anesthetic volume was 12 mL with the stimulating catheter and 25 mL with the nonstimulating catheter. They reported 100% successful block in the stimulating catheter group and 69% success rate in the nonstimulating group.

**Femoral Block**

**INDICATIONS**

The femoral nerve is the main LP branch nerve (L2–L4) and responsible for sensation of the anterior medial skin of the thigh and medial leg from the tibia to the medial aspect of the foot, with articular branches.
The femoral nerve block (FNB) provides adequate analgesia or anesthesia of the thigh, knee, and medial leg. It can be performed as a single injection or continuously via a catheter. The block usually requires supplementation as it does not completely cover the entire lower extremity. It usually requires supplementation with sacral plexus nerves if it is used as an anesthetic for the lower extremity.

**LANDMARKS**
The femoral nerve is one of the major branches of the LP. Consistently lateral to the femoral artery, it is encased by splitting of the fascia iliaca, superficial to the iliopsoas muscle. At the femoral triangle, from medial to lateral, one should locate the femoral vein (compressible), femoral artery (noncompressible/pulsating), and femoral nerve.

**TECHNIQUES**

**Nerve Stimulator-Guided Femoral Block**
The common femoral artery and inguinal ligaments are palpated in the groin. The insulated needle is inserted just below the inguinal ligament and 1.5 cm lateral to the artery in an anterior-posterior direction. Stimulation of the femoral nerve produces a motor response of the quadriceps muscle. Optimal needle position is achieved when twitches are present between 0.3 and 0.5 mA. After negative aspiration, 20 to 30 mL of local anesthetic is injected in 5-mL increments, with aspiration between injections. A sartorius twitch, a band-like twitch along the medial side of the thigh, leads to unreliable analgesia because the sartorius branches run outside the femoral nerve sheath. The needle will need to be directed more posterior (Fig. 52.31).
FIGURE 52.31  Anatomic landmarks for the (1) lateral femoral cutaneous, (2) femoral, and (3) obturator nerve blocks. (Reprinted with permission from Yao FSF. Yao & Artusio’s Anesthesiology. 8th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2016. Figure 47.3.)

**Ultrasound Technique**

With the patient supine, the practitioner places the ultrasound transducer in the inguinal crease to identify the sonoanatomy (Fig. 52.32). The hyperechoic femoral nerve can be visualized lateral to the hypoechoic pulsatile common femoral artery and nonpulsatile femoral vein (Fig. 52.33). An in-plane or out-of-plane approach can be used. The needle is inserted and the tip placed adjacent to the nerve. The needle can be placed either above or below the femoral nerve. One should note that the nerve is enveloped in the fascia iliaca; if it is not penetrated, the block will be inadequate. Local anesthetic is injected adjacent to the nerve under ultrasound visualization (see Fig. 52.33).

(Reproduced with permission from Ouanes et al. http://anesthesiology.hopkinsmedicine.org/international-obstetric-and-regional-anesthesia/. Accessed July 18, 2018.)

**COMPLICATIONS**

Similar to other PNBs, complications include vascular puncture with subsequent local anesthetic toxicity, hematoma, and neurologic trauma.

Axillary and femoral PNCs pose a greater risk of infection than do other PNCs. The bacterial colonization rates have been reported to be between 13% and 57%. However, the progression to infection is between 0.05% and 3%.<sup>270–272</sup> Duration of catheter implant for more than 48 hours has been associated with increased risk of infection. Therefore, the block site should be examined daily for signs of inflammation.

Because of the high incidence of quadriceps weakness after FNB, adductor canal blocks (ACB) have become more popular as a postoperative analgesia choice for ambulating patients.

**CLINICAL EFFECTS**

When compared to IV opioids, FNBs have been shown to improve outcome after major knee and vascular surgery of the lower extremity.<sup>273–275</sup> Femoral nerve catheters used to be very popular for pain control after total knee arthroscopy (TKA). The perineural catheter offers an advantage over single injections as the postsurgical pain usually outlasts the duration of the longest acting single-injection PNB,<sup>276,277</sup> and a single-injection nerve block with a bolus of local anesthetic results in profound sensory and motor block.<sup>278</sup> A dense sensory and motor block provides
excellent pain control, but it is undesirable because it inhibits quadriceps function mobilization.\textsuperscript{278–280} A meta-analysis from 2013 highlights the evidence regarding FNB efficacy for postoperative pain control in patients with TKA.\textsuperscript{281} The authors report that FNB as either a single injection or a continuous infusion provides better pain control than PCA alone.\textsuperscript{281}

Continuous infusion of dilute ropivacaine (0.2\% at 5 to 8 mL per hour) has been the recommended local anesthetic for continuous femoral nerve catheters. This dosing has been shown to provide adequate analgesia while minimizing motor block.\textsuperscript{282} A Cochrane review showed that FNB was superior to PCA for other outcomes in addition to pain control. Chan et al.\textsuperscript{283} reported higher patient satisfaction, less nausea and vomiting, and improved postoperative range of motion. They also reported that continuous FNB provided equivalent analgesia for TKA with fewer side effects than epidural techniques.

Using a PNC after TKA is not without risk. A meta-analysis by Johnson et al.\textsuperscript{284} suggested that patients who received a PNC were at greater risk for perioperative falls than were patients who received either single-injection PNB or no block. The concern for falls is legitimate as femoral nerve blockade does result in quadriceps weakness.\textsuperscript{285} Memtsoudis et al.\textsuperscript{286} sites the incidence of fall for patients after TKA as 1.6\%. They did not attribute use of PNB to an increased risk for fall. Hence, caution should be used when mobilizing postsurgical patients with blocked lower extremities because of residual quadriceps weakness.

Adductor Canal Block

INDICATIONS
Enhanced recovery pathways and expedited early mobilization pathways after TKA have led clinicians to search for PNB sites that have minimal effect on ambulation while providing postoperative analgesia.\textsuperscript{287} Concern has been raised over the quadriceps weakness and delayed rehabilitation caused by the FNB. These concerns have led to growing support for the ACB (Fig. 52.34).
The ACB technique was introduced in 2009 as a feasibility study. In 2011, Lund et al. compared quadriceps strength after ACB and FNB in a randomized controlled trial. ACB offered the potential advantage of preserving quadriceps strength while providing pain relief comparable to that of FNB. Additionally, in a placebo-controlled, double-blind, randomized controlled trial, Nader et al. found that the ACB effectively reduced pain and opioid requirements in the postoperative period for TKA patients.

Three meta-analyses and systematic reviews have compared ACB and FNB. In a meta-analysis and systematic review of randomized controlled trials, Jiang et al. evaluated the efficacy and safety of the ACB for early postoperative pain management in patients undergoing TKA. The pooled results showed that the ACB resulted in less postoperative analgesic consumption than the saline group and less pain at rest and during activity. FNB and ACB had similar effects on postoperative analgesic consumption and pain, but the quadriceps strength
and ability to ambulate were better in the ACB group. The two groups had similar rate of complications.

Compared with placebo groups, patients receiving ACB have demonstrated decreased perioperative opioid requirements, decreased pain during active range of motion, and early ambulation. A noninferiority study by Abdallah et al. found that when compared with FNB, the ACB preserved quadriceps strength and provided noninferior postoperative analgesia for outpatients undergoing ACL reconstruction. However, despite evidence supporting preserved quadriceps strength, there have been case reports of quadriceps weakness after single-injection and continuous ACB. Proximal spread of local anesthetic in the femoral triangle or anatomic variations in the motor branches to the quadriceps muscles have been suggested as possible mechanisms for quadriceps muscle weakness after ACB.

ACBs have been described in the past to target only sensory function of the saphenous nerve. However, in light of recent meta-analyses demonstrating noninferiority to FNBs and improved quadriceps strength over the FNBs, several studies have examined the contents of the adductor canal and spread outside the canal. The sensory innervation of the knee is provided by branches of the femoral nerve and sciatic nerve, and some variable input from the obturator nerve. Cadaveric studies have demonstrated key nerves involved in analgesia after TKA. The adductor canal begins at the apex of the femoral triangle and ends at the adductor hiatus. The anatomic borders of the tunnel are anteriorly the aponeuroses of the surrounding muscles. The anterolateral border is the vastus medialis, the anteromedial border is the sartorius and the posterior border formed by the adductor magnus. Burckett-St Laurant et al. identified and traced the terminal branches of the saphenous nerve and the nerve to the vastus medialis and deep nerve plexus of the adductor canal. They found that both the vastus medialis and saphenous nerve provide innervation to the anteromedial joint capsule and subcutaneous tissues over the medial aspect of the knee.

Two studies of healthy volunteers support the claim that ACB is superior to FNB for patients undergoing TKA. Three studies of TKA patients also demonstrated preserved quadriceps strength with ACB over
FNB in both single-shot and catheter-based techniques.\textsuperscript{280,310,311} Two cohort studies showed earlier postoperative ambulation in the continuous ACB group than in the continuous FNB group.\textsuperscript{312,313} Mudumbai et al.\textsuperscript{312} showed that when used in an established TKA clinical pathway, patients who received adductor canal catheters instead of femoral nerve catheters as part of a multimodal regimen were able to ambulate further on the day after surgery without any difference in pain control.\textsuperscript{313} These findings support a functional advantage for using ACB that does not sacrifice pain control as long as a multimodal analgesic regimen is used.

**CLINICAL EFFECTS**

Several authors noted motor block with the ACB.\textsuperscript{298,299,303} Deloach and Boezaart\textsuperscript{314} noted that the ACB spreads proximal into the femoral triangle and thus covers more nerves than just the saphenous. Gautier et al.\textsuperscript{304} conducted a study in fresh human cadavers and demonstrated spread of the injectate outside the adductor canal and toward the popliteal fossa with some spread in the sciatic distribution. A cadaveric study by Andersen et al.\textsuperscript{315} also noted that 15 mL of injectate into the adductor canal spread throughout the canal and beyond both proximally to the femoral triangle and distally, potentially covering some sciatic distribution.

Because the current options for local anesthetic are not very selective to motor or sensory nerve, the anesthesiologist is limited to choosing the optimal site and concentration. van der Wal et al.\textsuperscript{316} compared the landmark transsartorial approach to the saphenous with saphenous field blocks and found that the transsartorial approach provided 94% success versus 40% success at providing complete anesthesia of the medial malleolus.

**TECHNIQUE**

**Ultrasound Guidance**

With the patient supine and leg and hip externally rotated, the practitioner places the ultrasound transducer on the midthigh, identifies the femur, and medially scans to identify the vastus medialis muscle until the sartorius muscle starts to appear superficial to the superficial femoral artery and vein. At this point, the probe is toggled to increase the echogenicity of the
hyperechoic nerve lateral to the artery. The ultrasound is scanned proximally until the sartorius muscle is symmetrical above the artery (Fig. 52.35). An in-plane or out-of-plane approach can be taken to inject the local anesthetic below the sartorius muscle and adjacent to the nerve (Fig. 52.36).

FIGURE 52.36 Left: Patient position and transducer for adductor canal block. Right: Needle position lateral to the nerve in the adductor canal with local anesthetic surrounding it. Green, local anesthetic. a, femoral artery; m., muscle; n., nerve; v, femoral vein. (Reproduced with permission from Ouanes et al. http://anesthesiology.hopkinsmedicine.org/international-obstetric-and-regional-anesthesia/. Accessed July 18, 2018.)

**Landmark Approach**

The approach of van der Wal et al. is to advance a 20-gauge blunt
Tuohy needle through the sartorius muscle by using a loss-of-resistance technique.

**COMPLICATIONS**

Similar to that seen in other PNBs, complications can include vascular puncture with subsequent local anesthetic toxicity, hematoma, and neurologic trauma. Neal et al. reported a case series of local anesthetic-induced myotoxicity after continuous ACB that significantly impacted the patients’ early rehabilitation and attributed to long-term impairment. Their institutional prevalence for this complication was 0.98/1,000. Clinical concentrations of all local anesthetics have been reported to be myotoxic in animal models, but these toxic effects are noted to be subclinical in humans.

It was not clear why clinically apparent local anesthetic-induced myotoxicity had occurred in patients who received continuous ACB but not in those with known intramuscular injection such as psoas. Continuous ACB is unique in that it occurs in a location similar to that of thigh tourniquet. The authors noted that tourniquet inflation is associated with progressive acidosis within the muscle, whereas myotoxicity is associated with alkalosis. They felt that direct tourniquet injury was unlikely; however, they introduced the idea of a “double hit” contribution of the tourniquet plus continuous ACB.

The degree to which ACB affects quadriceps function or the patient’s ability to safely ambulate postoperatively is controversial. A number of studies have reported that these blocks result in little or no quadriceps weakness when compared with FNB. However, published studies have reported quadriceps weakness after ACB, and a logical explanation would be spread of local anesthetic outside the adductor canal. Therefore, patients should be monitored for motor strength to potentially reduce the risk of falls.

---

**Fascia Iliaca Block**

**INDICATIONS**

The fascia iliaca block (FIB) was originally described as the fascia iliaca
compartment block in children.\textsuperscript{322} Fascia iliaca compartment blocks are designed to be a three-in-one block. They are considered to be an anterior LP block that targets the femoral nerve, lateral femoral cutaneous nerve (LFCN), and obturator nerve.\textsuperscript{323} The goal is to deposit local anesthetic in high volume under the fascia iliaca and allow it to spread over the three earlier mentioned nerves. As it is a fascial compartment block, the FIB is thought to cause less risk of bleeding and nerve injury than the traditional approach to the LP block. The technique has evolved from a landmark fascial click procedure with poor rate of success to an ultrasound-guided procedure with higher rates of success.

The FIB may be used in combination with other techniques to provide anesthesia and postoperative analgesia to the lower extremity. It has been used in procedures such as skin graft harvesting,\textsuperscript{324} incisional pain,\textsuperscript{325} postoperative analgesia after total hip or total knee arthroplasty, and prehospital analgesia in patients with femur fractures.\textsuperscript{326,327}

**TECHNIQUES**

**Landmark Approach**

In the landmark approach, the practitioner should feel a sensation of two facial pops when the needle traverses the fascia lata and then the fascia iliaca. Penetration of both layers is essential to the success of the block. It is recommended that a short-beveled needle or pencil-point needle be used rather than a cutting needle in order to increase chances of appreciating the pops or clicks.\textsuperscript{247}

As described by Dalens et al.,\textsuperscript{328} a line is drawn between the pubic tubercle and the anterior superior iliac spine (ASIS). This line is divided into three equal parts and the junction of the middle and lateral thirds identified. The needle is inserted 1 cm below this point. The blunt needle is advanced until a double pop sensation is perceived. Then, the needle is presumed to have penetrated the fascia lata, and subsequently the fascia iliaca.

**Ultrasound Guidance**

Classic Technique

The patient is positioned supine and the ultrasound probe placed as for an
FNB. The practitioner slides the ultrasound probe laterally to identify the hyperechoic lines of the fascia lata and fascia iliaca. He or she may appreciate the femoral nerve and femoral artery medially on the screen and the iliopsoas deep to the fascia layers. The block may be performed with an in-plane or out-of-plane needle approach. In the out-of-plane approach, the needle is inserted inferior to the ultrasound probe with a slight cephalad direction. Tissue displacement of the fascial planes may be appreciated. Direct visualization of local anesthetic spread below the fascia iliaca confirms correct needle placement. With the in-plane approach, the needle is advanced from the lateral edge of the ultrasound probe and visualized until it reaches below the fascia iliaca and confirmed with injection of local anesthetic.

Suprainguinal Technique
With the patient supine, the ultrasound probe is placed in the parasagittal plane on the ASIS and tilted medially. The probe is then moved medially along the inguinal ligament and kept at the same angle until the “hourglass” or “bow-tie” pattern is recognized, usually at the junction of the lateral one-third and medial two-thirds of the inguinal ligament (Fig. 52.37). The inferior part of the hourglass is formed by the sartorius muscle and the superior part by the internal oblique. The deep circumflex iliac artery is seen just beneath the posterior part of superior hourglass (internal oblique) (see Fig. 52.1). The muscle under the hourglass is the iliacus muscle, and the fascia iliaca can be easily recognized overlying the iliacus muscle. Using an in-plane technique, the needle is introduced in an inferior-to-superior direction. It passes through the sartorius (inferior part of hourglass) and pierces the fascia iliaca. The correct placement of the needle is confirmed by the appearance of local anesthetic that pushes the iliacus down. The spread of local anesthetic is seen as a black lens sitting between the iliacus muscle and fascia. The black lens quickly disappears as the local anesthetic spreads between the fascia iliaca and the iliacus. The needle can be advanced into the hydro-dissected space for more proximal spread of local anesthetic toward the pelvic cavity.329
FIGURE 52.37  Suprainguinal ultrasound image of the fascia iliak block with the hourglass pattern. (Reprinted with permission from Singh H, Jones D. Hourglass-pattern recognition simplifies fascia iliaca compartment block. Reg Anesth Pain Med 2013;38[5]:467–468.)

All of these blocks have been described as volume blocks and require large volumes to sufficiently spread into the fascial plane.

CLINICAL EFFECTS
When comparing the landmark approach to ultrasound-guided FIB, Dolan et al. found that patients who were randomized to the ultrasound group had a greater loss of thigh sensation and greater motor blockade. They found that successful sensory loss in the anterior, medial, and lateral aspects of the thigh increased from 47% by landmark to 82% with ultrasound. The fascial pop or click landmark technique has had reported success rates of only 35% and 47%. The success rate with ultrasound guidance has been reported as 82% and 87%.

The evidence regarding efficacy of FIB for total hip arthroplasty is divided, as two randomized controlled trials have demonstrated no analgesic effect, whereas two others have demonstrated efficacy at decreasing pain scores and opioid consumption. All authors described different techniques. Shariat et al. and Kearns et al. each described using transverse infrainguinal techniques because they had been described as successful in previous studies. Stevens et al. and Bang et al. used suprainguinal approaches to the FIB. Stevens et al. used a double pop technique and Bang et al. used a suprainguinal parasagittal ultrasound technique. Following the article by Shariat et al.,
several letters to the editor pointed out that the distal injection site may explain the lack of effect from the FIB in total hip arthroplasty. Hebbard et al.\textsuperscript{337} described a novel suprainguinal parasagittal ultrasound approach that was successful in more than 150 patients. They supported their claim with a dye study in fresh cadavers, which showed consistent spread of dye in the lateral femoral cutaneous and femoral nerve distributions. Some studies have demonstrated a beneficial effect of the FIB in reducing the incidence of postoperative cognitive dysfunction and perioperative delirium in elderly patients.\textsuperscript{336,338} Others have reported beneficial effect for treating hip fracture pain in the elderly.\textsuperscript{339,340}

**COMPLICATIONS**

Transient femoral neuropathy has been reported after FIB.\textsuperscript{341} Also a knotted fascia iliaca catheter has been reported.\textsuperscript{342}

**Lateral Femoral Cutaneous Nerve Block**

**INDICATIONS AND LANDMARKS**

The LFCN is formed by the L2–L3 root. The nerve emerges from the lateral border of the psoas major muscle deep to the fascia iliaca. It perforates the inguinal ligament approximately 1 cm from the ASIS where it enters the thigh. The LFCN is a sensory-only nerve, and its innervation supplies an inconsistent area of skin over the lateral and anterior thigh.\textsuperscript{247}

Small studies have reported variable success rates with landmark and nerve-stimulation techniques. Hopkins et al.\textsuperscript{343} reported a success rate of 87.5\% with the landmark nerve stimulation technique. Shannon et al.\textsuperscript{344} reported a success rate of 100\% using nerve stimulation to achieve paresthesia for confirmation of LFCN block. The same group also reported a 40\% success rate when using the landmark fanning technique.

Anatomic studies have demonstrated that the distance from the LFCN at the inguinal ligament to the ASIS can range from 3 to 7.3 cm.\textsuperscript{345–347} Ultrasound guidance is particularly suited for injection of a structure such as the LFCN because of its anatomic variability.\textsuperscript{345–347} A study in cadavers and healthy human volunteers showed that the LFCN could be visualized consistently with ultrasound.\textsuperscript{348}
Hurdle et al.\textsuperscript{349} presented a technical description and case series in which they described successful and reliable blockade of the LFCN with ultrasound guidance. Others have described using the ultrasound technique as well.\textsuperscript{349–352} Ultrasound-guided injections of the LFCN provide consistent blockade of the nerve with minimal volumes between 2 and 8 mL.\textsuperscript{351}

**TECHNIQUES**

**Landmark Technique**

The patient position is supine. The LFCN block is performed with a modified field block technique in which a blunt needle is inserted perpendicular to the skin at a point 2 cm caudad and 2 cm medial to the ASIS (see Figs. 52.30 and 52.31). The needle is advanced until a pop is felt as it penetrates the fascia lata. Nerve stimulation can be added, and the patient should be asked if he or she feels a paresthesia or tapping in the lateral aspect of the thigh. If nerve stimulation is used, 5 to 10 mL of local anesthetic is injected whether or not the patient shows a response. If the patient shows no nerve stimulation response, the needle is withdrawn to the subcutaneous skin and redirected medially until a pop is felt and then an additional 5 mL of local anesthetic is administered. The needle is withdrawn to the subcutaneous skin and redirected laterally until a pop is felt and another 5 mL of local anesthetic administered.

**Ultrasound Guidance**

The ASIS is palpated and visualized with the ultrasound probe as a hyperechoic structure with posterior acoustic shadowing. The lateral end of the linear probe is placed on the ASIS, and the medial end extends medially in an anatomic transverse plane. With the probe in this position, the medial part of the probe is angled slightly in a caudal direction so the transducer is parallel with the inguinal ligament. The transducer is gently moved in a medial-caudal direction while the operator searches for the echo signature of the LFCN. With this approach, the LFCN will appear in cross-section as an oval hyperechoic structure containing several circular hypoechoic fascicles.\textsuperscript{349} Alternately, the FNB image is obtained (see Fig. 52.32) and the probe is slid laterally identifying the sartorius muscle. Just
lateral to the sartorius muscle, the LFCN can be visualized (see Fig. 52.37). This structure can be traced distally and often seen splitting into two separate structures and then retraced proximally to where it can be blocked easily (Fig. 52.38). The nerve is often found in the interfascial plane lateral to the sartorius muscle.

**FIGURE 52.38** Ultrasound image of the lateral femoral cutaneous nerve.

**CLINICAL EFFECTS**
Thybo et al.\(^{353}\) studied the effect of ultrasound-guided LFCN in a group of patients that underwent a posterior approach to total hip arthroplasty. They reported no additional analgesic effects of the LFCN block when combined with their standard analgesic regimen of paracetamol, ibuprofen, and oxycodone. They noted that overall, the pain scores were low in all groups. A year later, Thybo et al.\(^{354}\) published the effects of blocking the LFCN after total hip arthroplasty and found that movement-related pain during first hip flexion on postoperative day 1 or 2 was significantly reduced if the baseline pain was moderate or severe. They noted no effect on pain at rest.

LFCN blockade has been described for treating cases of meralgia paresthesia when patients do not respond to oral medications or conservative measures.\(^{355,356}\)

**COMPLICATIONS**
No complications have been reported with this block.

**Obturator Nerve**
INDICATIONS AND LANDMARKS
The obturator nerve arises from the nerve roots of L2–L4. It exits the pelvis inferior to the superior pubic ramus. The nerve travels with the obturator artery and vein through the obturator canal and into the thigh where it branches into anterior and posterior divisions. The anterior division provides innervation to the adductor brevis, adductor longus, pectineus, and gracilis muscles. It also gives off an articular branch to the anteromedial hip capsule and cutaneous branches to the skin over the medial aspect of the thigh. The posterior branch is primarily a motor nerve for the adductors of the thigh; however, it also may provide articular branches to the medial aspect of the knee joint.

The obturator nerve block was first described by Labat in his textbook in 1922. In 1973, Winnie and colleagues described it as part of the 3-in-1 technique along with the LFCN and FNB. In 1993, Wassef described the interadductor approach to blocking the nerve. This block provides anesthesia of the medial distal thigh and can be used in combination with femoral, lateral femoral cutaneous, and sciatic blocks for procedures on the distal thigh and lower leg, and prevention of tourniquet pain during lower leg surgery. The obturator nerve is occasionally blocked to prevent stimulation of the adductor muscles during transurethral resection procedures. The obturator nerve runs close to the lateral bladder wall, where direct surgical stimulation can result in adductor spasm, which causes bladder perforation and other anatomic injuries. Several papers report efficacy of obturator nerve block during transurethral resection surgery.

TECHNIQUES
Landmark Technique
With the patient positioned supine, the femoral artery is palpated and the tendon of the adductor muscle identified at the pubic tubercle. In the inguinal crease, a line is drawn from the femoral artery to the medial border of the adductor longus muscle (identified by abduction of the thigh) (Fig. 52.39). An insulated block needle is inserted at the midpoint of this line aimed cephalad and advanced until stimulation of the adductor muscle is elicited (see Figs. 52.31 to 52.33). The needle is advanced further and
slightly lateral until hip adduction motor response. At that point, 10 mL of local anesthetic is injected. Then, the needle is withdrawn until the original motor response is obtained, and another 10 mL of local anesthetic is injected.

**FIGURE 52.39** Lateral femoral cutaneous nerve block. **Left:** Labeled sonoanatomy. **Right:** Corresponding ultrasound image during injection. LFCN, lateral femoral cutaneous nerve; m., muscle. Green, local anesthetic. (Reproduced with permission from Ouanes et al. [http://anesthesiology.hopkinsmedicine.org/international-obstetric-and-regional-anesthesia/](http://anesthesiology.hopkinsmedicine.org/international-obstetric-and-regional-anesthesia/). Accessed July 18, 2018.)

**Ultrasound Guidance**

With the patient supine and leg externally rotated, a linear ultrasound probe is placed in the transverse orientation in the inguinal crease, and the femoral nerve, artery, and vein are identified. The probe is moved medially to enable visualization of the pectineus, adductor longus, adductor brevis, and adductor magnus muscles. The anterior branch of the obturator nerve is a hyperechoic structure found between the adductor longus and brevis muscles. The posterior branch is a hyperechoic structure found between the adductor brevis and magnus muscles (**Fig. 52.40**). The needle approach may be either in plane or out of plane. The needle is directed in the fascial planes between the adductor longus and adductor brevis muscles for the anterior branch of the obturator and between the adductor brevis and adductor magnus muscles for the posterior branch.
Helayel et al. described a comparison of the interductal approach in 12 cases to the traditional approach in 12 other patients of ultrasound-guided obturator nerve blocks with a success rate of 91%. Kakinohana described the interductal approach to the obturator nerve block in a case series of 12 patients.

**COMPLICATIONS**

Intravascular injection; local anesthetic toxicity; and bladder, rectum, vagina, and spermatic cord injury have all been reported with Labat’s classic approach to the block.

**Sacral Plexus-Sciatic Nerve Block**

**INDICATIONS**

The sciatic nerve block is performed to achieve anesthesia and analgesia of the distal lower extremity, including the anterior and posterior lateral leg, ankle, and foot. The saphenous nerve (branch of the femoral/LP) is the only sensory nerve that innervates the medial aspect of the leg. It is required to achieve complete analgesia or anesthesia to provide sensory block to the medial aspect of the leg below the knee in addition to
landmark technique

**landmarks**

The sacral plexus is formed within the pelvis by L4–L5 and S1–S4. It provides motor and sensory innervation to portions of the entire lower extremity, including the hip, knee, and ankle. The most important nerves of the sacral plexus for surgery of the lower extremity are the sciatic nerve and its terminal branches. The sciatic nerve is a mixture of two large nerves initially bound together by connective tissue. The sciatic nerve exits the pelvis via the greater sciatic notch and beneath the piriformis muscle. In the upper part of the popliteal fossa, the sciatic nerve lies posterolateral to the popliteal vesicles. The sciatic nerve usually divides into the tibial and common peroneal nerves at the upper aspect of the popliteal fossa.\(^{247}\) Vloka et al.\(^{367}\) reported a mean distance of 6 ± 3 cm above the popliteal crease. The tibial nerve provides motor innervation to the ankle flexors and sensory to the plantar aspect of the foot. The peroneal nerve is smaller than and lateral to the tibial nerve. It provides motor supply to the ankle extensor muscles and sensory innervation to the web space of the first two toes. The sural nerve is purely sensory and travels with the tibial and common peroneal nerves. It supplies the posterolateral aspect of the leg and ankle and the dorsal surface of the foot.

**techniques**

Several approaches can be made to this nerve. It can be targeted proximally or distally. The classic proximal approach was first described by Gaston Labat in 1922.\(^{368}\) This approach has undergone several described modifications since the original description.\(^{369–372}\)

**landmark technique**

Classic Labat Approach

The patient is positioned in a modified lateral Sims position with the operative side up. A line is drawn connecting the posterior superior iliac spine with the greater trochanter of the femur. A second line is drawn from the greater trochanter of the femur to the sacral hiatus. A third line is drawn from midline of line 1 to bisect line 2. At this point where the two
lines cross, an insulated block needle is advanced until motor response or paresthesia is elicited. If bone is contacted, the needle is redirected laterally (Figs. 52.41 and 52.42).

FIGURE 52.41 Patient position for the classic Labat approach to the sciatic nerve.

FIGURE 52.42 Illustration of the anatomic landmarks of the classic Labat approach to the sciatic nerve. (Reprinted with permission from Yao FSF. Yao & Artusio’s Anesthesiology. 8th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2016: Figure 47-7.)

Subgluteal Approach
The patient is positioned in a modified lateral Sims position with the operative side up. A line is drawn connecting the ischial tuberosity with the greater trochanter of the femur. A second line is drawn from the center of the first line 4 to 6 cm caudad. Anywhere along line 2 is where the block can be attempted. An insulated block needle is advanced until motor response or paresthesia is elicited (Fig. 52.43). If no motor response or paresthesia is elicited, the needle is redirected medially or laterally.
Anterior Sciatic Nerve Block

With the patient supine and the surgical leg in a neutral position, the practitioner draws a line from the greater trochanter of the femur to the medial thigh parallel to the crease of the groin. At the midpoint of that line, an insulated block needle is inserted perpendicular to the skin until the femur is contacted. The needle is walked off in a cephalad medial direction until it walks off the lesser trochanter of the femur. Motor stimulation of the foot is elicited (Fig. 52.44).
Popliteal Fossa
With the patient in the prone position, the practitioner identifies the borders of the popliteal fossa by slightly bending the knee. The lateral border of this anatomical triangle is the biceps femoris, and the medial border is the semimembranosus muscle. The practitioner measures 5 to 9 cm proximal from the base of the anatomical triangle and inserts a stimulating block needle just off the medial aspect of the lateral border of the triangle until a motor response is observed with nerve stimulation or paresthesia is elicited (Fig. 52.45).
Ultrasound Technique

Classic Technique

The patient is placed in the modified lateral Sims position. Choice of an ultrasound probe depends on the patient’s body habitus. Typically, a low-frequency curvilinear probe is used. The probe is placed on the posterior thigh to identify the hyperechoic femur (with dropout shadow below). The practitioner traces the femur proximally until the greater trochanter is encountered and then slides the probe medially on the gluteus maximus muscle. Deep to the gluteus maximus is the sciatic nerve, and deep to the nerve is the quadratus femoris muscle. The nerve at this level is oval or triangular. It is often visualized at the level of the bones between the ischium and the femur. An in-plane or out-of-plane technique can be employed (Figs. 52.46 and 52.47).

(Reproduced with permission from Ouanes et al. http://anesthesiology.hopkinsmedicine.org/international-obstetric-and-regional-anesthesia/. Accessed July 18, 2018.)

Alternative Technique (Anterior Approach)
The patient is positioned supine with the block leg externally rotated and knee slightly bent. The low-frequency curvilinear probe is placed in the transverse plane over the medial thigh approximately 10 cm below the femoral crease. The sciatic nerve appears as a hyperechoic nerve medial and deep to the femur. It is located between the adductor magnus muscle and the hamstrings. The nerve may be approached in an in-plane or out-of-plane technique.

Lateral Ultrasound Technique with Popliteal Approach
The patient position is usually lateral but may be prone or supine. With the patient in the lateral position, a high-frequency linear ultrasound probe is
placed transversely in the popliteal crease, and the popliteal artery and popliteal vein are identified. Lateral and superficial to the vessels are the two component branches of the sciatic nerve. The tibial is usually larger and medial, and the common peroneal is usually smaller and lateral. The probe usually needs to be tilted toward the foot to increase the echogenicity of the nerves. The nerves are traced cephalad until they join to become the sciatic nerve. The needle may be inserted proximal or distal to the branch point of the nerves. Either an in-plane or out-of-plane needle technique can be used. The needle needs to be adjacent to the nerves in order to coat them with local anesthetic (Figs. 52.48 and 52.49).

Accessed July 18, 2018.)
CLINICAL EFFECTS

Ultrasound guidance has been shown to enhance the quality of popliteal sciatic nerve block compared to that with a single-injection, nerve stimulator-guided block that uses either a tibial or peroneal motor response. According to one study, ultrasound guidance resulted in higher success rates, faster onset, and faster progression of sensorimotor block, without increasing complications. Another study reported that at the transgluteal level, ultrasounds allow a practitioner to easily identify the greater trochanter, the ischial tuberosity, and the sciatic nerve located between them.

A paraneural sheath that surrounds the sciatic nerve needs to be penetrated for optimal local anesthetic spread. Two studies analyzed injections in this space. Andersen et al. showed that dye injected under the paraneurium of cadavers spread along the nerve both proximally and distally. They also noted that when the sheath was not penetrated, the dye did not spread as well. The second study compared patients who had injections of local anesthetic outside the paraneurium to those whose injections were inside the paraneurium. Using three-dimensional ultrasound reconstruction and clinical correlation with sensory exam, the authors concluded that block efficacy was superior when injections were made under the paraneurium. A subparaneural injection hastens the onset time and also increases the duration of the sensory blockade compared to that with circumferential extraneural injection. Another study supported the findings of the first study and further defined the target for local anesthetic injection as the subparaneural space.

Tran et al. performed a randomized comparison between ultrasound-guided subepineural popliteal sciatic nerve block proximal to the bifurcation and ultrasound-guided injection of the individual branches of the peroneal and tibial nerves distal to the bifurcation. They found that compared with separate injections around each nerve (without being subepineural), a single injection at the neural bifurcation has a faster onset time, provides higher success rates, and can be performed more quickly.

Several studies have looked at minimal dosing, optimal local anesthetics, and optimal injection sites. The effective local anesthetic volume for the sciatic nerve block ranged from 0.10 to 0.15 mL/mm² of
cross-sectional nerve area.\textsuperscript{379,380} Other groups have identified the ED50 and ED95 for 0.5% ropivacaine in ultrasound-guided popliteal sciatic nerve block as 6 and 16 mL, respectively.\textsuperscript{381} They had success rates of sensory blockade of 69\% for the tibial nerve and 88\% for the peroneal nerve.\textsuperscript{381} Bang et al.\textsuperscript{382} undertook a prospective study to identify the minimum effective dose of 0.75\% ropivacaine in subparaneural ultrasound-guided popliteal nerve blocks. They found the ED90 to be 9 mL. Taboada et al.\textsuperscript{383} published a prospective randomized comparison between the popliteal and subgluteal approach. They reported the ED95 for adequate block of the sciatic nerve to be 17 mL in the subgluteal group and 30 mL in the popliteal group. The authors concluded that a larger volume of local anesthetic is necessary to block the sciatic nerve at a more distal site (popliteal) than at a more proximal level (subgluteal).

**COMPLICATIONS**
The incidence of nerve injury associated with sciatic PNCs has ranged from 0\% to 1.0\%\textsuperscript{282,384–387} and includes persistent paresthesia after a popliteal sciatic catheter in a patient population followed for an 18-month period.\textsuperscript{282,386} Bondar et al.\textsuperscript{388} reported a pudendal nerve injury after sciatic nerve block with the posterior approach.

**Ankle Block**

**INDICATIONS**
The ankle block was first described in 1922 by Gaston Labat in his Textbook of Regional Anesthesia.\textsuperscript{389} It is carried out to achieve anesthesia and analgesia of the foot. It does not provide anesthesia or analgesia to the ankle. The ankle block targets the terminal branches of the sciatic nerve and saphenous nerve. Five nerves need to be anesthetized. Two are located beneath the deep fascia, and three are in the subcutaneous tissue. The posterior tibial nerve and deep peroneal nerve are found in the deep layer, and the superficial peroneal, saphenous, and the sural nerves are superficial.

**TECHNIQUES**
Landmark Technique
To anesthetize the deep fascial nerves (deep peroneal, posterior tibial), place the patient in the supine position. Start with the deep blocks because subcutaneous infiltration can often deform the surface anatomy (Fig. 52.50).

Deep Peroneal Nerve
Palpation of the extensor hallucis longus (EHL) is often achieved by asking the patient to dorsiflex his toes. Just lateral to the EHL, the block needle is inserted until it contacts bone. Gentle pressure is released from the needle and 2 to 3 mL of local anesthetic without epinephrine is injected. Because this is a blind procedure, a fanning technique is used to increase the chances of successfully blocking the nerve. Fanning is
redirecting the needle and repeating the block in a medial and lateral position with the same puncture site.

Posterior Tibial Nerve
The block needle is inserted posterior to the medial malleolus. Similar to the deep peroneal nerve block, the needle is advanced until bone is contacted. Then, pressure from the needle is released, and 2 to 3 mL of local anesthetic without epinephrine is injected. This procedure is repeated with the needle redirected in a medial and lateral position through the same puncture site.

Superficial Nerves (Sciatic Terminal Branches—Sural and Superficial Peroneal, Femoral Terminal Branch—Saphenous)
The three superficial cutaneous nerves are blocked by injecting local anesthetic without epinephrine into the subcutaneous tissue at the level of the medial malleolus along a line that joins both malleoli over the anterior aspect of the ankle. Usually, an injection volume of 10 to 20 mL is sufficient.\(^{390}\)

**Classic Ultrasound Technique**
To identify the four nerves of sciatic origin, a linear high-frequency probe is used (Fig. 52.51). The tibial nerve is usually located between the medial malleolus and the Achilles tendon posterior to the posterior tibial artery and veins. On the anterolateral aspect of the ankle next to the anterior tibial artery, the deep peroneal nerve can be identified. The superficial peroneal nerve is scanned before it becomes subcutaneous 10 to 15 cm proximal to the lateral malleolus. The sural nerve is located between the lateral malleolus and the Achilles tendon, close to the saphenous vein.\(^{391}\) Injection of 3 to 8 mL of local anesthetic per nerve has been described.\(^{391}\) The goal is to surround the nerve in anesthetic.
FIGURE 52.51  Probe position and ultrasound images of the nerves at the level of lower leg and ankle. AT, Achilles tendon; DPN, deep peroneal nerve; MM, medial malleolus; PM, peroneal muscles; SPN, superficial peroneal nerve; SuN, sural nerve; TN, tibial nerve. (From López AM, Sala-Blanch X, Magaldi M, et al. Ultrasound-guided ankle block for forefoot surgery: the contribution of the saphenous nerve. Reg Anesth Pain Med 2012;37[5]:554–557.)

CLINICAL EFFECTS

Compared with the conventional approach, the application of ultrasound increases the success rate and reduces the onset time of the ankle block.\textsuperscript{392–394} Rudkin et al.\textsuperscript{390} conducted a prospective study on 1,000 landmark ankle blocks. They found a success rate of 94.7\% and attributed the short time frame between block and incision as a risk factor for block failure. Meyerson et al.\textsuperscript{395} published their landmark ankle block experience on 1,295 patients and reported a success rate of 95\%.

Redborg et al.\textsuperscript{392} randomized 18 volunteers to ultrasound-guided or landmark sural nerve block at the ankle. They found that ultrasound use led to a more complete and longer lasting sural nerve block than did the traditional landmark technique. Although multiple techniques have been described, little evidence-based medicine is available to evaluate different techniques for blocking the tibial nerve at the ankle. Therefore, the same researchers also compared the effectiveness of ultrasound-guided and landmark-guided blocks of the tibial nerve at the ankle. The tibial nerve is arguably the most important nerve to anesthetize during an ankle block because it provides the majority of sensation to the foot. They noted a 72\% success rate (defined as complete block at 30 minutes) with the ultrasound-guided technique but only a 22\% success rate in the landmark group.\textsuperscript{394}
Lopez et al.\textsuperscript{391} found that the ultrasound-guided ankle block was highly effective for bunion surgery and that every nerve in the ankle was successfully blocked within 10 minutes of injection.

**COMPLICATIONS**

Noorpuiri et al.\textsuperscript{396} raised concern for the possibly of masking acute compartment syndrome after forefoot revision arthroplasty in a patient with ankle block. Myerson et al.\textsuperscript{395} published a complication rate of 0.3\% and described it as local anesthetic toxicity.

**Quadratus Lumborum Block**

**INDICATIONS**

The quadratus lumborum block (QLB) is a more posterior extension of the TAP block. It was first described by Blanco in 2007 at a scientific meeting as a technique for postoperative abdominal analgesia. He later wrote that the analgesic efficacy obtained from the TAP was superior when it spread beyond the TAP plane and into the thoracic paravertebral space.\textsuperscript{397} Several variations of optimal injection points have been described. Blanco originally described deposition of local anesthetic at the anterolateral border of the QL, a technique he named the QL1 block. He noted that the spread pattern of local anesthetic obtained by the QL1 was similar to that of the landmark TAP with thoracic paravertebral spread.\textsuperscript{397,398} In a randomized controlled trial for postoperative pain control, Sauter et al.\textsuperscript{399} published a modified version of the block that used a transmuscular QL injection and clearly identifiable landmarks, which they coined the “shamrock” method. The shamrock sign is made up of the following four components: the erector spinae, the QL, the psoas major muscle, and the transverse process of the L4 vertebra (Fig. 52.52). Borglum’s group\textsuperscript{400} demonstrated that the original QLB is characterized by a 30-minute block onset time and that a single 30-mL injection of ropivacaine 0.375\% will anesthetize both the lateral and anterior cutaneous branches from T7 to L1–L4. The transmuscular approach involves injection of local anesthetic in the plane between the QL and psoas major muscles. This technique has mostly been described as a single-shot procedure. Chakraborty et al.\textsuperscript{401}
reported success when they left the catheter between the QL and transversalis fascia. Blanco also offered the possibility of depositing the local anesthetic posterior to the QL muscle between the QL and transversalis fascia and coined this the QL2 block\textsuperscript{397} (Fig. 52.53).

**FIGURE 52.52** Shamrock lumbar plexus block. **A:** The psoas muscle, erector spinae muscle, quadratus lumborum (QL) muscle, and the L4 transverse process represent the pattern of a shamrock. **B:** The star and arrow indicates the L3 spinal nerve root. **C:** The point of needle insertion is situated on a line representing the intersection of the ultrasound beam with the skin. **D:** The cannula (marked with arrowheads) is advanced in a posterior-anterior direction. (From Sauter AR, Ullensvang K, Niemi G, et al. The Shamrock lumbar plexus block: a dose-finding study. Eur J Anaesthesiol 2015;32:764–770.)
The QLB is indicated for abdominal surgeries because it provides analgesia to visceral and somatic nerves. Some say that it produces better analgesia than a TAP block because it not only provides analgesia to the anterior abdominal wall but also blocks visceral pain.

A landmark approach has not been described.

ULTRASONIC TECHNIQUE

Quadratus Lumborum 1

With the patient in a lateral or prone position, a curvilinear probe in the transverse orientation is placed superior to the iliac crest. The transducer is then moved dorsally until the QL muscle is identified with its attachment to the lateral edge of the transverse process of the L4 vertebra. The shamrock landmarks are identified as the psoas major muscles anteriorly, the erector spinae muscle posteriorly, and the QL muscle adjacent to the transverse process (Fig. 52.52A).
FIGURE 52.54  Modified single-injection technique for PECS I and PECS II. A: Scanning ultrasonogram showing the third rib (R), pleura (P), serratus anterior (SA), pectoralis minor muscle (Pmm), and pectoralis major muscle (PMm). B: Needle (N) enters in plane, strikes the rib, and withdraws a little to lie above SA. C: Needle is withdrawn to give the PECS I injection (1) between PMm and Pmm, after injecting the PECS II injection (2) between SA and Pmm. The local anesthetic (LA) is seen spreading between the muscles as a hypoechoic layer. (From Chakraborty A, Khemka R, Datta T, et al. COMBIPECS, the single-injection technique of pectoral nerve blocks 1 and 2: a case series. J Clin Anesth 2016;35:365–368.)

CLINICAL EFFECTS
The literature available for the QLB includes several case reports describing the successful use of the QLB and continuous QLB catheters. A review of the evidence by Abrahams et al. in 2016 gave the evidence a grade of B based on one level Ib study, one level IIb study, and five level III studies that all supported the use of ultrasound for QLBs.

COMPLICATIONS
No complications have been reported as of the writing of this chapter. However, because possible damage to intraperitoneal structures have been reported in the TAP literature and this block was developed as an extension of the TAP, it is not unreasonable to be concerned by the
potential for similar complications to that seen with TAP blocks. 

**PECS/Serratus Anterior Plane Block**

**INDICATIONS**

Thoracic wall blocks, which include PECS I, PECS II, and the serratus anterior plane (SAP) block, are novel, ultrasound-guided fascial plane blocks that are thought to provide anesthesia or analgesia to the chest wall without the neuraxial risk associated with epidural and paravertebral blocks. The PECS I was originally described by Blanco in 2011. The report described depositing local anesthetic adjacent to the thoracoacromial artery in the fascial plane between the pectoralis major (PMm) and Pmm to target the lateral pectoral nerve and medial pectoral nerve. The original block was subsequently modified by Perez et al. and further refined to include more analgesic coverage by Blanco et al., which the group called PECS II. The PECS II is performed more laterally with the local anesthetic deposited in the fascial plane between the Pmm and the serratus anterior muscle at the level of the third and fourth ribs (see Figs. 52.55 and 52.56). The broader coverage of the PECS II includes the long thoracic nerve and thoracic intercostal nerves. Sensory testing showed analgesia of T2–T4 dermatomes. Blanco et al. described good results with single injections and catheters in over 100 patients. Chakraborty et al. even further modified the block to a single insertion site (Fig. 52.54). Two years after the PECS I was introduced, Blanco’s group went on to describe a variation of the PECS II block known as the SAP block, with improved analgesia. Blanco et al. described the SAP block in four healthy volunteers and reported that it provided sensory dermatomal analgesia of T2–T7. The local anesthetic could be injected either superficially or deep to the serratus anterior muscle with the superficial one providing double the analgesia (see Figs. 52.55 and 52.56).

The indications for PECS blocks include superficial anterior chest wall procedures such as pacemaker insertions; postoperative analgesia for breast surgeries such as lumpectomies, mastectomies, and breast tissue expanders; and even arteriovenous fistulas revision to cover the intercostobrachial nerve.
A landmark approach has not been described.

**ULTRASOUND TECHNIQUE**

**PECS I and PECS II**

The patient is placed supine, and a linear array ultrasound probe is held in the parasagittal plane. The clavicle is identified cranially, and the pertinent sonoanatomy is identified from superficial to deep: the PMm and the Pmm deep to it. Between the PMm and Pmm, the thoracoacromial artery is identified. Deep to the pectoral muscles are the axillary artery, vein, and cords of the brachial plexus. With a medial tilt of the ultrasound probe, the serratus anterior muscle, intercostal muscles, ribs, and pleura are identified. The second rib is usually encountered first if the probe is traveling from a cephalad to a caudad path, with the clavicle identified first on screen. The probe is rotated toward the axilla. The needle is introduced from a cephalomedial orientation to caudolateral position. The practitioner should pass the needle through PMm, avoiding the thoracoacromial artery, and deposit 10 to 20 mL of local anesthetic between the Pmm and serratus muscle at the level of the third rib. The targeted nerves here are the lateral rami of the intercostal nerves and the long thoracic nerve. The practitioner then withdraws the needle and injects 10 mL of local anesthetic into the interfacial plane between the PMm and Pmm lateral to the thoracoacromial artery (Figs. 52.55 and 52.56).
Serratus Anterior Plane Block

With the patient lateral, the ultrasound probe is moved caudally and laterally from the PECS II position toward the midaxillary line. At the level of the fifth rib, 20 mL of local anesthetic is deposited either superficial or deep to the serratus anterior muscle. Directing the needle trajectory toward the fifth rib decreases the chance of pneumothorax by providing a bony stop for the needle if it is inadvertently advanced too
The described difference of analgesic duration was double if local anesthetic was injected superficial to the serratus anterior muscle (see Figs. 52.55 and 52.56).

**CLINICAL EFFECTS**

The advantage of the PECS blocks over paravertebral or thoracic epidural is that they are theoretically less risky and simple to perform for those facile with the ultrasound and are not contraindicated when a patient is on anticoagulation.

Because it is a relatively new block that has undergone refinement and evolution, not many clinical studies have evaluated the efficacy of this technique. Wahba and Kamal\(^{416}\) compared ultrasound-guided PECS I and PECS II blocks with landmark-guided thoracic paravertebral block at the T4 level in patients undergoing a modified radical mastectomy. They found that the PECS group required less opioid intraoperatively and reported better postoperative pain control. The study compared an ultrasound technique to landmark-guided, single-level paravertebral block with half the local anesthetic volume as the PECS group. Additional studies are warranted to compare multiple-level paravertebral blocks.

The literature available for the SAP block is limited to case reports describing successful single-shot and catheter techniques for breast surgeries and thoracotomies.\(^{410,417–420}\) A review of the evidence by Abrahams et al.\(^{404}\) in 2016 gave the evidence a grade of A based on one level Ib study, one level IIb study, and two level II studies that all supported the use of ultrasound for PECS blocks.

**COMPLICATIONS**

No complications have been reported as of the writing of this chapter. However, pneumothorax and vascular injury to the thoracoacromial vessel are possible with this technique.

**Complications of Peripheral Nerve Blocks**

Complications associated with PNBs are rare. In addition to the complications specific to certain blocks that were discussed earlier, some
complications are relevant to all PNBs. They can be divided into two groups: neurologic complications resulting in sensory deficits, paresthesia, motor deficits, and pain; and nonneurologic complications, including those related to local anesthetic systemic toxicity, infection, and bleeding.

**NEUROLOGIC COMPLICATIONS**

The reported incidence of neurologic complications associated with regional anesthesia can vary because of multiple factors such as inadequate sample size, the different definitions of complications and their duration, the accuracy of patient follow-up to identify potential complications, and the limited ability of postoperative testing to discern among different causes for postoperative neurologic injury.\(^4\) Horlocker et al.\(^5\) reported that 89% of postoperative neurologic injuries after ANB were the result of the surgical procedure, whereas 11% were related to the anesthetic technique. Although early postoperative neurologic symptoms are relatively frequent during the first month, their incidence reduces progressively with time. According to the largest studies performed since 2002, the incidence is 1.49/10,000 for deficits lasting up to 6 months (Table 52.2).

The mechanisms associated with peripheral nerve injury (PNI) may be mechanical, ischemic, or neurotoxic. Mechanical trauma related to the block needle may distort the nerve anatomy and cause histologic derangement, particularly when the needle tip disrupts the perineurium, resulting in an intrafascicular injection. Intraneural injections can increase intraneural pressure, potentially causing neural ischemia. Additionally, intrafascicular injections elevate the neurotoxic effect of local anesthetics by direct exposure to the axons, while simultaneously prolonging the duration of this exposure. Current ultrasound technology does not allow for differentiation between intrafascicular and interfascicular (also referred to as subepineurial) injections. The introduction of ultrasound for regional anesthesia in the last few decades has not been associated with a decrease in PNI. Although some small studies have reported intrafascicular injections not resulting in PNI, the American Society of Regional Anesthesia and Pain Medicine advises against intentional intraneural injections. In addition to anesthetic factors, surgical-related risk factors may also result in mechanical and/or ischemic PNI from traction, stretch, transection, or compression injuries related to tourniquet, casts, dressings, hematoma formation, or compartment syndrome.

Additionally, certain risk factors may also predispose patients to
anesthesia-related PNI. Such factors involve preexisting neuropathies, whether clinical or subclinical, related diabetes, prior exposure to chemotherapy, entrapment neuropathies, or other metabolic diseases. A recent retrospective review of 380,680 anesthetic cases found diabetes, tobacco use, and hypertension to be independent risk factors for postoperative PNI.\textsuperscript{430}

**POSTSURGICAL INFLAMMATORY NEUROPATHY**

Awareness has increased in recent years of the role of autoimmune or inflammatory pathways leading to neurologic deficits in postoperative patients. This condition has been termed postsurgical inflammatory neuropathy and is believed to result from an immune-mediated response to a physiologic stress such as surgery, vaccination, or infection.\textsuperscript{431} The distinctive features that set it apart from other postsurgical neuropathies are as follows: delayed appearance (within 30 days, although immediate symptoms have also been described) with a return of neurologic function to postoperative baseline before the onset of symptoms, deficits in a distribution unrelated to anesthetic or surgical procedures, and symptoms originating with pain that subsequently subside and give rise to weakness. Radiographic imaging is negative, and the diagnosis is confirmed with a peripheral nerve biopsy, which demonstrates microvasculitis and axonal loss.\textsuperscript{432} Current treatment of choice is immune suppression with high-dose corticosteroids or immunoglobulin.\textsuperscript{421} It is important to consider the possibility of postsurgical inflammatory neuropathy when confronted with patients exhibiting typical symptoms because most will improve if diagnosed and treated early. This approach is in contrast to the common management of conservative observation for other postoperative neuropathies.\textsuperscript{431}

**NONNEUROLOGIC COMPLICATIONS**

Most case reports of hematomas associated with PNBs involve patients on anticoagulants despite observance of the ASRA guidelines. At highest risk are PNBs near vascular structures in expandable or noncompressible sites. Many of the cases of hematoma after PNB in patients with anticoagulation involve lumbar paravertebral blocks.\textsuperscript{258,262,433} Consequently, these blocks
traditionally have been managed according to ASRA’s guidelines for neuraxial anesthesia, whereas evidence to support recommendations with most other PNBs in patients taking anticoagulation or antiplatelet therapy is lacking. In the guidelines for pain procedures in patients on anticoagulant or antiplatelet therapy, ASRA included PVBs and epidurals in the same intermediate-risk procedure category. Symptoms associated with PNB hematoma include pain, drop in hemoglobin concentration, hypotension, and sensory or motor deficits. Diagnosis involves ultrasound or CT, and treatment may be conservative or require surgical evacuation.

Infectious complications related to PNBs are rare. Capdevila et al. reported the incidence of bacterial colonization of PNB catheters to be 28%, with 3% of patients exhibiting local signs of inflammation. There were no cases of bacteremia. Independent risk factors for local infection were postoperative monitoring in intensive care, catheter duration greater than 48 hours, male sex, and absence of antibiotic prophylaxis.

Local anesthetic systemic toxicity also has a very low incidence that ranges from 0.08 to 0.98/1,000 PNBs according to different studies. Patients may show signs of CNS toxicity (agitation, confusion, seizure, somnolence, and apnea) and/or cardiovascular toxicity (hypertension, tachycardia, arrhythmias, hypotension, bradycardia, asystole). Cardiac toxicity occurs from binding of local anesthetic to sodium channels. Especially susceptible are patients in the extremes of age and those with heart failure or ischemic heart disease. The treatment is supportive, managing the patient’s airway to prevent hypoxia and acidosis (both of which increase local anesthetic toxicity), treatment of seizures with a benzodiazepine or propofol, and lipid emulsion therapy. If cardiac arrest ensues, advanced cardiac life support (ACLS) algorithm should be initiated, with slight modifications: Epinephrine should be used with smaller initial doses because it is arrhythmogenic, and vasopressin is not recommended.

**SUMMARY OF TREATMENT OF LOCAL ANESTHETIC SYSTEMIC TOXICITY**

- Get help.
- Initial focus
Airway management: Ventilate with 100% oxygen.
Seizure suppression: Benzodiazepines are preferred; avoid propofol in patients with signs of cardiovascular instability.
Alert the nearest facility having cardiopulmonary bypass capability.

- Management of cardiac arrhythmias
  - Basic and ACLS with medication adjustments
  - Avoid vasopressin, calcium channel blockers, β-blockers, or local anesthetic.
  - Reduce individual epinephrine doses to <1 µg/kg.

- Lipid emulsion (20%) therapy
  - Bolus 1.5 mL/kg (lean body mass) intravenously over 1 minute
  - Continuous infusion 0.25 mL/kg/min
  - Repeat bolus once or twice for persistent cardiovascular collapse.
  - Double the infusion rate to 0.5 mL/kg per minute if blood pressure remains low.
  - Continue infusion for at least 10 minutes after attaining circulatory stability
  - Recommended upper limit: approximately 10 mL/kg lipid emulsion over the first 30 minutes

For local anesthetics dosing recommendations, see Tables 52.3, 52.4, and 52.5.

**Summary**

Regional anesthesia techniques are one of the analgesic strategies available
when implementing a multimodal approach to postoperative analgesia. Such techniques include neuraxial as well as PNBs and involve depositing local anesthetics perineurally. The blocks may be performed as continuous techniques for prolonged duration of action, and adjuvants can be added to the local anesthetic in order to improve analgesia, prolong the effect of the block, or reduce adverse effects. The choice of block is largely dependent on the location of the target area, and the majority of the blocks can successfully be performed via landmark techniques, nerve stimulation, ultrasound guidance, or a combination thereof.

If burn injuries in themselves are not the most painful type of trauma a person can sustain, then they likely reach this status once the nature of their treatment is considered. Contemporary treatment of burn injuries involves a multitude of invasive and rehabilitative procedures that continue—often on a daily basis—for days, weeks, or months. Each intervention is critical to achieving optimal wound healing and long-term physical/occupational function yet has the potential for inflicting more pain, on a repeated basis, than that of the initial trauma. Burn injuries are pervasive in both industrial nations and developing countries around the world and affect individuals across a wide demographic span. In the United States, it is estimated that burn injuries account for 40,000 hospitalizations annually (about half of these hospitalizations are children or adolescents) and 3,275 deaths.\(^1\) This is down from 5,500 deaths just 15 years ago. As death rates for burn injuries decline, due primarily to burn prevention strategies and improved surgical care, more patients with large burns are surviving and pose unique physical and psychological rehabilitation challenges such as scarring, contractures, amputations, psychological adjustment, and pain.\(^2\)

Despite this increased challenge to provide effective pain relief, there has long been substantial evidence that pain from burn injuries is undertreated, particularly in children and the elderly.\(^3,4\) Furthermore, the magnitude of pain reported after burn injury and during burn care correlates strongly with long-term adverse psychological outcome in this patient population.\(^5,6\) Thus, there are humane, medical, and economic reasons to better control burn pain in a practical and cost-effective fashion. Pain management is closely tied to a patient’s satisfaction with care, and uncontrolled pain is associated with poorer long-term outcomes in both
adults and children.\textsuperscript{7–11} Evidence-based pain management protocols have been shown to reduce pain.\textsuperscript{12} Both the United States and New Zealand have developed clinical guidelines for the management of burn pain that were based on rigorous standards for evaluation and treatment,\textsuperscript{13,14} and the American Burn Association has identified priority topics for research and additional clinical guidance.\textsuperscript{15}

**The Nature of Burn Pain**

Treating the human suffering from burn pain is challenging from the perspectives of both the patient and clinician. It is well known that a burn injury results in one of the most intense types of sensory nociception imaginable, attributable to the unique tissue injury that results from a thermal insult to the dermal sensory organs and acute inflammatory response that, at least in the early postburn period, is related to the depth of tissue injury (Figs. 53.1 and 53.2).

![FIGURE 53.1 Anatomic layers of skin. Graphic representation of skin layers including the outer epidermis, the thin papillary dermis, the collagen-dense reticular dermis, and the deep subcutaneous fat. The dermal sensory neurons of mechanoheat receptors and dermal capillaries are shown, relative to a first-degree burn injury (confined to the outer epidermal skin layer). (Reprinted from Sharar SR, Patterson DR, Wiechman-Askay S. Burn pain. In: Waldman SD, ed. Pain Management. 1st ed. Philadelphia: Saunders-Elsevier; 2007:240–256. Copyright © 2007 Elsevier. With permission.)](image-url)
First-degree burns (e.g., sunburn) are characterized by tissue injury that is limited to the epidermal skin layer and an inflammatory response in the superficial dermal layers and results in hyperemia (manifest as erythema), an intact epidermis (no skin blistering), and sensitization of dermal sensory organelles producing hyperalgesia and mild to moderate pain. Second-degree or partial-thickness burns involve tissue injury that extends to variable depths into the dermis; superficial second-degree burns involve only the upper, papillary dermis and are more likely to heal spontaneously, whereas deep second-degree burns involve the deeper, collagen-dense reticular dermis and are more likely to require surgical treatment. Because second-degree burns consistently injure and/or inflame sensory receptors in the dermis, these burns are associated with marked hyperalgesia and produce moderate to severe pain. Third-degree burns are characterized by complete destruction of the dermis, including its sensory and vascular...
structures, such that although pain may still be a presenting symptom, hypalgesia to cutaneous stimulation, a leathery skin texture, and lack of capillary refill are common. Complaints of acute pain with third-degree burns are typically minimal but can be variable and are universally present with respect to the transition zone between burned and unburned skin. All burn injuries involving the dermis (i.e., second- and third-degree) result in sensitized and reorganized states of both peripheral mechanoeheat receptors and dorsal horn neurons. Models of these cellular alterations provide a conceptual framework for understanding how such peripheral neuronal injuries that are present after a burn can cause acute and subacute pain, hyperalgesia, and chronic pain and are described in detail elsewhere.\textsuperscript{16,17}

In addition to the significant pain caused by the burn injury itself, the major clinical analgesic challenge results from procedural and postoperative pain associated with contemporary burn care, which incorporates a series of aggressive procedures that stimulate nociceptive peripheral afferent fibers on a daily basis for days, weeks, or months after the initial injury. In the typical treatment paradigm, a burn injury will first be assessed as to its depth and then treated accordingly. Shallow burns will be left to heal on their own, and full-thickness thermal injuries will typically be excised and covered with a skin graft. Burns of indeterminate depth in many burn centers will undergo a series of wound débridements and dressing changes, typically on a daily basis, until burn depth can be more accurately determined. Burn care–related pain can be anticipated and treated, to a large degree, based on the clinical setting in which the pain occurs. Wound débridement, limb/joint mobility exercises, therapeutic skin stretching, and other medical procedures result in procedural pain, which is of high intensity but limited duration. Patients who are between procedures and have minimal physical activity continue to experience resting pain that is relatively less intense but almost constant in duration. When pain control interventions fail to control resting pain, patients will experience breakthrough pain. Finally, because surgical interventions are a frequent treatment for severe burn injuries, postoperative pain is an additional type of pain to be considered. Each of these four types of burn pain has specific treatment strategies, as described later in this chapter.

In addition to these four distinct yet overlapping clinical settings, burn
pain varies somewhat temporally with the phase of treatment, most often divided into the resuscitative, healing, and remodeling phases.\textsuperscript{17} In the resuscitative phase immediately after the injury, the patient is stabilized hemodynamically and initial wound treatments are performed. This phase is usually of short duration (e.g., hours), but depending on the size of injury can last up to 72 hours, as in the case of large surface area burns. Initial wound care in this phase is often intensely painful and, in the rush of treating life-threatening events, analgesia may be unintentionally deemphasized. Pain in the healing phase is characterized by repeated episodes of burn wound care and dressing changes, wound examinations, needle sticks for intravenous (IV) access or blood sampling, and surgical procedures including débridement and grafting. The healing phase can last from days to several weeks depending on the severity of the burn and progress of the systemic response to the injury. It has been reported that hyperalgesia is more severe during this phase, independent of the size and degree of the burn. In the remodeling phase, the systemic and local inflammatory responses decrease, wound healing is nearing completion, and rehabilitative activities gain emphasis. Depending on the characteristics of the wound scar, this phase is characterized by not only reductions in resting pain but also ongoing episodic procedural pain associated with physical and occupational therapy sessions. It is important to note that the duration and sequence of these phases can vary depending on the clinical progress of wound treatment. For example, a patient who has progressed to the remodeling phase can return to the healing phase after a surgical procedure recreates an open wound (e.g., burn site or skin graft donor site).

Although the clinical and temporal settings of burn care can provide some prediction as to the pain a patient might experience, the magnitude and quality of a given individual’s pain experience have proven extremely difficult to anticipate. The sensory and affective qualities of burn pain have received scant attention in the literature, and few studies have addressed pain patterns over the course of hospitalization. For example, Choinière and colleagues\textsuperscript{18} observed the evolution of burn pain experienced over the course of hospitalization and found that it varied substantially both within and across patients over time. They also reported that burn pain was not
accurately predicted by sociodemographic factors or burn size (the latter finding is contrary to the inaccurate assumptions of many clinicians inexperienced in treating burns). Similarly, patient pain reports do not correlate with the quantity of opioid analgesics received, a finding first published in 1981 and still reported over two decades later.\textsuperscript{3,19} This unpredictable and often opioid-resistant nature of burn pain has been hypothetically linked to underlying sensory nerve damage\textsuperscript{20,21} and contributes to the difficulty of effectively treating burn pain.

Although capturing the pain experience of an individual patient will likely continue to prove elusive for the reasons listed, it remains important to continue to treat burn pain aggressively. Not only can burn recovery (like that from any trauma) be hindered by the presence of acute pain,\textsuperscript{22–24} burn pain has also been reported to influence posthospitalization emotional recovery more than the size of the burn, the duration of hospitalization, or even the patient’s preinjury mental health. Ptacek and colleagues\textsuperscript{5} reported that inpatient pain scores in adults correlated more strongly with distress and quality of life scores at 1 month after discharge than did any other independent variable studied, a finding that persisted at 1- and 2-year follow-up periods.\textsuperscript{6} Similarly, Saxe et al.\textsuperscript{25} reported that the amount of morphine received by burn-injured children may impact their subsequent development of posttraumatic stress disorder (PTSD). Future studies will likely further substantiate the practical utility of adequately treating burn pain.

**Psychological Factors**

It is well known that pain processing may be largely subjective and that the degree to which pain is interpreted as a threat will influence how much patients will suffer. A burn injury is a form of trauma that has dire emotional consequences for many survivors, and the threat value of the injury will likely have an impact on the amount of pain they perceive. Moreover, the nature of a patient’s preinjury psychological makeup also has a great deal to do with how much pain he or she will perceive. In considering psychological factors, it is then important to consider the preinjury status of patients as well as their emotional adjustment during
and after hospitalization.

Burn injuries often occur when people are at risk because of low social resources or because of personality and/or psychiatric factors. The estimates of preinjury psychological problems in some studies of burn patients are so high that injuries of this type should be considered to be, in part, a symptom of social ills.26 Estimated rates of psychiatric diagnoses in patients admitted for burn care have ranged from 25% to 75%, with the most prevalent diagnoses including depression, personality disorders, and substance abuse.26 Psychopathology and psychological problems are common in patients with burn scars that impact body function and image.27 In addition, the nature in which the burn injury occurred is often cause for concern: suicide attempts, child and elder abuse (or neglect), domestic violence, illicit drug manufacturing (methamphetamine production, hash oil production), and juvenile fire setting are all common sources of the injury. Psychological disturbances that predate the burn injury have the potential to increase complications, lengthen hospital stays, and lead to more serious long-term adjustment problems.28,29 A number of these preinjury complications have direct relevance to pain control. Patients with drug and alcohol histories may show lower pain tolerance, more delirium, and higher drug-seeking behaviors. Particularly, those with a prior opioid addiction will be more sensitive to pain and greater have a greater tolerance to opioids. Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) Axis II character disorders can present a particular challenge to clinicians. Patients with such personality predispositions may show not only drug-seeking but also dramatic acting out behaviors, manipulation, staff splitting, and low frustration tolerance. Patients with borderline personality disorders, in particular, engage in parasuicide behavior and self-mutilation. All of these factors might complicate pain control, in addition to making the patient’s overall management a challenge.

Both the burn care environment and psychological reactions to burn injuries contribute to pain and complications in its management. Patients with large unhealed burn areas or other significant medical complications are usually placed in intensive care units (ICUs). In the critical care setting, delirium and other psychotic reactions are common.30,31
been recent emphasis on managing delirium more aggressively in the ICU as it leads to complications such as more infections, respiratory problems, and longer lengths of hospitalization. Unfortunately, there is a dilemma in achieving optimal management as opioids and anxiolytics are needed for pain control but are the primary contributors to delirium. Furthermore, uncontrolled pain can also increase delirium. Finding appropriate doses requires constant vigilance and adjustment. Poor communication from altered mental status or endotracheal intubation may further impede pain assessment. Anxiety is commonly reported by burn-injured patients, both at greater levels than reported to be tolerable and for prolonged periods throughout hospitalization. As a result, anxiety assessment tools specific for burn-injured patients have been reported and validated and may predict burn pain and postdischarge functional capacity better than other anxiety assessment tools. As hospitalization persists and patients show greater mental capacity, depression becomes increasingly common and is well known to interact with pain. Depressive symptoms have a prevalence as high as 54% during postburn hospitalization and are a significant predictor of physical health at 2 months postdischarge. PTSD is another complication that can negatively impact pain control as PTSD can cause agitation and hypervigilance.

The manner in which the burn environment and patients’ personality factors can amplify pain is particularly notable in children, for whom the burn unit environment can be extremely strange and frightening. There is little opportunity for the burn staff to prepare children psychologically for the repeated medical procedures they must endure, and conditioned anxiety to the stimuli associated with burn care can be expected. Children will also often demonstrate regression and behavioral acting out in response to hospitalization, making pain control during procedures a particular challenge. It should be noted that although many burn centers have pediatric-specific pain protocols, their emphasis is appropriately on safety; hence, they are often not aggressive enough to adequately address pain or prevent procedural anxiety in every child. As previously mentioned, aggressive treatment of pain may serve to reduce the subsequent development of PTSD in children. A comprehensive review of issues specific to pediatric burn pain can be found elsewhere.
There is growing evidence that although pain was once thought to be a problem only during the early phases (e.g., resuscitative and healing phases) of burn care, a significant number of patients experience ongoing pain long after hospital discharge. For example, a long-term, neuropathic pain syndrome has been recently described in burned patients, presenting approximately 4 months after the initial injury \(^{40}\) and persisting for an average of 13 months. Similarly, in a survey of 358 respondents of a burn survivor support group, \(^{41}\) 52% reported ongoing pain, 66% said that it interfered with their rehabilitation, and 55% said the pain interfered with their daily lives. Respondents in this study also reported that thoughts of the accident and depression made their pain worse. Although much research has been done to address acute pain control after a burn injury, little is known about ongoing opioid needs once patients are discharged. Wibbenmeyer et al. \(^{42}\) tracked opioid use from discharge to the outpatient setting and found that 85% of patients were on opioids at discharge with a morphine equivalent (ME) of 114. Although 90% had weaned off by 14 days postdischarge, these high doses are within the range (50 to 100 ME) associated with harmful drug effects reported in nonburn populations. \(^{43}\) Furthermore, patients may show persistent depression, anxiety, or PTSD that can interfere with pain control, with both depression and anxiety predicting worse outcomes in pain, fatigue, and physical functioning assessments up to 2 years postdischarge. \(^{44}\) Sleep problems are prevalent, yet frequently overlooked in postdischarge phase, and may reflect inadequate pain treatment. \(^{45}\) When psychological or pain problems persist long after hospital discharge, the possibility of social or financial disincentives should be entertained. Although some patients will certainly have internally generated psychological problems, for others, the issues will persist because of such factors as litigation or the desire to avoid returning to an undesirable job.

**Generalized Treatment Paradigm for Burn Pain**

Because burn pain is highly variable and cannot be reliably predicted by either clinical assessment of the patient or his or her burn wound, we recommend a structured approach to burn analgesia that incorporates both
pharmacologic and nonpharmacologic therapies, targets specific pain issues unique to the burn patient, and can be tailored to anticipated variations in patient need and institutional capability. One clear goal of such a paradigm is to avoid the undertreatment of burn pain.

In the generalized burn pain management paradigm, selection of an analgesic regimen is individualized and based on two broad categories: (1) the clinical need for analgesia (i.e., treatment of background vs. procedural vs. postoperative pain) and (2) limitations imposed by the patient (e.g., presence of IV access, endotracheal tube, or opioid tolerance) or by clinical facilities (available monitoring capabilities and personnel). The presence or absence of IV access directly influences analgesic drug choice, particularly in children in whom IV access may be problematic. Patients who are endotracheally intubated and ventilated are “protected” from the risk of opioid-induced respiratory depression; thus, opioids may be more generously administered in these individuals, as is often indicated for complex burn débridement procedures in patients with more extensive or severe burn injuries. Individual differences in opioid efficacy should be considered in all patients, including opioid tolerance in patients requiring prolonged opioid analgesic therapy or in those with preexisting substance abuse histories. Due to the development of drug tolerance with prolonged medical use or recreational abuse of opioids (both commonly seen in burn patients), opioid analgesic doses needed for burn analgesia may significantly exceed those recommended in standard dosing guidelines. One clinically relevant consequence of drug tolerance is the potential for opioid withdrawal to occur during inpatient burn treatment. Thus, the period of inpatient burn care is not an appropriate time to institute deliberate opioid withdrawal or detoxification measures in the substance-abusing patient because such treatment ignores the very real analgesic needs of these patients. Similarly, when reductions in analgesic therapy are considered as burn wounds heal, reductions should occur by careful taper, in order to prevent acute opioid withdrawal syndrome.

Institutional capability to provide adequate monitoring as required for “moderate sedation” (as defined by the American Society of Anesthesiologists; Table 53.1)\textsuperscript{46} may also dictate which agents are used for procedural analgesia, as some of the more potent opioids (e.g.,
fentanyl) and anesthetic agents (e.g., ketamine, propofol) may unpredictably result in potentially dangerous levels of sedation (“deep sedation” or “general anesthesia”). The use of potent opioids and anxiolytics should only occur in settings with adequate monitoring, personnel, and resuscitation equipment appropriate for the degree of sedation anticipated. For many burn wound débridement procedures and most rehabilitative therapy sessions in the hospital ward or outpatient clinic setting, opioid analgesia with “minimal sedation” is sufficient and no special monitoring is required. Larger or more potent doses of opioids, or the concurrent use of anxiolytic sedatives (e.g., benzodiazepines), may not only produce more pronounced sedation (“moderate sedation”) but could also progress to “deep sedation” where patient–staff communication and/or patient consciousness are lost. Current guidelines of The Joint Commission, as well as adult and pediatric physician specialty professional organizations, dictate both general and specific levels of monitoring (e.g., continuous pulse oximetry, presence of an independent observer specifically responsible for monitoring ventilation and vital signs) for patients requiring each of these levels of procedural analgesia and sedation.

Because nociception at the burn site is the predominant mechanism of pain and suffering in these patients during the resuscitative and healing phases, pharmacologic treatment with potent opioids, anxiolytics, and other agents (e.g., ketamine) is the first line of therapy. However, nonpharmacologic methods of treating burn pain are also extremely useful. Some pain control techniques should be second nature to the staff and integrated into standard care (e.g., minimizing the number and intrusiveness of dressing changes, limb elevation, brief educational approaches). Other, more novel nonpharmacologic analgesic techniques are more practically implemented after a stable pharmacologic regimen is established or may require special expertise (e.g., hypnosis). To reinforce a consistent approach to analgesic management, particularly in centers where house staff physicians or nursing staff may rotate or change frequently, the establishment of succinct yet detailed institutional guidelines may help physicians and nurses with choosing and administering analgesics that target specific analgesic needs, as shown in Table 53.2. To maximize simplicity and utility, it is recommended that such guidelines be safe and effective over a broad range of ages, be explicit in their dosing recommendations, have a limited formulary to maximize staff familiarity, and allow the bedside nurse to continuously evaluate efficacy and safety. In addition, the regular use of a weight-based pediatric medication worksheet (placed at the bedside and in the patient record), containing all analgesic and resuscitation drugs likely to be administered, provides a supplemental safeguard against accidental overdose, particularly in the young pediatric age group.

NOTE: Medications are to be given orally unless otherwise specified. Exception: fentanyl ACTIQ is given transmucosal. Analgesic and anxiolytic choices are simplified to a minimum number of agents to encourage staff familiarity and are targeted to specific pain and anxiety needs. Therapy can be individualized to include agents not in this guideline when clinically indicated. This chart is laminated and prominently displayed in all patient care areas.

ICU, intensive care unit; IH, inhalation; NA, not applicable; Nitrox, 50% nitrous oxide/50% oxygen inhaled; NSAIDs, nonsteroidal anti-inflammatory drugs; PRN, as needed.

In recent years, a number of comprehensive reviews of burn pain management that emphasize such a systematic and multidisciplinary approach to burn pain management have been published,\textsuperscript{17,52–55} including practice guidelines from the American Burn Association.\textsuperscript{14} The reader is referred to these sources for additional perspective and detail.
Pharmacologic Approaches

In describing pharmacologic approaches for burn analgesia, three consistent observations can be made. First, for patients with injuries extensive enough to require hospitalization, pain from the burn itself is severe. Thus, potent opioids form the cornerstones of pharmacologic pain control in these patients, leaving few indications for the sole use of nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen, with notable exceptions of minor burns and outpatient treatment. Second, because burn pain has well-defined components described previously—notably background, procedural, breakthrough, and postoperative pain—pharmacologic choices for analgesia should target each pain pattern individually. Final, because burn pain will vary somewhat unpredictably throughout hospitalization due to surgical intervention and activity levels, analgesic regimens should be continuously evaluated and reassessed to avoid problems of under- or overmedication. Pain assessment is facilitated by the regular use of standardized, self-report scales for adults and older children and observational scoring systems for the very young, as described in Chapter 20. A reliance on nurse assessment of patients’ burn pain can be problematic, however, as it is well documented that nurses’ and patients’ assessment of burn pain and analgesia are not always comparable with nursing staff typically underestimating the need for analgesic therapy.

OPIOIDS

Opioid agonists are the most commonly used analgesics in the treatment of burn pain, in part because (1) they are effective, (2) the benefits and risks of their use are familiar to the majority of care providers, and (3) they provide some dose-dependent degree of sedation that can be advantageous to both burn patients and staff, particularly during burn wound care procedures. The wide spectrum of opioids available for clinical use (see Chapter 79) provides dosing flexibility (i.e., variable routes of administration, variable duration of action) that is ideal for the targeted treatment of burn pain. The pharmacokinetics of opioids in burn patients are not consistently different from nonburn patients, although
decreased volume of distribution and clearance and increased elimination half-life have been reported for morphine. Similarly, pharmacodynamic potency of opioids has inconsistently been reported as increased and decreased in burn patients.

The route of opioid administration is an important consideration in burn patients, with the principal choice between IV, oral, or transmucosal administration dictated by the severity of burn (critically ill patients require IV access and may have abnormal gut function) and high risk of burn patients for developing IV catheter–related sepsis (hence, physician reluctance to maintain long-term IV access). Intramuscular opioid administration is avoided because of the need for repeated, painful injections and because of variable vascular absorption due to unpredictable compartmental fluid shifts and muscle perfusion in burn patients, particularly in the resuscitative phase. Patient-controlled analgesia (PCA) with IV opioids offers the burn patient a safe and efficient method of achieving more flexible analgesia for both background and procedural analgesia. PCA also offers the patient some degree of control over his or her medical care, this being a major issue for burn patients whose waking hours are often completely scheduled with care activities ranging from wound care to physical and rehabilitation therapy. Some studies comparing PCA opioid use to other routes of administration in the burn population have shown potential benefits of PCA. The PCA administration of potent, short-acting opioids (e.g., fentanyl, alfentanil, remifentanil) for procedural analgesia may also have a useful role in burn analgesic management, but this has not been extensively investigated.

Because IV access is infrequently present in hospitalized burn patients outside of the critical care setting (for reasons noted previously), oral and transmucosal opioid delivery are frequently employed. For background pain, long-acting oral opioids (e.g., methadone) or sustained-release opioids are often utilized. However, the latter agents are not available in appropriate dose ranges for pediatric patients, so a reliance on shorter acting oral opioids is often necessary. For background pain control in this population, the use of regularly scheduled oral opioids is recommended over as needed (PRN) dosing so that more stable plasma opioid concentrations and analgesic effects may be obtained. Similarly, the use
of short-acting oral opioids is common for anticipated procedural pain, emphasizing early administration of the drug so that adequate plasma levels and associated analgesia are present prior to beginning the procedure. Alternatively, oral transmucosal administration of opioids is reported in burn patients to be particularly advantageous in those patients without IV access and in children, in both the inpatient and outpatient clinic settings.

**NONOPIOIDS**

The list of nonopioid analgesics in widespread use for the treatment of burn pain is relatively extensive, although clinical evidence to support such use is variably found in the published literature. Oral NSAIDs and acetaminophen, as outlined previously, are only mild analgesics and exhibit a ceiling effect in their dose–response relationship, rendering them unsuitable as sole agents for the treatment of typical, severe burn pain. However, they are of benefit in treating minor burns, particularly in the outpatient setting and in combination with more potent analgesics for their “opioid-sparing” effects. Topical application of NSAIDs on burn wounds can theoretically inhibit nociception at the injury site with minimal systemic uptake yet does not result in significant analgesia. The opioid agonist-antagonist drugs (e.g., nalbuphine, butorphanol) not only produce “mixed” actions at the opiate receptor level, theoretically providing analgesia (agonist property) with lesser side effects (antagonist properties) but also exhibit ceiling effects. Although studies have shown this class of drugs to be effective in treating burn pain, experience with them is both limited and suggestive of efficacy in patients with only relatively mild burn pain.

Antidepressants, anticonvulsants, antipsychotics, α₂ agonists, and systemic administration of local anesthetics have been proposed as potential analgesic agents for burn pain based on their known mechanisms of action in other pain states yet have not been studied extensively in the setting of burns. As neuropathic pain can occur in patients with healed burns, these agents may have specific application in this setting, as suggested by a preliminary reports with a variety of nonopioid agents including gabapentin, dexmedetomidine,
clonidine,\textsuperscript{78} IV lidocaine,\textsuperscript{79} and haloperidol.\textsuperscript{80}

**ANXIOLYTICS**

Current, aggressive therapies for cutaneous burn wounds, together with the persistent and repetitive qualities of background and procedural pain, make burn care an experience that is likely to engender anxiety in both adult and pediatric patients. It is also recognized that anxiety can exacerbate acute pain.\textsuperscript{22} This has led to the common practice of using anxiolytic drugs in combination with opioid analgesics, a practice that has persisted since the 1980s.\textsuperscript{81} A recent survey of North American burn centers reported that up to 39\% of hospitalized pediatric burn victims regularly receive anxiolytics as part of their pain and sedation management regimen.\textsuperscript{82} Intuitively, this practice is particularly useful in premedicating patients for daily wound care procedures, due to the anticipatory anxiety experienced by these patients prior to and during débridement. Although previously shown that benzodiazepine therapy improves postoperative pain scores in nonburn settings,\textsuperscript{83} it is also reported that low-dose benzodiazepine administration significantly reduces burn wound care pain reports.\textsuperscript{84} It appears that the patients most likely to benefit from this therapy are not those with high trait (premorbid) anxiety but rather those with high state (at the time of the procedure) anxiety or those with high baseline pain scores.

**ANESTHETICS**

Inhaled nitrous oxide is an analgesic agent safe for administration by nonanesthesiology personnel to achieve moderate sedation. It provides safe and effective analgesia without loss of consciousness for moderately painful procedures in other health care settings (e.g., dentistry) and is also a commonly used, although less well-studied, agent for the treatment of burn pain.\textsuperscript{85,86} It is typically used as a 50\% mixture in 50\% oxygen and is self-administered by an awake, cooperative, spontaneously breathing patient via a mouthpiece or mask. A secondary benefit of nitrous oxide use, like that of PCA opioid administration, is the element of control given to the patient for his or her care. Nitrous oxide is less useful with critically ill or uncooperative patients. It has also been implicated in a very small but measurable incidence of toxicity issues (e.g., spontaneous abortion, bone
marrow suppression) to patients or staff exposed for prolonged periods, although not in the setting of burn pain treatment. Although it is obvious that general anesthesia is required for the surgical excision and grafting of deep burn wounds, it is not uncommon to encounter specific wound care procedures that are on a scale below that of surgical burn care yet are nevertheless difficult to perform on a conscious patient, particularly a child. These procedures are ideally suited for deep sedation or general anesthesia and include (1) the removal of hundreds of skin staples from recently grafted wounds, (2) meticulous wound care of recently grafted and often tenuous skin on the face or neck, and (3) wound care procedures in variably cooperative children. Historically, IV, intramuscular, or oral ketamine have been used for these procedures, and there is limited evidence that ketamine administration acutely after experimental skin burns may prevent hyperalgesia and “wind-up.” More recently, some high-volume burn centers have developed specific training and skill retention programs in ketamine administration by nonanesthesiologists and report that satisfactory sedation for bedside procedures can be achieved in children with a low incidence of side effects. However, ketamine is a dose-dependent anesthetic that can produce deep sedation and general anesthesia in an unpredictable manner; thus, appropriate patient monitoring is requisite, and nonanesthesiologists administering the drug must have specialized training and airway management skills as well as anesthesiologist backup. In addition, its use is limited by the potential risk of associated emergence delirium reactions (5% to 30% incidence), particularly in the elderly.

The extension of full anesthetic care capabilities with anesthesiology staffing outside of the operating room and into the burn unit has been successfully implemented in some specialized burn centers. This has been facilitated by the recent introduction into clinical anesthetic practice of a variety of drugs with a rapid onset and short duration of action, a more rapid awakening/recovery, and fewer associated side effects—ideal qualities for agents to be used for procedural burn wound care. These agents include IV propofol and remifentanil and inhaled sevoflurane and desflurane. Propofol is particularly advantageous and can be titrated to effect both in terms of level of consciousness and duration of action using
continuous IV infusion techniques.\textsuperscript{95} The provision of brief, dense analgesia/anesthesia in a comprehensively monitored setting by individuals specifically trained to provide the service appears safe and efficient, both in terms of allowing wound care to proceed rapidly under ideal conditions for patient and nursing staff and in terms of cost-effective use of the operating room only for true surgical burn care procedures.

Local anesthetics are of obvious use in regional blockade for wound care procedures but have also been used for burn pain analgesia as a topical gel or IV infusion. Topical local anesthetic use on the burn wound is controversial. Prilocaine-lidocaine cream (EMLA) has no effect on burn pain in volunteers\textsuperscript{96}; however, topical 5\% lidocaine applied at 1 mg/cm\textsuperscript{2} offers analgesic benefit without associated side effects.\textsuperscript{97} Topical lidocaine use is significantly tempered by reports of local anesthetic-induced seizures due to enhanced systemic absorption at the open wound site.\textsuperscript{98} The analgesic benefit of an IV lidocaine bolus (1 mg/kg) and 3-day continuous infusion (40 mg/kg/min) has also been reported acute burn injuries,\textsuperscript{99} although whether its mechanism is due to anti-inflammatory or analgesic actions is unclear. Subcutaneous tumescent infiltration of local anesthetics for cutaneous surgery may provide adequate surgical anesthesia, with less blood loss from the graft donor sites.\textsuperscript{100–102} In one feasibility study (n = 8 patients), postoperative pain was decreased by continuous infusion of subcutaneous bupivacaine into the donor sites.\textsuperscript{103} Neuraxial administration of local anesthetics (and/or opioids) via epidural catheter would seem to be of benefit in patients with lower extremity burns, resulting in both analgesia (particularly during procedural burn care) and sympathectomy (of theoretical benefit to wound healing).

However, such use has only been reported anecdotally.\textsuperscript{104} A major drawback of this technique is the use of an indwelling catheter in patients densely colonized with infectious organisms at the wound site, thus increasing the risk for epidural abscess formation.\textsuperscript{105} Nonneuraxial regional blocks have recently been reported to be of benefit for the pain associated with surgical skin donor site preparation on the anterolateral thigh, both a single injections\textsuperscript{106} and as continuous infusions.\textsuperscript{107}

**PHARMACOLOGIC OPTIONS FOR BACKGROUND**

2850
PAIN MANAGEMENT
Because background pain is relatively constant, it is best treated with mild to moderately potent analgesics administered so that plasma drug concentrations remain relatively constant throughout the day. Examples include the continuous IV infusion of fentanyl or morphine (± PCA), the oral administration of long-acting opioids with prolonged elimination (e.g., methadone) or prolonged enteral absorption (e.g., sustained-release morphine, sustained-release oxycodone), or oral administration on a regular schedule of short-acting oral analgesics (e.g., oxycodone, hydromorphone, codeine, acetaminophen). Background pain generally decreases with time as the burn wounds (and associated donor sites) heal so that analgesics can be slowly tapered in the absence of significant analgesic tolerance.

PHARMACOLOGIC OPTIONS FOR PROCEDURAL PAIN MANAGEMENT
In contrast to background pain, procedural pain is significantly more intense but shorter in duration; therefore, analgesic regimens for procedural pain are best composed of moderately to highly potent opioids that have a short duration of action, with a sedation target level of moderate sedation. IV access is helpful in this setting, with ketamine and short-acting opioids (e.g., fentanyl, alfentanil) offering a potential advantage over more longer acting agents (e.g., morphine, hydromorphone). In the absence of IV access, orally administered opioids (e.g., morphine, hydromorphone, oxycodone, codeine) are commonly used, although their relatively long durations of action (2 to 6 hours) may potentially limit postprocedure recovery for other rehabilitative or nutritional activities. Oral ketamine, oral transmucosal fentanyl, and nitrous oxide are agents of particular use when IV access is not present, due to their rapid onsets and short durations of action. Finally, when a particularly painful dressing change or one that requires extreme cooperation in a noncompliant patient (e.g., face débridement in a young child) is anticipated, the provision of brief deep sedation or general anesthesia with appropriate patient monitoring, administered by anesthesiologists or appropriately trained nonanesthesiologists may be
helpful. A variety of approaches to managing procedural pain associated with burn wound care have been recently summarized.\textsuperscript{108}

**PHARMACOLOGIC OPTIONS FOR POSTOPERATIVE PAIN MANAGEMENT**

Postoperative pain deserves special mention because of the increased analgesic needs that should be anticipated following burn excision and grafting. This is particularly true when donor sites have been harvested, as these are often the principal source of increased postoperative pain complaints, rather than the grafted burn. Typically, this increased analgesic need is limited to 1 to 4 days following surgery before returning to preoperative levels.

**Nonpharmacologic Approaches**

**COGNITIVE INTERVENTIONS AND COPING STYLES**

In terms of pain control, cognitions can be thought of as behaviors that can be modified and that may influence the amount of pain that patients experience. Although such approaches are common in chronic pain control, there are few studies of cognitive-behavioral interventions in patients with burn injuries.\textsuperscript{109,110} In understanding such interventions, it is important to emphasize that burn injuries are unexpected and have far-reaching consequences for patients. Furthermore, as noted previously, the aggressive procedural medical care typically associated with burn injuries adds further stress and uncertainty through the daily demands of surgery, rehabilitation, dependency on caregivers, and pain. Such uncertainty often leads to feelings of helplessness in both adult and pediatric burn patients. It is almost impossible to predict the style with which an individual patient reacts and responds to such stress; however, if one is able to determine some characteristics of the patient’s cognitive style, this insight can be useful in choosing the most appropriate psychologically based interventions.

Burn patients bring different cognitive styles in the manner in which they respond to stressful medical procedures. One critical distinction lies in how much information patients desire regarding their injury and care.
Whereas some patients will seek out as much information as possible, others would just as soon leave their care to health care professionals. In applying cognitive interventions to burn patients, it will be useful for the clinician to be aware of how they cope with stressful medical procedures. Paramount to such thinking is whether the patient will approach procedures with a tendency toward cognitive avoidance, in which case they will distract or dissociate themselves from painful stimuli. This is in contrast to patients who tend to respond to acute pain by focusing on the procedures. Such patients may take a hypervigilant stance toward pain and may find distractions difficult. Patients often fall into position along a continuum of coping styles, from an approach coping style to an avoidance coping style. If one can determine where they fall along this continuum, it is easier to determine what type of psychological intervention will be most useful (Fig. 53.3).

FIGURE 53.3 Control coping continuum and associated nonpharmacologic techniques. The spectrum of coping styles from approach to avoidance is depicted, including specific clinical interventions for patients whose coping styles fall on different positions along the continuum (see text for details).

If patients fall on the avoidance end of the continuum, too much information and focus on the details of care procedures will likely make them more anxious. In contrast, distraction will likely be useful for patients who possess this coping style. In the burn unit, simple distraction is more likely to be of benefit with brief procedures such as blood draws or line placements, and studies have reported that music can be effective for such simple distraction with burn pain. Children at certain development levels may benefit from not seeing their wounds or by being more engaged by the clinicians. Such distraction will be less effective with older children or adults during the more extensive wound care procedures. In such instances, engaging patients in deep relaxation with distracting imagery will likely be more useful, although imagery often requires
substantially more training time for both patients and staff. A particularly elaborate form of distraction involves the use of computer-generated immersive virtual reality (see the following text). For both children and adults, deep breathing has been found to be a simple and effective means of reducing pain during procedures. In contrast, when patients cope with painful procedures by carefully focusing on them and even participating in their own care (i.e., approach coping style), they are usually less viable candidates for distraction techniques. Such patients may benefit from reappraisal techniques. Rather than focusing away from pain, reappraisal techniques might encourage patients to attend to their nociception. They can then be encouraged to differentiate sensory from affective components of pain as well as evaluate the meaning of the sensation. As is the case with chronic pain, patients may benefit from being taught to differentiate “hurt from harm” with respect to their pain sensations. It is also useful to teach such patients that increased pain sensation is usually a positive sign with respect to burn wound healing. Specifically, full-thickness burns often destroy nerve endings and the capacity for nociception, but as these burn wounds heal, skin buds emerge which are highly enervated and sensitive to pain and temperature. Teaching patients the latter two principles will likely be useful to them independent of their cognitive styles in response to acute pain. Furthermore, with enough focus on pain sensations, some patients are able to gain the sense that they are able to modify them and thus be in more control of their perceptions.

**PREPARATORY INFORMATION**

Providing patients with information about impending procedures can provide a powerful means of mitigating pain and anxiety. Such interventions have been found to enhance pain control with acute pain from a variety of different procedures. Patients may be provided with preparatory information (what steps will be taken during a procedure) or sensory information (what they will likely feel). The use of preparatory information has not been studied with burn patients, but there is evidence that it can be useful with a variety of medical procedures such as cardiac catheterization, endoscopies, cast removal, and surgery.
Unfortunately, burn injuries often do not easily lend themselves to such interventions. Certainly, it is not possible to anticipate that a burn injury will occur and medical procedures are often performed quickly and in an invasive matter. There is little time to prepare patients, and this can be particularly difficult for children. In addition, with some medical procedures in nonburn settings, understanding what will occur may reduce anxiety and pain associated with those procedures. Unfortunately, the frequent challenge with burn care is that the procedures are very painful, invasive, and truly threatening, unlike many other types of medical procedures that simply have the appearance of being threatening.

Preparation is particularly relevant to two phenomena associated with burn care. First of all, nociceptive input may often increase as a burn wound heals. As mentioned earlier, full-thickness burn injuries may not be that painful, whereas healing injuries with new skin buds may be particularly sensitive. Care providers should take care to communicate to such patients that increased pain is actually a sign that the wound is healing, information that may help allay patient anxiety. The second beneficial instance of preparatory information involves informing patients’ family members of important medical issues. For example, burn patients often show periods of delirium when in the ICU, a clinical phenomenon that can be frightening to both patients and their family members. Letting them know in advance that such confusion is a common and usually benign occurrence can mitigate subsequent anxiety.

**BEHAVIORAL INTERVENTIONS**

Behavioral interventions might seem more applicable to chronic pain conditions yet have surprising relevance to burn pain treatment. The application of such principles to burn can be divided into classical (stimulus) and operant (respondent) strategies. Stimulus conditioning applications have to do with the patient’s state prior to wound care. Certainly, decreasing the patient’s level of arousal through relaxation training, or any other means available, can minimize the ensuing cycle between anxiety and nociception. With children, the stimulus context of painful procedures can be particularly relevant. Children and many adults will often show heightened anxiety and fear just by being exposed to the
stimuli associated with painful procedures (e.g., nursing scrubs, procedures rooms). If the threatening nature of the wound care environment can be reduced, pain control can be enhanced by virtue of stimulus–response principles. As a nonburn example, some children’s hospitals have instituted the creative approach of having a magnetic resonance imaging (MRI) scan tunnel appear as a cave in a jungle environment (rather than the morgue-like drawer such equipment more typically seems to resemble). What follows from this logic is that the burn-injured child’s room should be considered a safe environment in which painful procedures do not occur.

Operant (reinforcement) principles are also highly applicable to burn pain management. One application has to do with medication scheduling. The tendency in many acute care settings is to simply medicate patients on a PRN schedule, an approach that is nonsensical for several reasons in burn care. Certainly, the notion of waiting until the patient hurts does not make sense from a pharmacologic perspective. However, operant principles would also suggest that PRN medication schedules reinforce patients’ pain complaints, both in terms of the euphoria-producing properties of opioid analgesics and the attention received from caregivers. Providing opioid analgesics on a regular schedule that reflects their pharmacokinetic properties will minimize the potential for operant factors to exacerbate the pain problem. For emotionally dependent or anxious patients, as-needed pain scheduling can actually create a paradigm for creating more pain behaviors and pain perception.

A regular analgesic drug administration schedule is particularly important with patients who have substance abuse histories. Such patients may demonstrate frequent pain complaints and/or drug-seeking behaviors on the burn unit. The tendency of such patients to approach multiple caregivers for analgesics has the potential to create “staff splitting” and resentment (i.e., counter-transference) toward the patients. Accordingly, the burn unit staff may hold punitive attitudes about the patient’s substance abuse history and/or the excessive nature of his or her pain complaints. Regularly scheduled medications will often minimize such conflict, as well as provide more transparent management of the patient’s pain. In addition, channeling communications and negotiations about changing doses or
types of medication through a single caregiver can be very useful in decreasing conflict between the patient and staff members.

In rare instances, the patient’s pain behavior might be so exaggerated in the face of apparently adequate analgesia that burn staff must consider an operant-based model of pain management. Effective burn team members are trained to be highly attentive to the pain complaints of their patients. However, occasional patients may show excessive complaints based on such factors as strong dependency needs or somatic tendencies. As in any case, it is important that such patients receive adequate doses of analgesics. However, operant approaches, in which discussions of pain are minimized and patients are distracted from their complaints, may become the prominent intervention. In other words, there would be discussions with the patient that medications changes will be limited to circumscribed periods and, in between such times, the patient will be encouraged to focus away from the issue of pain.

Burn rehabilitation involves continuously increasing activity levels, and patients may become simply overwhelmed with the pain associated with such movements. The quota system represents a useful application of operant principles to burn care in such instances. The repeated, invasive nature of burn care has the potential to create a state of learned helplessness in patients. The quota system uses rest as a reinforcement for activity and keeps activity levels well within the patient’s level of physical endurance. Ehde and colleagues have reported that with overwhelmed, seemingly unmotivated patients, it is useful to encourage the burn team to reduce their overall demands, take baseline behaviors, and gradually increase demands on what the patient’s baseline behavior suggests is within their range of tolerance. Such interventions can create steady increases in activity in patients who have been overwhelmed by care, and also a sense of mastery, as they are able to see steady improvement in their activities.

Avoiding the rewarding of escape behavior during procedures is a final application of operant principles. With children, it is particularly essential to do all the interventions possible to enhance pain control during procedures such as adequate analgesics and anxiolytics, sufficient emotional preparation, optimizing the wound care environment, and
including parents when appropriate. Children also do better if allowed to have control of their wound care procedures, perhaps by doing their own dressing removal.\textsuperscript{124} However, there are times when it is important to set firm limits during wound care by following through with procedures; otherwise, pain behaviors can exacerbate. Establishing this balance can certainly be a challenge for caregivers because it is not appropriate to force treatment when children are inadequately medicated. The point here is that once all that can be done that is possible in terms of analgesia, the timing of when a child can refuse or rest during wound care becomes an important issue in operant management.

**HYPNOSIS**

In terms of randomized controlled studies, hypnosis is one of the areas where the most evidence exists for psychologically based interventions in burn care.\textsuperscript{125} A recent review by Patterson and Jensen\textsuperscript{126} indicates that burn pain constitutes some of the best evidence in the literature that hypnosis can be effective. Furthermore, a number of additional reports have focused on the use of hypnosis to treat complications from burns other than pain, although with few exceptions; these reports have been anecdotal.\textsuperscript{127,128}

There are a number of reasons why burn patients appear to be such good candidates for hypnotic-based pain control interventions.\textsuperscript{129} First, because burn patients are in high levels of pain, they are motivated to engage in hypnosis, a technique that they might ordinarily resist. In support of this, patients with high levels of initial pain seem to show a better analgesic response to hypnosis.\textsuperscript{130,131} Second, patients with unanticipated traumatic injuries, such as burns, may be more cooperative because of the dependency that might often be a normal reaction to trauma care (i.e., a willingness to allow others to take care of one). Third, the dissociation that may accompany a burn injury may also be a factor that moderates hypnotizability. Certainly, dissociative tendencies have been related to hypnosis,\textsuperscript{132} as well as the acute stress disorder is a typical early reaction to burn injuries. Finally, and on a more simplistic level, hypnosis is most effective when it can be applied to a predictable, discrete event—a description that characterizes most burn wound care procedures, as painful
as they are.

There have been two recent publications describing the delivery of hypnosis through immersive virtual reality technology (see the following text) in order to treat burn pain.\textsuperscript{133,134} The advantage of this approach is that the clinician can rely on technology to achieve hypnotic induction and suggestion; thus, extensive training for hypnosis is not required. Although these reports are anecdotal, their preliminary results with this technology demonstrate analgesic effects that are equivalent to those obtained when a “live” clinician is used.

**VIRTUAL REALITY**

Immersive virtual reality is a particularly attention-grabbing distraction technique and is designed to give users the illusion of going inside a computer-generated virtual environment (Fig. 53.4). Virtual reality appears to provide significant cognitive distraction to users because it is interactive and places significant cognitive demand on patients through the provision of multisensory input (visual, aural, and sometimes tactile). In addition, it utilizes a head-mounted display that blocks visual and aural input to the user from the immediate and often frightening, real-world burn care environment. Thus, virtual reality may exert its analgesic effect by diverting conscious attention away from concurrent nociceptive stimulation, resulting in an attenuated subjective pain experience. Functional brain imaging studies have shown the virtual reality results in pain reduction that is similar to that of systemic opioid administration, both in terms of magnitude of analgesia and brain activity changes, and is also additive to opioid analgesia when administered concurrently.\textsuperscript{135} The use of adjunctive, immersive virtual reality was first reported to provide clinically meaningful pain relief in the setting of burn wound débridement,\textsuperscript{136} with findings subsequently replicated in larger populations of burn patients.\textsuperscript{137,138} Virtual reality analgesia is also advantageous for the less severe pain associated with certain types of postburn rehabilitation activities\textsuperscript{139–141} (Fig. 53.5) and has been combined with hypnotic suggestion (as noted previously) to provide nonpharmacologic analgesia for burn wound care.\textsuperscript{133,134}
FIGURE 53.4 Virtual reality environment “SnowWorld” as seen by the patient/user. Snow/ice motif and blue/white/lavender colors suggest a cool temperature setting in direct contrast to the hot setting in which most burn injuries occur. Virtual igloos, penguins, and snowmen on canyon walls facilitate user interaction with the virtual world through user-targeted shooting of virtual snowballs at these virtual objects.

FIGURE 53.5 Clinical use of virtual reality distraction during burn wound care. A burn patient undergoes postburn skin stretching and passive joint range of motion while experiencing immersive virtual reality analgesia. Both auditory and visual stimulation are provided through a lightweight head-mounted display that can track the user’s position in the virtual environment by assessment of head position, and user interaction with objects in the virtual environment is controlled by manual trackball.

Conclusion

Effective treatment of burn injuries requires an appreciation of the unique patterns of nociception caused by this trauma and their interaction with
psychological factors. Aggressive use of opioid analgesics tailored to the
nature of the pain (e.g., procedural, background, postoperative) serves as
the cornerstone of a multifaceted approach to burn pain. Procedural pain
often involves consideration of a variety of supplemental pharmacologic
approaches, ranging from mild sedation to general anesthesia.
Nonpharmacologic approaches should be woven into the structure of burn
care as adjuncts to pharmacologic analgesia (i.e., multimodal analgesia).
The undertreatment of burn pain remains an unfortunate reality,
particularly because adequate analgesia may facilitate recovery and
posthospital adjustment as well as represent a more humane course of
treatment.

Persistent pain problems in children, as in adults, may stem from a wide variety of causes. They may be associated with ongoing illnesses such as cancer or sickle cell disease (SCD), may be the residua of pathologic processes that have resolved but have sensitized the peripheral or central nervous system such as postinfectious myalgias, or may represent a nonprogressive disorder whose main manifestation is pain such as headaches, widespread musculoskeletal pain, or functional abdominal pain. Regardless of the etiology of the pain, its assessment, its impact, and, often, the modalities used to treat are remarkably similar and often distinct from approaches used to address acute pain. For example, although the broader context of pain, including an array of genetic, developmental, environmental, and individual factors, is rarely a major focus of assessment in acute pain, these factors are essential to consider when pain is recurrent or persistent. Likewise, treatment goals may shift from pain eradication in acute pain to pain reduction, rehabilitation, and improved coping in chronic pain.

In this chapter, we describe the epidemiology of chronic pain, define its impact on children and families, and offer general approaches to its evaluation and treatment. Discussion of cancer pain is contained elsewhere in this book, as are more detailed descriptions of specific pain problems.

**Epidemiology of Chronic Pain in Children**

The epidemiology of the various chronic pain problems in children is often hard to ascertain primarily due to variability in the methodologies in the
available research. Although this fact is an issue for adults as well, the relative limitations of the pediatric literature in the area of chronic pain, the added dimension of development when applying diagnostic criteria, child variants of adult disorders, the potential association between various pain syndromes, and the limitations in the young child’s ability to report symptoms give us pause as we sift through data on the prevalence of persistent pain syndromes in children.

Recent efforts have been made to refine the taxonomy of chronic pain conditions, and the need to maintain a life span developmental approach was highlighted. This implies that rather than parse out pediatric conditions as separate entities, it is imperative to view the emergence of chronic pain as a developmental phenomenon from birth, through adulthood, and into the elderly years. Included is a focus on continuities and discontinuities in pain problems, highlighting longitudinal data to understand the specific genetic, epigenetic, and environmental roots of pain problems. Simply stated, children are not little adults, but adults are big children! With this as background, a sample of the epidemiology of selected persistent pain problems in children follows.

**MUSCULOSKELETAL PAIN**

One of the most common sites for pain in children and adolescents is the musculoskeletal system, including joint pain, bone pain, and muscle pain. Discomfort may arise from disease processes (e.g., inflammation associated with arthritis), may be related to central pain processing difficulties (e.g., juvenile fibromyalgia syndrome), or may be related to trauma or injury, typically focusing on a specific area of the body (e.g., back pain or neck pain). A recent study sought to better identify the etiology of musculoskeletal pain, which is a major first step in better grasping its epidemiology. Demographic, clinical, and laboratory data were gathered on over 400 pediatric patients presenting with musculoskeletal pain, swelling, or limitation of movement. The etiology of these difficulties was identified in over 97% of cases, with by far the most common being noninflammatory and mechanical conditions (42.2%), followed by rheumatic diseases (31%), infection-related disorders (21.6%), and malignancy (2.4%). Age differences were noted, such that the
prevalence of rheumatic disease was higher in those over 12 years, whereas younger age was associated with higher prevalence of infectious issues.

**Arthritis**

Estimates of the prevalence of juvenile arthritis have shifted a good deal over the years due to a number of factors, including diagnostic difficulties, changes in the classification schemas used, differences in research methodology, cohort effects, and factors occurring with the passage of time. Estimates of prevalence range from 10 to 220 cases per 100,000. Recent estimates suggest that 294,000 children between 0 and 17 years of age are being affected by “arthritis or other rheumatic conditions.”

Regarding pain in this population, Schanberg et al. found that children with polyarticular juvenile arthritis had pain an average of 73% of the days. Although for most children this pain was in the mild to moderate range, 31% reported pain in the severe range. Baseline and up to 5-year follow-up data from the Childhood Arthritis Prospective Study helped identify pain trajectories over time in children with arthritis. Patients between the ages of 1 and 16 years with new-onset juvenile idiopathic arthritis were followed, and three basic trajectories were identified: consistently low pain (53%), improved pain (30%), and consistently high pain (17%). A study in Canada showed similar results, with five pain severity trajectories: mild-decreasing pain (56%), moderate-decreasing pain (29%), chronically moderate pain (7%), minimal pain (4%), and mild-increasing pain (4%).

**Nonrheumatologic Musculoskeletal Pain**

A number of studies have tried to identify the prevalence of musculoskeletal pain in children and adolescents not associated with arthritis or other rheumatologic conditions. De Inocencio reported on a review of 6,500 office visits of children 3 to 14 years of age and found that 6.1% were for musculoskeletal complaints, the majority of which were for arthralgias and soft tissue pain. Common etiologies included trauma as well as mechanical or overuse pathology.

More generally, many children and adolescents report significant
episodes of chronic nonspecific pain at least once in their lifetime, including limb pain (4.2% to 33.6%), knee pain (up to 18.5%), and back pain (7.6% to 34%).

Mikkelsson et al. followed third and fifth graders over 1 year and found that pain occurring at least once per week persisted in 52.4%, with neck pain having the highest persistence.

Recognizing the risk of contiguity between chronic pain problems in children and adolescents with challenges later in life, a group of Danish researchers conducted a prospective 3-year school-based cohort study of children 8 to 14 years of age at baseline to gather information about musculoskeletal pain. Through weekly mobile phone contacts, parents reported on the presence or absence of musculoskeletal pain in their children; a subset of children also underwent a more thorough clinical assessment. It was found that approximately half of the children had lower extremity pain every study year. This was hardly trivial—children experienced an average of 2.5 episodes, lasting for a total of 8 weeks each study year. Upper extremity pain was also present, but less substantial, as it occurred in approximately one quarter of the sample, lasting on average 3 weeks during a study year (about 1.5 episodes). Upper extremity pain tended to be more related to trauma than lower extremity pain. The most common sites of pain included knees and the ankle and foot area. Of note, this same research group went on to conduct a systematic review of other population based studies, with similar results.

**Fibromyalgia Syndrome**
The prevalence of fibromyalgia syndrome in children and adolescents is difficult to determine. Mikkelsson et al. used a structured pain questionnaire in a large sample of Finnish third- and fifth-grade children and found that 22 of them (1.25% overall) met criteria for fibromyalgia syndrome. In a retrospective review of patients referred to a pediatric rheumatology clinic between 1989 and 1995, 7% were diagnosed with fibromyalgia syndrome. Data from the UK General Practice Research Database for the years 1990 to 2001 showed that the annual incidence of fibromyalgia increased from less than 1 per 100,000 to 35 per 100,000. Female gender predominance is a well-replicated finding. Although various studies have shown correlates to the presence of the syndrome,
such as chronic fatigue, joint hypermobility, temperament, familial aggregation, and psychiatric symptoms, causal relationships have not been shown.

**Complex Regional Pain Syndrome**

There are few studies reporting on the prevalence of complex regional pain syndrome (CRPS) in children and adolescents. A 2017 review found only 10 studies (only 1 population-based) with relevant data, which showed a mean age at onset of 12.5 years, with 85% of patients being female. The majority of patients (71%) had a history of trauma. Contrary to adults, lower limbs were affected in 75% of patients, with secondary site involvement in 15% of cases.

**Back Pain**

Back pain represents a somewhat distinct form of musculoskeletal pain. A recent comprehensive review indicated that low back pain is rarely seen in children younger than school age and prevalence rates rise until age 18 years, at which time rates parallel those of adults. Contrary to prior beliefs, sinister diagnoses are rare, as pain tends to be nonspecific and is self-limiting.

Beyond the incidence of chronic musculoskeletal pain, a critical issue is also the transition from the acute phase to more persistent pain problems. A recent study followed 88 10- to 17-year-olds who had presented to the emergency department or orthopedic clinic with new musculoskeletal pain complaints, approximately 35% of whom continued to have persistent pain 4 months later. Regression analyses showed that depressive symptoms and poorer pain modulation were key risk factors related to this transition.

An earlier systematic review identified 65 potential risk factors for the onset of and 43 potential prognostic factors for the persistence of musculoskeletal pain. Results showed that low socioeconomic status (strong evidence) as well negative emotional symptoms and regularly smoking in childhood or adolescence (moderate evidence) may be associated with persistence of pain. Interestingly, high body mass index, taller height, and joint hypermobility were not found to be risk factors for the onset of pain.
Temporomandibular Disorders

Temporomandibular disorder (TMD) pain is often underrecognized in children and adolescents. A systematic review and meta-analysis conducted to assess the prevalence of clinical signs of temporomandibular joint (TMJ) disorders in children and adolescents captured 17,051 participants. The overall prevalence of clinical signs of intra-articular joint disorders was 16%, the prevalence of TMJ sounds was 14%, clicking (10.0%), and jaw locking (2.3%). Significant correlates include bruxism and tooth-grinding as well as bite and tooth positioning.

HEADACHE

Determining the incidence of headache in the pediatric population is difficult due to changing diagnostic criteria and attempts to apply adult diagnostic criteria to children. In a review by Hershey et al., it was concluded that up to 75% of children have had significant headaches by the age of 15 years, with up to 28% of adolescents describing symptoms consistent with migraine headaches. Previous meta-analytic reviews suggested a gradual increase in headache incidence over childhood with 37% to 51% of children reporting a significant headache by 7 years and up to 82% by 15 years. A more recent meta-analysis of 64 cross-sectional studies (including a total of 227,249 subjects) yielded an estimated overall mean prevalence of headache was 54.4%, with an overall mean prevalence of migraine at 9.1%.

The distinction between migraine and tension-type headache is often complex, particularly in pediatric headache. For example, when applying International Classification of Headache Disorders-II criteria to a large sample of German children age 7 to 14 years, Kröner-Herwig and colleagues found that 7.5% of the headaches could be classified as migraine, 18.5% as tension-type, and the majority were unclassifiable. Virtanen et al. found that among children who were classified as having migraines at age 6 years, half were unchanged at age 13 years, whereas for 32%, there was a shift toward tension-type headaches. Other authors found a similar lack of stability in headache type over time with headache types shifting or disappearing entirely. For example, a 10-year longitudinal study of principally preadolescent children diagnosed with migraine, only 46%
continued to have migraine and the frequency of attacks had diminished.\textsuperscript{32}

Therefore, the precise relationship between various types of headaches in children remains unclear. In addition, various authors report close relationships between headache pain and other difficulties, including neck pain,\textsuperscript{33} back pain,\textsuperscript{34} abdominal pain,\textsuperscript{35} sleep disturbances,\textsuperscript{36} fatigue,\textsuperscript{37} epilepsy,\textsuperscript{38,39} epistaxis,\textsuperscript{40} psychiatric difficulties, and risk of suicide.\textsuperscript{41–43}

Nonetheless, headaches in children appear to be quite common; however, precisely what differentiates migraine headache from tension-type headaches is difficult to discern at times. Headaches increase in frequency and severity with age with a clear shift around the time of puberty and are more common and problematic in females, and health-related quality of life (HRQOL) may be significantly impacted.\textsuperscript{44}

**CHRONIC ABDOMINAL PAIN**

Chronic abdominal pain accounts for 2% to 4% of pediatric visits. Hyams et al.\textsuperscript{45} found that 75% of middle school and high school students reported abdominal pain, whereas 21% reported it was severe enough to affect activities, and 8% visited a physician for it. Like other pain problems, various definitions and correlates of persistent abdominal pain (recurrent abdominal pain, chronic abdominal pain, functional abdominal pain, functional gastrointestinal disorder [FGID] nonorganic abdominal pain, and psychogenic abdominal pain) have led to varying perspectives in its prevalence.

A recent study of parental reports of 4- to 18-year-olds in a representative community sample of the United States indicated that 23.1% had at least one FGID, with functional constipation and abdominal migraine being the most common (Rome III criteria). The Rome III criteria for abdominal pain–related FGIDs in children and adolescents include functional dyspepsia, irritable bowel syndrome (IBS), abdominal migraine, childhood functional abdominal pain, and childhood functional abdominal pain syndrome.\textsuperscript{46} A revision of these criteria, Rome IV, will include additional categories that include motility disturbance, visceral hypersensitivity, altered mucosal and immune functioning, altered gut microbiota, and altered central nervous system processing, all of which reflect recent advances in the field and will likely lead to more insight into
incidence and etiologies.\(^{47}\)

It appears that the roots of nonspecific abdominal pain may be identified quite early in development based on chart reviews of a cohort of children followed from birth to 5 years. Chitkara et al.\(^{48}\) found an incidence of abdominal pain of unknown origin of 4.5/1,000 person years leading to repeated visits to the pediatrician. Finally, as was the case with prior pain problems, there is growing evidence the difficulties with chronic abdominal pain early in life are associated with the risk of future abdominal pain, other pain problems (e.g., headache), and broader somatic concerns later in childhood and beyond.\(^{49,50}\)

### DISEASE- OR TREATMENT-RELATED PAIN

#### Sickle Cell Disease

For many years, the focus of pain management in children and adolescents with SCD were episodes of vasoocclusion. Dampier and colleagues\(^{51}\) gathered pain diary data in children and adolescents with SCD. They found that vasoocclusive pain is experienced on 2% of days in preschool-age children and on 5% to 10% of days in school-age children and young adolescents. School-age children tended to have less intense pain than adolescents, and girls tended to report a higher number of painful sites than boys. Subsequent data\(^{52}\) showed that 40% to 50% of school-age children experience one pain episode a month, whereas about 10% experience more than two episodes a month. Although the majority of these episodes lasted 1 day or less, about 5% of episodes in older children last longer than 2 weeks.

More recently, however, it is clear that children with SCD are affected by a number of recurrent chronic pain concerns beyond those related to vasoocclusion. Although Niebanck et al.\(^{53}\) found that overall the prevalence of tension-type and migraine headaches in children with SCD approximates that of healthy peers, they found that headache was more common in younger children with SCD and that there were relationships noted between frequency of headache and frequency of vasoocclusion. This suggests that factors related to SCD may increase the risk of headache pain. In addition, sequelae of splenic sequestration may lead to ongoing visceral pain in the left upper quadrant and irreversible joint damage, such
as related to aseptic necrosis, may cause ongoing discomfort.

**Cystic Fibrosis**

Koh et al. evaluated 46 children with cystic fibrosis (CF) and found that nearly half of the sample described pain occurring at least weekly with primary locations of the abdominal and pelvic region, chest, head, and neck. Although most children reported mild pain intensity and relatively short duration, a small subgroup reported moderately intense pain in the chest that was of longer duration. Pain in this group was thought to be musculoskeletal in nature, related to pulled or torn intercostal muscles, costochondritis, pleuritis, pneumothorax, or rib fracture. A Web-based study of adolescents and young adults with CF found that about half experienced moderate daily pain of 2 hours duration or less, with disability highest in areas of recreation, occupation, and social activities.

**Phantom Limb**

Phantom pain occurs when a limb has been amputated and the individual continues to feel pain in a part of the body that is no longer there. In an early attempt to ascertain the prevalence of such conditions in children, Krane and Heller conducted a retrospective survey of 5- to 19-year-olds who had undergone limb amputation in the preceding 10 years. Amputations were secondary to congenital deformity, trauma/infection, or cancer. Phantom sensations were experienced in all patients, and the overwhelming majority stated they experienced phantom pain as well. Melzack et al. reported that phantom limbs are experienced by 20% of those with congenital limb deficiencies and 50% of those who underwent amputation before age 6 years. Phantom pain was reported in 20% and 42% of these groups, respectively. Using diary data, Wilkins et al. found recurrent episodes of phantom pain due to congenital limb deficiencies, surgery, and trauma, with an average intensity of 6.43 out of 10.

**ADDITIONAL CONSIDERATIONS**

The earlier review should make it clear that there is an array of chronic and recurrent pain problems that affect children and adolescents. It is unwise, therefore, to focus on “chronic” or “recurrent” pain as a unified entity but
rather as diverse syndromes, perhaps with certain common factors. As is discussed in the following text, a broad biopsychosocial perspective is deemed optimal, which embraces genetic, developmental, and environmental influences.

In the remainder of this chapter, we discuss the impact of persistent pain on children and offer a general approach to evaluating and managing it. A more detailed review on a number of more common entities is offered as well. Additional information on many of these problems is available in other sections of this book, such as Chapters 25, 49, 57, and 61.

**Impact of Persistent Pain on Children and Families**

Recurrent and chronic pain can have a major impact on the daily lives of children, adolescents, and their families. Whereas some children experiencing pain symptoms have minimal day-to-day impairment, other children exhibit psychological distress and have significant activity limitations due to pain. The children who seek treatment for their chronic pain symptoms likely represent the group who is experiencing the most impairment. For many children, chronic pain has been associated with poorer HRQOL, psychosocial difficulties, academic problems, and disruptions in peer and family relationships.

Disability or activity limitations that results from chronic pain is a separate concept from pain itself, and it is equally important to consider in assessment and management of pediatric pain patients. Disability refers to those areas in an individual’s life that are limited due to pain. The domains of functioning that seem to be particularly impacted by chronic pediatric pain are participation in physical and social activities, school and academics, sleep, and family functioning. Specifically, chronic pain has been associated with more frequent school absences and academic difficulties. Missed schooling can have direct effects on academic performance and school success as well as important effects on socialization and maintenance of peer relationships. Difficulties with peer relationships have been found in children with chronic pain, with one study of children with juvenile fibromyalgia reporting that children were more isolated, less well liked, and less socially accepted than their healthy
peers.\textsuperscript{66,67}

Activities limited due to pain vary depending on the level of pain children experience. Higher levels of pain intensity, greater pain extent, and longer pain duration have been associated with greater activity limitations and impairment.\textsuperscript{68–71} Specific domains of activity restriction have also been associated with pain level. In one study of children with SCD, although children decreased participation in all activities (school, play, sports, social) when pain was high, they were able to maintain school attendance and social activities when pain levels were low.\textsuperscript{69} Future research is needed to better understand the relationship between pain and activity restriction among different populations.

Sleep disturbances are highly comorbid with chronic pain, affecting over half of youth.\textsuperscript{72,73} The most commonly experienced sleep disturbance is insomnia (i.e., difficulties falling asleep or staying asleep), which is reported by over 50\% of youth with chronic pain.\textsuperscript{73} It is associated with diminished physical function, poor quality of life, and increased depressive symptoms.\textsuperscript{74} Untreated, insomnia symptoms persist over a 1-year period for youth with chronic pain.\textsuperscript{67}

Psychological factors, including anxiety, depression, and coping, have been identified as important in the development and maintenance of chronic pain and disability in children (e.g., Simons and Kaczynski,\textsuperscript{75} Nodari et al.\textsuperscript{76}). Children with chronic pain report increased general anxiety, pain-specific anxiety, posttraumatic stress symptoms, and depressive symptoms than youth without pain conditions, which is associated with greater pain-related disability.\textsuperscript{60,77,78} In large-scale epidemiologic studies, individuals with a history of chronic pain in adolescence subsequently report higher rates of lifetime anxiety and depressive disorders, as compared with individuals without a history of adolescent chronic pain.\textsuperscript{79} Moreover, children’s coping style (particularly maladaptive coping) and catastrophizing behaviors are associated with increased psychological distress and physical limitations.\textsuperscript{80}

HRQOL refers to an individual’s perception of the impact a disease or condition has on his or her physical health status, psychological functioning, and emotional well-being. Chronic pain may impair school attendance, mobility, self-care, interpersonal interactions, life activities,
and community activities as well emotional functioning.\textsuperscript{62} Several examinations of HRQOL in children and adolescents with pain conditions (e.g., headache, SCD, mixed pain conditions) have found that they report significantly poorer HRQOL in comparison to healthy children.\textsuperscript{76,81} Moreover, unexplained chronic pain in adolescents has been associated with poor quality of life for the adolescent and his or her family.\textsuperscript{59} Predictors of poor HRQOL within pain populations include the presence of sleep problems,\textsuperscript{82} fatigue,\textsuperscript{83} pain-related hospitalizations,\textsuperscript{81} low socioeconomic conditions,\textsuperscript{84} and increasing child age.

Pediatric chronic pain is embedded in a broader family context that influences the child’s adjustment to chronic pain, so caregivers are a unique and integral part of pediatric chronic pain treatment.\textsuperscript{85} Studies show that caring for a child with chronic pain has a negative impact on parent caregivers, expressed in higher anxiety, depression, and increased parental role stress.\textsuperscript{80} Although it is unknown whether these symptoms precede the pain condition, or develop in response to parenting a child with chronic pain, high levels of parental distress have been linked to increased pain and disability in children.\textsuperscript{85,86} Furthermore, parents may respond with increased attention, sympathy, or discouragement of activity if they perceive their child’s pain as a potential sign of harm or damage. Such protective or solicitous responses can provide positive reinforcement and increase illness behavior, which may exacerbate or maintain children’s pain and disability.\textsuperscript{87,88} This bidirectional influence is illustrated in the integrative model of family and parent factors for children with chronic pain, developed by Palermo and Chambers,\textsuperscript{89} that outlines parent and family influences on child experience of pain. Consequently, caregivers have become important targets in psychological interventions for children with chronic pain.

Parents may experience significant financial burden due to the evaluation and management of their child’s recurrent and chronic pain. Pediatric chronic pain is costly to society, with estimates of $19.5 billion per year spent on pain treatment in the United States.\textsuperscript{90} Costs to parents and caregivers include lost employment time, transportation expenses, childcare, and incidental costs. The stress of chronic pain on families is also associated with increased levels of family conflict and poorer family
functioning. Previous studies have shown more family problems in children with chronic pain compared to healthy children and that poorer family environments are associated with increased disability.

Clinical Evaluation of the Child with Chronic Pain

BACKGROUND

In the position statement published by the American Pain Society, chronic pain in children was defined as the result of a dynamic integration of biologic processes, psychological factors, and sociocultural factors considered within a developmental trajectory. Therefore, evaluating a child with chronic pain can be time-consuming and complicated as a multitude of factors contribute to its development and maintenance. Children who present with persistent pain often receive extensive evaluations by both primary care providers and specialists in different disciplines due to the complexity of the pain presentation and the associated symptoms. If the pain appears to result from a previously or newly identified organic disease (e.g., ulcerative colitis, SCD, cancer), the treatment focus is on addressing the underlying illness while simultaneously treating the associated pain symptoms. In other situations, the source of the pain may be known and often time-limited but may not be amenable to direct treatment, and therefore, the focus is typically solely on addressing the pain (e.g., persistent postoperative, posttraumatic, or postviral pain). For both of these groups of children, there is no need for an extensive search for an explanation for their pain and the clinician can focus on its treatment.

The more challenging situations and the emphasis of the majority of this chapter occur when no obvious pathophysiologic source of the pain has been identified. The child is suffering, the parents are frustrated, extensive evaluation is often undertaken, and no treatable disease process emerges to explain the pain. In these situations, the clinician must attempt to identify those children who may have an as yet undiagnosed underlying progressive disease process and separate them from those who have chronic pain syndromes, which although uncomfortable, do not represent life-threatening illness. This is not an easy task, given the inherent
vagueness and subjectivity of the symptoms, the inadequacies of children as historians, the strong desire of most children and their families for an “organic treatable diagnosis,” and the vast differential diagnosis. In these situations when source of pain does not have a clear or treatable organic etiology despite adequate evaluation, the treatment focus changes and is ultimately on educating the family and patient on the pathophysiology of chronic pain including the process of central sensitization and on the value of a biopsychosocial rehabilitative approach.

Initially, however, a delicate balance must be struck between adequate evaluation and overinvestigation. The physician must be comfortable that he or she has enough information to rule out potentially serious or life-threatening causes of pain on the one hand while avoiding an endless search for the underlying etiology of the discomfort on the other. Continued laboratory investigation often convinces the child and family that there must be a biologic explanation for the problem and suggests to them that the “answer” may be found in the next laboratory test. Clinicians may report that they are ordering additional tests “for the sake of completeness” and both clinicians and families often find it difficult to draw a diagnostic line in the sand where all are content with extent of the investigation. Furthermore, pediatricians do not always agree on the diagnostic approach. Konijnenberg and colleagues highlighted this problem in a series of papers in which 17 different pediatricians reviewed the medical records of 134 children with unexplained chronic pain. Consensus of the group was defined as an agreement among 80% of the pediatricians on the panel. Yet, there was disagreement on diagnostic approach in over a third of the patients and on the primary cause of the pain in over one-half. Unfortunately, this diagnostic uncertainty often leads to further excessive and expensive laboratory and imaging studies. It is particularly unfortunate if, after completing an extensive battery of tests, which are negative, the doctor implies that the problem must be solely psychological and refers the child to a mental health professional.

Therefore, one of the most critical aspects of the evaluation of the child with unexplained chronic pain is the development of a trusting relationship with the child and family and their acceptance that the medical investigation has been sufficient to allow the primary focus of the
encounter to be on the management of the pain regardless of its etiology. Etiologically, chronic pain is thought to stem from an interplay between biologic vulnerability, psychological variables, and environmental variables which allow for abnormalities of sensory processing, enhanced responsiveness, and excitability in the central nervous system known as central sensitization and amplification. Central sensitization is discussed in numerous other chapters throughout this book in detail, but it is the term used to describe the dysfunction or pathology of the nervous system that results in an amplified responsiveness of the central nervous system to painful and nonpainful stimuli. This increased responsiveness of the nervous system is thought to be a key element in the development and maintenance of chronic pain.\textsuperscript{97–100}

These factors must be considered in the evaluation and treatment of all children with chronic pain. As outlined in the American Pain Society consensus statement,\textsuperscript{94} a comprehensive clinical assessment of a child with chronic pain should include a complete medical and pain history including onset, intensity, quality, location, duration, variability, predictability, exacerbating, and alleviating factors with ongoing management and reassessment emphasizing functional improvements. The physical exam should include a complete neurologic exam, with observation of the child’s general appearance, posture, and gait. Although laboratory and radiologic studies may be useful if a specific disease is suspected, the diagnosis of a chronic pain condition is predominately made by history and physical exam and best assessed by a pediatric interdisciplinary pain management team typically including pain medicine clinicians, mental health providers, and physical and occupational therapists.\textsuperscript{94}

**HISTORY**

Traditional elements of the pain history for adults are applicable to evaluating chronic pain in children. Although younger children are developmentally less capable of presenting a coherent narrative, they are capable of reporting on specific aspects of their pain. Using developmentally appropriate tools, children are able to define pain intensity as well as radiation, exacerbating and relieving factors of the pain, and quality of the pain. Chronic pain in children has a significant
impact on daily function which can be seen in school attendance and work quality, social relationships, and mood.\textsuperscript{78} The history of impact on daily function should be integral in ongoing reassessment of pain management as improvement in function may occur well before a decrease in pain intensity. Roth-Isigkeit and colleagues\textsuperscript{61} studied 750 German school children and found that 30\% to 40\% reported restrictions in daily living secondary to pain. Chalkiadis’s\textsuperscript{101} study of chronic pain in Australian youth revealed that 71\% of children had difficulty sleeping and over 90\% were unable to be involved in sports.

Because evidence supports that early exposure to painful stimuli and other adverse events potentially predisposes the child to changes in nociception, it is important to be aware of the child’s medical history. Fitzgerald and colleagues’\textsuperscript{102–105} study of rat pups has demonstrated long-lasting hypersensitivity to pain from early tissue injury. Grunau and coworkers,\textsuperscript{106–109} in a series of papers, compared toddlers who were born prematurely to babies of normal gestation and birth weight and found differences in pain sensitivity and somatization. Measurable differences between the groups were found even when the children had reached 8 to 10 years. Anand and Scalzo\textsuperscript{110} has even suggested that there are increased rates of attention-deficit/hyperactivity disorder (ADHD), substance abuse, and anxiety in children who have been exposed to repeated neonatal pain and stress.

Another essential element to query is the history of pain problems in the family. Although some authors, such as Borge and Nordhagen,\textsuperscript{111} question whether chronic pain symptoms run in families, on the whole, the majority of studies have suggested that parent and family history of pain are predictors of child pain. This pattern has been identified in children with rheumatologic disease,\textsuperscript{112} recurrent abdominal pain, migraine, and fibromyalgia.\textsuperscript{113} The mediators of this phenomenon are unclear. They may be physiologic (such as altered pain thresholds) or psychological (e.g., social modeling of catastrophizing behavior) or most likely a combination of both. Regardless of the mediators for this phenomenon, it is essential that family history of pain be examined. The child’s pain cannot be adequately addressed if the parent’s pain is not recognized.

Psychological and social factors should be explored in children with
chronic pain and their families regardless of the pain’s etiology. Such an exploration does not imply causation, but there is clearly a transactional relationship between chronic pain and anxiety and depression.\textsuperscript{114,115} As is evident throughout this chapter, anxiety, depression, and other mental health concerns frequently co-occur with chronic pain and need to be assessed. Questions regarding anxiety, depression, and excessive irritability should be posed to both the child and his or her family. The use of existing standardized questionnaires has been described earlier in this chapter and should be encouraged. In addition to mental health concerns in the child, Eccleston and colleagues\textsuperscript{116} report that parents who have chronically ill children are often anxious and depressed (60\% and 40\%), and these symptoms may be a response to parenting a sick child or may predate the child’s illness.\textsuperscript{113} Chronic pain is likely to bring severe disruption to the social and family structure,\textsuperscript{62,117} which should be examined as part of gathering the history of the pain and its impact.

The child’s school experience should also be explored in an effort to identify further impact on daily function.\textsuperscript{118} Increased school absenteeism is commonly reported in most chronic pain syndromes,\textsuperscript{119} widespread musculoskeletal pain,\textsuperscript{10} and abdominal pain.\textsuperscript{120} This may be a result of underlying stress from learning disabilities, attentional problems, or social difficulties such as bullying. Frequent absences may also become a source of extreme stress for the child when faced with the need to reintegrate making a frank discussion about the child’s grades, competencies, social skills, friendships, and existing school accommodations a necessary part of the history gathering. The Pediatric Pain Screening Tool (PPST) is a 9-item screening tool available to identify factors associated with adverse outcomes among youth who present with pain complaints, providing risk stratification and potential guidance for effective pain treatment recommendation in the clinic setting.\textsuperscript{96}

Finally, red flags or alarm signs specific to the common functional pain syndromes that help delineate a need for additional investigation is discussed in specific sections pertaining to each syndrome (headache, abdominal pain, and musculoskeletal pain).

\textbf{MEASUREMENT OF PAIN AND FUNCTIONING}
A thorough biopsychosocial assessment of the child with chronic pain is critical for individualizing pain treatment strategies. The clinician aims to gather detailed information about the child’s current pain and pain history and assess areas of child daily functioning that are disrupted by pain while considering the child’s developmental stage. Many evidence-based self-report questionnaires have been developed and validated across the pediatric age range, which complement a semi-structured interview. Assessment is considered an iterative process, with follow-up assessment conducted throughout treatment to track progress toward treatment goals.

Measurement of aspects of recurrent and chronic pain requires tools that measure the frequency, intensity, duration, time course, and activity interference due to pain. Validated measures have been developed to capture most of these domains (e.g., Eccleston et al., Stinson et al.). Developmental considerations will guide selection of the most valid and reliable tool. In children ages 4 through 12 years, Faces Pain Scales have demonstrated good validity and reliability. In youth 8 years of age and older, Visual Analogue Scales, using anchors such as “no pain” and “worst pain ever,” are considered most valid and reliable. The verbal Numerical Rating Scale (NRS) is often used clinically, on which participants rate their pain on an 11-point scale representing increasing pain intensity (e.g., 0 to 10). Data indicate that the NRS is a valid and reliable measure for ages 8 years and older.

In addition to assessment of pain intensity, there are other characteristics of pain (e.g., duration, frequency, pain quality, spatial distribution) that are important to evaluate in children with chronic pain. Daily monitoring of pain and using a diary or log provides information about pain patterns as well as variations in children’s behaviors (e.g., activities participated in) and emotions (e.g., positive or negative affect). A body map identifies the spatial distribution of pain, including the number of pain locations, and indicates how widespread the pain is. It is also helpful to obtain information from parents and children about the history and course of the pain problem, including past and present treatments for pain, perceived efficacy of treatments, and beliefs about the cause of pain and expectancies for pain relief. Electronic pain diaries (e.g., smartphones and Web sites) have become increasingly used in children and adolescents to document
chronic pain symptoms. For example, Stinson and colleagues\textsuperscript{125} developed a multidimensional electronic diary to collect data on pain intensity, duration, location, and impact in adolescents with arthritis.

A critical area to assess is function. Measures such as the Functional Disability Inventory\textsuperscript{63} and the Child Activity Limitations Interview\textsuperscript{126} provide information about interference of pain in normal daily activities. These measures are brief and can be administered easily to document children’s functional disability at baseline and treatment progress. Many children with chronic pain conditions experience significant school impairment including a high number of absences from school and difficulties making academic progress.\textsuperscript{127,128} Role functioning can be assessed on broadband measures, such as HRQOL and pain impact measures. To supplement interview and survey assessment, objective measures of school attendance and performance (e.g., report cards, attendance records) are useful to obtain.

There are several multidomain measures that can be used for efficient assessment of multiple domains of functioning. The Patient-Reported Outcomes Measurement Information System (PROMIS) is a National Institutes of Health initiative. The PROMIS Pediatric Cooperative Group developed self-report item banks to assess general health domains, including depressive symptoms, anxiety, mobility, pain interference, fatigue, peer relationships, and pain intensity in children.\textsuperscript{129} When used as a comprehensive battery, 25-, 37- and 49-item versions are available to assess multiple domains. These measures are appropriate for children ages 8 to 17 years\textsuperscript{130} and can be supplemented by a parent proxy report. The Bath Adolescent Pain Questionnaire\textsuperscript{131} assesses seven domains of functioning affected by pain (social functioning, physical functioning, depression, general anxiety, pain-specific anxiety, family functioning, and development), and a parent report is also available.\textsuperscript{132} The Pediatric Quality of Life Inventory\textsuperscript{133} is a well-validated HRQOL measure for children (age 5 to 18 years) to self-report functioning in four broad domains (physical, emotional, social, school) and has a parent proxy instrument for younger children.

Psychosocial assessment is an important component in the assessment of a child with chronic pain in order to evaluate psychological, social, and
family functioning which may contribute to pain or pain-related disability. Psychosocial assessment may consist of clinical interviews, administration of standardized psychological measures, and observation of child and family members. A detailed clinical interview should cover developmental, behavioral, and psychiatric concerns in the patient’s and family’s history. Potential stressors and areas of maladaptive coping should be inquired about as well as a comprehensive school history and history of peer and social relationships. Ideally, a separate psychosocial assessment is conducted with child and parent alone in order to obtain their individual perspectives. Many outpatient pediatric pain clinics use intake questionnaire packets that cover demographics, developmental history, and other aspects of psychological functioning in order to consistently obtain this information in the evaluation of new patients. Review of intake packets may then provide details that serve as a springboard for more focused clinical interviews or additional psychological assessments during the intake visit.

Depending on the particular presenting concerns, standardized psychological measures may be administered to screen for mental health diagnoses, in particular, anxiety and depressive symptoms, to assess coping behaviors and family functioning. A variety of standardized instruments can be used in the clinical setting with the advantage of obtaining a quick assessment of children’s psychological functioning given the limited time available for in-depth psychological evaluation in the medical setting. Many valid and reliable measures are available to assess anxiety and depression in youth such as the Revised Child Anxiety and Depression Scale, and PROMIS Emotional Distress anxiety and depressive symptoms. Posttraumatic stress disorder (PTSD) symptoms can be measured using standardized tools like the 24-item Child PTSD Symptoms Scale. When psychological measures are used to screen for psychological distress, it is important to consider the limitations of self-report and, in particular, that children may want to present themselves in a favorable light (social desirability response bias), which has been described in children and adolescents with chronic pain.

Beyond general internalizing symptoms, it is also useful to assess pain-specific dimensions of anxiety (e.g., catastrophizing, pain-related fear).
There are developmentally adapted versions of the Pain Catastrophizing Scale available to assess child catastrophic thoughts about pain\textsuperscript{139} as well as parent catastrophic thinking about their child’s pain.\textsuperscript{140} Other measures are available to assess pain-related anxiety, such as the Child Pain Anxiety Symptoms Scale\textsuperscript{141} and the Fear of Pain Questionnaire,\textsuperscript{142} which also has a parent report.\textsuperscript{143}

Parental and family functioning has also been a major area of focus in pediatric chronic pain assessment.\textsuperscript{89} There are measures available to assess parent behaviors (e.g., frequently attending to pain symptoms or allowing avoidance of regular activities) that may contribute to pain-related disability (e.g., Adult Responses to Children’s Pain Questionnaire).\textsuperscript{144} In addition, overall family functioning can be assessed with several measures including the Family Assessment Device.\textsuperscript{145} In some cases, it may be important to screen parents for their own psychological distress, given the risk for high levels of caregiver stress in this population (e.g., Brief Symptom Inventory). For a comprehensive review of measures available to assess parental impact of chronic pain, see Eccleston et al.\textsuperscript{121}

There are also measures of child coping that have been validated on pediatric chronic pain samples including the Pain Response Inventory\textsuperscript{146} and the Pain Coping Questionnaire.\textsuperscript{147} Measures of specific areas of coping, including catastrophizing, are available such as the Pain Catastrophizing Scale, Child Version (PCS-C).\textsuperscript{139}

Well-established measures of sleep in pediatric chronic pain include the Children’s Sleep Habits Questionnaire (CSHQ),\textsuperscript{148} the Adolescent Sleep-Wake Scale (ASWS),\textsuperscript{149} and the Adolescent Sleep Habits Scale (ASHS).\textsuperscript{149} The CSHQ is a parent-report measure used to assess multiple aspects of sleep in school-age children (ages 4 to 10 years), including bedtime behavioral issues and symptoms of sleep disordered breathing.\textsuperscript{148} The ASWS and ASHS are complementary measures of sleep quality and sleep habits, respectively. Although reliable and relevant to pediatric pain, all three questionnaires are lengthy and potentially burdensome to complete. A short form (10-item) of the ASWS was recently developed that may be useful to integrate into quick-paced tertiary care settings.\textsuperscript{90} For a comprehensive review of available sleep measurement tools in pediatric pain, see de la Vega and Miró.\textsuperscript{150}
PHYSICAL EVALUATION

Information gathered from the physical examination in conjunction with the history can help differentiate a primary/functional pain disorder from pain secondary to an underlying disease. General appearance (sickly or well appearing) may be helpful, although individuals who are in pain for a prolonged period of time may look pale and wan. Growth parameters should be examined as chronic illness may well impede growth. Because of the association between chronic pain and postural orthostatic tachycardia syndrome, heart rate should be obtained both supine and standing.

The child should be asked to localize his or her pain. The differential diagnosis and intervention strategies are very different for generalized discomfort versus highly localized pain. Specific discussion of the examination of the back, abdomen, and joints is beyond the scope of this review, but regardless of the origin of the pain, the clinician should obtain general impressions of the child’s mood, cooperativeness, irritability, and eye contact along with a comprehensive neurologic exam and more focused musculoskeletal exam, noting the child’s gait and posture.

Although hypermobility does not predict future musculoskeletal pain in the preteen and adolescent population, literature currently supports the association of chronic musculoskeletal pain with hypermobility. The Beighton score is a valid measurement of generalized joint hypermobility in children. A score of 6/9 indicates hypermobility. When positive, discussion regarding hypermobility can be helpful both in its suggestion of biologic vulnerability to pain as well as providing guidance in the development of additional goals for physical therapy such as joint protection, postural control, and improved proprioception as a part of the multidisciplinary plan. Regardless of the origin, a Beighton score should be calculated on all children with chronic pain.

CLINICAL FORMULATION

The task for the clinician is to examine the data that emerged from the history and physical and determine whether or not there are sufficient red flags to warrant further investigation for progressive disease. If there are, the child and family should be informed that the investigation is ongoing.
If there are not, the clinician should report to the child and family that the child most likely has a chronic pain syndrome. In either situation, the pain should be treated appropriately, although the approach, both philosophically and practically, will vary between the two. If the pain is thought to be a manifestation of a time-limited disease process, although the approach will be multifactorial, there will often be an emphasis on more aggressive pharmacologic intervention while the disease process runs its course. If the pain is associated with a chronic condition or represents a chronic pain syndrome, the emphasis is more typically on a rehabilitative approach.

FEEDBACK WITH THE FAMILY
During initial evaluation, history and physical may warrant further investigation for progressive disease, in which case, further evaluation should be discussed with the child and family. However, if the need for additional investigation is not indicated, the clinician should review with the child and family that the more likely cause is a primary/functional pain disorder.96 This initial feedback is, in effect, the first treatment intervention and will set the tone for the subsequent relationship with the child and family.114,115

Regardless of the etiology of the pain, feedback should include a number of elements. Ensuring the family at this time that the pain is “real” is critical as many families of children with chronic pain report that they have felt dismissed and feel that their child has not been believed. It is imperative that the clinician informs the family that he or she is familiar with the pain symptom complex. Even if the exact problem is not clearly defined, chronic pain problems share numerous overlapping features which need to be addressed such as sleep disturbances, school reintegration, and return to physical and social activities. Another key element is that of optimism. It is clear that expectations can influence the outcomes of chronic pain treatment.156

Providing an understandable explanation of the pain is a critical element of the initial feedback. The current conceptualization of chronic pain is that it results from the interplay between biologic vulnerability and psychological and environmental variables which ultimately lead to
abnormalities of sensory processing, enhanced responsiveness, and excitability in the central nervous system known as central sensitization. Central sensitization is discussed in numerous other chapters throughout this book in detail, but it is the term used to describe the dysfunction of the nervous system that results in an amplified responsiveness to painful and nonpainful stimuli. This increased responsiveness of the nervous system is thought to be a key element in the development and maintenance of chronic pain.97–100 Because chronic pain typically represents nerve “hypersensitivity” and not progressive disease and damage, the traditional dichotomization of pain into organic or psychological causation is inaccurate and often harmful.98–100 It is also essential therefore that the child and family be aware that pain persistence does not serve a warning protective function as it does in acute pain and that although pain may “hurt,” it is not causing “harm.” This all must be explained to the child and family in an understandable way as Moseley and others have documented the importance of “neuroeducation” in promoting recovery and compliance with recommendations.157,158 The use of metaphors (“pain is a false alarm”; “the pain is a software glitch, not a hardware problem”) may be quite helpful in conveying this message.159,160

As previously stated, due to the complex relationship between biologic, psychological, individual, social, and environmental factors which result in chronic pain, treatment recommendations should be multidimensional. The massive stress of school, the loss of normal opportunities to socialize with friends, and the impact of the immobilization and sleep deprivation often accompanying chronic pain further contribute to its maintenance and persistence and therefore should be a part of the treatment plan elucidated during the feedback.114 Evidence of the positive impact of a multidisciplinary approach was demonstrated in 5 out of 8 outcome domains recommended by PedIMMPACT including pain intensity, disability, school functioning, anxiety, and depressive symptoms114 as well as by numerous other investigators.161 Lack of acceptance of the multifactorial nature of pain and its treatment has been identified as one of the causes of treatment failure.162

The final element that the feedback should convey is that although the ultimate goal is reduction of pain, initially, it is the return of the child to
functioning. Pain reduction or elimination will often follow.

**Treatment**

**GENERAL PRINCIPLES OF TREATMENT**

Interventions offered by multidisciplinary teams for the management of chronic pain are centered on three main components: pharmacotherapy, physical therapy, and psychological therapy for a multimodal approach focusing on improving daily function. Dimensions of daily function include “the 4 S’s”: sports, social, sleep, and school, with a primary goal to improve physical function and facilitate reengagement in age typical activity. As mentioned previously, educating the child and family that chronic pain does not offer the warning protective function of acute nociceptive pain and stating that although the pain is unpleasant, it is not causing “harm” is essential to alleviate familial anxiety and promote participation in the main components shown to allow for improved function.

Initially, frequent scheduled follow-up appointments help the child and family build confidence through careful monitoring as the child engages in these therapies. Symptom diaries may provide interim data between appointments. This approach has been labeled “watchful waiting” and can reassure parents that if new symptoms develop, a potentially unrecognized disease process will not be missed.

Interventions typically employed to address chronic pain must allow the child to return to a “normal” life. As a result, medications which significantly alter the child’s sensorium are inadvisable, along with prolonged hospital or home stays. Pharmacotherapy to reduce central sensitization such as antidepressants and anticonvulsants are often the mainstay of pharmacologic treatment regardless of the etiology of the chronic pain; however, utilized as a sole therapy for primary pain disorders, they tend to be ineffective. Although there are limited clinical trials to support their use, antidepressants and anticonvulsants are used in children for primary pain disorders. Two of the most common, amitriptyline and gabapentin, are approved for use in children; however, few other antidepressants and anticonvulsants have been. Analgesic
agents for mild acute pain, such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), may be helpful, but there is the risk of rebound headache or abdominal pain secondary to excessive nonsteroidal usage.\textsuperscript{166,167} Guidelines for opioid use for chronic pain have not been applied to children and adolescents.\textsuperscript{168} When used for primary pain disorders, opioids are generally associated with worse clinical outcomes.\textsuperscript{169} That said, appropriate use may be indicated in conditions such as osteogenesis imperfecta, congenital degenerative spine conditions, other neurodegenerative conditions, and erythromelalgia.\textsuperscript{168–170}

Physical therapy is of particular value in musculoskeletal pain syndromes such as fibromyalgia but is also valuable in any pain syndrome in which the child’s activity level has been diminished and he or she has become deconditioned.\textsuperscript{171–174} Graded exercise increases the child’s feelings of well-being and provides reassurance and confidence as the child regains lost abilities.\textsuperscript{174} Other physical and occupational therapy modalities such as desensitization, transcutaneous electrical nerve stimulation, and stretching or strengthening particular muscle groups are also helpful.\textsuperscript{173–177} Physical therapy is also of particular benefit in individuals who are hypermobile where the focus is on joint protection and proprioception. Active mind–body techniques, such as biofeedback and guided imagery, integrate cognitive and emotional processes with physiologic function and have also demonstrated efficacy in modulating the pain pathway in chronic pain conditions.\textsuperscript{178,179}

Evidence supports psychological interventions as effective treatment of chronic pain in children. Multiple reviews and meta-analyses confirm the strong impact of these approaches which include cognitive-behavioral as well as psychotherapeutic strategies.\textsuperscript{180–183} Although many of the cognitive-behavioral strategies were developed to help cope during acute, painful procedures, many of these strategies, such as meditation, hypnosis, and mindfulness, are also effective for chronic pain.\textsuperscript{178,184} Acceptance and commitment therapy (ACT) was developed to help individuals function in the context of ongoing pain.\textsuperscript{185} Guidance of the child and the family toward resuming daily function is the overall goal of treatment. Educating parents on the best way to support their child with ongoing pain symptoms is an integral step in this process. The natural protectiveness of parents for
their child with pain can hinder progress and become detrimental in primary pain syndromes. Parents often need help ushering crying, complaining children off to school when the path of least resistance is to allow them to remain in bed. Specific criteria for school attendance with modifications can help the child regain a rhythm of daily school attendance. In general, school should be mandatory except for those times when the child has a fever. When efforts to incorporate these dimensions in an outpatient setting fail to enable a child to normalize daily function, more intensive daily rehabilitation centers with an interdisciplinary team approach are shown effective in regaining daily activity and should be considered.\textsuperscript{114}

In summary, the treatment of chronic pain in children needs to address the pain itself as well as the life context in which that pain is occurring. As a result, a multimodal approach incorporating pharmacotherapy, physical therapy, and cognitive therapy with the goal of regaining normal daily function are important dimensions of the treatment of chronic pain.

**SPECIFIC INTERVENTIONS FOR CHRONIC/PERSISTENT PAIN**

Children who receive care in a multidisciplinary pediatric pain clinic are typically offered a multicomponent treatment plan, which often involves psychological therapy, physical therapy, and medication management. Philosophically, most programs incorporate a rehabilitation approach in which pain is accepted as a symptom that will be diminished but might not be entirely eradicated. Therefore, the focus is typically on improving function and quality of life. The specific structure of each program differs depending on local factors with some providing inpatient rehabilitation, whereas others are solely outpatient. Many new programs are developing in the United States and abroad. Zeltzer and Schlank\textsuperscript{186} list many pediatric pain programs in the United States, Canada, and internationally.

**Pharmacologic Interventions**

Pediatric analgesic pharmacology is summarized in greater detail elsewhere in this book (see Chapter 50). The current discussion emphasizes specific uses of analgesics in the setting of chronic persistent
pain, as opposed to acute pain. Pharmacotherapy of chronic pain in children and adolescents requires patience and balance of risks, benefits, and side effects. For most patients coming to a chronic pain clinic, pharmacotherapy should not be used in isolation but only as a component of a multimodal treatment program. In considering a medication trial, clinicians’ discussions with patients and parents strike a difficult balance. The aims of drug therapy and expected benefits should be outlined. Side effects and risks should be discussed in a manner that is honest but is tailored to the style of the individual patient and family. There is a growing literature on how patients hear risk discussions.\textsuperscript{187}

Discussions of side effects do have the potential to generate nocebo (negative placebo) effects.

For some conditions, treatments can be specific and mechanism-driven. For example, for children with rheumatoid arthritis, pharmacotherapy is largely directed at underlying inflammatory processes, and for most patients, treatment of inflammation serves to treat the pain. Similarly, pharmacotherapy for migraine and for specific subtypes of chronic abdominal pain may be directed at underlying mechanisms in some cases.

Acetaminophen and NSAIDs are widely used for pediatric acute pain management, and NSAIDs are an integral component of management of chronic inflammatory disorders. Daily use of either of these classes of medications can produce rebound headaches. There is comparatively little studies on chronic daily administration of acetaminophen in children. Chronic administration of NSAIDs in children with rheumatoid arthritis has been associated with gastropathy and nephropathy but overall with a lower risk than has been reported in adults.

A majority of trials of cyclooxygenase (COX)-2 inhibitors in children have involved short-term use. A recent 3-month trial comparing celecoxib to naproxen showed equal efficacy and no statistically significant difference in adverse events.\textsuperscript{188}

Opioids have been extensively studied for pediatric acute pain management and for pain in children with cancer. As with adults, there is little consensus regarding which children with chronic noncancer pain have a favorable risk–benefit ratio for long-term opioid analgesia. Overall, prospective studies on adults in pain clinic populations with non–life-
shortening conditions have not shown good effect of long-term use of opioids on either pain scores or measures of quality of life or functioning. Those who defend chronic opioid therapy in adults may argue that these studies did not address ideal patient subgroups. With children and adolescents, there are additional concerns. First, opioid tolerance and opioid-induced hyperalgesia are likely to proceed more rapidly for children compared to adults. Second, long-term opioid administration may have detrimental effects on endocrine function. Third, with many chronic medical conditions in childhood, longevity is difficult to predict, and advances in treatment have changed prognosis for many chronic illnesses of childhood and young adult life. For these reasons, we do use opioids on a long-term basis for a small subset of children with chronic pain not due to life-limiting illnesses, but we do so with some caution and with consideration of alternatives. There is a theoretical argument in favor of selection of either methadone or buprenorphine for long-term opioid therapy in younger patients based on a hypothesis that relates the development of tolerance and hyperalgesia to differential activation of receptor-mediated activation of second messenger systems versus receptor-mediated endocytosis.

For adults with many forms of chronic pain, especially neuropathic pain disorders, there is evidence for efficacy of several anticonvulsant and antidepressant medications. We cite some limited pediatric information in the following text, but at present, most information regarding efficacy must be extrapolated from clinical trials in adults. In adults, these medications are side effect–prone and inconsistently effective; they generally produce partial, rather than complete, pain relief. In adults, there are very few randomized controlled trials (RCTs) that compare one antidepressant to another or that compare an antidepressant to an anticonvulsant. There is remarkably sparse evidence for selecting one medication over another in general for adults with chronic pain except for specific conditions that are uncommon in pediatrics, such as trigeminal neuralgia.

One publication is cited here mainly to recommend caution in its interpretation. The authors use an “indirect meta-analysis” to compare duloxetine to the anticonvulsants gabapentin and pregabalin for treatment
of neuropathic pain in adults. What is actually done is to use outcomes from active treatment groups in studies comparing duloxetine to placebo to the active treatment groups in studies comparing gabapentin or pregabalin to placebo.\textsuperscript{193}

For antidepressants in trials for neuropathic pain in adults, numbers needed to treat (NNTs) range from 2 to 4 for trials involving tricyclics (mostly with “global improvement” as an endpoint) to as high as 5 for trials involving duloxetine with 50% pain relief as a primary endpoint. Overall, tricyclics appear to be more effective than selective serotonin reuptake inhibitors (SSRIs) for neuropathic pain in adults.

For children and adolescents, we commonly choose nortriptyline as a first-line tricyclic. We encourage starting at a very low dose (e.g., 10 mg every night for adolescents and older children and 5 mg every night for younger children). The rate of dose escalation is determined by clinical circumstances and side effects. For an outpatient who experiences no adverse symptoms, dosing might be increased every 3 days until there is good analgesia or he or she reaches a dose around 40 or 50 mg daily. Dosing is occasionally even more rapid for inpatients with severe neuropathic cancer pain. Conversely, if the child does experience side effects, dose escalation proceeds more slowly. If there is no indication of analgesia or side effects by the time dosing is escalated to 50 mg/daily (and if we are convinced that the child is taking the medication), we will often obtain a blood level prior to further dose escalation. Clearance of tricyclics in children is enormously variable. An electrocardiogram is widely recommended either prior to initiating treatment or after dose escalation. We adhere to this recommendation while recognizing that there is little evidence that electrocardiography can identify patients at risk for sudden cardiac events.

There are a number of clinical trials and case series on antidepressants for migraine prophylaxis in pediatrics, including amitriptyline, nortriptyline, and trazodone, although many have involved open-label designs or crossover comparisons to other drugs.\textsuperscript{194,195}

There is a widely quoted case series on the SSRI citalopram for treatment of recurrent abdominal pain in children. Although there is apparent improvement in a large percentage of patients, this should be
interpreted with great caution because of the open-label and uncontrolled
design of the study.\textsuperscript{196}

There has been extensive controversy regarding potential risks of
antidepressants in triggering suicidal ideation and completed suicide
among adolescents. What is clear to us is that these medications require
close monitoring for changes in a child’s mood and behavior. Prescribing
should begin in low doses, doses should be escalated in a gradual and
stepwise manner, and there should be a system for frequent reassessments,
ideally including regular phone calls in between clinic visits. For guidance
of families, there is a well-written statement on the National Institute of
Mental Health Web site.\textsuperscript{197}

Anticonvulsants are also widely used for treatment of neuropathic pain
in adults. As with antidepressants, side effects are common, treatment
responses tend to be partial rather than full, and NNTs generally range
from as low as 3 to over 5.

Gabapentin emerged as a widely prescribed medication for neuropathic
pain in the 1990s in part because of the widespread belief that it was safer
or easier to prescribe compared to other anticonvulsants. There is a
remarkable dearth of trials comparing anticonvulsants to each other for
neuropathic pain in adults.

As with tricyclics, our recommendation for gabapentin dosing is to start
with small doses and escalate slowly, particularly in ambulatory patients.
Different clinicians begin adolescents in a dose range from 100 mg daily to
300 mg daily. Our preference is to start for a few days with nighttime-only
dosing, to begin morning and then afternoon dosing after about 3 days, and
to escalate every few days as tolerated until there is pain relief, significant
side effects, or dosing reaches a range around 1,800 mg daily over a period
of about 3 weeks. Again, some patients tolerate escalation with no side
effects, and others may tolerate daily doses as low as 300 mg. We
commonly recommend giving half the daily dose at night, with one quarter
in the morning and one quarter in the afternoon. As with tricyclics, dose
escalation of gabapentin may be considerably more rapid for children with
advanced cancer and refractory neuropathic pain.\textsuperscript{198}

In our view, if trials of gabapentin or pregabalin produce minimal
benefit or problematic side effects, there is reason to consider trials of
anticonvulsants with different mechanisms. In particular, for peripheral neuropathic pain, we often try anticonvulsants with actions on sodium channels, such as oxcarbazepine.\textsuperscript{199,200}

In our practice, topiramate is used primarily for migraine prophylaxis. Among the anticonvulsants, topiramate has a relatively high risk for neurocognitive side effects, especially effects on memory, word finding, and mental clarity.\textsuperscript{201}

Some of our colleagues have tended to select anticonvulsants rather than antidepressants as first-line agents because of the aforementioned controversy regarding suicidal ideation and suicide attempts with antidepressants in pediatrics. Unfortunately, anticonvulsants may increase these risks as well. An analysis of placebo-controlled trials of anticonvulsants for a range of indications found increased frequencies of suicidal ideation and attempts in the active drug groups compared to control groups, and this increased risk was apparently not limited to a particular drug class or a particular patient group.\textsuperscript{202}

**Psychological Interventions**

A range of psychological therapies has been delivered to youth with chronic pain conditions, either as single modalities or in combination with other types of interdisciplinary pain care. The evidence base for psychological therapies for children with chronic pain is moderate and growing, with 41 RCTs published across three Cochrane reviews.\textsuperscript{203–205} Systematic reviews investigating psychological therapies for pain management including cognitive-behavioral therapy (CBT), behavioral interventions, hypnotherapy, intensive rehabilitation, and ACT have found significant declines in children’s pain intensity and disability at posttreatment, and these were small to moderate size effects. However, these treatment effects were not maintained at long-term follow-up. Psychological treatments did not have any effect on depression or anxiety outcomes at posttreatment or follow-up compared to controls. Although promising, further work is needed to enhance duration of treatment effects.

CBT is the most frequently delivered psychotherapy to youth with chronic pain conditions and typically includes a combination of education, cognitive, and behavioral skills. Cognitive skills involve teaching patients
to identify and alter maladaptive cognitions related to pain. This may include working with children to recognize negative thoughts and beliefs about pain and activity engagement. Behavioral skills are intended to modify what a patient does to manage pain. Thus, these skills focus on improving patient function by increasing patient activity levels and involvement in pleasant and valued activities, such as activity pacing and pleasant activity scheduling. Relaxation is one of the most common behavioral skills used with children with chronic pain. For example, Van Der Veek et al. taught deep breathing to children with functional abdominal pain by asking them to breath calmly through the abdomen (rather than the chest). Cottrell et al. instructed progressive and cued muscle relaxation to youth with migraine over the phone.

Teaching parents appropriate strategies for managing their child’s pain-related behaviors (e.g., reinforcing adaptive coping, discouraging maladaptive pain behaviors) is beneficial in treatment, and these strategies are increasingly being incorporated into psychological therapies.

For example, Levy et al. worked with parents to recognize when their attention was directed to sickness behaviors and to redirect attention toward wellness behaviors, and this led to a reduction in maladaptive parent behaviors.

Problem-solving skills training (PSST) is based on the social problem-solving model and focuses on teaching parents a positive orientation and rational skills for solving problems in order to reduce emotional distress. In a pilot RCT, Palermo et al. delivered PSST to parents of youth with chronic pain using this model to teach five problem-solving steps (identify a problem, generate alternative solutions, decide and implement a solution, and then determine whether it worked), finding promise effects for reducing parent distress. Findings demonstrated that PSST reduced emotional distress in parents of children with chronic pain compared to a usual care condition.

Although effective psychological treatments have been developed, major barriers exist for children and adolescents to access care due to the geographical distance from treatment centers with behavioral health providers, scheduling constraints, and long wait–lists, leaving a significant unmet clinical need. Availability of information and communication
technology has expanded opportunities for intervening with individuals remotely. An emerging evidence base now exists for remotely delivered psychological interventions in both adult and pediatric populations; a recent systematic review of the pediatric literature identified eight RCTs, which all delivered CBT, and patients showed improvements in pain and disability. As one recent example, in a large multicenter RCT with 273 adolescents with chronic abdominal, headache, or musculoskeletal pain, Palermo et al. found improvements in daily physical functioning, depressive symptoms, and parent-perceived impact of pain in families receiving an 8-week Internet pain self-management program compared to an Internet pain education control group.

Pilot studies are emerging in the application of ACT to children with chronic pain. ACT is an increasingly popular form of CBT that emphasizes the importance of accepting pain symptoms and working toward valued goals, using interventions such as exposure, cognitive defusion, and mindfulness. Parents are also integrated into treatment using similar interventions emphasizing exposure to previously avoided private experiences, acceptance, and defusion exercises. In the only RCT to evaluate ACT in children with chronic pain, Wicksell et al. delivered exposure treatment within an ACT framework, which emphasized acceptance of pain and negative thoughts and setting goals with youth consistent with their values to a small group of youth with chronic pain, compared to a group receiving standard multidisciplinary and pharmacologic treatment with amitriptyline. The ACT group reported reduced symptoms across all outcomes and had significantly lower pain intensity, pain-related discomfort, and fear of reinjury as well as improved perceived functional ability at posttreatment and follow-up, relative to the control group. Given the clinical interest in ACT, it is anticipated that larger scale studies will be forthcoming using this approach to treat children and adolescents with chronic pain.

Complementary and alternative medicine (CAM) interventions are becoming increasingly popular in the treatment of chronic pain and have been successful in helping children and adults manage pain symptoms. CAM refers to therapies (e.g., hypnosis, acupuncture, yoga, and biofeedback) commonly used in conjunction with conventional medical
Biofeedback is one type of CAM therapy effective in the treatment of persistent pediatric pain. Biofeedback involves connecting a patient to a machine that monitors physiologic responses (e.g., muscle tension, heart rate). One form of feedback, thermal biofeedback, involves using electronic instruments (e.g., a temperature probe on the finger) to measure temperature and a computer monitor to display reinforcing information back to the patient. Using relaxation approaches, patients can use the objective biofeedback information to learn to increase peripheral temperature.

Biofeedback, especially thermal biofeedback, has undergone empirical evaluation in children with migraine and tension headache, and there is evidence to recommend biofeedback and/or relaxation to any child who suffers from headaches. Recently, biofeedback has been evaluated in children with chronic abdominal pain. Although results from these studies suggest that biofeedback is effective in reducing pain, RCTs using larger sample sizes are needed. Like CBT, research shows that incorporating parenting strategies into biofeedback treatment may increase the effectiveness of treatment. Children whose parents received behavior management strategies in combination with the child’s standard biofeedback treatment demonstrated more clinically significant improvement in headache pain and showed greater reductions in headache frequency than those who received biofeedback alone.

**School and Social Reintegration**

School and social functioning are impaired in many children with chronic pain. In industrialized societies, school is the work of children. Numerous studies have documented that children with chronic pain have difficulties with consistent school attendance and making progress with academic work, although there may also be specific impairments in peer and social relationships that are amplified in the school setting. On average, children with chronic pain miss more school days than do children with other chronic health conditions, and they often identify school as the most problematic stressor. For example, Stang and Osterhaus estimated that several hundred thousand school days are missed each month as a result of pediatric headache alone. In a sample of children with SCD-related pain,
Shapiro and colleagues\textsuperscript{221} reported that on average, children missed 21\% of school days, which is the equivalent of 6 to 8 weeks of the school year. There is also evidence that children with chronic pain may experience problems with social competence and peer relationships in the school setting. In one study, adolescents with juvenile fibromyalgia syndrome were perceived as being less popular, more isolated, and withdrawn compared to matched classroom comparison peers.\textsuperscript{66} Moreover, these adolescents were less well liked, were selected less often as a best friend, and had fewer reciprocated friendships. Negative peer interactions were explored in one study,\textsuperscript{222} finding that children with chronic abdominal pain had higher levels of relational victimization in comparison to pain-free peers.

The school setting may also be perceived as stressful due to problematic interactions with teachers and perceptions that adults are not supportive of children with chronic pain. In a study using vignettes, teachers’ attributions about the causes of chronic pain revealed a lack of knowledge of the biopsychosocial framework and a primary perception that pain was either physical or psychological.\textsuperscript{223} Teachers responded more positively to students when medical evidence supporting the pain problem was available, and responses were associated with parental attitudes toward the school. Teachers were more likely to report children were entitled to accommodations if parents approached the school in a collaborative manner rather than using a confrontational approach.\textsuperscript{224}

There is variability in how children and families respond to impairments that may arise in the school setting. Some children and adolescents have worked out accommodations that allow them to have reduced class time, in home tutoring, or online courses. Several mechanisms in public education laws can be used in this regard, including individualized education plans and Section 504 plans for other health impairments. Some families opt to remove their child from the school setting and engage in home schooling. Regardless of the exact setting where school is to occur, addressing the impairments in school and social functioning are a primary focus of treatment for the child with persistent pain. Some children and adolescents have spent extensive time outside of their usual school and social settings, and therefore, graded plans for reintegration into these settings are needed.
In the context of CBT, parent management guidelines have been implemented in clinical settings and in treatment studies focused on operant techniques. In general, parents are encouraged to establish a reduction of attention paid to pain symptoms in favor of increased attention paid to functional improvement. Such guidelines often include recommendations to reduce status checks, that is, allowing the child to communicate directly about pain symptoms rather than having the parent repeatedly check in with the child about his or her pain level. Most parents experience tremendous relief in being released from the role of documenting the child’s pain level. Often, the focus on pain intensity and a specific numerical value (e.g., 8 out of 10) provides little in the way of adaptive coping behaviors and may lead to difficulties making decisions to reintegrate in school and social settings because of lack of change in pain levels.

Formal operant systems can be devised with families where children earn points or rewards for school attendance and participation in other social activities. The goal is to shift the pattern of contingencies so that the child experiences reinforcement for their efforts in school or social activities. An example of a point system would include specifying a target activity such as attendance at school for 4 hours each day and then developing rewards for reaching the goal (such as full computer and television privileges) and consequences for failure to achieve the goal (such as removal of access from computer and television). Psychologists and other members of the pain team can work in treatment with children and parents to develop clear, graded plans for increasing activity. Typically, an explanation to children and parents is provided that functional improvement often precedes rather than follows pain relief. It is important to start where the child is at in terms of their perceived ability to sit in a chair and focus on school work for an operant system to be successful. Sometimes, very short time periods of school attendance (e.g., 1 hour) will need to be built on gradually, and the child will need to have some control over his or her schedule. For example, it can be helpful to have the child choose what time of the day (and what classes) he or she would like to begin with upon the reintegration to school.

Carrying out a graded plan for increasing school and social functioning
requires considerable effort from the parents who must arrange transportation and other logistics with getting the child to the school setting at specific times. Clinicians need to communicate sensitively to parents about their role and make clear the logical sequence of the plan to ensure its success. Additional interventions may be needed to assist children with problems related to peer relationships, interactions with teachers, or specific problems related to the school setting. There are not yet any published treatment studies evaluating school-related interventions for children with chronic pain.

Sleep
Sleep difficulties are commonly reported by children and adolescents with chronic pain in the community as well as in clinical samples (e.g., juvenile rheumatoid arthritis, headache, SCID, abdominal and musculoskeletal pain, and CRPS). For example, a recent systematic review found that children with juvenile idiopathic arthritis experience greater difficulties with night awakenings, sleep anxiety, and excessive daytime sleepiness compared to otherwise healthy children. Most commonly, across types of chronic pain conditions, children and adolescents with chronic pain describe difficulties falling asleep, frequent night and early morning awakening, and excessive daytime sleepiness. Important consequences of sleep problems have also been identified including decrements in children’s HRQOL, mood, and physical functioning. Day-to-day variability in pain, mood, and sleep has been examined in children with SCD, finding that negative mood partially explained the relationship between more intense pain and poor-quality sleep on the same and subsequent days. Other studies in youth with mixed pain conditions have found temporal relationships between pain and sleep, where nighttime sleep predicted next-day pain. Early models described a bidirectional relationship between pain and sleep, where uncontrolled pain can cause sleep disruptions, and in turn, disturbed sleep can enhance pain sensitivity. Recent research has demonstrated that more studies now support the direction of sleep impacting pain than vice versa. That is, sleep deficiency has now been shown to lead to subsequent increased pain. Findings are from studies.

However, there has been very limited attention to either the assessment or management of sleep problems in children with chronic pain. In clinical practice, it can be very informative to assess sleep problems in all pediatric patients with chronic pain and to offer specific sleep interventions to those patients with significant sleep disturbances. In particular, a detailed history of sleep patterns should be obtained to identify problems related to insufficient sleep duration, poor sleep habits, phase delays, or difficulties falling asleep or staying asleep. Insufficient sleep duration is common during adolescence with reported sleep in healthy samples of about 7 hours per night, although optimal developmental sleep requirements for adolescents have been estimated at 9 hours per night. In chronic pain samples, similar restricted sleep of about 7 hours per night has been reported. Poor sleep habits including use of caffeine in the evening, lack of consistent bedtime routines, and the presence of electronics in the bedroom can also be clear barriers to children receiving adequate sleep duration. Children with chronic pain may also develop a high level of vigilance and arousal at bedtime and a high focus on pain when the distractions of the day are not present. These children may describe negative thoughts, worries, and somatic tension that interfere with falling asleep.

Interventions may be needed to help children increase their duration of sleep, to modify problematic sleep habits, and to teach behavioral strategies to reduce insomnia symptoms. Sleep interventions can be included as a component of CBT for chronic pain or as a stand-alone treatment. Typically, interventions include modifying sleep hygiene (e.g., no phones or screens in bed, regular and relaxing bedtime routine), keeping a regular bedtime and wake time which allows for adequate duration of sleep, limiting naps, and reducing negative thoughts about sleep as well as teaching specific strategies to decrease insomnia symptoms. For review, see Wu et al. Cognitive-behavioral therapy for insomnia (CBT-I) is recommended by the American Academy of Sleep Medicine as first-line treatment for adult insomnia.
Meta-analyses conclude that CBT-I produces reliable and durable improvement in sleep in adults with co-occurring pain conditions including arthritis and fibromyalgia.\textsuperscript{241} There is emerging evidence suggesting that changes in sleep as a result of behavioral treatment lead to changes in pain symptoms. For example, in a recent trial of CBT-I in patients with knee osteoarthritis and insomnia, patients who received CBT-I had greater improvements in sleep and the baseline-to-posttreatment change predicted subsequent decreases in pain.\textsuperscript{242} Moreover, CBT-I is a flexible treatment with evidence emerging that it can be delivered in group settings and remotely through the internet with similar positive benefits.

Although the treatment literature for child and adolescent insomnia interventions is more limited, there has been a recent uncontrolled trial in an adolescent pain population. In this study, adolescents with a range of physical and psychiatric comorbidities (e.g., depression, chronic pain, anxiety, GI problems) received a brief four-session CBT-I intervention.\textsuperscript{243} CBT-I was associated with treatment improvements in insomnia symptoms, sleep quality, sleep hygiene, presleep arousal, and sleep patterns as well as improvements in psychological symptoms and HRQOL. Sleep interventions appear promising and further research is needed to understand the impact of sleep interventions on chronic pain and when these interventions should ideally be delivered to children.

\textbf{Intensive Rehabilitation Therapy}

Intensive rehabilitation for children with chronic pain occurs in either a day treatment or inpatient setting, during which an interdisciplinary team of three or more health care professionals works together to increase patient function. These programs have developed over the past decade in response to limitations in effectively treating children, especially those extremely disabled by pain, in the outpatient setting. Psychological treatment is typically delivered in individual or group-based treatment. A systematic review evaluating the effectiveness of intensive rehabilitation programs identified one RCT and nine nonrandomized trials.\textsuperscript{115} At posttreatment, the meta-analysis of all included studies showed large effects for reducing disability and small to moderate effects for programs at reducing pain and depression. These benefits were maintained for 3
months after treatment and a recent study demonstrated cost-effectiveness, saving families a projected $27,000 the year following admission.\textsuperscript{244}

\section*{Specific Entities}

\textbf{MUSCULOSKELETAL PAIN}

Musculoskeletal pain accounts for more than 50\% of all the recurrent pains reported in the pediatric population.\textsuperscript{245} Differential diagnosis of musculoskeletal pain is vast. Two questions can help differentiate primary pain syndromes from progressive disease. Is the pain localized or widespread? Does the child appear well or unwell? If the pain is localized and the child is well, the differential diagnosis includes “growing pains,” CRPS, mechanical pain, pauciarticular juvenile rheumatoid arthritis, and spondyloarthropathy. If the pain is localized and the child is unwell, the infectious arthritides should be considered. If the pain is diffuse and the child is well, hypermobility and diffuse idiopathic pain syndrome (juvenile fibromyalgia) should be considered. If the pain is diffuse and the child is unwell, malignancies or autoimmune diseases top the list. Red flags in the history to guide us in determining the differential include pain in the morning, swelling, nocturnal pain not relieved by analgesics, poor growth, or bony tenderness.\textsuperscript{246}

Diffuse or widespread musculoskeletal pain is the term typically used for generalized musculoskeletal pain which in adults may be termed fibromyalgia. Diagnostic criteria for “fibromyalgia” in children and adolescents are not validated. The onset of diffuse idiopathic pain can be gradual. The pain may have an identified initial insult such as infection, but often, there is no identified trigger. A number of studies have identified an increased association between widespread muscular pain and hypermobility.\textsuperscript{151} As more evidence is collected, hypermobility-related disorders also appear to have a strong interrelationship with many primary pain disorders.\textsuperscript{153} This may be secondary to central sensitization, induced by constant subluxation and slippage or may have other etiologies that cause repeated microtrauma in joints and ligamentous structures with associated pain leading to disordered sensory processing.\textsuperscript{151,153,247,248} It is also important to address syndromes that are associated with
hypermobility such as Ehlers-Danlos or Marfan syndromes which may have additional problems associated with them.

Treatment for widespread musculoskeletal pain incorporates a multimodal approach and typically has physical therapy at its cornerstone.249,250 There is the attempt to restore the normal range of movement, even if the joint is hypermobile, strengthen the surrounding musculature to add joint stability, and improve the general level of fitness in the individual. Premedicating with an analgesic prior to therapy may be warranted as pain may promote noncompliance with the prescribed regimen. Improving the child’s level of fitness may help with sleep promotion and improve his or her general sense of well-being. Bulbena and others have reported an association between hypermobility and anxiety disorder in adults and believe that the tissue disorder is a predisposing factor for trait anxiety.251–253 Even in children without hypermobility who have chronic musculoskeletal pain, cognitive-behavioral and, if necessary, pharmacologic interventions which reduce catastrophizing and panic and promote coping are often appropriate. Disordered sensory processing has been identified in many individuals with widespread musculoskeletal pain. Regardless of its origin, anticonvulsants and/or antidepressants may have a role in dampening central sensitization and therefore in the management of chronic musculoskeletal pain. Eccleston and colleagues254 report on the success of their multidisciplinary program emphasizes family oriented CBT, physical activity, goal setting, pacing, relaxation, and communication.255,256 As with other chronic pain problems, a holistic rehabilitation approach to musculoskeletal pain appears to have better outcomes than a unidimensional one.

**COMPLEX REGIONAL PAIN SYNDROMES**

CRPS1, also known as reflex sympathetic dystrophy (RSD), involves limb pain with neuropathic descriptors (allodynia, paresthesias, dysesthesias) and variable combinations of neurovascular disturbances (coldness, mottling, nonarticular swelling, cyanosis or rubor, delayed capillary refill), sudomotor disturbances, motor abnormalities (spasms, dystonia, “jumping movements”), and trophic changes, including atrophy, abnormal hair
growth, or joint contractures. Where these findings occur with clinical signs of injury to a nameable nerve trunk, the terms CRPS2 or causalgia are used. For purposes of the current discussion, we use the term RSD/CRPS to refer to these disorders inclusively.

CRPS in children and adolescents has distinct epidemiologic features. It is much more common in girls than boys, it is uncommon before age 6 years, the apparent onset is most common from around ages 10 to 12 years, and the lower extremities are affected much more commonly than the upper extremities.\textsuperscript{257}

For a majority of children with CRPS, an effective treatment program emphasizes patient and parent education about the nonprotective character of the pain, intensive rehabilitation that involves active exercise, resumption of weight-bearing, desensitization, and psychological interventions based primarily on individual and family-based CBT. For some children, this can be accomplished on an outpatient basis.\textsuperscript{177} For others who fail to improve with outpatient treatment, a next step is to do this type of multidisciplinary rehabilitation program in an inpatient or intensive day-hospital program.\textsuperscript{176}

In adult pain medicine practice, at least in the United States, there is a considerable emphasis on early use of nerve blocks and other invasive approaches, especially sympathetic nerve blocks; spinal cord stimulation; operative, chemical, or radiofrequency sympathectomies; and, more recently, intravenous ketamine infusions in the treatment of RSD/CRPS. In our view, these approaches are not evidence-based in adults, and they are even less supported by evidence for children and adolescents. In a previous case series, even though some of the patients did receive regional anesthetic interventions and even though some reported benefit, there was no clear association between the duration of symptoms prior to blockade and the eventual benefit.\textsuperscript{258}

Some pediatric case series report marked improvement in function and pain scores with no use of nerve blocks.\textsuperscript{176} Overall, most case series suggest a good long-term prognosis for the majority of children and adolescents with CRPS. Hence, in our view, the initial therapeutic approach should be to emphasize intensive rehabilitation whenever possible.
We do make selective use of regional anesthetic approaches for patients who fail to progress despite a very good rehabilitation program and for selected patients with very severe limb swelling, dystonia, or very limited limb movement. In general, our preference is to use combined somatic–sympathetic blockade using continuous catheter approaches rather than selective sympathetic blockade or other repeated single-shot blocks. For lower extremity CRPS confined to a stocking distribution in the lower leg, our practice is to place continuous popliteal fossa sciatic perineural catheters under combined ultrasound–nerve stimulation guidance.\(^{259}\)

For lower extremity involvement in a wider distribution, we place an epidural catheter using fluoroscopy and/or nerve stimulation guidance to ensure proper dermatomal level and sidedness. For upper extremity CRPS, brachial plexus catheters are placed in either supraclavicular or infraclavicular sites using combined ultrasound and nerve stimulation guidance. For all forms of continuous regional anesthesia, catheters are placed with meticulous attention to sterile technique in the operating room, and they are tunneled to facilitate skin care and to reduce the chances for dislodgment. Prophylactic antibiotics are used. Patients are typically admitted to the hospital for infusions and intensive rehabilitation for periods of 5 to 8 days. Although outpatient rehabilitation assisted by peripheral blockade has been described, in our view, there is merit to inpatient admission to optimize intensive rehabilitation during the course of the infusions. In addition, our preference is to run higher infusion rates at nighttime and lower rates during the day to facilitate “cycle-breaking” at night and active mobilization during the day.

Evidence is lacking for efficacy of many types of analgesic medications commonly prescribed for adults with CRPS. Pediatric data are limited to case reports and uncontrolled case series. We do try tricyclic antidepressants and anticonvulsants for many of these patients. Responses are inconsistent.

**BACK PAIN**

Back pain is very common in adults and a major contributor to absence from the workplace. Persistent back pain is relatively common in adolescents but uncommon in younger children, and in younger children,
its occurrence mandates earlier consideration of a range of diagnostic possibilities, including infections (osteomyelitis, pyelonephritis, intervertebral discitis), tumors, and congenital anomalies of the spine and central nervous system (tethered spinal cord, diastematomyelia).\textsuperscript{260,261}

In specialist referral practice, back pain in adolescents is commonly seen in athletes, dancers, gymnasts, and cheerleaders and in children who are significantly overweight. For many patients with features suggestive of muscular pain and a normal neurologic exam, initial treatment should emphasize resumption of daily activities, a moderate exercise program including core stabilization and postural exercises, and avoidance of high-impact, high-velocity, or repetitive stresses on the spine. For patients with significant obesity, dietary counseling may be appropriate. Axial low back pain that worsens with back extension is commonly seen with spondylolysis and spondylolisthesis.\textsuperscript{262,263} There is some support for bracing in the treatment of these conditions.\textsuperscript{264}

Symptomatic lumbar disk disease is uncommon in children and relatively less common in adolescents. In our referral practice, lumbar disk disease is most commonly seen in adolescent athletes. There is an extensive literature on the advantages and disadvantages of operative treatment for lumbar radiculopathy in adults; pediatric literature is mostly limited to relatively small case series and, with few exceptions, to relatively short-term follow-up. We recently reviewed experience with fluoroscopically guided epidural steroid injections for lumbar radiculopathy in children and adolescents. A majority of patients reported reductions in pain and improvements in straight-leg raising, and the safety profile was excellent. In 2- to 5-year follow-up, less than 40% of patients in this case series came to discectomy.\textsuperscript{265}

**HEADACHE**

Systematic review of pediatric headache burden found that 58% of children experience a headache at some time in childhood.\textsuperscript{245,266} Differentiating whether the pediatric headache is primary or secondary is critical in its evaluation.\textsuperscript{267} Primary headaches include migraine, tension-type headache, and cluster headaches. They are classified by their features as compared to secondary headaches which are classified by the
underlying disorder responsible for them. Secondary headaches are those attributed to head and neck trauma; intracranial vascular and nonvascular disorders; substance administration or withdrawal; infection; or pain associated with disorders of the eyes, cranium, ears, sinuses, or teeth. Red flags in the history which suggest secondary headache are sudden onset of a severe headache, neurologic symptoms such as ataxia, lethargy, seizures, visual impairments, associated symptoms such as depressed mood or aura, headache associated with systemic illness such as hypertension and sinusitis, new headache type in a patient with cancer or human immunodeficiency virus, sudden onset of the “worst headache in your life,” headaches associated with straining, change in a headache pattern, or headache in a child under 3 years old. Positive answers to these questions clearly demand additional investigation as well as imaging studies.\textsuperscript{268–270}

Primary headaches in children are more often a continuum that may change with age rather than a discrete entity.\textsuperscript{271–276} Zebenholzer and colleagues\textsuperscript{274} found that in a 1.5-year period, 30% of children were headache-free, 20% had swapped headache type, and 50% continued having the same type of headache. Such fluidity makes diagnosis and treatment complex. Criteria for the diagnosis of migraine in children require five or more headaches that last between 1 and 48 hours (shorter duration than in adults), are bilateral or unilateral, have a throbbing or pounding quality, and are aggravated by physical activities. They are typically accompanied decreased appetite, nausea, vomiting, and photophobia and phonophobia.\textsuperscript{277} Tension headaches are typically categorized by their frequency: episodic (< once monthly), frequent (greater than once per month but <15 days per month), and chronic daily headache (>15 days per month). These headaches are typically mild to moderate pain, “band-like” pressure around the head, bilateral, not pulsating, not aggravated by physical activity, without nausea, vomiting, photophobia, or phonophobia. Precipitating factors may include illness, stress, and muscular tension.

Once the secondary causes of headache have been excluded, the general approach to primary headache treatment is similar to other primary chronic pains—a multidisciplinary approach, consisting of cognitive-behavioral approaches, physical therapy modalities with thoughtful use of
medications in an overall attempt to regain function and improve pain coping abilities. Maintaining a regular routine and regular exercise is helpful. Limited evidence supports a specific diet or dietary exclusion, although there may well be individuals for whom food is an important trigger. Overall, SMART (Sleep, Meals, Activity, Relaxation, Trigger avoidance) lifestyles changes are recommended. Behavioral interventions are effective at reducing headache burden regardless of the headache type. These include biofeedback, progressive muscle relaxation, distraction, and hypnosis. In a systematic review of the RCTs of psychological interventions for chronic pain (12 headache and 1 recurrent abdominal pain trial), Eccleston and colleagues reported the odds ratio for a 50% reduction in pain was 9.62, indicating the success of psychological interventions.

Pharmacologic treatment of pediatric headache is divided into abortive and preventative treatment. Early intervention is an essential feature of successful abortive treatment of migraine or tension headache. Early hydration, ibuprofen, naproxen, and acetaminophen are often effective. For more severe headache, NSAIDs combined with acetaminophen and/or caffeine should be tried. Triptans (5-HT-1 receptor inhibitor) such as sumatriptan nasal spray in the appropriate circumstances can be considered for severe headache. Oral triptans have also been studied in children. Rizatriptan can be used in children >6 years old and almotriptan, a combination of sumatriptan and naproxen in adolescents greater than 12 years old is approved.

Regarding preventive therapy, it is recommended that patients with disabling headache greater than 4 days a month be considered for daily preventative therapy. Initiation of these medications should be done with the guidance that they will take 6 to 12 weeks to become effective. With this said, few medications have been studied in randomized controlled studies in pediatric populations. Of them, topiramate, tricyclic antidepressants such as amitriptyline, nortriptyline, and β-blocker, propranolol, are used. More recent evaluation by the Childhood and Adolescent Migraine Prevention (CHAMP) study did not detect a difference between topiramate, amitriptyline, or placebo.

There is emerging literature on the use of specific vitamins and minerals
for headache prevention. High-dose riboflavin, B2 (400 mg per day), has been found to reduce migraine frequency and appears safe. Magnesium has been shown to reduce headache frequency. Melatonin may be beneficial in the ability to initiate sleep and promote improved lifestyle.

In summary, there is convincing evidence that cognitive-behavioral approaches are beneficial in primary pediatric headaches, regardless of etiology. The evidence on abortive and preventative medications is not limited, but a number of analgesics, 5-HT receptor agonists, anticonvulsants, antidepressants, and β-blockers have been shown to be somewhat effective in children.

**FUNCTIONAL GASTROINTESTINAL PAIN**

Chronic abdominal pain is defined as long-lasting intermittent or constant abdominal pain with either functional or organic etiology. Chronic abdominal pain accounts for 2% to 4% of all pediatric office visits and is one of the most common complaints in children. Red flags for organic disease include pain that awakens the child from sleep, nocturnal diarrhea, persistent vomiting, weight loss, persistent right upper or lower quadrant pain, or dysphagia and should prompt a referral to a gastroenterologist. Adolescent females presenting with chronic abdominopelvic pain should be evaluated for gynecologic causes, such as endometriosis particularly those with GI symptoms and dysmenorrhea or irregular uterine bleeding. Evaluation and management of endometriosis includes hormonal and surgical intervention while incorporating a multidisciplinary approach for chronic symptoms, including neuropathic agents, physical therapy, and cognitive-behavioral strategies.

If the history and physical examination do not suggest underlying pathology, more than likely, the patient has one of the pain predominant FGIDs. FGIDs refer to a group of disorders that are diagnosed according to the Rome IV criteria when symptoms cannot be explained by inflammatory, anatomic, metabolic, or neoplastic processes. FGIDs are the most common cause of abdominal pain in children and adolescents worldwide. The associated term functional abdominal pain has been replaced by central mediated abdominal pain syndrome (CAPS) central
sensitization with disinhibition of pain signals as opposed to increased peripheral afferent excitability.\textsuperscript{291} Children with chronic abdominal pain have lower quality-of-life measures compared with healthy peers and at risk for school absences, social isolation, depressive disorders, and increased somatic complaints.\textsuperscript{292,293} Williams and colleagues\textsuperscript{294} demonstrated this in preadolescent females with IBS when compared to healthy peers by showing an impaired endogenous inhibition of somatic pain. As previously stated, CAPS in childhood and adolescence increased the risk for a chronic primary pain disorder in adulthood.\textsuperscript{295,296}

In addition to the general strategies for addressing chronic pain, evidence supports the efficacy of famotidine, pizotifen, CBT, biofeedback, and peppermint oil enteric-coated capsules.\textsuperscript{218} For functional dyspepsia, they suggested treatment with antisecretory agents such as H\textsubscript{2} blockers or proton pump inhibitors is appropriate for pain predominant symptoms, whereas prokinetics seem appropriate for symptoms dominated by discomfort such as bloating. For IBS, peppermint oil is suggested, and when IBS is diarrhea-predominant, the use of antibiotics to treat bacterial overgrowth is recommended. Antidepressants and serotonergic agents had limited support in pediatrics despite their efficacy in adults. For abdominal migraine, avoidance of potential triggers such as caffeine was advised. Treatment with the preventative agents used for migraine (cyproheptadine, sumatriptan) are appropriate when paroxysms are frequent. Functional GI pain syndrome, reduction of psychosocial stressors, and behavioral treatment are effective for management.\textsuperscript{267,275,297–300} Dietary interventions low in fermentable carbohydrates and polyols (FODMAP) and high in fiber incorporated treatment are effective in subgroups of patients reducing bloating and improving stool pattern.\textsuperscript{275,301}

**Barriers to Care**

Most health care systems are stymied by the complicated care necessary to address the issues raised by children with chronic pain. The family’s search for a satisfying answer may cause them to solicit multiple opinions for the pain problem. Additionally, children with chronic pain often report pain in more than one site and, as a result, multiple specialists are often
involved in their care, each one focusing on one particular pain complaint. For example, headache and abdominal pain are frequent fellow travelers. The family may seek the opinion of a neurologist for the headache and a gastroenterologist for the abdominal pain. They may seek out alternative providers such as chiropractors, acupuncturists, or naturopaths as well. Laboratory and imaging studies are frequently performed in multiple settings. The primary care provider who typically provides care coordination must collate the records, reconcile often disparate opinions, be alert to the possibility of interactions among the drugs prescribed by the myriad of involved physicians, and be on the front line to address each new symptom and concern without overmedicalizing it. Care coordination is, therefore, a critical time-consuming and often unreimbursed aspect of the care for children with chronic pain, and its absence is a barrier to adequate treatment.

Another problem is the lack of facilities and practitioners capable of addressing both the biologic and psychological dimensions of chronic pain. In the outpatient arena, few individuals are comfortable addressing both realms, and multidisciplinary teams, an alternative, are often not viable economically. Inpatient facilities are rarely geared to individuals who may have both psychological and physical problems. A busy inpatient unit with desperately ill children is not the appropriate setting for a child with chronic pain, as it tends to overmedicalize the problem. Likewise, the typical psychiatric ward is often unprepared to deal with the patient who is moaning in pain and may have an as yet undiagnosed medical illness.

Finally, the inherent vagueness and poignancy of the symptom of persistent pain often leads families to seek out additional opinions and to feel that their search is never quite completed. This can create uneasiness between provider and patient which may interfere with the therapeutic alliance.

**Conclusion**

Persistent pain is a relatively common experience for children and may stem from a variety of causes: ongoing organic disease, persistence of pain which resulted from organic disease, as well as disorders whose primary
manifestation is pain. Regardless of its origin, however, it has significant impact on the child and his or her family. In general, the goal of the clinician is to identify red flags for organic disease and, if not present, focus on symptom reduction and increasing function. Specific attention should be given to sleep, mood, school, activity, and family functioning. Typical interventions include analgesia, physical therapy, cognitive-behavioral strategies, and other medications targeted to specific symptoms. Success in the management of chronic pain should be monitored by improvement in function and not specifically through immediate reduction in pain intensity.

Overview

Medical science continues to expand its capacity to forestall death. As a result, people are living longer but increasingly spend their final years with daily, unrelenting pain.\textsuperscript{1–3} Pain is emerging as a more formidable foe than death, whose conquest will demand stretching the limits of our technology and ability to provide compassionate care. Because of its increasing incidence, high economic costs, and negative impact on quality of life of patients and their families, uncontrolled pain has become a public health priority.\textsuperscript{2,4}

Dramatic increases in people over age 65 years globally suggest that older adults will challenge the capacity of health systems with the complexity of multiple conditions contributing to pain and its sequelae. Estimates indicate that by 2050, older adults will comprise a third of the population in developed countries.\textsuperscript{5} Although not all older adults have severe or ongoing pain, a majority do when they seek health care services. Chronic back and neck pain are the leading cause of disability worldwide, and the prevalence of chronic pain–producing diseases like arthritis, diabetes, and cancer continues to increase.\textsuperscript{6} Older adults have the highest rates of surgery, hospitalization, injury, and disease, which increases their risk of pain.\textsuperscript{7} The problem of pain in older adults has not diminished even though evidence to guide pain assessment and management has grown over the past decade.

THE PREVALENCE OF PAIN IN OLDER ADULTS

Although pain is not an inevitable aspect of aging, older persons are at greater risk for many disorders associated with pain. Delineating the prevalence of pain with advancing age is a challenge because
epidemiologic studies differ in the age cut points, methods of data collection and measurement of pain, and the types of pain studied. However, data across settings and samples suggest that pain is prevalent and a significant factor impacting quality of life. Approximately 65% of older persons living in the community have persistent pain* conditions, with more frequent pain (up to 85%) noted in those living in institutions, particularly nursing homes, and those in the final months of life (over 80%). Prevalence of pain in hospitalized older adults is also high with 67% on geriatric units reporting pain present.

A nationally representative sample of American adults showed back, knee, and shoulder as the most prevalent pain sites in those 65 to 69 years old, with little change in this pattern in cohorts of those 90 years old or older. Over 60% of older adults report pain in multiple locations with women reporting more pain sites and a greater intensity of pain than male counterparts, which impacts physical and psychosocial function. Older women and those with obesity, musculoskeletal conditions, and depressive symptoms are at higher risk for pain.

Other common conditions associated with pain in older persons include atherosclerotic peripheral vascular disease, herpes zoster, trigeminal neuralgia, diabetic neuropathy, temporal arteritis, polymyalgia rheumatica, osteoporosis with vertebral compression fractures, lumbar spinal stenosis, and fibromyalgia. Also, injuries, such as hip fractures resulting from falls, are more common in this population and may result in both acute and chronic pain.

### Pain in the Older Person

#### IMPACT OF PAIN ON FUNCTIONING AND QUALITY OF LIFE

Pain in the older adult interferes with the ability to manage and recover from health challenges given its important and often unrecognized impact on impaired function and quality of life. Acute and persistent pain have adverse health outcomes in older people. Poorly managed acute pain contributes to delayed ambulation, increased incidence of delirium and cognitive dysfunction, respiratory complications, longer hospitalization,
and mood disorders.\textsuperscript{20} Additionally, long-term consequences include impaired ability to complete activities of daily living (ADL), impaired mobility development of persistent pain, and cardiovascular disease.\textsuperscript{19,21,22} More widely studied, persistent pain is known to negatively impact older adult physical and psychosocial function, including impaired nutrition and sleep, functional abilities, mood and cognitive function, and social interactions.\textsuperscript{23–25} Pain from osteoporosis, osteoarthritis, and chronic back pain has been shown to significantly affect ADL, placing the older adult at risk for declining health and potentially institutionalization.\textsuperscript{26,27} According to Hunt et al.,\textsuperscript{9} 43\% of those with dementia are able to acknowledge and self-report significant functional limitations, including the ability to perform ADL.

Combined with impaired physical health, the decline in social and recreational activities produces emotional distress, contributing to depression,\textsuperscript{8,28} which is capable of worsening both pain and disability.\textsuperscript{29} Pain-related factors that worsen health-related quality of life include pain presence, pain severity, and number of pain sites.\textsuperscript{6,10,25,30–32} Persistent pain also is associated with frailty, a syndrome of physiologic decline, and should be a component assessed when determining frailty phenotype to improve the prediction of adverse outcomes.\textsuperscript{33}

**UNDERTREATMENT OF PAIN IN OLDER PERSONS**

Given these potentially serious pain-related consequences, evidence that pain is commonly undertreated or untreated in older adults is disturbing. Among those with pain, a significant portion of those over age 65 years do not receive analgesics or receive inadequate treatment, including 53\% of elders transitioned from acute to skilled nursing care,\textsuperscript{34} 17\% to 65\% of institutionalized elders,\textsuperscript{10,11,35} 51\% of elders admitted to emergency departments with pain complaints,\textsuperscript{20,36} and 20\% of elders living with pain in the community.\textsuperscript{37} Older patients in emergency departments are more likely to experience delays in analgesic treatment and have acute pain undertreated compared to younger patients.\textsuperscript{38} Pain, depression, and functional limitations due to pain are particularly undertreated in low-income and minority older populations.\textsuperscript{39}

The diagnosis and treatment of pain in older persons is more difficult in
those who present with multiple medical problems and a history that reveals many potential sources of pain. Although there is an undeniable need to prevent harm from pain-relieving treatments, this focus must be balanced with a concerted effort to avoid pain-induced harm. Guidelines for the assessment, treatment, and monitoring of older patients with pain have been widely distributed advocating for individualized approaches to pain and balancing concerns for the safety and efficacy of treatments. 40–42

It is time to replace unrealistic fears and mistaken beliefs with guidelines that delineate prudent, safe, effective use of available treatments. Approaches to managing pain in older adults should incorporate noninvasive treatments, along with tailored pharmacologic management, based on a careful risk/benefit analysis of treatment options and the older person’s unique characteristics and goals. 43

**CHANGE IN PAIN PROCESSING AND MODULATION**

Mounting evidence suggests that strong unrelenting pain changes the structure and function of nerves that create widespread degenerative alterations in brain functioning, 44,45 which may explain the learning, memory, and emotional difficulties experienced by older adults with persistent pain. 46 Physiologically, aging alters functions, including a degeneration of peripheral neuronal structures, which slow transduction and transmission involved in signaling pain. 47 These changes may result in a slowed pain response, but aging does not decrease sensitivity to pain, which may actually increase with age. 48 Once pain is established, the lower density of descending inhibitory circuits and an impaired ability to recover from hyperalgesic states are attributed to aging. 49 Although some of these changes are partially reversible with effective treatment, 50,51 changes in endogenous pain modulation increase older adults’ risk for developing persistent pain following an illness, surgery, or trauma. 52

Concerns arise regarding how pain processes, including judgment of its presence and severity, is experienced in those with dementia. Although research is mixed, recent studies suggest persons with Alzheimer disease are less sensitive to the detection of thermal pain but do not differ in affective response to unpleasant stimuli, contributing to greater pain and potential damage before identifying and reporting pain. 53 Thus,
A comprehensive approach to assessment is necessary when evaluating pain in older adults and developing an effective treatment approach, including identification of the underlying cause of pain, pain characteristics, and impact on physical and psychosocial function and quality of life. The scope and nature of the pain assessment will depend on a number of factors such as the physiologic stability of the patient, whether the situation is an emergency or planned event, and the severity of the presenting pain complaint. If the older adult presents in moderate to severe acute pain (e.g., greater than 4 on a 0-to-10 numeric rating scale), the first priority is to complete an initial, rapid pain assessment and treat the pain. Once the older person’s pain is alleviated, a comprehensive pain assessment should be completed.

As with younger patients, self-report of pain is the criterion standard for determining pain presence and severity. The numeric rating scale, verbal descriptor scale, and faces pain scale are the most established tools for the alert, cognitively intact older adults. The Iowa Pain Thermometer demonstrated comparable results to these scales and is most preferred by many older adults. Cultural differences in tool understanding and preference also inform the need to solicit individual tool preferences. These scales can be used more effectively in older persons by addressing sensory deficits (uses eyeglasses, hearing aids, large font/bold print written tools, etc.). Cognitive impairment can result in underreporting of pain; however, recent studies document that standard assessment techniques can
be used effectively in older adults with mild to moderate cognitive impairment.\textsuperscript{65,66} It is useful to adopt more than one validated tool for use in clinical settings to accommodate needs and preferences of different older patients. All team members (including caregivers) need to use the tool that patient prefers consistently for all pain assessments.

As a multidimensional experience, pain evaluation includes intensity, affect (how bothersome, distressing and effect on mood), sensory qualities (such as aching, stabbing, burning), spatial quality (e.g., location), temporal quality (including pattern and duration), and impact on or interference with daily activities (including physical and psychosocial functioning).\textsuperscript{17} Multiple biopsychosocial factors (e.g., anxiety, depression, beliefs, insomnia, fear avoidance, biomechanical issues) contribute to the experience of pain and should be evaluated for their contribution to impairment or dysfunction.\textsuperscript{67} Evidence of pain impact includes disrupted social and family relationships, changes in eating and sleeping patterns, and altered mood and ability to continue previous activities. Determining the impact of pain on the older adult’s life requires gathering information on key quality of life variables from different sources, including the older adult, significant others, other health care workers, roommates, and activity therapists. The Brief Pain Inventory (BPI) is useful in many settings because it records dimensions of pain in addition to intensity (e.g., interference with functionality).\textsuperscript{68} Other tools are available that gather data on pain and its impact in a clinically useful manner, including one called the PEG, that examines three BPI items of Pain intensity, Enjoyment in life, and General activity.\textsuperscript{68}

Expanded assessments including the underlying conditions known to be painful and comorbid diseases, the desired and undesired effects of prior and current pain treatments, and current medications (including over-the-counter drugs) provide important information to guide treatment planning. A complete physical examination of the pain source, including potential pain contributors such as leg length discrepancy and myofascial pain, focuses on the most common sources of pain: the musculoskeletal, peripheral vascular, and neurologic systems. Laboratory tests to determine renal and hepatic functioning may be indicated, but diagnostic tests should be used sparingly given that more than half of older patients with
radiographic evidence of degenerative joint disease are pain-free and imaging studies are often not necessary or useful.69

For a comprehensive review of pain assessment, the reader is referred to the clinical practice guidelines on acute and persistent pain available through the University of Iowa Csomay Center for Gerontological Excellence (http://www.iowanursngguidelines.com).41,70

NONVERBAL, COGNITIVELY IMPAIRED OLDER ADULTS

When the patient is unable to reliably self-report the presence or nature of pain due to severe cognitive impairment or critical illness, clinicians rely on a combination of assessment strategies to fill this void. An approach for recognizing pain in nonverbal older adults includes a process of data gathering that includes (1) attempting self-report, (2) identifying pathologic conditions or procedures that usually cause pain, (3) identifying behaviors associated with pain, (4) obtaining input from a family member or others knowledgeable of the older adult, and (5) attempting an analgesic trial to verify that suspected behaviors are pain-related.58

Even if the patient is unconscious, intubated, or chemically paralyzed, the clinician’s understanding of the pain typically associated with the medical conditions/procedures allows them to make assumptions about the presence of pain and guide pain prevention and treatment interventions regardless of cognitive/verbal abilities. A good history and physical examination provides information on pain-related diagnoses and conditions that support a judgment of pain present.

Directly observable behaviors, such as grimacing, moaning, guarding, bracing, and posturing as well as those less common such as agitation, aggression, restlessness, resisting care, and changes in usual behavior patterns, are recognized as important indicators of pain in those who cannot communicate their pain verbally.71,72 Among the behaviors displayed by people unable to communicate their pain, facial expression is being recognized as a common and essential element of the behavioral assessment.71,73 A large number of behavioral pain assessment tools have been developed for use in this population. Systematic reviews have evaluated the strengths and limitations of existing behavioral tools
reaching similar conclusions that there is no single tool appropriate for all patients and settings. Updates on existing tools and psychometric properties, as well as recommendations for use, are available. Research is ongoing to refine pain behavior indicators and tools to advance clinically useful methods of pain evaluation in this challenging population.

Evidence from any of the aforementioned steps can inform clinician judgment and decision making about pain presence in the older person with advanced dementia. Use of an analgesic trial has shown positive effects in improving disturbing and distressing behaviors, confirming underlying pain etiologies. Pain treatment planning is often oversimplified, expecting patients to respond similarly to the same noxious stimuli and therapeutic intervention. This may work with mild, fleeting pain, but when pain is severe and/or persistent, developing a safe, effective plan needs to be tailored to the patient’s unique perceptions, capabilities, comorbid conditions, and responses. The initial goal of any pain treatment plan is to find and eliminate its source if possible and then balance concerns for pain reduction, functional improvement, and avoidance of treatment-related harm. Frequent, ongoing reassessments enhance understanding of the patient’s unique pain and response to therapy and refinements need to ensure optimal safety and effectiveness.

Pharmacologic Treatment of Pain in Older Persons

PHARMACOKINETICS AND PHARMACODYNAMICS ASSOCIATED WITH AGING

With the exception of the rectal route, the rate of medication absorption is not typically affected by aging. The pattern of drug distribution does change because of less total body water and more body fat seen in many older adults. This favors the distribution and accumulation of lipophilic (fentanyl) agents while decreasing that of hydrophilic (morphine) drugs. The decline in serum protein concentrations with age can increase the bioavailability of drugs, like nonsteroidal anti-inflammatory drugs (NSAIDs), that are highly protein-bound. This effect is magnified in frail, protein-depleted older adults and patients taking multiple
medications that displace NSAIDs from protein-binding sites. The metabolism and excretion of NSAIDs is often compromised due to the smaller size, lower blood flow, and reduced function of the liver with age. These hepatic changes combined with fewer drug-metabolizing enzymes, increase drug elimination time, and slow the metabolism required to produce active metabolites. Reductions in renal size, glomerular filtration rate, and renal blood flow raise the risk of side effects and toxicity from slowed elimination of the drug and active and toxic metabolites. NSAIDs can further contribute to this slowed clearance by lowering renal blood flow and glomerular filtration rate through its antiprostaglandin effect.

Pharmacodynamic changes with aging increase sensitivity to both the desired and undesired effects of opioids. Combined with other age-related changes in the neurologic and pulmonary systems, there is a greater risk of sedation, sleep apnea, and respiratory depression with opioid analgesics. Combined, these pharmacokinetic and pharmacodynamic changes warrant using lower doses and longer dosing intervals with advanced age, especially with known hepatic or renal impairment, and frailty, with or without cognitive impairment.

SAFE, EFFECTIVE USE OF NONOPIOIDS IN THE OLDER PERSON

Acetaminophen

Acetaminophen is considered the safest nonopioid analgesic and is the first-line analgesic of choice for older patients when pain is mild or moderate. Compared to other nonopioids, it has similar or lower analgesic potency but lacks undesirable gastroduodenopathy and platelet dysfunction. Limited effectiveness compared to placebos or other analgesics call into questions its inclusion as a first-line, first-choice analgesic for older adults for all types of pain. When combined with warfarin, over-anticoagulation can result. Persistent excessive use of acetaminophen may impair renal function and cause hepatotoxicity, especially in frail elders and those with chronic alcohol consumption and/or liver disease. A systematic review of observational studies showed a consistent dose–response association between acetaminophen and the
same serious gastrointestinal (GI), renal, and cardiovascular adverse drug events that are often observed with NSAIDs.\textsuperscript{87} Dosage limits in the range of 2,400 to 3,250 mg daily have been suggested to minimize the risk of renal or hepatic toxicity in these populations with the caveat that most harm results from inadvertent use of multiple acetaminophen-containing drugs.\textsuperscript{85,86}

**Nonsteroidal Anti-inflammatory Drugs**

NSAIDs are effective at alleviating pain, especially types that result from inflammation. When combined with acetaminophen for acute pain, NSAIDs have a similar potency to weak opioids (e.g., codeine or tramadol).\textsuperscript{86,88} NSAIDs have both analgesic and anti-inflammatory properties; however, there is little evidence they are useful for neuropathic pain, and they have little effect on back pain.\textsuperscript{89,90} The use of long-term NSAIDs needs careful monitoring in older people because of increased risk of GI ulceration and bleeding and renal and cardiovascular morbidity. Cautious use of NSAIDs is advised because a quarter of hospitalizations resulting from adverse drug effects are linked to NSAIDs in older patients. Thus, use of NSAIDs for more than a several days should be avoided unless alternatives are ineffective and the patient can take gastroprotective misoprostol or a proton pump inhibitor (PPI).\textsuperscript{40,91,92} The PPI option tends to be better tolerated but exposes older adults to the risk of bone loss, fractures, Clostridium difficile infections, and subacute cutaneous lupus erythematosus with long-term use.\textsuperscript{92,93}

Concerned that medication-related problems are a leading cause of hospitalization and death among older adults, the American Geriatrics Society updates the Beers Criteria, a list of medications and drug classes that are inappropriate to prescribe older adults, regardless of frailty. As a class, the chronic use of any NSAID should be avoided without gastroprotection. Any use should be avoided in those with a history of gastroduodenal ulcers, stage IV kidney disease, or congestive heart failure. Use for more than 8 days, certain products (indomethacin or ketorolac) are particularly concerning when used in older adults, as is the combination with other NSAIDs, corticosteroids, antidepressants, anticoagulants, or antiplatelet agents.\textsuperscript{94,95} Despite these warnings, NSAIDs are prescribed to
40% of older adults with chronic pain, which may contribute to 3,300 NSAID-linked deaths and 41,000 hospitalizations observed in the United States per year.\textsuperscript{85,92,96}

The COX-2 selective NSAIDs appear to have less risk of GI ulcerations and bleeding in the elderly than do nonselective NSAIDs.\textsuperscript{95} However, the GI safety advantages of COX-2 selective NSAIDs are significantly reduced if high doses are used or when used in combination with aspirin or other NSAIDs. Although celecoxib has been suspected of placing patients at higher risk of cardiovascular death, a recent 3-year prospective randomized control trial using 200 mg of celecoxib per day showed a similar or better cardiovascular, GI, and renal safety profile when compared with ibuprofen or naproxen.\textsuperscript{95} When the risks specific to rofecoxib were examined in a meta-analysis, it was that drug, rather than COX-2 selectivity, that contributed to elevated risks of cardiovascular deaths observed with long-term use of these medications.\textsuperscript{97}

**Safe Nonsteroidal Anti-inflammatory Drug Product Selection and Monitoring Use**

The decision to use an NSAID in the management of persistent pain for an older adult requires individualization considering the (pain reduction and functional improvement) effectiveness balanced against potential harms considering comorbidities, concomitant medications, and associated risk factors. If short-term NSAID therapy is considered and GI risk is considered low, it may be reasonable to select celecoxib, ibuprofen, or naproxen. Continuing NSAID therapy beyond a few weeks should be done cautiously with baseline and periodic monitoring of vital signs, renal functioning, and occult GI bleeding.\textsuperscript{98} Given an analgesic ceiling, patients are started at a low dose and asked to record the analgesic effect for 1 to 2 weeks before increasing the dose. If, after titrating to a higher dose, there is no analgesic advantage, return to the lower dose. To lessen the risk of GI and renal toxicity, urge the patient to drink a full glass of water with the NSAID to maintain adequate hydration throughout therapy.

In general, after acetaminophen is deemed inadequate or contraindicated, NSAIDs with the highest safety margin should be used in the lowest effective dose for the shortest duration.\textsuperscript{92} For patients at highest
GI risk (history of ulcers), celecoxib 100 to 200 mg per day plus a PPI is considered. Because traditional NSAIDs (except naproxen) inhibit the effects of cardioprotective aspirin and increase GI risk, this combination is avoided. Other options for high-risk patients include nonacetylated salicylates or topical NSAIDs and may have better safety margins than more traditional options. Salsalate (Disalcid) has advantages of minimal GI toxicity, no effects on platelets, and a twice-daily dosing regimen.

Topical NSAIDs are a viable therapeutic option with a more desirable tolerability profile, less end-organ dysfunction, and GI bleed compared with their oral counterparts. Topical agents are particularly beneficial when pain is localized, acute, and superficial, as it places a higher concentration at the target tissue for appropriately selected inflammatory conditions. Additional advantages include fewer systemic side effects (dry skin is the primary side effect), a lower pill burden, and avoidance of drug interactions.

SAFE, EFFECTIVE USE OF OPIOIDS IN THE OLDER PERSON POTENTIAL RISKS OF OPIOID ANALGESICS
Declines in NSAID use by older adults have paralleled increased utilization of opioids. An estimated 9% of those older adults living in the community and 70% of those with persistent pain in nursing homes have been prescribed opioids. The American Geriatric Society guidelines identified opioids as the cornerstone for treating moderate and severe pain unresponsive to other therapy. The place of opioid therapy is now being scrutinized given renewed concerns about potential harms, especially for older adults who are sensitive to their effects and those with renal or hepatic dysfunction. Although older adults are generally less likely to receive opioids than their younger counterparts, they ironically are more likely to receive opioids when they sustain a fracture. Despite literature continuing to support the undertreatment of older adults with pain, more opioid therapy does not guarantee better pain control.

Although far from a panacea for all types of pain, a meta-analysis showed opioids to be as effective for older adults as younger patients in yielding pain reduction, functional improvement, better sleep, and quality of life. As many as two-thirds of older adults who start an opioid for
chronic musculoskeletal conditions achieve pain relief, but it remains unclear how long those benefits are sustained, especially because nearly half of older adults discontinue therapy because of poorly tolerated constipation, mental status changes, and nausea.\textsuperscript{17} It isn’t clear what percentage of patients would continue therapy if the GI side effects were effectively treated prophylactically, but every effort should be made to do so.\textsuperscript{84,100} It also is unclear about the effect opioids have on mental status changes in older adults because higher pain, more intravenous fluids, and baseline antidepressant medication contribute to these changes.\textsuperscript{106} A study examining rates of delirium after hip fracture surgery found that severe pain and the use of low doses of opioids were correlated significantly with progression to delirium. In contrast, those using higher doses of opioids did not develop or worsen delirium regardless of their baseline level of cognitive functioning.\textsuperscript{107} What is clear is that given known risks associated with opioid use, the potential negative effects must be weighed against the consequences of untreated or partially treated pain.

**Potential Safety Concerns with Opioids**

Opioids increase the risk of falls, particularly during the first 2 weeks of use.\textsuperscript{108} This risk is compounded when used in combination with other medications (e.g., benzodiazepines, antipsychotics, antidepressants) that affect the central nervous system.\textsuperscript{80} Patients prescribed with opioids should be told to abstain from driving or other potentially dangerous activities until they have been free of visual or cognitive impairment for several days on a steady dose. As a drug class, opioids can be appropriate for older adults without a history of falls or fractures with the exception of propoxyphene, meperidine, and pentazocine which do carry additional risks for older adults.\textsuperscript{92} Tramadol, meperidine, and fentanyl can also increase the risk of serotonin syndrome in older adults when given with other serotonergic drugs.\textsuperscript{80}

The established risks associated with opioid use must be weighed against the consequences of poorly controlled pain. Systematic reviews express concern that effectiveness may wane over time, but the risks for serious harm remain, especially at higher doses.\textsuperscript{102,109} Apart from estimates that tramadol is no stronger than NSAIDs, there is no evidence
to support the superiority of opioid over another. Reluctance to prescribe opioid drugs has probably been overly influenced by political and social pressures to control illicit drug use. Among adults 65 years and older, 736 fatalities were reported among the 33,091 opioid overdose deaths in 2015. That represents 2% of opioid overdose deaths for the year and the lowest rate for any adult age group. Conversely, adults 45 to 54 years old had the highest death rate (8/100,000) of any age group. Aside from prescription opioids, overdoses from heroin and illicit synthetic opioids rose at an overall rate of 21% and 72%, respectively, in 2014 and 2015 accounting for 22,569 deaths compared to 12,727 deaths attributed to prescription natural and semisynthetic opioids. Many prescription opioid deaths are caused by abuse or misuse of prescription opioids and being combined with benzodiazepines, which increases the overdose risk 10-fold. In contrast to young adults who misuse opioids seeking euphoria, older adults may take additional medication as a result of forgetfulness, being desperate to achieve pain control, or as part of a suicidal intent. The estimated prevalence of opioid misuse in older adults is 1% to 3%, which remains lower and may account for significantly less prevalent opioid overdoses than their younger counterparts. Although substance abuse, diversion, and addiction disorders do occur in older adults, many are deprived prescriptions or refuse them because of overstated risks that fail to discriminate legitimate use from illicit nonmedical opioid use.

**Prudent Product Selection and Use**
The decision to initiate opioids is made cautiously including screening patients for biopsychosocial risk factors, starting with weak, short-acting, low-dose opioids after discussing risks and the need for vigilant monitoring with the patient and caregiver. Weak, atypical opioids may also be effective and have reduced likelihood of side effects such as constipation, a predictable side effect that should be treated prophylactically in older adults. Tapentadol or transdermal buprenorphine are weak/mixed opioids with less risk for the toxicities associated with conventional opioids. For adults over age 75 years with chronic arthritis or low back pain, tapentadol was shown to be as
effective as oxycodone with fewer side effects over a 2-year trial period.\textsuperscript{117,118} Transdermal buprenorphine is simple to administer (improves adherence) and avoids the first-pass metabolism which results in fewer drug–drug interactions, with less respiratory, hormonal, and immune system effects than oral opioids.\textsuperscript{119} The absorption, distribution, metabolism, and excretion of buprenorphine, as well as the ceiling to its respiratory depressant effects, make it a good choice for older adults.\textsuperscript{119} Given the limits of existing data, however, more familiar and less expensive opioids are generally preferred.\textsuperscript{120}

Oxycodone and morphine are probably the best first-line opioids agents for an opioid-naive patient with acute pain. The adage, start low–go slow, would have the prudent clinician starting as low as 2.5 mg oxycodone, 5 mg oral morphine, or 1 to 2 mg parenteral morphine and then basing adjustments on the individual response. Tramadol is commonly chosen, but it has low potency and an association with seizures that requires cautious patient selection and attention to potential drug–drug interactions.\textsuperscript{17,79}

For opioid-tolerant patients, methadone is an effective, relatively low-cost choice for carefully selected and monitored patients with refractory pain. Its use is limited by pharmacokinetic, cardiac, and drug-interaction pitfalls that require methadone to be used by highly informed experienced prescribers.\textsuperscript{100,121} Levorphanol offers several therapeutic advantages similar to methadone but without its pharmacokinetic and drug-interaction pitfalls.\textsuperscript{100} Drug selection decisions should ultimately depend on severity of pain, functional status, expected pain duration, and prescriber and patient preference. Regardless of selection, the lowest tolerated dose that leads to acceptable relief of pain is used, with frequent, vigilant evaluation of desired and undesired effects.\textsuperscript{17,80}

Chronic opioid therapy requires additional safeguards be in place.\textsuperscript{122} This is particularly true for older adults with preexisting respiratory dysfunction, including chronic obstructive pulmonary disease, emphysema, kyphoscoliosis, severe obesity, or cor pulmonale. Patients with persistent pain taking opioids often develop sleep disordered breathing, with older age and higher doses associated with both central and obstructive forms of sleep apnea that must be evaluated and treated.\textsuperscript{82}
Opioids can also cause peripheral vasodilatation which may produce orthostatic hypotension and a corresponding risk of falling. The impact of endocrine effects, immune system suppression, and opioid-induced hyperalgesia on older adults is currently being investigated, as is the emergence of novel opioids to offset known risks that limit their use.

SAFE, EFFECTIVE USE OF ADJUVANTS IN THE OLDER PERSON

Adjuvant analgesics include a variety of agents with analgesic activity whose primary approved indication is for conditions other than pain. Many of these adjuvants are used “off-label” and have been found clinically useful for specific pain types. These drugs may be used alone, or in combination with analgesics to treat persistent pain conditions, including neuropathic pain. A systematic analysis of 52 Cochrane reviews on anticonvulsants, antidepressants, behavioral, and analgesics found no treatment for chronic pain met the Centers for Disease Control and Prevention (CDC) criteria for “adequate long-term trials.” Those reviews also failed to show any published evidence of a chronic pain treatment that has stronger evidence of effectiveness than opioids. Thus, adjuvant therapy may need to be used in addition to, rather than instead of, opioid therapy to achieve optimal benefits.

Among antidepressants with analgesics properties, amitriptyline has the longest track record of positive trials but should be avoided in older adults due to its cardiac, anticholinergic, and sedative effects. There are fewer anticholinergic adverse effects with a second-generation tricyclic antidepressants (nortriptyline or desipramine), suggesting these are better choices for older adults. In hospitalized patients, however, their use is an independent predictor of postoperative delirium, increased costs, and prolonged length of stay. Serotonin and norepinephrine reuptake inhibitors (SNRIs) like duloxetine and venlafaxine have fewer of these undesired effects but a greater risk of drug interactions and elevation of liver enzymes. This class of drugs should be used cautiously as antidepressant-related deaths rose nearly 40% in the past 15 years, half of which were suicides.

Antiepileptic drugs are first-line agents to treat neuropathic pain in older
Gabapentin and pregabalin have labeled indications for specific neuropathic pain disorders and are frequently used for postherpetic neuralgia, painful diabetic neuropathy, and fibromyalgia. For these conditions, they provide similar analgesia to antidepressants, with improvements in mood, sleep, and quality of life. Although pregabalin is regarded as the most effective in the class, a recent study found it no better than placebo for sciatica over an 8-week treatment course. Thus, it cannot be assumed to be effective for all neuropathic pain types. The side effects of sedation, mental clouding, and dizziness are dose-limiting initially, and some patients are unable to tolerate these medications at the required therapeutic doses. Older antiepileptic drugs like carbamazepine may also be useful, but drug interactions, renal, liver, and hematologic toxicity make them less than ideal in older adults. This class of medications carries a similar warning as opioids regarding avoiding their use in patients with a history of falls and fractures.

Topical capsaicin is available over the counter at very low concentrations (0.025% to 0.075%) for the treatment of neuropathic and musculoskeletal conditions. This medication is very safe except for a redness and burning sensation with thermal hyperalgesia on treated skin. Residual medication must be removed from the fingers that applied it to avoid exposing and irritating sensitive mucous membranes. The higher concentration (8%) synthetic capsaicin adhesive patch is a selective agonist of transient receptor potential vanilloid 1 channel, approved for treating peripheral neuropathic pain. A single 30-minute application of the capsaicin 8% patch significantly improves postherpetic neuralgia pain. Additional studies examining a single 60-minute application or several 30-minute applications 2 months apart have provided good pain relief for different painful neuropathies. Although widely used with reports of clinical success, topical lidocaine has failed to demonstrate efficacy from large, good-quality randomized controlled studies treating neuropathic pain.

Other adjuvant drugs can be used in the older adult for their coanalgesic effect or to offset side effects of pain relievers. They are often selected for their general ability target mechanisms believed to cause or amplify the patient’s pain, such as α2-adrenergic or γ-aminobutyric acid (GABA_B)
agonists, N-methyl-D-aspartate (NMDA) receptor antagonists, or cannabinoids. Effects vary considerably based on a variety of factors; therefore, it is prudent to start one agent at a time at a low dose, titrate carefully, and have frequent monitoring to establish the safety and efficacy before adding, subtracting, or adjusting other medications.\textsuperscript{135}

### Additional Treatments for Pain of Older Person

Pharmacologic management is the foundation of pain treatment in most settings; however, medications often fall short of providing optimal pain reduction and functional improvement. Guidelines are now recommending a trial of nondrug techniques before starting medications.\textsuperscript{136} When ineffective alone, nondrug therapies should continue when analgesics are added for their medication-sparing benefits.\textsuperscript{136} In conventional medicine, physical or psychosocial (cognitive/behavioral) modalities are often provided by a physical therapist, physiatrist, and/or psychologist. A variety of nonmainstream approaches to relieving pain when combined with conventional therapy are called complementary and integrative health (CIH) approaches. Alternative medical systems (e.g., Ayurvedic medicine, traditional Chinese medicine, homeopathy, and naturopathy) are not included as CIH approaches when they exclude conventional medical approaches.

Multidisciplinary pain treatment programs integrate physical, cognitive-behavioral, and some complementary approaches to optimize the treatment for patients with complex pain that has not responded to sequential treatment attempts.\textsuperscript{137} Many nondrug approaches are underused in older patients, and professionals are urged to integrate these modalities, especially cognitive-behavioral therapy (CBT) and exercise into treatment plans.\textsuperscript{17}

### INTERVENTIONAL APPROACHES

Interventional approaches can provide significant benefit to older adults whose severe, disabling pain is not responsive to less invasive measures. Proper patient selection and highly trained professionals are needed to perform specific procedures with precision, followed by ongoing vigilant
monitoring. Many specialists use fluoroscopic verification of needle placement for many nerve blocks procedures to avoid the life-threatening risk of intravascular injections. Older adults are particularly at higher risk in the setting of anticoagulation, uncontrolled diabetes, or cardiovascular or progressive neurologic disorders.

Guidelines for interventions like facet joint and epidural spinal injections (ESIs) were developed by a Multisociety Pain Workgroup out of a concern that the number of these procedures more than doubled between 1994 and 2001 among Medicare patients. Their 17 recommendations provide strict guidance for patient selection and safety, which have been widely adopted by payers. Recommendations include that cervical and lumbar interlaminar ESIs be performed with image guidance and transforaminal ESIs be conducted under real-time fluoroscopy or digital subtraction angiography. Cervical interlaminar ESIs above C6–C7 are not advised, and cervical transforaminal ESIs should only be done using nonparticulate steroids. Safety guidelines include limiting sedation levels and using precautions to prevent infections. Despite these safeguards, the evidence of effectiveness is still not well established for older adults.

Implanted spinal cord stimulator technology has rapidly advanced for back, leg, and phantom pain, holding promise to control pain with few if any drugs needed. Innovative less invasive approaches are being developed that may benefit older adults who are not candidates for existing surgical procedures or dorsal column stimulation used to treat pain. Exciting developments in noninvasive interventions, such as pulsed electromagnetic field (PEMF) therapy, hold promise for common ailments with advancing age, such as arthritis. This PEMF therapy can be administered three times a week for several weeks, or patients can self-apply bands around their affected joint (e.g., knee) every day to reduce pain, stiffness, and medication use while improving their functioning.

**PHYSICAL MODALITIES**

Physical modalities to pain control range from simple applications of heat/cold, orthotics, or electrical stimulating devices patients can self-manage to more technical interventions requiring professional expertise.
like low-level laser treatments. Active techniques, like therapeutic exercise and aquatic therapy, work better for able-bodied older adults than passive approaches like superficial heat, transcutaneous electrical nerve stimulation (TENS), and acupuncture.\textsuperscript{148} Physical therapists have developed graded activity programs to tailor treatments best aligned with the physical capacity of older adults with pain.\textsuperscript{149} There are a variety of therapeutic exercises, salves, nutritional supplements and self-management techniques commonly used to reduce pain and medication use while improving well-being.\textsuperscript{150,151}

Promoting active involvement in pain management, like home exercise programs, pacing activities, or the application of salves, are increasingly being used to provide relief while reducing medication-related problems.\textsuperscript{150,151} Simple advice to remain physically active despite pain, in the absence of a specific exercise routine, is ineffective.\textsuperscript{17} More structured exercise interventions for older adults with chronic pain are evidenced-based and underutilized and should be a core component of any long-term treatment plan, even for nursing home residents.\textsuperscript{151} Moderate pressure massage and Iyengar yoga (focusing on poses) is increasingly being used to reduce pain and improve balance and mobility, even for hospitalized older patients with pain.\textsuperscript{152,153} Physiotherapists often integrate exercises that promote balance, flexibility, body mechanics, pacing, endurance, and strengthening to not only lower pain but also reduce catastrophic thinking and avoidance behaviors known to make back pain worse.\textsuperscript{149}

Although generally safe, some precautions are advised. Protect the skin of older adults when topical heat or cold compresses are applied and use extra lotion or gel when applying TENS pads or giving a massage.\textsuperscript{154,155} Although commercially available natural products and supplements are safe when they do not interact with drugs, some herbal remedies have been tainted with drugs or heavy metals.\textsuperscript{156,157} Safety precautions are needed for older adults receiving physical manipulation and body-based therapies (e.g., chiropractors, osteopaths, physical and massage therapists) because of the high risk for falls observed among individuals who use these therapies.\textsuperscript{158}

**PSYCHOSOCIAL MODALITIES**

2952
A variety of psychosocial modalities strive to change the perception of pain or alter the unhelpful thoughts, feelings, or behavioral responses that worsen pain and suffering. Specific techniques include education and counseling, distraction, coping skills training, relaxation, imagery, hypnotherapy, and facilitating emotional disclosure that help older adults with pain.\textsuperscript{153,159,160} Structured programs like CBT, acceptance and commitment therapy (ACT), and peer-led self-management programs help older adults despite barriers to accessing them.\textsuperscript{17,84} New models of bringing these programs to older adults are proving feasible and effective.\textsuperscript{161–164} Although these and other psychosocial modalities help many older persons, some lack the physical or mental capacity to participate, and interventions need to be tailored to their specific (e.g., visual or auditory impairment, limited mobility) circumstance.\textsuperscript{154,165}

When psychological attributions for pain, emotional awareness, emotional approach coping, and alexithymia are directly addressed, large effects were seen with sustained improvements in pain, functioning, and mood.\textsuperscript{160} Pain self-management group programs suggest a smaller but significant sustained benefits can be achieved through that approach.\textsuperscript{166} Perhaps a common thread in some of these approaches is moving away from a traditional style of trying to persuade patients to change behavior and toward asking thought-provoking questions that prompt desire, ability, reasons, and need to change, so the patient can take action based on their individual values and motivators.\textsuperscript{167}

Older adults do benefit from structured CBT or ACT programs and may be more likely to respond than younger adults.\textsuperscript{168} It is unclear if “booster sessions” would help because the effects of pain reduction do persist, but measures of functional improvement are not sustained.\textsuperscript{169} Even if physical functioning is not improved, psychological flexibility, social functioning, and mental health is improved.\textsuperscript{170}

**COMPLEMENTARY AND INTEGRATIVE HEALTH**

Pain is the most common health problem driving people to use CIH approaches. American spend 3 times more in out-of-pocket expenses ($15 billion per year) for complementary therapies than they do for conventional medicine.\textsuperscript{171,172} Three-quarters of adults over age 50 years
who use CIH methods reportedly did so to treat a painful condition.\textsuperscript{173} Arthritis and low back pain are commonly treated with mind–body therapies, acupuncture, yoga, massage, spinal manipulation, thermotherapy, and tai chi.\textsuperscript{172,174} In fact, slightly more older adults use CIH measures than conventional therapies for low back pain (96\% and 95\%, respectively),\textsuperscript{150} which is aligned with recommendations of recent guidelines.\textsuperscript{90,136} For older adults, yoga, massage, and natural products are especially appealing and are demonstrating their cost-effectiveness.\textsuperscript{159,175} Despite a lack of strong evidence that yoga or qigong decreases low back pain, the physical postures, breathing techniques, and focused intention do improve functioning, balance, mood, self-efficacy, and quality of life.\textsuperscript{152,176,177} Yoga may also improve memory and cognitive functioning and reverse some of the atrophic changes in the brain brought on by chronic pain and aging.\textsuperscript{178,179}

There is evidence spinal manipulation, mind–body therapies, and natural products CIH modalities are cost-effective for older adults with pain.\textsuperscript{175,180} Access to CIH, however, may be limited by cost, ease of access, facility policies, or physician concern. Even when they are used, patients do not disclose CIH use to health professionals.\textsuperscript{181,182} Even though CIH is reluctantly used in frail older adults, many methods have demonstrated safety, with the added safety of reducing exposure to potentially dangerous drugs, or the need for physical or chemical restraints.\textsuperscript{183,184} Some potential danger exists with some CIH methods, as acupuncture-related infections, nerve injuries, organ perforation, serious bleeds, and pneumothorax have been reported in older adults.\textsuperscript{185,186} To offset these concerns, some are using the less invasive acupressure to alleviate chronic pain, but a high dropout rate suggests it is not for everyone.\textsuperscript{187} Aromatherapy has provided transient relief of pain, improved mood, and reduced stress levels among older adults, but additional studies are needed.\textsuperscript{188,189}

**MULTIDISCIPLINARY PAIN TREATMENTS**
Multidisciplinary pain treatment programs are underutilized for older adults who respond similarly as younger adults with persistent pain.\textsuperscript{84,190,191} Multidisciplinary pain clinics have better outcomes in terms of pain reduction, functional improvement, and lower health care
utilization than those who receive only single-modality interventions. About a third of patients with chronic low back pain that has not responded to other treatments gain significant control of their pain as a result of a multidisciplinary pain treatment program. Even patients who do not achieve significant pain control in this type of a program are satisfied with the treatment and feel better able to self-manage their symptoms, which may be why some emergency departments now provide multidisciplinary education improved pain outcomes.

Although the cost–benefit ratio has not clearly been delineated for older adults, there is no compelling evidence to suggest that they should be denied such treatment. In fact, the potential adverse effects of untreated pain and/or polypharmacy suggest that multidisciplinary treatment should be considered for all geriatric patients with significant pain complaints.

Summary

Certainly, there are risks when treating older adults with severe or persistent pain. In fact, the undertreatment of pain is an important risk that can contribute to physical harm, mental despair, and social isolation during what has been dubbed “the golden years.” Although much remains to be learned, we currently have sufficient knowledge to improve the way pain is assessed and treated while refining methods to further improve the safety and efficacy of pain relief efforts. Clear consistent assessment methods are needed by choosing and using tools validated for older adults. The patient’s understanding of the tool should be confirmed so that meaningful information is gathered and recorded. When planning interventions, a shared decision-making approach is appropriate, where patients and their loved ones are informed of the risks, benefits, and variable responses typical for particular treatment options. This shared decision making engages the patients as active participants in the treatment process and educates them about desired and undesired effects that may be encountered and need to be recorded. Cautious drug and dose selection is needed for the older adult. Lower starting doses and longer dosing intervals are justified until the patient’s response to analgesics is known. Monitoring the patient’s response early in therapy for side effects, drug (or
herbal) interactions, and toxicity is important, especially for those with comorbid conditions that add risks. Continued monitoring for older adults on sustained treatment is important as several late-onset toxicities (e.g., GI bleed, hypertension, liver/renal impairment, opioid-induced hyperalgesia) may not emerge until months or years of therapy have passed. The prudent use of nonoperative interventions (e.g., nerve blocks) and nondrug or complementary, integrative therapies should be considered for older adults with persistent pain. Given the breadth of options available to treat pain, allowing it to go untreated in older adults is a mistake. Whereas not all treatments are good options for older adults, failing to treat pain is unacceptable, especially for those who are so vulnerable to the harmful effects of unrelieved pain.

*The terms chronic pain and persistent pain are often used interchangeably to denote pain that lasts for more than 3 months. Persistent pain is used in this text to avoid negative connotation often associated with the label chronic pain, as is recommended by the American Geriatrics Society.

CHAPTER 56
Obstetric Pain

CYNTHIA A. WONG

Historical Notes

Childbirth pain is arguably the most severe pain most women will endure in their lifetimes. The modern era of childbirth analgesia began in 1847 when Dr. James Young Simpson administered ether to a woman in childbirth and later, in the same year, chloroform. The use of analgesia for childbirth aroused violent opposition from some physicians, the public, and the clergy.\(^1\) Simpson was labeled a heretic, blasphemer, and an agent of the devil. The furor died down somewhat in 1853, when John Snow successfully administered chloroform to Queen Victoria for the birth of her eighth child.

In the ensuing years, public opinion regarding obstetric analgesia began to change, thus forcing the medical community to offer analgesia. Women enthusiastically embraced labor analgesia. Fanny Longfellow, the wife of poet Henry Wadsworth Longfellow and the first woman in the United States to receive labor analgesia in the modern era, wrote that “this is certainly the greatest blessing of this age.”\(^2\) Pain began to lose its theologic connections.\(^3\) It was no longer considered punishment for sin or divine retribution. Instead, disease and pain were considered biologic processes that could be studied and treated.

Following this auspicious beginning in the 19th century, however, childbirth analgesia was largely neglected by the medical community. The next major step occurred in the early 20th century when Dämmerschlaf, or “twilight sleep,” was introduced in Europe.\(^4\) The combination of scopolamine and morphine was enthusiastically accepted by women but not by the medical profession. Medical professionals expressed concern about the effect of childbirth analgesia on the progress of labor. In addition, with the advent of twilight sleep, physicians began to appreciate
that anesthetics cross the placenta and had potentially adverse effects on the newborn. This was the stimulus for Virginia Apgar, an anesthesiologist, to develop an evaluation tool to assess neonatal well-being in 1953.\textsuperscript{5} A salutary effect of the Apgar score was that scientific studies comparing the effects of different anesthetic techniques on neonatal outcome were now possible.

Regional anesthesia was first introduced in 1884, when Carl Koller described the use of cocaine to anesthetize the eye.\textsuperscript{6} Descriptions of regional anesthesia, including spinal, lumbar epidural, caudal, paravertebral, and pudendal nerve blocks, were published in the obstetric literature between 1900 and 1930.\textsuperscript{3} In the 1930s and 1940s, Cleland\textsuperscript{7} contributed to our understanding of the innervation of the uterus and applied this knowledge to regional anesthesia in the care of the obstetric patient. Continuous neuraxial analgesia, as it is practiced today, had its birth in 1943, when Hingson and Edwards\textsuperscript{8} published the first report of continuous caudal analgesia for childbirth. Flexible, disposable catheters replaced the original malleable needles, and refinements were made, and continue to be made, in technique, drugs, doses, and delivery techniques.

Although other regional nerve block and systemic analgesic techniques are often used for analgesia, women continue to request neuraxial labor analgesia for childbirth at ever-increasing rates. In the most recent survey performed in 2012, over 85% of women in large maternity hospitals in the United States received neuraxial analgesia during labor.\textsuperscript{9} Spinal and epidural anesthesia accounts for over 95% of the anesthetics for elective cesarean deliveries. Multimodal analgesic therapy, which often includes a regional technique component, is the norm for postcesarean analgesia. This chapter summarizes the physiology of childbirth pain, physiologic changes of pregnancy that influence the provision of analgesic and anesthetic care, specific labor analgesic techniques, the effects of analgesia on the mother and infant, and the treatment of nonobstetric pain during pregnancy and lactation.

\textbf{Pain of Childbirth}

Although it is a common observation that parturients vary in the amount of
pain and suffering associated with labor and vaginal delivery, few well-designed studies on the prevalence, intensity, and quality of labor pain have been performed. Melzack et al.\textsuperscript{10} used the McGill Pain Questionnaire to assess childbirth pain. The mean total pain rating index (PRI) was 34 for nulliparous and 30 for parous women. Significant differences were also found between nulliparas and parous women in the sensory qualities of pain. Labor pain scores were 8 to 10 points higher than those associated with cancer pain, phantom limb pain, and postherpetic neuralgia (Fig. 56.1A), although there was a wide range of scores ranging from mild to excruciating (Fig. 56.1B).
FIGURE 56.1  
A: Comparison of pain scores using the McGill Pain Questionnaire obtained from women during labor and from patients in general hospital clinics and an emergency department. The pain rating index (PRI) represents the sum of the rank values for all words chosen from 20 sets of pain descriptions. B: Distribution of PRI scores from nulliparous and parous women in six intervals of the total PRI range. (Redrawn after Melzack R. The myth of painless childbirth [the John J. Bonica lecture]. Pain 1984;19[4]:321–337, with permission.)

CHILDBIRTH PAIN MECHANISMS AND PATHWAYS

Most data support the concept that the pain of the first stage of labor originates predominantly in the cervix and the lower uterine segment rather than the body of the uterus. Dilation of the cervix and lower uterine
segment results in distension, stretching, and tearing of tissues. During the late first stage and second stage of labor, the descent of the fetus and intense stretching and tearing of the tissues of the vagina and perineum become additional sources of pain.

Based on animal and human studies, Cleland\(^7\) concluded that the sensory afferents from the uterus and cervix that transmit pain during the first stage of labor enter the spinal cord at T11 and T12 (Fig. 56.2). He demonstrated that these visceral sensory afferents are intermingled with sympathetic efferents by demonstrating that bilateral paravertebral lumbar sympathetic blockade abolished the pain of the first stage of labor. Second-stage pain from descent of the fetus in the birth canal is primarily somatic in nature and is transmitted through sacral nerves to the S2–S4 segments of the spinal cord.

**FIGURE 56.2** Schematic depiction of the peripheral nociceptive pathways involved in the pain of childbirth. A: The uterus, including the lower uterine segment and cervix, is supplied by afferents that pass from the uterus to the spinal cord by accompanying sympathetic nerves through the cervical plexus; the superior and inferior hypogastric plexuses (SHP, IHP); the lumbar and lower thoracic sympathetic chain; and to the T11, T12, and L1 nerve roots. The vagina and perineum are supplied by afferents that travel to the spinal cord via the pudendal nerve to the S2–S4 nerve roots. B: The nerves involved in the transmission of nociceptive impulses are provoked by noxious stimulation of pelvic structures.

Bonica\(^11\) used a series of discrete nerve blocks of various nociceptive pathways, including paracervical, segmental epidural, caudal, and transsacral blocks, to further refine our knowledge of the nerve pathways that transmit labor pain to the central nervous system. He demonstrated that the upper part of the cervix and lower uterine segment are supplied by afferents that accompany the sympathetic nerves through the uterine and
cervical plexus; the inferior, middle, and superior hypogastric plexuses; and the aortic plexuses. The nociceptive afferents then pass to the lumbar sympathetic chain and course cephalad through the lower thoracic sympathetic chain via the rami communicantes of the T10, T11, T12, and L1 spinal segments. Finally, they pass through the dorsal roots of these nerves to make synaptic contact with the interneurons of the dorsal horn.

Typical of pain arising from viscera, the pain of the first stage of labor is often referred to the T10–L1 dermatomes. Additionally, during the late first stage and second stage of labor, some parturients experience referred pain to the lower lumbar and sacral dermatomes as a result of stimulation of pain-sensitive structures within the pelvic cavity and pressure on one or more roots of the lumbosacral plexus. The pain may be severe if the fetus is in an abnormal position.

Visceral C fibers transmitting pain during the first stage of labor terminate in the spinal cord in a loose network of synapses in the ipsilateral, superficial, and deep dorsal horn and the ventral horn as well as cross the midline to the contralateral dorsal horn with extensive rostrocaudal extension. In contrast, somatic afferent fibers tend to terminate in the ipsilateral superficial laminae of the dorsal horn with minimal rostrocaudal fiber extension. This explains the diffuse localization of visceral first-stage labor pain compared to somatic second-stage labor pain. It may also explain why the neuraxial administration of lipid-soluble opioids in early labor provides complete analgesia, as these drugs penetrate deeply into the spinal cord.

Understanding the anatomic basis of the transmission of labor pain underlies the current treatment of labor pain using regional anesthesia techniques. The visceral pain of the first stage of labor can be blocked with bilateral cervical plexus, lumbar sympathetic blocks, or central neuraxial blockade. The somatic pain caused by descent of the fetus in the birth canal can be blocked with bilateral pudendal nerve blocks or neuraxial blockade.

Our current understanding of the neurophysiologic basis of labor pain is superficial at best. Better understanding of the pain pathways, neurotransmitters, and receptors involved in labor pain will open up new avenues for the treatment of labor pain in the future.
FACTORS THAT AFFECT THE PAIN OF CHILDBIRTH
In addition to physiologic factors such as intensity, duration, pattern of contractions, and descent of the fetus, the amount or degree of pain and suffering associated with childbirth is influenced by physical, psychological, emotional, and motivational factors.

Physical factors that are associated with the severity and duration of childbirth pain include age, parity, history of previous pain or dysmenorrhea, fatigue, the condition of the cervix at the onset of labor, and the relationship between the size and position of the fetus to the size of the birth canal. Generally, an older nullipara experiences longer and more painful labor than a younger nullipara. The cervix of parous women begins to soften even before the onset of labor and is less sensitive than that of the nullipara. The intensity of uterine contractions in early labor tends to be higher in nulliparous compared to parous women, whereas the reverse is true as labor advances. Pain is greater in the presence of dystocia caused by a contracted pelvis, a large baby, or abnormal presentation or position. Women who go on to require cesarean delivery following a period of labor have more breakthrough pain and require more epidural and systemic analgesia during labor than women who deliver vaginally.

Psychological factors, such as fear, apprehension, and anxiety, also influence the degree of pain and suffering during childbirth. The presence of family members or birthing companions during labor and delivery may decrease anxiety and positively affect the progress of labor. Education, intense motivation, and cultural influences can influence the affective and behavioral dimensions of pain, although they probably minimally affect actual pain sensation. Bonica observed women who had had predelivery training in psychoprophylaxis manifested little or no pain behavior during childbirth, although when questioned the next day, most of them indicated the process had been quite painful. Jewish health providers rated the labor pain of Jewish women higher than that of Bedouin women who were delivering in the same institution, whereas the level of pain assessed by the women themselves was not different.

EFFECTS OF PAIN ON THE MOTHER AND FETUS
Labor and vaginal delivery produce tissue damage and, similar to tissue
injury from other causes, result in pain and local segmental, suprasegmental, and cortical responses. These responses include marked stimulation of respiration and circulation as well as the hypothalamic, autonomic centers of neuroendocrine function, limbic structures, and psychodynamic mechanisms of anxiety and apprehension. These may have a deleterious impact on the mother, fetus, and newborn. Many of these responses are mitigated by effective pain relief.

The pain of childbirth is a powerful respiratory stimulus, resulting in a marked increase in minute ventilation and oxygen consumption during contractions. Compensatory periods of hypoventilation between contractions cause transient maternal hypoxemia and, potentially, fetal hypoxemia (Fig. 56.3). Maternal hyperventilation causes severe respiratory alkalosis and a left shift of the maternal oxyhemoglobin dissociation curve, thus diminishing oxygen transfer to the fetus. The pain and stress of labor activates the sympathetic nervous system, resulting in an increase in plasma catecholamine concentrations, cardiac output, and blood pressure (Fig. 56.4). Epinephrine and norepinephrine levels increase by 200% to 600% during unmedicated labor, and this increase is associated with a decrease in uterine blood flow (UBF). Pain and anxiety and the accompanying increased catecholamine levels may contribute to prolonged or dysfunctional labor. Epinephrine is a tocolytic, and physicians have long observed that an apparent dysfunctional labor pattern can be corrected with effective analgesia. Finally, unrelieved severe pain can produce serious mental health disturbances that may interfere with maternal–fetal bonding, future sexual relationships, and contribute to postpartum depression and, rarely, posttraumatic stress disorder.
FIGURE 56.3  Continuous recording of uterine contractions (UC), maternal thoracic impedance, maternal transcutaneous oxygen tension (partial pressure of oxygen [Pao2]), fetal oxygen tension, and fetal heart rate (FHR) in a nullipara breathing room air 120 minutes before spontaneous delivery. Marked hyperventilations during UC were followed by hypoventilation or apnea between contractions. After the first and fourth contractions, the maternal Pao2 fell to 44 and 46 mm Hg, with a consequent decrease in fetal Pao2, and variable decelerations, which reflect fetal hypoxemia. (Redrawn after Huch A, Huch R, Schneider H, et al. Continuous transcutaneous monitoring of fetal oxygen tension during labour. Br J Obstet Gynaecol 1977;84[suppl 1]:1–39. Reprinted by permission of John Wiley & Sons, Inc.)

FIGURE 56.4  Effect of noxious stimulus (application of an electric current to the skin) on maternal arterial blood pressure, norepinephrine blood level, and uterine blood flow in a pregnant ewe. The increase in arterial pressure is transient, and the decay in norepinephrine level is more
protracted and is reflected by a mirror image decrease in uterine blood flow. (Redrawn after Shnider SM, Wright RG, Levinson G, et al. Uterine blood flow and plasma norepinephrine changes during maternal stress in the pregnant ewe. Anesthesiology 1979;50[6]:524–527, with permission.)

The healthy parturient easily tolerates the large increase in cardiac work, but parturients with heart disease, severe preeclampsia, or pulmonary hypertension may not tolerate these changes without adverse outcome. Similarly, the healthy fetus tolerates the changes in UBF; however, these changes may be deleterious in the setting of uteroplacental insufficiency (e.g., preeclampsia, intrauterine growth restriction).

In summary, there is large individual variation in how women experience childbirth pain and suffering. Pain associated responses to noxious stimuli during childbirth are net effects of highly complex interactions of various neural systems, modulating influences, and psychological factors. These interactions are responsible for the complex physiologic, behavioral, and affective responses that characterize the pain of childbirth.

Physiologic Changes of Pregnancy

Pregnancy is associated with significant anatomic and physiologic changes. Many of these changes impact the treatment of pain during pregnancy, parturition, and the puerperium. Safe care of these women requires a thorough understanding of these changes and their impact on the treatment of pain. In addition, a thorough understanding of the fetal–placental complex is necessary for the safe care of the fetus and neonate. These changes and their anesthetic implications are summarized in Table 56.1 and discussed in the following text.

**RESPIRATORY CHANGES**

Pregnancy is associated with anatomic and physiologic changes involving the airway, lung volumes, ventilation, and the dynamics of breathing. Capillary engorgement, an increase in upper airway soft tissue mass, and enlargement of the breasts contribute to making endotracheal intubation more difficult in pregnant compared to nonpregnant women.\(^{25}\) Failed intubation and pulmonary aspiration (often associated with difficult airway management) are the most common causes of anesthesia-related maternal mortality.\(^{26}\) Therefore, in addition to the ability to provide complete analgesia, continuous neuraxial labor analgesia has the added benefit of avoiding the need for general anesthesia and endotracheal intubation should emergency cesarean delivery be required.

Oxygen consumption, carbon dioxide production, and minute
ventilation increase during pregnancy. Functional residual capacity (FRC) decreases and closing capacity may exceed FRC in supine pregnant women at term. Obesity, recumbency, and anesthesia (neuraxial or general) further decrease FRC.

During parturition, minute ventilation and oxygen consumption increase markedly, and hyperventilation results in partial pressure of carbon dioxide ($\text{Paco}_2$) values as low as 10 to 15 mm Hg. Maternal aerobic oxygen requirements exceed oxygen consumption resulting in a progressive maternal lactic acidemia.

**CARDIOVASCULAR CHANGES**

The cardiovascular system is hyperdynamic during pregnancy. Total blood volume increases by approximately 50% during pregnancy, as does cardiac output (Fig. 56.5). Plasma volume increases more than red cell mass, resulting in the physiologic anemia of pregnancy. Organ perfusion is markedly increased, particularly perfusion of the uterus. Systolic blood pressure falls minimally, whereas diastolic pressure decreases by approximately 20%. Both return to prepregnant levels at term. Hemodynamic stability is more highly dependent on sympathetic nervous system activity, and arterial responsiveness to vasopressors is reduced.

![FIGURE 56.5](#) Changes in heart rate, stroke volume, and cardiac output during pregnancy and in the puerperium. (Redrawn after Bonica JJ. Obstetric Analgesia and Anesthesia. 2nd ed. Seattle, WA: University of Washington Press; 1980:5. Reprinted by permission of World Federation of Societies of Anaesthesiologists.)
Aortocaval Compression
At term, compression of the aorta and vena cava by the gravid uterus in the supine position results in decreased right ventricular preload and a 10% to 20% decrease in cardiac output compared to the standing position. Vena cava compression begins as early as 13 to 16 weeks’ gestation and may be nearly complete at term (Fig. 56.6). Partial aortic compression in the supine position results in decreased blood flow to the pelvis and lower extremities. Aortic compression is completely relieved by the lateral position. Data regarding the degree of compression of the vena cava in the lateral position are inconsistent; however, in the lateral position, collateral circulation through the azygous system maintains venous return and cardiac output. The left lateral position is superior to the right lateral position for maintenance of venous return.

During labor, cardiac output increases due to increased central blood volume secondary to autotransfusion during uterine systole and because of increased sympathetic nervous system activity. Due to the adverse effects of aortocaval compression, parameters of fetal well-being deteriorate when parturients labor in the supine compared to lateral position. Adverse effects may be more profound in the parturient with neuraxial blockade induced sympathetic blockade.
Implications for Labor Analgesia

Shunting of lower extremity blood through the azygous system results in venous engorgement in the epidural space. This functionally reduces the size of the epidural and subarachnoid spaces, thus reducing the amount of anesthetic necessary to produce neuroblockade. Sympathetic blockade in the term parturient (e.g., as a consequence of neuraxial analgesia/anesthesia) results in a marked decrease in blood pressure compared to nonpregnant control subjects. Pregnant women may require higher doses of vasopressors compared to nonpregnant individuals to treat
CENTRAL NERVOUS SYSTEM CHANGES
Anatomy of the Spinal Column and Analgesic Implications
Anatomic and physiologic changes in the nervous system alter responses to pain and susceptibility to both general and regional anesthesia. Specifically, anatomic changes in the spinal canal may affect neuraxial anesthesia techniques. The epidural and vertebral foraminal veins are enlarged, resulting in an increased risk of intravascular injection. Additionally, there is decreased nonvascular space in the spinal canal and decreased egress of epidural anesthetic agents from the epidural space. Engorged epidural veins and increases in abdominal pressure are associated with a decrease cerebral lumbosacral cerebral spinal fluid (CSF) volume.

Anatomic changes also occur to the ligamentous and bony structures of the vertebral column. The hormonal changes of pregnancy may cause the ligamentum flavum to feel less dense and “softer” in pregnant women compared to nonpregnant patients; thus, it may be more difficult to feel the passage of the epidural needle through the ligamentum flavum. Progressive accentuation of lumbar lordosis during pregnancy alters the relationship of surface anatomy to the vertebral column. The line joining the iliac crests (Tuffier’s line) assumes a more cephalad relationship to the vertebral column, and accentuated lumbar lordosis results in less space between adjacent lumbar spinous processes. The apex of the lumbar lordosis is shifted caudad during pregnancy, and the typical thoracic kyphosis in women is reduced in pregnant women. This may influence the spread of hypo- or hyperbaric intrathecal anesthetic solutions in supine patients.

Subarachnoid dose requirements may also be affected by the lower specific gravity of CSF in pregnant compared with nonpregnant women and the higher CSF pH. Widening of the pelvis may lead to a relative head-down position in women in the lateral position, thus affecting movement of hypo- or hyperbaric anesthetic solutions in the CSF. Because of the gravid uterus, it may be more difficult for a pregnant woman to achieve flexion of the lumbar spine. Finally, labor pain may make it
difficult for women to assume and maintain an ideal position while the anesthesiologist initiates neuraxial anesthesia.

**Neurohormonal Changes and Analgesic Implications**

Pregnancy-induced neurohumoral changes may alter responses to pain. Lower plasma substance P concentrations\(^{47}\) and higher CSF progesterone levels\(^{48}\) are found in pregnancy. In a rat model, the pregnancy-associated increased concentration of plasma β-endorphin was associated with an increased tolerance to visceral stimulation, and this effect was reversed by naloxone.\(^{49}\) Pain thresholds are increased during pregnancy\(^{50}\) and labor.\(^{51}\) Both peripheral and central nervous tissue from pregnant animals (including human) appears to be more susceptible to many different analgesic and anesthetic agents, including local anesthetics, volatile anesthetic agents, and thiopental. Possible mechanisms of enhanced neural blockade during pregnancy include potentiation of the analgesic effect of endogenous analgesic systems, hormone-related changes in the actions of spinal cord neurotransmitters, increased permeability of the neural sheath, or other pharmacodynamic or pharmacokinetic differences between pregnant and nonpregnant women.

Together, these anatomic and physiologic changes result in a 25% reduction in the segmental dose requirement for spinal anesthesia\(^{48}\) and a similar segmental dose reduction for epidural anesthesia.\(^{52}\)

**PHARMACOKINETIC CHANGES**

Pregnancy alters disposition of drugs by several mechanisms.\(^{53}\) Volume of distribution may be altered. For example, the plasma concentration of antibiotics and, therefore, antimicrobial efficacy are decreased in pregnancy secondary to a large increase in the volume of distribution.\(^{53}\) Plasma protein concentration decreases, leading to altered drug binding.\(^{54}\) For example, lidocaine is less protein-bound during pregnancy, resulting in a higher free fraction in the blood.\(^{55}\) Increased renal blood flow and glomerular filtration and altered hepatic microsomal activity change renal and hepatic drug clearance.

**UTEROPLACENTAL UNIT**
Blood flow to the uterus increases markedly during pregnancy, from 50 to 100 mL per minute before pregnancy, to 700 to 900 mL per minute at term. UBF is directly related to uterine perfusion pressure and indirectly related to uterine vascular resistance.

\[
\text{UBF} = \frac{\text{uterine arterial pressure} - \text{uterine venous pressure}}{\text{uterine vascular resistance}}
\]

UBF is not autoregulated; therefore, decreases in uterine arterial pressure (systemic hypotension), increases in venous pressure (caval compression, uterine contraction or increase in uterine tone, Valsalva maneuver), or increases in uterine vascular resistance (increase in uterine vasoconstriction relative to systemic vasoconstriction) result in decreased UBF.

The net effect on UBF of any therapeutic intervention depends on relative changes in systemic and uterine vessels and effect on uterine tone. Labor analgesia may directly and indirectly affect UBF, both positively and negatively. For example, neuraxial analgesia may increase UBF because of decreased sympathetic outflow (secondary to both pain relief and direct sympathetic blockade), and decreased maternal hyperventilation. Conversely, neuraxial analgesia-induced maternal hypotension may decrease UBF. Additionally, neuraxial analgesia may be associated with transient uterine tachysystole secondary to an acute decrease in circulating epinephrine levels and loss of its tocolytic (β₂-adrenergic agonism) effects. Uterine tachysystole may also result from high concentrations of local anesthetic in uterine tissue, for example, after a paracervical block.

**Transfer of Drugs across the Placenta**

Most drugs administrated to the mother cross the placenta to the fetus to some degree. Placental transfer depends on several factors, including plasma drug concentration and electrochemical gradients across the placenta, molecular weight, lipid solubility, degree of ionization, membrane surface area and thickness (changes during pregnancy), maternal and fetal blood flow, placental binding and metabolism, and degree of maternal and fetal protein binding. Direct drug teratogenicity
may manifest as death, structural abnormalities, growth restriction, and functional deficiencies. Teratogenic potential is influenced by the timing of exposure, drug dose, duration of exposure, and genetic predisposition. The risk of structural teratogenicity is greatest during the period of organogenesis (day 31 to 71 after the first day of the last menstrual period). Functional or behavioral teratogenicity may result from drug exposure during pregnancy, and even after birth, as the central nervous system continues to develop during this period. Nondrug teratogens include hypoxia, hypercarbia, hyperthermia, hypoglycemia, and ionizing radiation.

Nonpharmacologic Methods of Labor Analgesia

Nonpharmacologic methods to relieve the pain and suffering of childbirth include childbirth education, emotional support, massage, aromatherapy, audotherapy, and therapeutic use of hot and cold. More specialized techniques that require specialized training or equipment include hydrotherapy, intradermal water injections, biofeedback, transcutaneous electrical nerve stimulation (TENS), acupuncture or acupressure, and hypnosis. Many of these techniques are inadequately studied in that study quality is poor and sample size is small, and therefore, conclusions about efficacy are not possible.

ANTENATAL CHILDBIRTH EDUCATION

Childbirth education is widely practiced. Unfortunately, studies of childbirth education lack scientific rigor. Study results are inconsistent as to whether participation in childbirth education classes influences outcomes, such as use of analgesia, duration of labor, mode of delivery, and incidence of nonreassuring fetal status.

LABOR SUPPORT

Emotional support is commonly provided by the parturient’s husband or a friend. “Continuous labor support” refers to the nonmedical support of the parturient by a trained person. Prospective, controlled trials and several systematic analyses have concluded that women who receive continuous
labor support have shorter labors, fewer operative deliveries, fewer analgesic interventions, and greater satisfaction.\textsuperscript{63}

**HYDROTHERAPY**

Hydrotherapy is the immersion of the parturient in warm water (deep enough to cover the abdomen) during labor (not birth). Systematic reviews of randomized controlled trials have concluded that women experience less pain and use less analgesia without change in the duration of labor, rate of operative delivery, or neonatal outcome.\textsuperscript{64}

**INTRADERMAL WATER INJECTIONS**

Intradermal water injection consists of the injection of 0.05 to 0.1 mL of sterile water, using an insulin or tuberculin syringe, at four sites on the lower back: over each posterior superior iliac crest, and 1 cm medial/3 cm caudal to these injections (Fig. 56.7). The technique is used to treat back pain during labor. The injections themselves are acutely painful for about 20 to 30 seconds, but as the injection pain fades, so does lower back pain. A 2012 systematic review that included seven studies and 766 study subjects reported a greater reduction in pain scores in women who received sterile water injections compared with women in the control group.\textsuperscript{65} However, the authors determined that a meta-analysis of the data was not appropriate and four studies were at high risk of bias. Further study is warranted.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure56_7.png}
\caption{Placement of intradermal water blocks: four intradermal injections of 0.05 to 0.1 mL of sterile water to form four small blebs over each posterior superior iliac spine and 3 cm below}
\end{figure}
and 1 cm medial to each spine. The exact locations of the injections do not appear to be critical to
the block success. (Redrawn after Simkin P, Bolding A. Update on nonpharmacologic approaches

Sons, Inc.)

HYPNOSIS
Self-hypnosis for treatment of childbirth pain has been practiced for
several centuries. Hypnosis requires prenatal training of the mother, and
sometimes her partner, by a trained hypnotherapist. A meta-analysis of
nine randomized controlled trials that included 2,954 women found the
overall use of pharmacologic analgesia methods was decreased in the
hypnosis compared to control groups, but neuraxial analgesia use was
not.66 Data were inconclusive or limited regarding progress of labor and
neonatal outcomes.

TRANSCUTANEOUS ELECTRICAL STIMULATION
TENS involves the application of low-intensity, high-frequency electrical
impulses to the skin of the lower back. The buzzing, electrical current
sensation caused by the TENS unit may reduce the mother’s awareness of
contraction pain. Studies of TENS are inconsistent, but in general, labor
pain does not appear to be lessened or is the use of other analgesic
modalities.67

ACUPUNCTURE AND ACUPRESSURE
Acupuncture is a component of traditional Chinese medicine that has
gained popularity in Western cultures in recent years. A 2011 systematic
review concluded that the use of acupuncture and acupressure during labor
may have a role in reducing pain and the need for pharmacologic
analgesia.68 However, authors of a 2014 review of systematic reviews of
acupuncture therapy during labor concluded that the trials included in this
and other systematic reviews differ in terms of study design and outcome
measures, and therefore, it may be inappropriate to include the studies in a
pooled analysis.62 Further study is warranted.

Systemic Analgesia
INHALATIONAL ANALGESIA

Inhalation analgesia for labor and vaginal delivery, common in other countries, is gaining popularity in the United States. The only inhaled anesthetic agent currently in common use is nitrous oxide. It is commercially available as a mixture of 50% nitrous oxide and 50% oxygen. Special equipment is required to ensure the safe administration of the drug without contamination of the labor room. The mother must be taught to breathe the mixture correctly, so that peak brain nitrous oxide concentrations coincide with peak contraction pain. Studies are conflicting as to whether nitrous oxide provides benefit to the parturient; most studies are of a poor quality. Although the intermittent use of nitrous oxide appears safe for the fetus and neonate, neonatal studies are also of poor quality. There is accumulating evidence that nitrous oxide use in other settings may not be benign; neurologic, genologic, and hematologic toxicity as well as adverse immunologic effects have been described. Risk may depend on genotype; thus, further study of its use for childbirth analgesia is warranted. The concomitant use of nitrous oxide and systemic opioids may increase the risk of maternal hypoxemia.

PARENTERAL OPIOID ANALGESIA

Systemic opioid analgesia, administered by the subcutaneous, intramuscular, or intravenous route, is widely used around the world either as the sole analgesic modality or prior to the administration of regional labor analgesia. The use of systemic opioids for labor analgesia lacks rigorous scientific study. There is a high incidence of side effects (e.g., sedation, nausea, and vomiting), and analgesia is incomplete, at best, during active labor. Historically, meperidine has been the most commonly used systemic opioid; however, its use in the United States has declined in the past decade as practitioners have come to better appreciate its long maternal and neonatal half-life and that of its active metabolite, normeperidine. There is little scientific evidence that any one opioid is better than another. All have dose-related, maternal, fetal, and neonatal side effects. Maternal side effects include nausea, vomiting, delayed gastric emptying, dysphoria, and respiratory depression. All opioids cross the placenta. In utero, opioids may result in a slower fetal heart rate and
decreased beat-to-beat variability. The likelihood of neonatal respiratory depression depends on the dose and timing of administration.

**Patient-Controlled Intravenous Analgesia**

Patient-controlled intravenous analgesia (PCIA) has theoretical advantages to nurse-administered opioid analgesia, including superior analgesia with smaller drug doses, resulting in a lower incidence of side effects. PCIA studies have been reported using meperidine, nalbuphine, fentanyl, and, more recently, remifentanil with and without a background infusion. Remifentanil has the theoretical advantage of rapid onset and offset compared to the other opioids, although its peak effect still occurs after the contraction if the parturient self-administers a bolus dose at the beginning of a contraction. Multiple studies have used different bolus doses, rates of bolus-dose administration, lockout intervals, and background infusion rates. In a 2016 review, Van de Velde and Carvalho suggested a fixed bolus dose of 20 to 50 µg with a lockout interval of 1 to 3 minutes and no background infusion. The bolus dose may require upward adjustment as labor progresses. However, as with other systemic opioid techniques, it is unclear whether remifentanil PCIA can provide satisfactory analgesia without an unacceptably high incidence of side effects. In a randomized trial comparing epidural to remifentanil PCIA, apnea episodes were recorded in 53% of women in the remifentanil group. Monitoring oxygen saturation (SpO₂) was insufficient to identify most of the apnea episodes. Experts agree that remifentanil PCIA should only be used when the parturient is under continuous observation by a midwife or labor nurse.

**Neuraxial Analgesia**

Neuraxial labor analgesia is the most effective method of pain relief during childbirth and the only method that provides complete analgesia without maternal or fetal sedation. The use of neuraxial analgesia for childbirth has increased dramatically in the United States over the past 40 years. The most common techniques are continuous lumbar epidural analgesia and combined spinal-epidural (CSE) analgesia. Single-shot spinal, continuous spinal, and caudal analgesia are occasionally used.
Contraindications to neuraxial analgesia and anesthesia include patient refusal, infection at the puncture site, preexisting coagulopathy, and lack of experienced anesthesia providers. Relative contraindications include hemorrhage or other causes of hypovolemia, untreated systemic infection, preload-dependent disease states, and lumbar spine pathology. The anesthesiologist should weigh the risk and benefits of a neuraxial procedure for each patient, and the specific neuraxial analgesic technique should be tailored to individual patient needs. The risks and benefits of the procedure should be discussed with each parturient, preferably early in labor. The advantages and disadvantages of specific neuraxial techniques are listed in Table 56.2.

| TABLE 56.2 Advantages and Disadvantages of Specific Neuraxial Techniques for Labor Analgesia |
|---------------------------------|---------------------------------|---------------------------------|---------------------------------|---------------------------------|
|                                | Continuous Epidural             | Combined Spinal-Epidural        | Single-Shot Spinal              | Continuous Spinal               |
| Advantages                      | Continuous technique            | Rapid onset                    | Rapid onset                    | Rapid onset                    |

|                                | Requires greater mass of        | Limited duration of analgesia   | Limited duration of analgesia   | with large gauge needle\(^c\)  |
|                                | anesthetic\(^b\)                |                                 |                                 | Potential for accidental       |
|                                | Delayed sacral blockade/sacral  |                                 |                                 | intrathecal injection of       |
|                                | sparing                         |                                 |                                 | dermatome                      |

\(^a\) Limited duration of analgesia \(^b\) Requires greater mass of anesthetic \(^c\) Requires volume of anesthetic to block T10 dermatome
Large doses of epidural opioid may provide near-complete analgesia for early labor but at the expense of significant systemic absorption and with accompanying side effects.

Greater vascular absorption of anesthetic agents and greater likelihood for accidental intravascular injection of a toxic amount of local anesthetic.

Increased risk of postdural puncture headache.

May not be able to achieve T4 sensory blockade necessary for cesarean delivery.

**EPIDURAL ANALGESIA**

Lumbar epidural analgesia has been the mainstay of regional labor analgesia. Placement of an epidural catheter allows analgesia to be maintained until after delivery. Additionally, it allows conversion to epidural anesthesia should cesarean delivery be necessary. No dural puncture is required. Randomized studies consistently demonstrate that pain scores are lower and patients are more satisfied with epidural analgesia compared to nonneuraxial analgesia. Injection of anesthetics in the lumbar epidural space allows spread of the anesthetic solution both cephalad and caudad. Neural blockade to the T10 dermatome is necessary to relieve uterine and cervical pain, whereas blockade of the sacral dermatomes is necessary to block the pain of vaginal and perineal distention.

Compared to spinal analgesic techniques, the onset of epidural analgesia is significantly slower (15 to 20 minutes compared to 2 to 5 minutes), particularly the onset of sacral analgesia. It may take several hours of lumbar epidural infusion, or several bolus injections of local anesthetic into the lumbar epidural space, to achieve sacral analgesia. This is particularly disadvantageous in a rapidly laboring parturient who requires rapid onset of sacral analgesia for the late first and second stages of labor. In addition, epidural compared to spinal analgesia requires significantly more drug(s) to attain comparable analgesia, thus increasing the risk of systemic toxicity. Finally, there is significantly more systemic absorption of anesthetic agents, and therefore, maternal and fetal plasma drug concentrations are higher with epidural compared to spinal analgesia.

Lumbar epidural analgesia is initiated in either the sitting or lateral position.
position. The epidural space is identified with a 17 or 18G epidural needle, usually using a loss-of-resistance to air of saline technique. A flexible catheter is passed through the needle approximately 4 to 5 cm into the epidural space, the epidural needle is removed, and the catheter is secured. A test dose is frequently administered to rule out intrathecal or intravascular catheter placement. The most common test dose is lidocaine 15 mg/mL with epinephrine 5 µg/mL, 3 mL. No matter whether a test dose is injected, drugs should be injected incrementally into the epidural space, as no test is 100% sensitive and catheters may migrate during use. Pregnant women are very difficult to resuscitate from local anesthetic systemic toxicity.

Analgesia is initiated by bolus injection of anesthetic(s) through the epidural needle, catheter, or both. Analgesia is maintained with intermittent bolus injections or a continuous infusion. The catheter is removed after delivery when there is no further need for analgesia/anesthesia.

**Drugs for Initiation of Epidural Analgesia**

Drugs commonly used for epidural labor analgesia are listed in Table 56.3. Local anesthetics, primarily bupivacaine, have been the mainstay of epidural analgesia for many years. The amount of epidural local anesthetic required for satisfactory analgesia increases as labor progresses. Low bupivacaine concentrations (≤1.25 mg/mL) provide excellent analgesia with minimal motor block. The ED$_{50}$ of bupivacaine 1.25 mg/mL was lower than the ED$_{50}$ of bupivacaine 2.5 mg/mL, suggesting that the use of low concentrations is associated with less overall drug requirement. Bupivacaine is highly protein-bound with minimal placental transfer, and duration of analgesia is approximately 2 hours. Onset to peak effect is approximately 20 minutes. Lidocaine and 2-chloroprocaine have shorter latency, but their duration of analgesia is shorter, limiting their usefulness for routine labor analgesia. In addition, lidocaine is less protein-bound than bupivacaine and therefore has a higher umbilical vein/maternal vein ratio. 2-Chloroprocaine is most useful for rapidly converting epidural analgesia to epidural anesthesia for urgent operative delivery.

NOTE: The actual drug dose will depend on the stage of labor (women in advanced labor require higher doses), the progress of labor (women with rapid progress of labor will require higher doses), and whether or not an anesthetic containing test dose has been administered.

<sup>a</sup>Local anesthetics and opioids are commonly administered together, in which case a lower dose of each is required.

<sup>b</sup>Clonidine is not approved for use in obstetric patients in the United States.

<sup>c</sup>This dose should be combined with local anesthetics, as higher doses used alone cause sedation and hypotension.

Ropivacaine is a homologue of bupivacaine, formulated as a single levorotatory enantiomer. Its onset and duration of action are similar to bupivacaine,<sup>85</sup> but it has less potential for cardiac toxicity. Although potency studies suggest that ropivacaine is approximately 40% less potent than bupivacaine,<sup>86</sup> clinical studies comparing low concentrations of ropivacaine and bupivacaine for labor analgesia suggest that they are equipotent in terms of sensory blockade for labor analgesia.<sup>87,88</sup> However, ropivacaine may be associated with less motor blockade than equipotent doses of bupivacaine.<sup>89</sup> Levobupivacaine, the S-enantiomer of bupivacaine, is not available in the United States. Similar to ropivacaine and bupivacaine in its onset and duration of action, it is less cardiotoxic than bupivacaine and is associated with less motor blockade compared to bupivacaine.<sup>87,89</sup>

Opioids, particularly the lipid-soluble opioids, fentanyl and sufentanil, are commonly added to local anesthetics for epidural analgesia. Epidural opioids and local anesthetics interact synergistically to provide analgesia.<sup>90,91</sup> The addition of opioids shortens latency; allows for
decreased concentration of local anesthetic, thus decreasing motor block; and prolongs analgesia. Although epidural opioids alone can provide moderate analgesia for early labor, analgesia is incomplete, and the necessary dose is accompanied by bothersome side effects (e.g., pruritus, nausea, vomiting, maternal sedation, neonatal respiratory depression). Combining local anesthetics with opioids allows for effective analgesia while minimizing the side effects of both drugs.

Fentanyl and sufentanil are ideal for labor analgesia because of their rapid onset (5 to 10 minutes). Their short duration of action (60 to 90 minutes) is overcome by maintaining analgesia with a continuous epidural infusion. Doses commonly used for epidural analgesia initiation and maintenance have been shown to be safe for both the mother and neonate. Morphine has a much slower onset (30 to 60 minutes) and longer duration of action (12 to 24 hours) than fentanyl or sufentanil. The long duration of action is not beneficial, as the bothersome side effects of morphine (pruritus, nausea, and vomiting) continue to be present after delivery.

Adjuvants for epidural labor analgesia include epinephrine and clonidine. Epidural epinephrine may contribute to analgesia by decreasing the uptake of local anesthetics and opioids from the epidural space secondary to vasoconstriction and by binding to spinal cord \( \alpha_2 \)-adrenergic receptors. Clonidine also binds to \( \alpha_2 \)-adrenergic receptors and has been shown to supplement epidural labor analgesia. The U.S. Food and Drug Administration (FDA) has not approved neuraxial clonidine for use in obstetric patients because of the risks of sedation and hypotension. However, it is useful for the treatment of breakthrough pain (75 to 100 µg) when the administration of additional local anesthetic is likely to contribute to worsening motor block; any resulting hypotension is usually readily treated.

**COMBINED SPINAL-EPIDURAL ANALGESIA**

CSE analgesia has become increasingly popular for labor analgesia. There are advantages and disadvantages to CSE compared to traditional epidural analgesia (see Table 56.2). Onset of analgesia is significantly faster compared to epidural analgesia. Complete analgesia for early labor can
be accomplished with the intrathecal injection of lipid-soluble opioids without the addition of local anesthetics, thus avoiding motor blockade and decreasing the risk of hypotension. This is ideal for patients who wish to ambulate, or for those with preload-dependent conditions such as stenotic heart lesions. The effective opioid dose is significantly less than for systemic or epidural administration. Therefore, systemic drug absorption is minimal, as are direct fetal effects. The addition of local anesthetic to a lipid-soluble opioid results in sacral analgesia within several minutes. This is a decided advantage compared to lumbar epidural analgesia, as sacral analgesia is difficult to accomplish after a single lumbar epidural dose of local anesthetic. Therefore, CSE analgesia provides more complete analgesia for women in advanced stages of labor or women whose labor is progressing rapidly. Finally, use of the CSE technique may decrease the incidence of failed epidural analgesia (e.g., a nonfunctioning epidural catheter).  

There are several undesirable side effects of CSE analgesia. The incidence of pruritus is higher with intrathecal versus epidural opioids. Dural puncture is required to initiate CSE analgesia. The risk of postdural puncture headache (PDPH) may be minimally higher with the CSE compared to pure epidural technique (estimated excess rate of 3 in 1,000). However, a more serious concern is that dural puncture in the obstetric patient may be a risk factor for postpartum neuraxial infection, a rare but potentially life-threatening complication.  

Several techniques for CSE analgesia/anesthesia have been described, including using two skin punctures in two interspaces, two punctures in one interspace, and the needle-through-needle technique. The most common CSE technique for labor analgesia is the needle-through-needle technique in a midlumbar interspinous space. The epidural space is identified with an epidural needle in the standard fashion. The epidural needle then functions as an introducer needle as a long spinal needle is passed through it until the dura is punctured. The intrathecal drug(s) is injected through the spinal needle, the spinal needle is withdrawn, and an epidural catheter is threaded through the epidural needle. Analgesia is maintained via the epidural catheter, as with traditional epidural analgesia.
Drugs for Initiation of Combined Spinal-Epidural Analgesia

CSE labor analgesia is usually initiated with a lipid-soluble opioid (fentanyl or sufentanil) or a combination of opioid and local anesthetic (Table 56.4). Morphine is not commonly used because of its long latency and long duration of action (a disadvantage, as women usually deliver before regression of side effects). However, morphine has been successfully combined with intrathecal bupivacaine and fentanyl in order to shorten latency and increase duration of analgesia. This combination of drugs may be particularly useful in settings where continuous epidural infusion techniques are impractical. Meperidine is unique among the opioids in that it has weak local anesthetic properties. However, meperidine was associated with a significantly higher incidence of nausea and vomiting compared to combined fentanyl and bupivacaine.

<sup>a</sup> Opioids alone provide complete analgesia for early labor, but the addition of local anesthetics is required for late first-stage and second-stage analgesia.

<sup>b</sup> The combination of bupivacaine-fentanyl-morphine may be advantageous in the settings where continuous epidural infusions for maintenance of analgesia are impractical and single-shot techniques are an alternative.

Intrathecal opioids can provide complete analgesia early in labor when the pain stimuli are primarily visceral. Onset of analgesia occurs within 5 minutes and lasts 70 to 100 minutes. The reported ED<sub>95</sub> of intrathecal fentanyl varies from 14 to 23 μg. The relative potency ratio of intrathecal sufentanil to fentanyl for labor analgesia is 4.4:1. When administered at twice the ED<sub>50</sub>, the duration of sufentanil analgesia was 25 minutes longer than fentanyl, although the incidence of side effects was not different. The duration of action of intrathecal opioids is dose-
related, although fentanyl doses greater than 25 µg do not increase
duration of analgesia and are associated with a higher incidence of side
effects.\textsuperscript{103}

In the late first stage and second stage of labor, local anesthetic must be
added to the opioid to block somatic stimuli from the vagina and
perineum. The local anesthetic works synergistically with the opioid; thus,
lower doses of both drugs can be used.\textsuperscript{105} Bupivacaine is most commonly
combined with fentanyl or sufentanil. The ED$_{95}$ of bupivacaine combined
with sufentanil 1.5 µg was 3.3 mg\textsuperscript{106} and was 1.66 mg when combined
with fentanyl 15 µg.\textsuperscript{107} Bupivacaine doses between 1.25 to 2.5 mg are
commonly used. Levobupivacaine and ropivacaine are not approved for
intrathecal use in the United States. They are less potent than bupivacaine
for intrathecal labor analgesia.\textsuperscript{106}

Bupivacaine without opioid is not commonly used for labor analgesia.
Doses high enough to provide analgesia are associated with significant
motor blockade, and lower doses either do not provide satisfactory
analgesia or are associated with an unacceptably short duration of
action.\textsuperscript{108}

**MAINTENANCE OF EPIDURAL ANALGESIA**

Epidural analgesia may be maintained with intermittent bolus injection,
continuous epidural infusion, patient-controlled epidural analgesia
(PCEA), with or without a background infusion or programmed
intermittent epidural bolus injections. Continuous epidural infusions result
in less need for bolus injections\textsuperscript{109,110} and increased patient satisfaction\textsuperscript{111}
but higher total drug dose\textsuperscript{109,111} compared to intermittent injections.
However, the infusion of lower concentration bupivacaine at a higher rate
may result in similar analgesia with less motor block and no increase in
total dose.\textsuperscript{111,112} Common infusion solutions and protocols are listed in
Table 56.5.

NOTE: Continuous infusions rate: 10 to 15 mL/hour. Patient-controlled epidural analgesia (PCEA) parameters: PCEA bolus 5 to 10 mL, lockout interval 10 to 20 minutes, background infusion 0 to 15 mL/hour (commonly 30% to 50% of hourly dose requirement).

PCEA allows for both a continuous epidural infusion and patient-titrated bolus injections. PCEA results in greater patient satisfaction and a lower average hourly dose of bupivacaine (and therefore less motor block) and less need for physician intervention.\textsuperscript{113,114} The protocols for PCEA vary widely, and it is unclear whether this affects analgesia and outcome. At one extreme, most of the hourly dose is administered via a background infusion which the parturient may supplement with self-administered boluses. At the other extreme, there is no background infusion and the entire dose is self-administered via intermittent boluses. Bupivacaine consumption is higher with background infusions compared to a pure PCEA technique without a background infusion.\textsuperscript{115} Although data are conflicting as to whether a background infusion improves analgesia,\textsuperscript{114,116} it may be helpful in selected parturients (e.g., nulliparas with long labors).\textsuperscript{114} Solutions for PCEA generally mimic those used for continuous infusions (see Table 56.5). The parturient administered bolus dose is 5 to 10 mL, the lockout interval is 10 to 20 minutes, and the background infusion varies from 0 to 15 mL. Commonly, 30% to 50% of the hourly dose is administered as a background infusion.

The bolus administration of epidural anesthetic solution appears to result in improved analgesia with a lower total drug dose compared with continuous infusion administration. Historically, the anesthesia provider or the patient (PCEA) administered a bolus dose, whereas an infusion pump delivered a continuous infusion. In a new mode for maintaining epidural analgesia, the infusion pump is programmed to intermittently administer a bolus dose rather than a continuous infusion. Compared with continuous infusion analgesia or PCEA, programmed intermittent epidural bolus analgesia results in improved parturient satisfaction, less drug use, longer duration of analgesia, and less breakthrough pain compared to a
continuous infusion of the same mass of drug per unit time. There may be better distribution of anesthetic solution within the epidural space when large volumes are injected as a bolus compared to a slow infusion. The optimal bolus volume, interval, and administration rate have yet to be determined. Most clinicians are currently using programmed bolus volumes between 5 and 10 mL, administered every 30 to 60 minutes.  

OTHER CENTRAL NEURAXIAL TECHNIQUES

Single-Shot and Continuous Spinal Analgesia

In general, single-shot spinal analgesia is not useful for most laboring patients because of its limited duration of action. It may be indicated in parturients who require analgesia or anesthesia shortly before anticipated delivery or in settings where continuous epidural analgesia is not possible. Drugs for single-shot spinal analgesia mimic those used for the initiation of CSE analgesia (see Table 56.4).

Continuous spinal analgesia is currently not practical for most parturients. The 23G spinal catheter that is available in the United States is inserted using a “catheter-over-needle” technique. An initial observational trial reported that the catheter may have clinical utility; however, further study is required to characterize ease of use and complications, particularly the rate of PDPH. The placement of a continuous spinal catheter is a management option in patients with unintentional dural puncture with an epidural needle or when rapid analgesia is necessary in an obese patient. In this case, the “epidural” catheter is threaded into the subarachnoid space. Care must be taken not to confuse a catheter sited in the subarachnoid space with one sited in the epidural space, given the much larger anesthetic dose required for epidural analgesia. Continuous spinal labor analgesia is commonly maintained with the same solution used for epidural analgesia but at a rate of 1 to 2 mL per hour.

Dural Puncture Epidural Analgesia

Dural puncture epidural (DPE) analgesia is a modification of CSE analgesia that aims to exploit the advantages of the CSE analgesia without its attendant disadvantages. The technique mimics that of CSE analgesia, except that no drug is injected into the subarachnoid space after puncturing
the dura with a spinal needle. It is hypothesized that the dural puncture made by the spinal needle augments transdural migration of the local anesthetic/opioid solution injected into the epidural space, resulting in faster onset and improved sacral analgesia compared with epidural analgesia. Studies are conflicting as to whether DPE offers an advantage compared to epidural or CSE analgesia\textsuperscript{120–123}, further investigation is warranted.

**Caudal Analgesia**
Continuous caudal epidural analgesia is used infrequently in the practice of modern obstetric anesthesia. Large volumes of local anesthetic are required for first-stage analgesia and result in higher maternal plasma concentrations of drug. There is a risk of needle/catheter misplacement and direct injection into the fetus. However, this technique is an option in patients in whom access to the lumbar neuraxial canal is not possible (e.g., fused lumbar spine).

**SIDE EFFECTS OF NEURAXIAL ANALGESIA**
Common side effects of neuraxial labor analgesia include hypotension and pruritus. Other side effects include urinary retention, delayed gastric emptying (after opioid techniques but not pure local anesthetic techniques), oral herpes simplex virus recrudescence, shivering, maternal hyperthermia, and fetal bradycardia.

**Hypotension**
Blockade of the sympathetic nervous system by local anesthetics causes vasodilation, increased venous capacitance, and decreased afterload. Hypotension may result in decreased uteroplacental perfusion and fetal heart rate decelerations or bradycardia. Therefore, maternal blood pressure and fetal heart rate should be monitored for 15 to 30 minutes after the induction of neuroblockade. Although intravenous volume expansion prior to initiating neuraxial analgesia has traditionally been used to reduce the incidence and degree of hypotension, it is not clear that this has any real benefit with modern low-dose neuraxial labor analgesia techniques.\textsuperscript{124} The mother should be positioned in the full lateral position after initiation of
neuraxial blockade, and hypotension should be treated with small bolus doses of intravenous vasopressor.

**Pruritus**
Pruritus is common side effect of neuraxial opioid administration. It is more common after intrathecal (as high as 100%) than epidural administration, and the incidence and severity are dose-related.\(^{104,108}\) The cause is unknown, but it is not thought to be histamine-related. Pruritus may be generalized or localized to the nose, face, or chest and is typically self-limited. Concomitant local anesthetic administration decreased the incidence and severity of pruritus compared to fentanyl alone,\(^{125}\) whereas the addition of epinephrine worsened the pruritus.\(^{126}\) The one-time administration of naloxone (40 to 80 µg) or nalbuphine (2.5 to 5 mg) is usually effective for the treatment of pruritus induced by fentanyl or sufentanil. A naloxone infusion may be required for the treatment of morphine-induced pruritus.

**Fetal Bradycardia**
Fetal bradycardia, not associated with maternal hypotension, occurs after initiation of both epidural and CSE analgesia, although the incidence is likely higher after CSE analgesia.\(^{127}\) Clarke and colleagues\(^{128}\) hypothesized that fetal bradycardia may be due to the acute decrease in plasma epinephrine levels following the initiation of neuraxial analgesia.\(^{56}\) Epinephrine is a tocolytic, and the acute decrease in maternal plasma concentration may result in temporary imbalance of uterine tocolytic/tocodynamic forces, resulting in uterine tachysystole, decreased uterine perfusion, and, ultimately, fetal bradycardia. Nitroglycerin has been used successfully to treat uterine tachysystole associated with the initiation of neuraxial analgesia.\(^{129}\)

**Maternal Hyperthermia**
Epidural labor analgesia is associated with maternal fever (temperature \(\geq 38^\circ C\)) in some women.\(^{130}\) In randomized controlled trials, the incidence ranges between 20% and 30%.\(^{130}\) The mechanism is unclear; current evidence supports a noninfectious inflammatory mechanism. It is also not
understood why some women become febrile and others do not.

**COMPLICATIONS OF NEURAXIAL ANALGESIA**
Complications of neuraxial labor analgesia include inadequate or failed analgesia, unintentional dural puncture, subdural injection, respiratory depression, high- or total-spinal anesthesia, systemic local anesthetic toxicity, needle or catheter trauma to central nervous system tissue (spinal cord and nerve roots), direct tissue local anesthetic toxicity (cauda equina syndrome, arachnoiditis), pneumocephalus, spinal or epidural hematoma, spinal or epidural abscess, and meningitis.

**Unintentional Dural Puncture**
Unintentional dural puncture with an epidural needle occurs in 1.5% of obstetric patients receiving epidural analgesia or anesthesia, and 52% will develop a PDPH.\(^{131}\) This is a particularly troublesome complication of epidural analgesia because women are usually quickly mobile after childbirth with the need to care for their newborn infants. A therapeutic epidural blood patch with autologous blood remains the gold standard treatment. Approximately 60% to 75% of women get partial or complete relief.\(^{132}\) In a multicenter randomized controlled trial comparing an epidural blood patch with 15-, 20-, or 30-mL autologous blood, there was no difference in the rate of permanent or partial headache relief among the groups, but the 20- and 30-mL groups had a higher rate of permanent relief.\(^{132}\)

Other treatment modalities for the prevention and treatment of PDPH have not proven effective (e.g., epidural saline infusion, caffeine, prophylactic blood patch) or are inadequately studied (e.g., placement of an intrathecal catheter, prophylactic neuraxial morphine administration, prophylactic intravenous cosyntropin administration).

**Respiratory Depression**
Severe respiratory depression or arrest has been reported after the intrathecal injection of sufentanil in laboring women.\(^{133}\) The risk appears to be increased when intrathecal opioids are administered before or after systemic opioids. Respiratory depression is opioid dose-dependent.\(^{104}\)
generally occurs within 2 hours after the intrathecal administration of fentanyl and sufentanil. In contrast, respiratory depression after epidural and intrathecal morphine usually presents 6 to 12 hours after administration of drug.

Other Regional Analgesic Techniques

Neuraxial analgesia is the most effective and flexible analgesic technique for labor and delivery. However, some parturients may not be candidates for neuraxial analgesia or may not want it. Other nerve blocks may provide acceptable, albeit less flexible, analgesia.

PARACERVICAL BLOCK

A paracervical block blocks transmission of visceral afferent nerve impulses from the uterus and cervix through the paracervical (Frankenhäuser’s) ganglion. Advantages include excellent analgesia for the first stage of labor, before fetal descent, without somatic sensory or motor block. However, the block is not continuous, and it does not relieve somatic pain caused by distension of the pelvic floor, vagina, or perineum. Serious maternal complications are unusual; however, serious fetal complications are not uncommon. Fetal bradycardia is the most common fetal complication. Recommendations to reduce complications include (1) perform the block only in parturients with no evidence of uteroplacental insufficiency; (2) perform the block when the cervix is dilated <8 cm to avoid unintentional injection of the fetal scalp; (3) monitor uterine activity and fetal heart rate continuously; (4) after injecting local anesthetic on one side, wait 5 to 10 minutes before injecting anesthetic on the second side; and (5) consider using 2-chloroprocaine.\textsuperscript{134}

LUMBAR SYMPATHETIC BLOCK

Paravertebral lumbar sympathetic blockade interferes with transmission of visceral afferent nerve impulses from the uterus and cervix at the level of the L2–L3 sympathetic chain. Similar to a paracervical block, it provides analgesia for the first stage but not the second stage of labor. Disadvantages include a technique that is not continuous and that it is
technically difficult to learn and perform and requires bilateral injections. Advantages include that it is associated with less fetal bradycardia than a paracervical block, it provides first-stage analgesia without any motor block, it is useful for patients with previous back surgery, and the progress of labor is accelerated compared to epidural analgesia.\textsuperscript{135}

**PUDENDAL BLOCK**

A pudendal nerve block interrupts pain signals from vaginal, vulvar, and perineal distension. It provides satisfactory analgesia for spontaneous vaginal and low- or outlet-forceps delivery but not midforceps delivery or exploration of the upper vagina, cervix, or uterine cavities.\textsuperscript{136} The pudendal nerve can be blocked via the transperineal or transvaginal route. Most obstetricians in the United States employ the transvaginal route immediately before delivery.\textsuperscript{134} Maternal and fetal complications of pudendal nerve block are rare. Fetal complications include fetal trauma and/or direct fetal injection of local anesthetic.\textsuperscript{134}

**PERINEAL INFILTRATION**

Perineal infiltration is often used immediately before delivery to provide anesthesia for an episiotomy or repair. It provides no motor relaxation. Five to 10 mL of local anesthetic are injected into the posterior fourchette. Perineal infiltration may be complicated by direct injection of local anesthetic into the fetal scalp resulting in neonatal local anesthetic toxicity.\textsuperscript{137}

**Effects of Analgesia on the Progress of Labor**

There has been much controversy concerning the effect of neuraxial labor analgesia on the progress of labor and mode of delivery. Early investigators noted that regional analgesia appeared to be an effective treatment for dysfunctional labor.\textsuperscript{24,138} Observational studies, however, have uniformly found an association between neuraxial analgesia, prolonged labor, and operative delivery. A number of randomized controlled trials have compared neuraxial labor analgesia to systemic opioid analgesia, and most found no difference in the rate of cesarean
delivery between groups. The probable explanation for observed association between epidural analgesia and cesarean delivery is that women who have more pain during labor (and thus more likely to request analgesia) have a higher risk of cesarean delivery. Fetal macrosomia, malposition, and dysfunctional labor are associated with more painful labor and a higher rate of cesarean delivery.

Another concern is whether neuraxial analgesia adversely affects the first stage of labor, particularly when administered in the latent phase. Again, observational studies suggest that early labor initiation of neuraxial analgesia is associated with an increased rate of cesarean delivery. Randomized controlled trials, however, uniformly demonstrated that early labor initiation of neuraxial compared to systemic opioid analgesia does not adversely affect the outcome of labor, and in fact, may result in faster labor.

Randomized controlled trials comparing neuraxial to systemic opioid analgesia have assessed the risk of instrumental vaginal delivery and duration of labor as secondary outcomes. Systematic review of these trials have found that the duration of the second stage of labor is prolonged by approximately 15 minutes and the rate of instrumental forceps delivery is increased. Initiation and maintenance of epidural labor analgesia with high concentration local anesthetic solutions (defined as ≥0.1% bupivacaine, ≥0.17% ropivacaine) is associated with a higher instrumental vaginal delivery rate compared to low-concentration solutions, mostly likely secondary to the increased incidence of motor blockade with higher concentration solutions. Thus, it is the responsibility of the anesthesiologist to use a neuraxial technique that minimizes motor block in order to decrease the risk of instrumental vaginal delivery.

**Nonobstetric Drug Therapy during Pregnancy and Lactation**

The management of pain during pregnancy is complicated by the need to limit the transfer of drugs across the placenta, particularly during the first trimester, as well as the necessity of limiting radiation exposure. Key management concepts (Table 56.6) include assessment of risk versus
benefit. For example, withholding seizure medications at the risk of recurrent seizures is not sensible. In general, using older drugs with a longer history is advisable as well as using the minimum effective dose. Drugs with an active metabolite should be avoided if possible, and nerve blocks are preferable to systemic analgesia.

Most drugs administered to the mother cross into breast milk, although neonatal drug exposure is much lower than fetal exposure. Principles of drug administration during lactation are listed in Table 56.6. Drugs undergo first-pass metabolism in the neonatal gut, and neonatal exposure is generally 1% to 2% of the maternal dose. Determinants of drug transfer to milk and neonatal exposure include maternal plasma concentration, drug pKa (breast milk is slightly acidotic compared to plasma), volume of milk, and the maturity of neonatal drug metabolism and elimination pathways. Hepatic drug-metabolizing enzymes appear to mature at different rates but are generally reduced in the neonate compared to the adult. Glomerular filtration rate does not reach adult
values until 2.5 to 5 months of age.

**DRUG CLASSIFICATION DURING PREGNANCY AND LACTATION**

The FDA previously required manufacturers to label drug risk for use during pregnancy using a five-category classification system (Categories A, B, C, D, X). This classification had some major limitations and was replaced in 2015 with a new Pregnancy and Lactation Labeling Rule (PLLR).\(^{144}\) The new rule requires three label sections: Pregnancy (including labor and delivery), Lactation, and Females and Males of Reproductive Potential. Each section includes a narrative text summary of the risks of using the drug, a discussion of the data supporting the summary, and information to help health care providers make decisions and counsel women about the risks of using the drug during pregnancy and lactation. Several Internet databases offer information on drug use during pregnancy and lactation as well as a well-known reference book.\(^{59,145}\) Some drug companies maintain pregnancy registries for specific drugs.

The American Academy of Pediatrics has categorized drugs in terms of safety for the nursing infant.\(^{143,146}\) Most drugs, including most analgesics, are listed as compatible with breastfeeding.

**Analgesic Drugs during Pregnancy and Lactation**

Acetaminophen is the first-line analgesic during pregnancy for the treatment of mild pain. Low-dose aspirin is considered safe; however, higher doses should be avoided as they may be associated with an increased risk for placental abruption and other bleeding problems and fetal gastroschisis.\(^{147}\) Nonsteroidal anti-inflammatory drugs (NSAIDs) may cause constriction of the ductus arteriosus and may have adverse effects on fetal renal function, leading to oligohydramnios. Therefore, indomethacin and ibuprofen are not recommended for use for more than 2 days beyond the first trimester.\(^{147}\) Opioids are considered safe during pregnancy, although there is a potential for neonatal abstinence syndrome after delivery.

Acetaminophen is also considered safe for nursing infants, as are NSAIDs. However, aspirin should be used with caution during lactation.
because of the slow elimination of salicylates by neonates and resultant drug accumulation.\textsuperscript{146,147} Opioids are considered safe during lactation. However, meperidine should be avoided, as normeperidine has a markedly prolonged half-life in the newborn,\textsuperscript{148} and accumulation may result in neurobehavioral depression and seizures.

CHAPTER 57

Pain and Sickle Cell Disease

SAMIR K. BALLAS

Introduction

HISTORY

Sickle cell disease (SCD) was known in Africa before the 20th century. Inhabitants of West Africa realized that the disease was hereditary and gave it specific names such as Chwechwechwe, Ahotutuo, Nwiiwii, and Nuidudui. These names are characterized by alliteration of letters that seemingly signified the recurrent clinical manifestations of the disease and the crying sounds by children in pain.

SCD was first reported in the United States in November 1910 by James B. Herrick who referred to “peculiar elongated and sickle-shaped red blood corpuscles in a case of severe anemia.” In a sense and within the framework of annals, this event was of legendary mini-epic proportion. The heroes were a triumvirate of a patient, an intern, and an attending whose lives, by chance, intersected in 1904 in Presbyterian Hospital in Chicago, Illinois. The patient, Walter Clement Noel, was a student in the Chicago College of Dental Surgery, the intern was Dr. Ernest E. Irons, and the attending physician was Dr. Herrick.

Noel came to the United States from Grenada on his own using his own funds, driven by the desire to acquire new knowledge and become a dentist. In 2004, he had cough and fever and was admitted to the hospital under the care of Dr. Herrick. Dr. Irons was the intern who first examined a peripheral blood smear from Noel in 1904. He noticed the unusual shapes and sizes of blood cells in Noel’s blood, placed a written description and a pictorial illustration of these cells in Noel’s chart, and discussed his findings with his attending, Dr. Herrick.

Dr. Herrick, who already had an interest in blood and blood disorders, was baffled by these abnormal cells and could not associate them with any
of the diseases known at that time. He and Dr. Irons followed Noel for about 2.5 more years without an explanation for their findings. In 1910, Dr. Herrick, after consulting with other prominent physicians and pathologists around the country on the case, published the details in an article in November 2010 in the Archives of Internal Medicine\textsuperscript{2} with the hope that others might be able to shed light on the case or report similar cases.

Between 1910 and 1949, there was a plethora of descriptions of the various clinical factors of SCD by many physicians, most notably by Mason\textsuperscript{4} who coined the term “sickle cell anemia” (SS) and by Diggs\textsuperscript{5} who noted that the hallmark of SS is the recurrent and painful vascular occlusive crisis (VOC) interspersed with periods of stable state with no signs or symptoms other than those due to chronic hemolytic anemia.

Pauling and his associates\textsuperscript{6} introduced the concept of SS as a molecular disease. They demonstrated that hemoglobin (Hb) isolated from red cells of patients with SCD differed electrophoretically from the Hb of normal persons and that the Hb of those with sickle cell trait was a mixture of normal and sickle Hb. Neel\textsuperscript{7} showed that the inheritance of SS followed simple Mendelian genetics. Ingram\textsuperscript{8} reported that the only difference between normal and sickle Hb was the replacement of glutamic acid by valine. The work of several groups established the subunit structure and primary sequences of the subunits (\(\alpha, \beta, \gamma, \delta\)) of human Hb and localized the sickle mutation to the sixth residue of the \(\beta\)-globin chain (\(\beta^6\text{Glu}\rightarrow\text{Val}\)). The interaction of the sickle mutation with other Hb abnormalities clarified the spectrum of sickle cell syndromes. The advent of DNA technology in the 1970s and the 1980s paved the way for the molecular diagnosis of sickle cell disorders, prenatal diagnosis, and the identification of \(\alpha\)-genotypes and \(\beta^S\) haplotypes and their effect on the clinical picture of SCD. By the 1980s, it had become clear that SCD is a highly heterogeneous disorder not only at the clinical level but also at the cellular and molecular levels. The Human Genome Project initiated several studies by many investigators to determine genetic modifiers that may predict sickle-related complications.\textsuperscript{9} Advances by the end of the 20th century included preventative therapy by the induction of fetal Hb using hydroxyurea (HU),\textsuperscript{10} blood transfusion to prevent primary and secondary
strokes,\textsuperscript{11,12} and curative therapy in some patients using bone marrow/stem cell transplantation.\textsuperscript{13–19} By 2010, SCD was recognized as a global disease affecting an estimate of 100 million patients globally, mostly in Africa and India. Currently, progressive strides are underway including several randomized clinical trials, modified approaches to stem cell transplantations,\textsuperscript{20} and promising progress in gene therapy.\textsuperscript{21}

**NATURE OF THE SICKLE MUTATION**

Hemoglobinopathies are inherited disorders of the structure and/or function of the Hb molecule. Hemoglobinopathies are broadly divided into two major groups: structural variants and thalassemias. Structural variants are, most commonly, the result of single-base mutations in the globin genes. Thalassemias are characterized by decreased synthesis of any one or more of the globin chains.

The sickle mutation is the result of a single-base change (GAT\textrightarrow{}GTT) in the sixth codon of exon 1 of the β-globin gene responsible for the synthesis of the β-globin polypeptide of the Hb molecule (α\textsubscript{2}β\textsubscript{2}). This change, in turn, results in replacement of the normal glutamic acid with valine at position 6 of the β-globin chain and the formation of sickle Hb.\textsuperscript{7,8,22}

Over two million US residents are estimated to be either heterozygous or homozygous for the genetic substitution. Most of those affected are of African ancestry or self-identify as Black; a minority are of Hispanic or southern European, Middle Eastern, or Asian Indian descent.\textsuperscript{23} It is estimated that between 70,000 and 100,000 Americans have SCD. Although SCD is associated with major morbidity, currently more than 90% of children with SCD in the United States and the United Kingdom survive into adulthood.\textsuperscript{24–26} However, their life span remains shortened by two or three decades compared to the general population.\textsuperscript{27,28}

**CLASSIFICATION OF SICKLE CELL SYNDROMES**

Sickle cell syndromes, also collectively referred to as SCD, comprise a group of clinically significant hemoglobinopathies in which the sickle gene is inherited from at least one parent. SS is the homozygous state where the sickle gene is inherited from both parents. Sickle cell syndromes
also result from the co-inheritance of the sickle gene with Hb C gene giving rise to Hb SC diseases, with β-thalassemia genes (β^0 or β^+) giving rise to sickle-β^0-thalassemia or sickle-β^+-thalassemia, respectively, or with other β-globin structural variants giving rise to other combinations such as HbSO Arab, HbSD disease, and so on. The most prevalent SCD types include homozygous Hb SS and the compound heterozygous conditions HbSβ^0-thalassemia, HbSβ^+-thalassemia, and Hb SC disease. Hb SS and HbSβ^0-thalassemia are clinically very similar and therefore are commonly referred to as SS; these genotypes are associated with the most severe clinical manifestations. Table 57.1 lists the major types of sickle cell syndromes commonly seen in the United States. Certain complications of SCD may be more common in one category than another. Thus, frequent painful crises, severe anemia that requires blood transfusion, and acute chest syndrome (ACS) are more common in SS than other types of SCD. Sickle retinopathy, on the other hand, is more common in Hb SC disease than in SS. It must be emphasized that the order of severity in SCD is based on population statistics. Thus, if one compares the overall clinical picture of 100 patients with SS, for example, with that of 100 patients with Hb SC disease, then the latter will be milder as far as frequency of painful episodes, morbidity, and mortality are concerned. On the individual basis, however, there are exceptions. Thus, an individual patient with SS may have a mild disease, whereas an occasional patient with S-β^+-thalassemia may have a severe disease.

GENOTYPES

Sickle cell syndromes can also be divided into subcategories depending on the \( \alpha \) genotypes and \( \beta \) haplotypes.\(^{29-31}\) About 65% of patients with SS have normal \( \alpha \) genotypes (\( \beta^S/\beta^S; \alpha\alpha/\alpha\alpha \)), 30% have one \( \alpha \) gene deleted (\( \beta^S/\beta^S; -\alpha/\alpha\alpha \)), and the remaining 5% have two \( \alpha \) genes deleted (\( \beta^S/\beta^S; -\alpha/-\alpha \)). The effect of \( \alpha \)-gene deletion on the clinical picture of sickle cell syndromes is controversial. Generally speaking, \( \alpha \)-gene deletion is associated with milder anemia\(^{32}\) and less blood transfusion. The increased Hb level associated with \( \alpha \)-gene deletion, however, increases the blood viscosity, which is often accompanied by increased frequency of painful crises\(^{33,34}\) and vaso-occlusive episodes such as avascular necrosis (AVN).\(^{35,36}\) The effect of \( \alpha \)-gene deletion on the clinical picture is best illustrated in SS with two \( \alpha \)-gene deletions (\( \beta^S/\beta^S; -\alpha/-\alpha \)). Table 57.2 lists the unique features of this type of SCD.\(^{37,38}\) Noteworthy is that HbA\(_2\) is elevated in SS with two \( \alpha \)-gene deletions, a finding that confuses this diagnosis with S-\( \beta^0 \)-thalassemia that is, typically, also associated with elevated HbA\(_2\) levels. The clinical picture, family history, hematologic data, and molecular diagnostics can differentiate the two diagnoses.\(^{38}\)

β-Haplotypes refer to the nucleotide sequence 5′ and 3′ to the sickle gene. Three major types have been described in Africans and African Americans. These are the Senegalese (Sen), Benin (Ben), and Central African Republic (CAR) haplotypes. The significance of these haplotypes pertains to their effect on Hb F production. It has been established that the higher the Hb F level, the milder is the SS. Again, these conclusions are based on population data and may not apply to an individual patient.

Pathophysiology

Pain is the hallmark of SCD and dominates its clinical picture throughout the life of the patients (Fig. 57.1). Pain, also, may precipitate or be itself precipitated by the other components of the disease. Moreover, management of sickle pain must be within the framework of the disease as a whole and not in isolation by itself. This is unlike other pain syndromes where the provider can make decisions on treatment based solely on the pain and its associated behavior. Sickle pain could, often, be the prodrome of a serious and potentially fatal complication of SCD.
FIGURE 57.1  Sequence of complications of SS from birth through adult life. Cure is possible in selected patients. The mainstay of management in most patients is palliative, with pain management being most important. ACS, acute chest syndrome; AVN, avascular necrosis; CVA, cerebrovascular accident. VASO-OCLUSION

Vascular occlusion plays a pivotal role in explaining the clinical course of SCD. It may involve both the microcirculation and the macrocirculation. The former underlies the VOC, and the latter is associated with organ failure including stroke and pulmonary hypertension.

The major pathophysiologic events that lead to microvascular occlusion are (1) polymerization of deoxyhemoglobin S (deoxy Hb S); (2) generation of dense sickled cells, both reversibly and irreversibly sickled; (3) microvascular occlusion; (4) tissue ischemia; (5) tissue damage secondary to hypoxia; and (6) stimulation of peripheral nerve endings leading to pain perception (Table 57.3 and Fig. 57.2). The precise dynamics of these events and their interrelationships are complex and poorly understood. Nevertheless, the primary process that leads to vascular occlusion is the polymerization of sickle Hb upon deoxygenation which, in turn, results in distortion of the shape of red blood cells (RBCs), cellular dehydration, and decreased deformability and stickiness of RBC that promotes their adhesion to vascular endothelium (Fig. 57.3). Progress in the pathogenesis
of vascular occlusion pertains to cellular dehydration, adhesion to endothelial cells, inflammatory state, and reperfusion injury.

CELLULAR DEHYDRATION
Cellular dehydration is secondary to loss of potassium (K+) and water. Two major transport mechanisms appear to play a significant role in cellular dehydration. The first mechanism is the potassium chloride (KCl) cotransport pathway activated by acidification and cell swelling.\(^{46-48}\) This pathway is most active in reticulocytes and is a feature of low-density sickle cells. Reticulocyte dehydration appears to contribute to the generation of dense sickle cells directly without going through repetitive cycles of oxygenation and deoxygenation.\(^{49}\) The second transport system is the calcium (Ca\(^{2+}\))-activated K\(^{+}\) channel or Gardos pathway, which is activated by Ca\(^{2+}\) reflux–induced deoxygenation.\(^{46-48,50-52}\) Although much of the intracellular Ca\(^{2+}\) in sickle cells is sequestered within endocytic vesicles,\(^{53-55}\) transient reflux of Ca\(^{2+}\) during deoxygenation-induced sickling appears to be responsible for stimulating the Gardos pathway. Unlike KCl cotransport, the Gardos pathway appears to be most
active in the dense fraction of SS RBCs. However, in most patients, both transport systems are operative.

A phase III randomized controlled trial of senicapoc, a Gardos channel inhibitor, was terminated early because there was no difference observed between the treatment and control groups in the primary endpoint of painful crises. The reason is that rehydration of RBC increased their survival resulting in increased Hb level which, in turn, increased blood viscosity that is known to be associated with increased frequency of VOCs.\textsuperscript{56,57}

**ADHESION TO VASCULAR ENDOTHELIUM**

Adhesion of sickle RBC to vascular endothelium is a pathophysiologic contributor to vaso-occlusion. Sickle RBC adhere to cultured endothelial cells in vitro under both static and dynamic conditions, whereas normal cells do not.\textsuperscript{58–61} These findings suggest that sickle RBC have sticky surfaces that promote their attachment to monolayers of cultured endothelial cells. These in vitro observations have been documented to occur also in ex vivo perfusion studies in rats\textsuperscript{62} and transgenic mice.\textsuperscript{63} Both cellular and plasma factors have been reported to affect adhesion of sickle RBC to vascular endothelium. Thus, young deformable sickle RBCs appear to be more adherent to vascular endothelium than are dense, rigid, irreversibly sickled cells (ISCs).\textsuperscript{61,64,65} Paradoxically, SS with few painful crises has been characterized by decreased red cell deformability and increased number of dense cells.\textsuperscript{66}

Adherence of sickle RBC to vascular endothelium results in intimal hyperplasia in larger vessels that may lead to vascular occlusion and tissue infarction.\textsuperscript{67,68} Hebbel et al.\textsuperscript{58} reported strong correlation between the degree of adhesion of SS RBC to endothelial cells in vitro and the severity of the disease in patients with SS or other variants of SCD. Adhesive interactions of sickle erythrocytes with endothelium have been described in detail by Hebbel.\textsuperscript{69,70}

**INFLAMMATION AND REPERFUSION INJURY**

In vivo studies in transgenic mice suggest that vaso-occlusion results in the creation of an inflammatory state.\textsuperscript{71,72} The sequence of events seems to be
as follows: (1) Reticulocytes carrying the $\alpha_4\beta_1$ receptor adhere to endothelial cells; (2) this is followed by logjam where there is propagation of occlusion caused by the accumulation of rigid deoxygenated mature RBC proximal to the site of adhesion; (3) the obstruction eventually clears leading to reperfusion and its associated injury; and (4) a new cycle of adhesion starts, thus creating a viscous cycle of occlusion and reperfusion. Evidence of reperfusion injury includes (1) inflammatory response in the vascular bed of the transgenic mouse with increased leucocyte rolling, adhesion, and emigration after 3 hours of mild hypoxia followed by reperfusion; (2) local production of free radicals; and (3) the complete inhibition of (1) and (2) after the infusion of monoclonal murine anti-P-selectin antibody, before reoxygenation. The implication of this sequence of events is that restoration of oxygen to ischemic tissue results in the generation of free radicals associated with inflammatory endothelial and tissue damage.

Sickle RBC from patients with a high level of Hb F seem to be less adherent to vascular endothelium than those from patients with low Hb F levels. Specifically, Setty et al. found that pediatric SS patients with high levels of F cells had a concomitant decrease in the number of CD36+, very late antigen (VLA) 4+, and CD71+ erythrocytes and, hence, less adherent RBC. Moreover, Hb F seems to affect the exposure of phosphatidylserine on the surface of RBC and coagulation activation. In vivo cycles of sickling/unsickling with resulting membrane changes and microvesicle formation are one factor responsible for phosphatidylserine exposure. Phosphatidylserine-exposing RBC in the transgenic sickle mouse were found to have shortened red cell survival. Children with SS and high Hb F levels were reported to have less phosphatidylserine-exposing RBC and, hence, milder hemolytic anemia suggesting a possibly milder clinical picture.

**GENETIC MARKERS**

SCD is a complex genetic disorder characterized by intricate genotypic/phenotypic interactions that include correlations among multiple genetic and environmental markers and modifiers. Genetic markers may predict the severity of the disease and the possible or probable incidence of
certain complications. This, in turn, allows for the implementation of certain therapeutic measures that may prevent or ameliorate the severity of some of these complications. Traditional approaches to identify genetic markers have included studies of the transgenic sickle cell mouse and natural history studies and family pedigrees. With the advent of the Human Genome Project, novel genetic polymorphisms associated with disease have been identified, thus allowing for the performance of genetic association studies.

The genetic markers described to date include three categories. The first includes α-thalassemia, Hb F level, and β-globin haplotypes that apply globally to SCD. These were mentioned earlier. The second category includes markers of complications associated with pain, and the third category includes complications associated with tissue damage not always associated with pain (Table 57.4 and Fig. 57.4).

| TABLE 57.4 Association of Complications of Sickle Cell Disease with Genetic Polymorphisms |
|---------------------------------|------------------|---------------------------|
| Complications                   | SNP              | Clinical Relevance        |
| Complications with Pain as a Major Manifestation |
| Bilirubin levels and cholelithiasis | UGT1A1           | Bilirubin metabolism      |
| Priapism                        | KL, TEK, F13A1, ITGA2 | Nitric oxide metabolism, angiogenesis, coagulation |
| Avascular necrosis              | MTHFR, ANXA2, ITGA2, KL, BMP6, TGFBR2, TGFBR3 | Coagulation, cell growth, nitric oxide metabolism, TGF-β/SMAD pathway |
| Leg ulcers                      | BMP6, BMPR1B, MAP2K1, MAP3K7, SMAD7, SMAD9, SMURF1, TGFBR2, TGFBR3, KL | TGF-β/SMAD pathway, nitric oxide metabolism |
| Acute chest syndrome            | NOS3, NOS1, TGFBR3, SMAD7, SMAD3, KL, ITGA2 | Nitric oxide metabolism, TGF-β/SMAD pathway nitric oxide pathway, coagulation |
| Complications with Tissue Damage and Little or No Pain |
| Stroke                          | VCAM1, IL4R, TNFA, LDLR, ADRBZ, SELP, AGT, HLA, BMP6, TGFBR2, TGFBR3 | Cell adhesion, inflammation, cholesterol metabolism, blood pressure, immunity, TGF-β/SMAD pathway |
| Pulmonary hypertension          | ACVR1L1, BMP6, BMPR2, KL | TGF-β/SMAD pathway, nitric oxide metabolism |
Although these findings are novel and interesting, their validity and utility in predicting and treating the clinical complications of SCD should be confirmed by large controlled multi-institution studies. The studies performed to date are too small to make definite conclusions.

**OTHER FACTORS**
In addition to the factors mentioned earlier, there is growing evidence that psychosocial and environmental factors precipitate vaso-occlusion and affect the frequency and severity of painful episodes. Physical stress, trauma, dehydration, and infections are such known factors.

**Classification of Sickle Cell Pain Syndromes**

The classification of sickle cell pain syndromes entails the availability of accepted definitions of these syndromes. Such definitions would facilitate communications among providers, investigators, ancillary medical staff, administrators, insurers, the community, and patients and their families. Accepted definitions of the complications of SCD, including pain syndromes, did not exist until recently. This state of affairs made it difficult to establish cost-effective management of SCD and its complications. In an effort to fill this gap, the comprehensive sickle cell centers supported by the National Institutes of Health—published definitions of the phenotypic complications of SCD.\(^{85,86}\) These were based on whatever evidence was available in the literature and the experiences of a large number of hematologists caring for patients with SCD for decades. Each complication in those publications included (1) a definition, (2) diagnostic criteria, (3) a severity index if applicable, (4) classification if available, and (5) references. An accepted scheme of classification of sickle cell pain would facilitate communication and transfer of information pertinent to pain research, therapy, and clinical records. Table 57.5 shows a potential classification of sickle cell pain similar to that described by Turk and Okifuji.\(^{87}\) Pathophysiologically, sickle cell pain could be nociceptive or neuropathic; temporarily, it could be acute or chronic; anatomically, it could be somatic, visceral, unilateral, bilateral, localized, or diffuse; pathologically, it could be mild, moderate, or severe (Table 57.6); and etiologically, it could be due to the disease itself or secondary to therapy or to comorbid conditions. The etiologic classifications of sickle pain are listed in Table 57.7 and include acute pain syndromes, chronic pain syndromes, neuropathic pain syndromes, pain secondary to therapy, and pain due to comorbid conditions.

### TABLE 57.7 Etiologic Classification of Sickle Cell Pain

3029
### Acute Pain Syndromes
- Acute painful sickle cell crises
- Acute chest syndrome
- Acute abdominal pain syndromes
  - Right upper quadrant syndrome
  - Left upper quadrant syndrome
- Hand–foot syndrome (dactylitis)
- Priapism
- Acute multiorgan failure (AMF)

### Chronic Pain Syndrome
- With objective signs
  - Avascular (aseptic) necrosis
  - Arthropathies
  - Vertebral body collapse
  - Leg ulcers
  - Chronic osteomyelitis
- Without objective signs
  - Intractable chronic pain

### Neuropathic Pain Syndromes
- Syndromes unique/common in sickle cell disease
  - Mental nerve neuropathy
  - Ischemic optic neuropathy
  - Spinal cord infarction
  - Other neuropathies
- Neuropathic pain associated with chronic intractable pain

### Pain Syndromes Secondary to Therapy
- Postoperative pain
- Loose prosthesis (shoulders/hips)
- Iatrogenic pain
  - Withdrawal syndrome
  - Pseudo-addiction
  - Opioid-induced hyperalgesia

### Acute Sickle Cell Pain Syndromes

**THE VASCULAR OCCLUSIVE CRISIS**

3030
Vaso-occlusion is the de facto prerequisite for the development of the VOC. Tissue damage consequent to vaso-occlusion initiates a horde of complex biochemical, neurologic, electrochemical, and inflammatory sequence of events collectively referred to as nociception that culminates in the perception of acute pain. The inflammatory response due to vaso-occlusion may enhance sympathetic activity via interactions with neuroendocrine pathways and trigger release of norepinephrine, which, in the setting of tissue injury, causes more tissue ischemia, thus creating a vicious cycle. It is the combination of ischemic tissue damage and secondary inflammatory response that makes the pain of SCD unique in its acuteness and severity. Tissue injury generates several major pain mediators including, but not limited to, interleukin (IL)-1, bradykinin, K+, hydrogen (H+), histamine, substance P, and calcitonin gene-related peptide (CGRP). IL-1 is an endogenous pyrogen and also upregulates the cyclooxygenase gene leading to synthesis of prostaglandins E2 and I2. Bradykinin, K+, H+, and histamine activate nociceptive afferent nerve fibers and evoke a pain response. Prostaglandins sensitize peripheral nerve endings and facilitate the transmission of painful stimuli along Aδ and C fibers that reach the cerebral cortex via the spinal cord and the thalamus. Moreover, activated nociceptors release stored substance P, which itself facilitates the transmission of painful stimuli. Bradykinin, substance P, and CGRP also cause vasodilatation and extravasations of fluids that can lead to local swelling and tenderness. The pathway for pain stimuli is subject not only to activators, sensitizers, and facilitators but also to inhibitors. Serotonin, enkephalin, β-endorphin, and dynorphin are endogenous central pain inhibitors. Thus, in a given patient, the net outcome of tissue ischemia may be severe or mild pain, depending on the extent of tissue damage and the net balance of pain stimulators versus pain inhibitors. This may explain, in part, the considerable variation in the frequency and severity of painful sickle crises among patients and longitudinally in the same patient.

**Predisposing Factors**
The clinical manifestations of sickle cell syndromes vary widely from one patient to another and in the same patient over time. Some patients with SS have mild disease, whereas others suffer from a severe form and die at a
relatively young age. Some patients, mostly adults, may have a clinical picture characterized by waxing and waning of the frequency and severity of VOCs. Darbari et al. determined markers of severe VOC frequency in children and adolescents with SS. They compared clinical and laboratory characteristics of children with SS who had three or more VOCs requiring health care in the preceding year with patients who had less than three VOCs.

Seventy-five children (20%) had severe VOCs, and 232 (61%) had none. Increasing age, α-thalassemia, iron overload, milder anemia, lower lactate dehydrogenase (LDH) level, and higher tricuspid regurgitation velocity were associated with a greater frequency of severe VOCs. Details of the factors proposed as indicators of severity and frequency of VOCs are as follows.

There are at least three sets of predisposing factors that predict the frequency and severity of the VOC. These are genetic, cellular, and environmental (or epigenetic) factors. Genetic factors include Hb F level, the coexistence of α-gene deletion, β-thalassemia, β-haplotypes, and epistatic gene modifiers as was mentioned earlier. They also include gender because males constitute about 60% to 66% of admissions to the hospital. Females, however, have longer hospital stay per admission than males. Cellular factors with decreased RBC deformability and increased number of dense cells in the steady state have a salutary effect, most likely because these are associated with more severe anemia and hence relatively decreased whole blood viscosity. Patients with SS and relatively high Hb level are more likely to experience more frequent crises than those patients with SS and lower Hb level. Decreased level of vitamin A (less than 30 µg/dL) and nocturnal hypoxia are environmental factors amenable to preventative therapy.

Precipitating Factors

Like other acute episodes of illness, the acute VOC has precipitating features. Major reported factors that seem to precipitate VOCs include dehydration, stress of any kind (physical, traumatic, physiologic, emotional), infection, acidosis, sleep apnea, and pregnancy. Nevertheless, most painful episodes are not preceded by an obvious
precipitating factor. Gil et al.\textsuperscript{101} reported that daily mood and stress predict painful events, utilization of healthcare facilities, and work activity in adults with SCD.

In a retrospective study, Smith et al.\textsuperscript{102} found a complex relationship between temperature changes, temperature extremes, and their relationship to emergency department (ED) visits and hospital admissions for VOCs in adults. The most relevant finding of this study was an inconsistent confirmation of a relationship between daily ambient temperature and ED visits or hospital admissions for VOCs. Jones et al.\textsuperscript{103} studied retrospectively the number of admissions with acute pain and SCD to King’s College Hospital, London, together with daily meteorologic records collected locally. Data from 1,400 days and 1,047 separate admissions were analyzed. Increased admissions were significantly associated with increased wind speed and low humidity but showed no relationship to temperature, rainfall, or barometric pressure. The strongest effect was for maximum wind speed/humidity ratio with 464 admissions on days in the lowest two quartiles of this parameter and 582 in the highest quartiles. The effect of high wind and low humidity is likely to be related to skin cooling. Anecdotally, many patients report that sudden changes in temperature seem to precipitate VOCs. The effects of windy weather were later confirmed by Nolan et al.\textsuperscript{104} and Rogovik et al.\textsuperscript{105}

**Phases of the Acute Vaso-occlusive Crisis**

The literature strongly suggests that the uncomplicated VOC requiring hospitalization has four distinct phases: prodromal, initial, established, and resolving. Figure 57.5 and Table 57.8 show the temporal relation of these phases to the severity of pain, their synonyms, and their typical estimated duration. Plotting all of the observations reported in the literature on a specific day of the VOC, whenever applicable, shows that objective clinical and laboratory signs emerge along a certain pattern (see Fig. 57.5 and Table 57.9).
FIGURE 57.5 A typical profile of the events that develop during the evolution of a severe sickle cell painful crisis in an adult in the absence of overt infection or other complications. Such events are usually treated in the hospital with an average stay of 9 to 11 days. Pain becomes most severe by day 3 of the crisis and starts decreasing by day 6 or 7. The roman numerals refer to the phase of the crisis: I, prodromal phase; II, initial phase; III, established phase; and IV, resolving phase. Dots on the X axis indicate the time when changes became apparent, and dots on the Y axis indicate the relative value of change in comparison to the steady state indicated by the horizontal dashed line. Arrows indicate the time when certain clinical signs and symptoms may become apparent. Values shown are those reported at least twice by different investigators; values that were anecdotal, unconfirmed, or that were not reported to occur on a specific day of the crisis are not shown. CPK, creatinine phosphokinase; CRP, C-reactive protein; ER, emergency room; ESR, erythrocyte sedimentation rate; Hb, hemoglobin; HDW, hemoglobin distribution width; ISCs, irreversibly sickled cells; LDH, lactate dehydrogenase; RBC, red blood cells; RBC DI, red cell deformability index; RDW, red cell distribution width; SAA, serum amyloid A; WBC, white blood cell. CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; Hb, hemoglobin; HDW, hemoglobin distribution width; ISC, irreversibly sickled cells; LDH, lactate dehydrogenase; RBC, red blood cell; RDW, red cell distribution width; SAA, serum amyloid A; WBC, white blood cell.

**The Prodromal Phase**

A premonition of VOC (prodromal or pre-VOC phase) was first mentioned by Diggs, who noted that one mother could predict that her child would have
develop a VOC by noting that the fingernails were pale. This observation was not pursued further until Murray and May used a structured questionnaire with 102 patients and reported that 58% experienced a prodromal phase of an impending VOC up to 24 hours before developing features typical of their usual VOCs (see Fig. 57.5). Symptoms mentioned during the prodromal phase included numbness, aches, and paresthesia in the sites subsequently affected by pain. Akinola et al. studied 20 patients with SS over a period of 16 months. Patients were visited regularly at home by a nurse practitioner and were taught to keep a diary of clinical events and to mark a Visual Analog Scale. Twelve of 14 premonitions were followed by a typical VOC that required either home treatment (n = 4) or hospitalization (n = 8). Objective laboratory findings during this premonitory phase included decreased RBC deformability and increased number of both dense RBCs and ISCs compared to corresponding values at steady state.

The Initial Phase
The initial phase (also called first, evolving, escalation, or infarctive phase) is heralded by the onset of typical VOC pain that increases gradually in severity and reaches a peak by the second or third day (see Fig. 57.5). Given the paucity of objective signs during this initial phase, patients experience problems with care providers in the ED. Routine laboratory data may not be atypical, which often discourages the treating physician from repeating tests. Fear, anorexia, and anxiety are usually present in this initial phase. Major RBC changes during this phase include decreased RBC deformability, increased dense cells, increased ISCs, increased red cell distribution width (RDW), and increased Hb distribution width (HDW) compared to steady state. The increase in dense RBCs and ISCs may be (1) relative and secondary to preferential trapping of deformable discoid cells in the microvasculature, (2) absolute due to de novo formation of ISCs, or (3) a combination of both. Other cellular changes in this phase include a decrease in platelet (PLT) count compared to steady state.

The Established Phase
The established phase (also called second, postinfarctive, or inflammatory phase) is characterized by the persistence of severe steady pain and typically lasts 4 to 5 days in adults (see Fig. 57.5). Signs and symptoms of inflammation become predominant during this phase. Fever, leukocytosis, swelling, tenderness, and joint effusions are common. In addition, serum levels of acute-phase reactants such as serum C-reactive protein (CRP) and serum amyloid A (SAA) reach their peak values during this phase. Signs of hyperhemolysis, including decreased Hb, increased reticulocyte count, and LDH, may be seen. Tissue damage, especially bone marrow infarction, may be another source of increased LDH. An increase in creatinine phosphokinase (CPK) and aldolase usually indicates skeletal muscle injury. Billett et al. reported dramatic increases in CPK values on days 5 to 8 of VOC compared to values on days 1 to 3. Depression and problems with hospital care providers, who may become suspicious of patients because of the heavy use of opioid analgesics for several days, occur toward the end of this phase and the start of the resolving phase.

The Resolving Phase
The resolving phase (also called last, healing, recovery, or post-VOC phase) is signaled by a gradual decrease in pain severity and may last 1 to 2 days (see Fig. 57.5). Significant erythrocyte changes during this phase include a decrease in the abnormalities of the initial phase, with increased RBC deformability, decreased dense cells, and decreased ISCs, below steady state. Both RDW and HDW return toward steady state. However, rebound thrombocytosis occurs, and another set of acute-phase reactants (fibrinogen and orosomucoid) reach peak values during this phase. Plasma viscosity and erythrocyte sedimentation rate (ESR) increase above baseline during this recovery phase. The significance of these changes will be addressed in the following discussion.

The Relapsing or Postdromal Phase
The resolution of the VOC is associated with rebound thrombocytosis, elevated levels of fibrinogen, orosomucoid, RBC deformability, and plasma viscosity, indicating the presence of a hypercoagulable state that
may cause recurrence of the VOC (see Fig. 57.5 and Table 57.9). Ballas and Smith\textsuperscript{108} found that approximately 20\% of patients who were discharged from the hospital after the resolution of a VOC had recurrent VOC that required treatment with parenteral opioids in the ED or hospital within 1 week after discharge. A VOC appears to be a risk factor for the precipitation of another VOC. However, some patients, especially children, do well after the resolution of a VOC, with a pain-free period of variable duration before the onset of another VOC (Fig. 57.6). Others continue to have pain. According to the Pain in Sickle Cell Epidemiologic Study (PiSCES), adult patients reported SCD pain at home for approximately 55\% of the 31,017 days surveyed.\textsuperscript{122} Similarly, children reported SCD pain at home for approximately 9\% of the 1,515 days surveyed.\textsuperscript{123,124} In the Multicenter Study of Hydroxyurea (MSH) study, at-home analgesics were used for SCD pain on 40\% of diary days and 80\% of 2-week follow-up periods, with short-acting oxycodone and acetaminophen being the most frequently used analgesics.\textsuperscript{125,126} Descriptors and location of the pain at home were similar to those during hospitalization but milder. Patients prefer to treat pain at home with short-acting opioids rather than controlled-release opioids. In addition, those who take controlled-release opioids with short-acting opioids for breakthrough pain experience frequent attacks of breakthrough pain, resulting in the consumption of relatively large amounts of short-acting opioids. Moreover, patients prefer to be treated at a day unit rather than the ED whenever possible to avoid long hours of waiting before they are treated. Treatment of patients in day units with parenteral short-acting opioids decreased the frequency of hospital admissions and ED visits.\textsuperscript{127}
In a prospective, longitudinal, and observational cohort study of all adult patients with SS admitted to a single institution between January 1998 and December 2002, Ballas and Lusardi\textsuperscript{94} found the following: (1) Approximately 95% of all of the 1,540 admissions of 136 patients were for VOCs; (2) the intensity of pain score decreased significantly during the first 4 days of hospitalization from an average of 8.7 ± 1.17 to 7.5 ± 1.00 (P < .001) and then reached a plateau of 7.4 until discharge (Fig. 57.7); (3) the mean score of pain intensity was >7 throughout the hospital stay; and (4) approximately 50% of hospital admissions for VOCs were associated with readmission within 1 month after discharge, and approximately 16% of all admissions were associated with readmission within 1 week after discharge (Table 57.10). The major cause of hospital readmission was the same VOC that was not controlled with analgesics at home or in the ED. Withdrawal syndrome was the cause of readmission for only five patients who were readmitted collectively 46 times (~7% of all readmissions) within 1 week after discharge. Readmission within 1 week after discharge was associated with greater mortality than otherwise.

NOTE: The numerator of each fraction represents the number of readmissions and the denominator represents the total number of hospital admissions before discharge. About 16% of readmissions occur 1 week after discharge, and 50% of readmissions occur 1 month after discharge.

Jacob et al. showed a similar pattern of pain scores that plateaued ~5 days after hospital admission for VOCs in children. The high frequency of hospital readmission was confirmed in other studies. In a retrospective cohort of SCD-related ED visits and hospitalizations from eight states (Arizona, California, Florida, Massachusetts, Missouri, New York, South Carolina, and Tennessee) in the 2005 and 2006 Healthcare Cost and Utilization Project State Inpatient Databases and State Emergency Department Databases, Brousseau et al. found that the 30-day and 14-day readmission rates were 33.4% and 22.1%, respectively. Readmissions were highest for 18- to 30-year-old patients and for publicly insured patients. In another retrospective study in children with SCD, the most common admission and readmission (within 30 days) diagnosis was acute pain (78% and 70%, respectively). The major risk factor for readmission was lack of outpatient hematology follow-up within 30 days after discharge; asthma was another risk factor for readmission within 30 days. Sobota et al. performed a retrospective examination of 12,104 hospitalizations for VOC from July 1, 2006, through December 31, 2008, at 33 freestanding children’s hospitals in the Pediatric Health Information
System database. They identified 4,762 patients with 12,104 qualifying hospitalizations, of which 2,074 hospitalizations (17%) were readmissions for VOC within 30 days after discharge. Risk factors for readmission included older children, pain, and treatment with steroids.

**ACUTE CHEST SYNDROME**

Charache et al.\(^{132}\) introduced the term ACS to define acute episodes of fever, chest pain, increased leukocytosis, and pulmonary infiltrates (Fig. 57.8) in adult patients with SS, most of whom probably had pulmonary infarction. With time, the definition of ACS has expanded to include hypoxemia, cough, shortness of breath, wheezing, chills, and worsening anemia.\(^{133}\) The current definition of ACS complicating SCD includes chest pain, fever, hypoxia, dyspnea, cough, leukocytosis, decreasing Hb level, and new infiltrates on chest radiograph.\(^{132-134}\) Pain is pleuritic in most patients. Abdominal pain may indicate involvement of adjacent diaphragmatic pleura. These signs and symptoms vary from mild to severe or even life-threatening. Not all of these signs and symptoms occur in all cases of ACS, with the exception of the new pulmonary infiltrates, which are considered sine qua non for the diagnosis. The presence of new infiltrates with some of the other signs and symptoms is usually enough to make the diagnosis. An infiltrate is new when compared to a previous radiograph with no infiltrate. If a previous radiograph is not available, the infiltrate in question is considered to be new. It is obvious from this description that there are gaps in making an accurate diagnosis. For example, there is no agreement on the number and nature of the accompanying signs and symptoms to make the diagnosis. Moreover, an occasional patient may have all of the signs and symptoms mentioned earlier with no new infiltrate on chest radiograph, thus generating a dilemma for the provider. Suffice it to say that ACS, like other syndromes, is a spectrum of clinical manifestations that vary from mild to very severe. Some patients may develop rapid respiratory failure and/or involvement of other organs such as the brain, kidneys, or liver, a condition referred to as multisystem organ failure.\(^ {135}\) Observation and careful monitoring on a daily basis, or more often if needed, are most important in ruling the diagnosis in or out.
FIGURE 57.8 Chest radiograph showing diffuse pulmonary infiltrates of a patient with acute chest syndrome.

Risk factors for developing ACS are listed in Table 57.11.\textsuperscript{136,137} The incidence of ACS is age- and genotype-dependent, with no difference between sexes. It is approximately 3 times more common in young children than in adults but more severe in adults.\textsuperscript{133,134} ACS is most common in SS, sickle $\beta^0$-thalassemia, Hb SC disease, and sickle $\beta^+$-thalassemia in decreasing order of frequency. Coexistent $\alpha$-gene deletion, PLT count, and mean corpuscular volume (MCV) of RBCs do not appear to affect the incidence of ACS.\textsuperscript{134} The incidence of ACS decreases in the presence of high Hb F level and severe anemia but is directly proportional to the steady-state white blood cell count.\textsuperscript{134} ACS is closely associated with VOCs, especially in adults.\textsuperscript{137,138} It occurs in approximately 50% of hospitalized patients with SS for VOC.\textsuperscript{137,139–142} These episodes account for 15% of acute admissions and are potentially fatal.\textsuperscript{42,142–144} Moreover, ACS appears to be the most common cause of death among patients and second to VOC as the most common cause of hospitalization of patients with SCD.\textsuperscript{145–148} Although ACS is usually self-limited and resolves with treatment, it can be associated with respiratory failure, with a mortality rate of 1.8% in children and 4.8% in adults.\textsuperscript{136,137}

\textsuperscript{3042}
Causes of ACS include pneumonia, bone marrow fat embolism, pulmonary infarct due to in situ sickling, rib/sternal infarction, infection, and pulmonary embolism (PE).\textsuperscript{149–151} Approximately 50\% of patients with ACS have no identifiable etiology.\textsuperscript{137} Pulmonary bone marrow fat embolism in patients with SS appears to be more common than previously thought.\textsuperscript{136,137} The characteristic clinical picture is that of severe bone pain, usually in long bones, followed by dyspnea, hypoxia, and fever. Tissue infarction of the bone marrow within long bones appears to generate a source of fat and necrotic tissue that has been demonstrated in the lung on autopsy (Figs. 57.9 and 57.10). “Retrograde embolization,” described in the following discussion, is the probable mechanism by which fat and necrotic tissue reach the lungs and other organs. At the same time, the serum level of secretary phospholipase A2 (sPLA2), an inflammatory mediator, increases in patients with ACS,\textsuperscript{138,152} liberating free fatty acids from membrane phospholipids of the damaged tissue, which are believed to cause damage to the pulmonary endothelium, culminating in a leak syndrome, which if severe may be similar to adult respiratory distress syndrome. An elevated level of sPLA2 is both a marker and probably a predictor of ACS.

\textbf{FIGURE 57.9} Autopsy specimen of lung from a patient with sickle cell anemia and fatal acute chest syndrome showing intravascular emboli composed of necrotic bone marrow elements. (Reprinted by permission from Springer: Ballas SK. Sickle cell anaemia: progress in pathogenesis and treatment. Drugs 2002;62[8]:1143–1172. Copyright © 2002 Adis International Limited.)

Hb, hemoglobin; WBC, white blood cell.
FIGURE 57.10  Photomicrographs of lung and bone marrow (hematoxylin and eosin). Bone marrow emboli, consisting of particles of bone marrow surrounded by fibrin, are present in small pulmonary arteries (panels A and B). In panel C, a section of bone marrow shows the absence of cellular detail, indicating infarction (left), as compared with a section of normal bone marrow from the same patient (right). (Medoff BD, Shepard JA, Smith RN, et al. Case records of the Massachusetts General Hospital. Case 17-2005. A 22-year-old woman with back and leg pain and respiratory failure. New Engl J Med 2005;352:2425–2434, with permission.)
Diagnostic workup should include serial chest radiographs, cultures of sputum and blood, monitoring of arterial blood gases and Hb level, ventilation and perfusion (V/Q) scans, analysis of induced sputum, bronchial washings, analysis of urine for fat globules, and ruling out thrombophlebitis in the pelvis or lower extremities. The diagnosis of fat embolism entails the identification of fat-laden macrophages in induced deep sputum or better by bronchoalveolar lavage fluid obtained by bronchoscopy.\textsuperscript{137,153}

The management of ACS involves multiple modalities to prevent possible catastrophic outcomes. The most important aspect of management is to maintain adequate ventilation. In mild cases, incentive spirometry may be sufficient to achieve this. However, in severe cases, mechanical ventilation in the intensive care unit is essential. Once adequate ventilation is maintained, specific treatment includes oxygen, antibiotics, simple blood transfusion or exchange transfusion, judicious use of analgesics, bronchodilators, careful hydration, and possible vasodilators. Incentive spirometry prevents splinting and atelectasis and may actually prevent ACS in patients with rib infarction.\textsuperscript{151} Intravenous antibiotics are indicated because it is difficult to rule out pneumonia or infected lung infarcts. A combination of a third-generation cephalosporin and a macrolide or a quinolone antibiotic should be used to cover typical and atypical pathogens. Simple transfusion or exchange transfusion is indicated in patients with worsening respiratory function.\textsuperscript{154} The beneficial effects of blood transfusion may not be due simply to decreasing the proportion of sickled RBCs; other mechanisms may be involved. These include (1) an immunomodulatory mechanism by which inflammatory cytokines (IL-8 in particular) bind to the Duffy antigen present on transfused RBCs but often absent on RBCs of Africans and African Americans\textsuperscript{155} and (2) the albumin that is present in transfused units or used in blood exchange may bind free fatty acids, thus neutralizing their damaging effect on the pulmonary endothelium.

Although intravenous steroids may be beneficial for children with ACS,\textsuperscript{156,157} their use in adults with ACS is controversial. Steroids appear to have two paradoxical effects in SCD. They may shorten the duration of the VOC and ACS in children, but they may increase the risk of rebound
VOCs and stroke. Huang et al.159 reported two adult patients with SCD whose clinical picture deteriorated and was complicated by worsening pain, fat embolism, and coma after steroid therapy. Other investigators have reported similar experiences with steroids.160,161 The mechanism by which steroids cause these undesirable complications is not well known and includes two possible mechanisms. The first mechanism pertains to their anti-inflammatory effects. Steroids stabilize cellular membranes and prevent or decrease the cleavage of membrane phospholipids by the enzyme sPLA2 to form inflammatory mediators, including free fatty acids.138 The latter are known to cause damage to pulmonary endothelium, culminating in respiratory failure. However, once steroids are discontinued, their protective anti-inflammatory effect vanishes, with a rebound surge of inflammatory mediators that cause rebound phenomena.

The second mechanism refers to the retrograde embolization hypothesis described by Simkin and Downey.162 Although this hypothesis was first introduced to explain the mechanisms by which steroids cause osteoporosis, it applies very well to SCD. According to this hypothesis, obstruction of the vascular channels within the bone marrow by conglomerates of sickled RBCs leads to bone marrow infarction and necrosis of hematopoietic elements and fat. The increased intramedullary pressure disrupts the endothelium of the engorged sinusoids, thus allowing the retrograde movement of necrotic bone marrow and fat into adjacent intramedullary sinusoids, which communicate directly with arteries and veins, which in turn spread necrotic material systemically, resulting in fat embolism and other VOCs. Unlike children, adults have more adipose tissue that may hypertrophy with steroids, increasing the chances of retrograde embolization. Moreover, steroids may induce or worsen AVN, which is more common in adults than in children. Together, these aspects of the VOC, the bone marrow fat, and the effects of steroids appear to explain the severe VOCs associated with systemic steroids, especially in adults.

The excessive use of opioid analgesics may precipitate ACS due to their depressive effect on respiration. Recommendations to use nonsteroidal anti-inflammatory drugs (NSAIDs) should be considered carefully.136
Opioids have a few systemic side effects, and careful monitoring of their use ensures their safety. They should be discontinued if the respiratory rate is 10 breaths per minute, and their adverse effects can be quickly reversed with opioid antagonists. On the other hand, NSAIDs have considerable systemic side effects that may not be readily obvious. For example, NSAIDs decrease the levels of prostaglandins and prostacyclin, prostanoids that are essential in modulating the vascular tone of smooth muscle and renal blood flow. Thus, NSAIDs may worsen the clinical picture of ACS due to their vasoconstrictive effects and bronchospasm; NSAIDs are contraindicated in asthma for the same reasons.

The role of vasodilators, including nitric oxide (NO), in the management of SCD in general and ACS in particular is not finalized.\textsuperscript{163} It has been reported that NO had a beneficial effect on VOCs in children\textsuperscript{164} and in adults in the ED setting.\textsuperscript{165,166} Its use in hospitalized patients with VOC had no beneficial effect.\textsuperscript{167} An open trial using purified poloxamer 188 (Flocor), a nonionic surfactant, in patients with ACS showed no benefit.\textsuperscript{168,169} It is hypothesized that this agent reduces blood viscosity, prevents adhesion of RBCs to vascular endothelium, and improves microvascular blood flow. Other vasodilators, such as prostacyclin and calcium channel blockers, have not been reported in the management of ACS.

Given the relative frequency of ACS in SS, and the need to monitor arterial blood gases, it is important to establish steady-state blood gases and perform oximetry and pulmonary function tests for all patients. These determinations will be of value in evaluating patients with acute onset of pulmonary signs and symptoms.\textsuperscript{170}

**ACUTE ABDOMINAL PAIN SYNDROMES**

The abdomen is the second most common site of pain in SCD after musculoskeletal pain (including chest wall). The cause may be intra-abdominal pathology or pain referred from the lungs with pneumonia or from the lower ribs and the femoral heads with AVN. Specific abdominal pain syndromes due to SCD include right upper quadrant syndromes, left upper quadrant pain syndromes, and other acute abdominal episodes.
Right Upper Quadrant Pain Syndromes

Acute pain in the right upper quadrant is common in SCD.\textsuperscript{171–173} Differential diagnosis of this entity includes VOC, acute cholecystitis, hepatic sequestration, hepatic crisis, and intrahepatic cholestasis.\textsuperscript{174} Hemolysis of any etiology results in increased secretion of unconjugated bilirubin that precipitates in the gallbladder, causing cholelithiasis and sludge. Some reports implicate third-generation cephalosporins as causing crystallization in the gallbladder.\textsuperscript{175} It should be noted that liver involvement in SCD (sickle hepatopathy) is a spectrum that extends from mild (hepatic sequestration) to severe (intrahepatic cholestasis), with hepatic crisis in between. It is not unusual for the disease to progress from a mild form such as sequestration to severe intrahepatic cholestasis.\textsuperscript{176} Detailed history; physical examination; and monitoring of the clinical picture, liver size, and laboratory data will differentiate the components of the spectrum.

Cholelithiasis, Biliary Sludge, Choledocholithiasis, and Cholecystitis

The prevalence of pigmented gallstones is approximately 30\% in patients older than 10 years of age and approaches 70\% to 75\% in adults.\textsuperscript{139,177} Cholelithiasis occurs as early as 2 years of age,\textsuperscript{178} and approximately 30\% of patients with SCD have gallstones by the age of 18 years.\textsuperscript{179,180} Approximately 90\% of adult patients with SS and cholelithiasis have been reported to undergo cholecystectomy either prophylactically or after an acute episode ofcalculous cholecystitis.\textsuperscript{177} Acute cholecystitis may occur at any age, and the stones are often multiple and pigmented. Less than 10\% of patients with cholelithiasis develop cholecystitis.\textsuperscript{139} The incidence of cholelithiasis appears to be affected by diet and possible genetic factors.\textsuperscript{180} The coinheritance of α-thalassemia may reduce the incidence of stones because it may ameliorate hemolysis, which is thought to drive stone formation as mentioned earlier.\textsuperscript{181} The same applies to any condition with a mild hemolytic component. A genetic basis for the hyperbilirubinemia pertains to mutation of UDP-glucuronosyltransferase 1 (UGT1A), the enzyme that catalyzes bilirubin glucuronidation. It appears that genetic polymorphism of the UGT1A enzyme affects the metabolism of bilirubin. The bilirubin level, as well as gallstone formation, appear to
be significantly greater in patients with the 7/7 genotype compared to those with the 6/6 genotype. Similar findings were reported in patients with Hb E-thalassemia.

Acute cholecystitis should be treated conservatively with appropriate antibiotics and hydration until defervescence of the acute attack. Elective cholecystectomy may then be performed. Treatment of asymptomatic choledolithiasis remains controversial. Conservative measures, such as restriction of fatty diet, may be helpful. When gallstones are associated with chronic abdominal pain, elective cholecystectomy may be warranted. Unfortunately, only 50% of patients obtain pain relief after surgery. Advocates of elective surgery for asymptomatic stones argue that surgical morbidity in a properly prepared patient with SCD is minimal, whereas morbidity in an emergency cholecystectomy is high. Laparoscopic cholecystectomy is the procedure of choice for this indication. This also causes less abdominal muscle disruption and decreases postsurgical complications including ACS.

Biliary sludge is a common finding in patients with SCD. It is an echogenic, intraluminal sediment composed of calcium bilirubinate, cholesterol crystal, viscous bile, mucus, and protein. The natural history of biliary sludge in children with SCD shows that after a mean of 2.1 years of follow-up, approximately 65% of patients eventually develop gallstones, although not necessarily symptomatic. Approximately 40% of patients with biliary sludge do not develop gallstones despite the continued presence of sludge in most. Annual ultrasound to assess stone formation is recommended by most authors and reserve cholecystectomy only for patients with signs and symptoms of acute cholecystitis.

Choledocholithiasis is the presence of gallstones in the common bile duct. The prevalence of choledocholithiasis in patients with SCD appears to be <5% in patients with asymptomatic gallstones according to a survey of patients in steady state. The rate of choledocholithiasis is higher in symptomatic patients, affecting 20% to 60% of individuals with SCD compared to 15% of those without. Signs and symptoms are similar to those of cholelithiasis/cholecystitis. Duct obstruction is rare because pigmented stones are usually smaller than nonpigmented stones. If the common duct is obstructed, symptomatic and/or chemical pancreatitis
may be present. Endoscopic retrograde cholangiopancreatography and sphincterotomy are the best approach to remove the offending stones.

Hepatic Sequestration
Acute hepatic sequestration is sequestration of RBCs in hepatic sinusoids, leading to liver enlargement and decreased Hb concentration. It is characterized by a decrease of ≥2 g/dL in Hb concentration from baseline with reticulocytosis, without other explanation, and liver enlargement of ≥3 cm for children and ≥5 cm for adults (from previous physical examination), without other explanation and no appreciable disturbance in liver function tests. Hatton et al. first described the problem in two adult patients with SS and associated infection. Davies and Brozovic documented hepatic sequestration with associated infection in two young children (18 months and 4 years of age), which suggests that the syndrome may be present once autosplenectomy has occurred. Its most likely mechanism appears to be sequestration of sickled RBCs in the liver. The clinical progression is generally less acute than in splenic sequestration and develops over a few hours to days. The liver becomes progressively enlarged and palpable and may be painful as the liver capsule stretches. Other signs are falling Hb level and bone pain. Therapy is symptomatic, and blood transfusion may be indicated if the Hb level falls below 5 g/dL. Hepatic sequestration may be easily overlooked unless the size of the liver is regularly monitored in patients with VOC involving the right upper quadrant. Acute hemolysis and other causes of Hb decline should be ruled out. Recurrent episodes may occur.

Hepatic Crisis
Hepatic crisis is the most common liver complication in SCD. It may occur in 10% of patients admitted for VOC. An attack is characterized by right upper quadrant abdominal pain, jaundice, hepatomegaly, fever, leukocytosis, dark urine, and often bone or joint pain. Serum transaminases and serum bilirubin are elevated to variable degrees. According to some reports, the serum bilirubin level rarely goes above 15 mg/dL. However, others reported a relatively mild course of hepatic crisis, referred to as benign extreme hyperbilirubinemia, in children.
with serum bilirubin level as high as 57 mg/dL.\textsuperscript{208} Most of the elevated serum bilirubin (>50%) is usually unconjugated. The clinical picture may simulate acute cholecystitis, choledocholithiasis, or viral hepatitis. Liver biopsy helps to distinguish hepatic crisis from viral hepatitis by showing sinusoidal obstruction by sickle cells, hypertrophy of Kupffer cells, and engorgement with RBCs (Fig. 57.11). Additional findings may include hemosiderosis, occasional bile stasis, and mild centrolobular necrosis. The condition is usually transient but may last 2 to 3 weeks before complete resolution. Some authors recommended treatment with intravenous fluids and antibiotics and elective cholecystectomy for gallstones.\textsuperscript{139} Simple or exchange blood transfusion may be indicated.

**FIGURE 57.11** Liver biopsy from a patient with sickle cell anemia and hepatic crisis showing engorgement of hepatic sinusoids with sickled erythrocytes. (From Ballas SK. Sickle cell pain. In: Progress in Pain Research and Management. Vol. 11. Seattle, WA: IASP Press; 1998. This figure has been reproduced with permission of the International Association for the Study of Pain® (IASP). The figure may not be reproduced for any other purpose without permission.)

**Intrahepatic Cholestasis**

Intrahepatic cholestasis is intrahepatic obstruction of bile formation or flow, leading to hyperbilirubinemia. It is characterized by a marked increase in direct bilirubin (>50% of total) compared to baseline, absence of extrahepatic biliary system obstruction, and absence of evidence of marked accelerated hemolysis. It may be benign, without hepatic protein synthesis failure/coagulopathy, or severe and regressive, with hepatic protein synthesis failure, thrombocytopenia, and prolongation of coagulation tests.\textsuperscript{85,201,203,208} This severe form of hepatic crisis may, in rare cases, be complicated by fulminant cholestasis, leading to hepatic coma and death. An attack of intrahepatic cholestasis is characterized by a
sudden onset of abdominal or right upper quadrant pain, increasing jaundice (with conjugated bilirubin as high as unconjugated bilirubin), a progressively enlarging liver, light-colored stools, and hyperbilirubinemia without urobilinogenuria. The clinical picture suggests cholestatic jaundice or choledocholithiasis but with no evidence of common duct obstruction or cholangitis. The prothrombin time, partial thromboplastin time, LDH, and liver enzymes are all elevated. Total serum bilirubin level may be >100 mg/dL. Liver biopsy shows similar changes to those described in hepatic crisis but in a more severe form associated with lymphocytic infiltration, paracentral necrosis, cholestasis, and dilated canaliculi containing bile plugs. Intrahepatic cholestasis is a potentially fatal complication of SCD if not treated promptly. In early reports, only one of eight patients survived. The advent of exchange transfusion as a therapeutic modality reversed this prognosis. In the author’s opinion, patients who are suspected of having hepatic crisis should be watched carefully by monitoring their clinical status, hematologic parameters, serum bilirubin, liver function, and coagulation profile. If the total serum bilirubin level increases to >50 mg/dL or the prothrombin time increases to greater than 20 seconds, total blood exchange should be performed by replacing the removed blood with washed sickle-negative RBCs and fresh frozen plasma. The procedure should be repeated until Hb S decreases to <30% and the serum bilirubin and prothrombin time decrease to acceptable values.

**Left Upper Quadrant Syndrome**

**Acute Splenic Sequestration Crisis**

The spleen is the first organ to suffer from the destructive effects of sickle microvasculopathy that eventually lead to functional asplenia and autosplenectomy. During infancy, the spleen is enlarged in about 75% of patients with sickle anemia. Children between the ages of 5 months and 2 years are most vulnerable to splenic sequestration that varies in severity from mild to life-threatening episodes. In its full-blown picture, acute splenic sequestration is characterized by a pentad of (1) rapid fall in Hb level, (2) rise in reticulocyte count, (3) fall in PLT count, (4) sudden increase in spleen size associated with acute pain and tenderness in the left upper quadrant, and (5) signs and symptoms of hypovolemia. Minor
episodes may resolve spontaneously, but severe ones can be fatal and may be mistaken for the sudden infant death syndrome. Fibrosis occurs by the age of 8 years, and the risk for splenic sequestration decreases. Nevertheless, older children and adults with persistent splenomegaly in certain sickle cell syndromes (SS with two α-gene deletions, Hb SC disease, and sickle-β-thalassemia) continue to be vulnerable for relatively milder episodes of splenic sequestration and for splenic infarction or splenic hemorrhage.

Severe splenic sequestration that could be life-threatening, however, has been described in adults with SS.

The pathophysiologic mechanisms that lead to acute splenic sequestration are not well understood. One possible mechanism is acute obstruction of the venous flow from the spleen with a resultant damming effect associated with sudden enlargement of the spleen due to pooling of red cells and PLTs. The acidotic environment of the spleen, due to its sluggish circulation, stimulates sickling, increases viscosity, and contributes to further obstruction of blood flow. Infection can cause more vascular engorgement in addition to the rapid acceleration of sickling. Obstruction of the venous flow may be related to abnormal rheologic properties of sickle erythrocytes. Moreover, scanning electron microscopy has demonstrated trapping rigid sickle cells in the splenic cords of patients with SS.

Treatment of acute splenic sequestration consists of rapid restoration of intravascular volume and oxygen-carrying capacity. This goal is achieved by the transfusion of sickle-negative RBC at a rate of 15 to 20 mL/kg with careful monitoring to avoid sudden overexpansion of blood volume that may precipitate pulmonary edema. After successful treatment, the spleen usually shrinks within a few days and gradually regains its baseline size.

Acute episodes of splenic sequestration tend to recur within a few months to a year after the initial sequestration crisis. Thus, splenectomy has been recommended for those patients who survive the initial severe episode. The onset of splenic sequestration correlates with the increased risk for septicemia from Streptococcus pneumoniae and Haemophilus influenzae type b, and it is recommended that all patients with sickle cell syndromes receive pneumococcal and H. influenza vaccines. It is important to educate the family about acute splenic sequestration so the
parents can be alert for early symptoms and seek immediate medical intervention. The spleen is the major organ that produces immunoglobulin M (IgM). Patients with autosplenectomy typically have low levels of IgM, a finding that is similar to those patients with anatomic splenectomy.\textsuperscript{226}

**Other Acute Abdominal Painful Episodes**

An abdominal VOC is characterized by severe, usually generalized, abdominal pain and signs of peritoneal irritation. It may also be accompanied by fever, leukocytosis, and markedly elevated LDH level. Clinically, a severe abdominal VOC may closely mimic acute abdomen and may lead to exploratory laparotomy in search of surgically correctable pathology. Patients with SCD who arrive at the ED with an acute abdominal VOC may be misdiagnosed with acute appendicitis or acute cholecystitis and undergo laparotomy and often prophylactic appendectomy and/or cholecystectomy.\textsuperscript{227} In the author’s experience, one-third of adult patients with SCD give a history of appendectomy. Whether the procedure was performed for true acute appendicitis or misdiagnosis of abdominal VOC is unknown. Nevertheless, a 30% incidence of acute appendicitis is much higher than in the general population and raises questions about the authenticity of the diagnosis. Thus, acute abdominal pain in SCD should be considered a VOC until proven otherwise.

The abdominal pain has been attributed to enlarged mesenteric and retroperitoneal lymph nodes; bone marrow hyperplasia; and infarction of the vertebral bodies, hepatobiliary disease, splenic disease, or mesenteric arterial thrombosis.\textsuperscript{228} The abdominal pain seen in VOC may persist for several days, although protracted VOCs lasting longer than 5 days are not unusual.\textsuperscript{229} Differentiation from other causes of acute abdominal pain may be difficult.\textsuperscript{199,230}

Pain in the trunk in association with abdominal distention has been referred to as girdle syndrome by Davies and Brozovic.\textsuperscript{198} It is thought to result from sickling in the mesenteric blood supply. Fluid levels may be visible on radiographs of the abdomen. Mild cases are self-limiting over a 2- to 5-day period and are treated symptomatically with intravenous fluids because gut absorption is impaired. More severe cases have associated involvement of the liver and lungs, and in very severe cases, multiorgan
failure (MOF), including ACS, should be considered. Such patients may have markedly distended loops of bowel and require nasogastric suction and exchange transfusion. Infarction of segments of gut can occur, so it is important to involve surgeons in the evaluation of these patients.

**HAND–FOOT SYNDROME (DACTYLITIS)**

This acute pain syndrome occurs most commonly in infants and young children between the ages of 6 months and 2 years with a few case reports up to 7 years. The clinical picture is characterized by acute painful swelling of one or more extremities. It is caused by inflammation due to ischemic infarction of the bone of the affected extremity resulting in swelling, redness, and pain in affected areas. Fever and leukocytosis may be present. The episode is usually self-limited and resolves within 1 week, but recurrent attacks are common. Treatment is symptomatic, and if the attack persists, acute osteomyelitis should be ruled out.\(^99,100\)

**PRIAPISM**

Priapism is a sustained, unwanted, and recurrent painful penile erection. It is one of the most debilitating complications of SCD. The word priapism is derived from Priapus, the Greek god of fertility and the protector of horticulture. He was also recognized as the protector of all garden produce including goats, sheep, bees, and the vine; he is depicted in sculpture with a huge tumescent penis, symbolizing fertility.

Priapism is a common complication of SCD, affecting 35% of boys and men.\(^231\) It is most common in patients with SS, who account for approximately 80% to 90% of reported cases.\(^232–235\) However, it does occur in males with all forms of SCD including Hb SC disease, all types of sickle thalassemia, and in those with sickle trait.\(^232,236\) In one survey, a single episode of priapism was reported by 31% to 64% of patients, mostly children; approximately 50% of all patients had recurrent episodes, from 2 to 50 times or more, and the estimated mean duration of an episode was 125 minutes (range 50 to 480 minutes).\(^234,235,237,238\) Priapism is not unique to SCD; it could be secondary to trauma, infection, neoplasm, hemoglobinopathies other than SCD, polycythemia, other hemolytic disorders, or hematologic malignancies.\(^239–243\)
Clinically, priapism may be stuttering, minor, or major. Stuttering priapism is the occurrence of short, repetitive, and reversible painful episodes with detumescence occurring within a few hours after the onset of erection. This pattern has a good prognosis and is associated with normal sexual function and rarely requires medical intervention. The prevalence of stuttering priapism varies from approximately 2% of men with SCD according to some investigators\textsuperscript{235} to 40% to 60% of men and boys with SCD according to others.\textsuperscript{237,244}

Minor priapism is isolated and infrequent episodes of painful erection that last less than 4 hours and do not require medical intervention. By contrast, major priapism is a prolonged episode of painful erection lasting longer than 12 hours and that often requires hospitalization, with medical and/or surgical intervention, as described in the following discussion. Partial or total impotence is often associated with major episodes of priapism. Anatomically, priapism may be bicorporal or tricorporal. Magnetic resonance imaging (MRI) of the penis can differentiate these two patterns. Bicorporal priapism involves both corpora cavernosa and is common in children with stuttering pattern and with detumescence occurring within a few hours after the onset of erection. This pattern has a good prognosis and is associated with normal sexual function. Tricorporal priapism involves both corpora cavernosa and the corpus spongiosum and is more common in older patients. It is a painful erection that may last several days or weeks and may be followed by complete or partial impotence. Its prevalence varies between 6.5%\textsuperscript{235} and 38%\textsuperscript{237} of men with SCD. Stroke, chronic lung disease, chronic renal failure, and chronic leg ulcers were observed more frequently in men with tricorporal priapism, and death occurred in nine adults (25% of men with priapism) within 5 years of the first episode of priapism.\textsuperscript{235} Priapism in adult males with SCD appears to be a marker of severe disease and identifies patients who are at risk for other sickle cell-related organ failure syndromes.\textsuperscript{241,245}

Most episodes of priapism begin during sleep.\textsuperscript{234,238,246} Approximately 75% of priapism episodes occur between midnight and 6 AM or after sexual intercourse.\textsuperscript{237,247,248}

Acidosis resulting from dehydration and hypoventilation during sleep may be precipitating factors. Sexual intercourse\textsuperscript{249} masturbation,\textsuperscript{250}
alcohol intake,\textsuperscript{251} infection of the prostate or bladder, recent trauma, and medications with autonomic side effects are reported precipitating factors.\textsuperscript{252} In a Jamaican study, 16\% of patients reported attacks after intercourse.\textsuperscript{244,253} However, most episodes of priapism have no obvious etiology.\textsuperscript{254} Thrombocytosis, low Hb F level, and severity of hemolysis are reported risk factors for priapism.\textsuperscript{237,241,245} Recent studies have linked the severity of hemolysis to priapism, leg ulcers, and pulmonary hypertension.\textsuperscript{245} However, these associations are controversial and have been challenged by other investigators.\textsuperscript{255}

Management of priapism is highly controversial. Controlled studies are lacking, therapeutic approaches are controversial and often conflicting, and medical and surgical therapies fail in most patients. Minor episodes of priapism and stuttering priapism usually last less than 4 hours and are often treated at home with analgesics, benzodiazepines, or pseudoephedrine and do not require treatment at the ED or hospital. Patients are advised to report to the ED if an episode lasts longer than 4 hours. Initial treatment in the ED should include hydration and opioid analgesics. Catheterization of the urinary bladder may be indicated to promote emptying. If these measures fail to cause detumescence, penile aspiration and epinephrine irrigation should be performed. Mantadakis et al.\textsuperscript{256} recommend that aspiration of blood from the corpora cavernosa, followed by irrigation with dilute epinephrine, should be the initial therapy used for patients with SS and prolonged priapism.

Simple transfusion or exchange transfusion may be performed for patients whose priapism does not respond to aspiration and irrigation procedures and persists for 24 hours or longer.\textsuperscript{210,247,248} Siegel et al.\textsuperscript{257} and Rackoff et al.\textsuperscript{258} reported significant neurologic complications (the so-called Association of Sickle cell disease, Priapism, Exchange transfusion, and Neurologic events [ASPEN] syndrome) in patients with priapism who underwent exchange transfusion or partial exchange transfusion. However, analysis of their data shows that the Hb level after blood exchange was much greater than the patient’s baseline level. Thus, the neurologic complications were most likely due to transfusion-induced hyperviscosity. A larger study of blood exchange transfusion in patients with priapism, which maintained the post-exchange Hb level similar to baseline values,
showed no neurologic complication in any of the patients. Patients responding to transfusion therapy usually experience detumescence within 24 to 48 hours after the procedure. If detumescence does not occur within 24 hours after the completion of blood exchange transfusion, surgical intervention should be considered. Surgical intervention includes various shunt procedures between the cavernosa and the spongiosum. Without intervention, severe priapism results in impotence in >80% of patients. The combination of transfusions and surgery can decrease this to 25% to 50%. Patients who become impotent may benefit from psychological counseling and the insertion of a prosthetic penile implant.

The pharmacologic management of priapism includes approaches for acute episodes of priapism and preventative measures. The acute pain of the priapism is treated like other VOCs, with opioid analgesics and adjuvants. The adjuvants commonly used include diphenhydramine, antihistaminics, or benzodiazepines. Care should be exercised in choosing any combinations of drugs. For example, benzodiazepines should not be used with methadone because both cause prolongation of the QTc interval. A recent case report described successful management of priapism in a child with SS using neuraxial analgesia via epidural catheter. There are no evidence-based recommendations for the use of preventative therapies. However, potentially beneficial anecdotes and observations were reviewed by Rogers. These include HU, pseudoephedrine, leuprolide, diethylstilbestrol, etilefrine (not available in the United States), flutamide, and pentoxifylline. Leuprolide, a gonadotropin-releasing hormone antagonist, is associated with hypogonadism after extended use, and diethylstilbestrol has feminizing side effects.

However, the treatments for priapism in boys and men with SCD were reviewed in a Cochrane review to assess the benefits and risks of different treatments for stuttering and fulminant priapism in SCD. The review found only one study of 11 participants who met the criteria for inclusion in the study. The study compared diethylstilbestrol to placebo. The only outcome specified in this review was reduction in frequency of stuttering priapism, and there was no significant difference between groups. Three small series reported prophylactic benefit of sildenafil in sickle cell and thalassemia priapism. However, it appears unlikely at the present
that randomized trials of sildenafil versus placebo will be conducted, due to the fact that sildenafil increased the frequency of VOCs in the Treatment of Pulmonary Hypertension and Sickle Cell Disease with Sildenafil Treatment (Walk-PHaSST) trial.\textsuperscript{270} Certain medications, such as selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants, trazodone, and other antipsychotic drugs, are associated with priapism and hence should not be prescribed to patients with a history of priapism.\textsuperscript{271–273}

**ACUTE MULTIORGAN FAILURE**

This is a catastrophic life-threatening complication of SCD in the context of VOC that may even occur in patients with otherwise mild SCD.\textsuperscript{142,274} Fever, rapid decrease in Hb level and PLT count, nonfocal encephalopathy, and rhabdomyolysis are associated with MOF. Prompt and aggressive simple blood transfusion or blood exchange transfusion could be lifesaving with rapid recovery of organ failure in most cases. MOF may occur in patients with history of relatively mild disease with little or no evidence of chronic organ damage and may be recurrent. High Hb levels in the steady state may be a predisposing factor.

Differential diagnosis of MOF includes ACS and drug overdose. MOF is initially heralded by a rapid fall in Hb and PLT counts from baseline. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), total and direct bilirubin, serum creatinine, and CPK are elevated by the third or fourth day of a VOC.

**Chronic Sickle Cell Pain**

**AVASCULAR NECROSIS**

AVN (also called ischemic necrosis or osteonecrosis) is the most commonly observed complication of SCD after the number of VOCs in adults. Although it tends to be most severe and disabling in the hip area, it is a generalized bone disorder in that the femoral and humeral heads as well as the vertebral bodies may be equally affected. Figure 57.12 shows a “fish mouth” or step-like depression seen in some patients with SCD and is probably caused by AVN or infarction of the central portion of the
vertebral body and may lead to vertebral collapse. The limited terminal arterial blood supply and the paucity of collateral circulation make these three areas especially vulnerable to sickling and subsequent bone damage. Patients with SS and α-gene deletion have a higher incidence of AVN because the relatively high hematocrit increases blood viscosity and thus enhances microvasculopathy in the aforementioned anatomic sites.\textsuperscript{35,36} The MCV and AST levels are negatively correlated with vascular necrosis.\textsuperscript{36}

\textbf{FIGURE 57.12} “Step-like” or “fish mouth” deformity of the lumbar vertebrae of a patient with SS. (From Ballas SK. Sickle cell pain. In: Progress in Pain Research and Management. Vol. 11. Seattle, WA: IASP Press; 1998. This figure has been reproduced with permission of the International Association for the Study of Pain \textsuperscript{\textregistered}(IASP). The figure may not be reproduced for any other purpose without permission.)
Figure 57.13 shows an example of the radiologic picture of AVN of the hips in SCD. The therapeutic approach to AVN depends on the stage of the disease. Ficat proposed a four-stage radiographic classification of AVN of the hip based on plain radiography. MRI was not available at the time. Steinberg et al. expanded the Ficat staging system into six stages using MRI data. A report from the Comprehensive Sickle Cell Centers (CSCC) investigators defined an adaptation from the Ficat and Steinberg systems that combines radiography, MRI, and bone scans as shown in Table 57.12. At the time of diagnosis of AVN, 47.4% of the patients showed stage II disease, 29.6% showed stage III, and 23% showed stage IV.

Medical treatment of AVN is symptomatic and includes providing nonopioid and/or opioid analgesics for pain relief as well as physical therapy. Advanced forms of the disease (stage III or IV) require total bone replacement. Core decompression (Fig. 57.14) in the management of AVN appears to be effective if done in the early stages of AVN.\textsuperscript{278} This, however, was not supported by a prospective randomized multicenter comparing physical therapy alone with core decompression and physical therapy for femoral head AVN in 46 patients with SCD.\textsuperscript{279} Physical therapy alone appeared to be as effective as hip core decompression followed by physical therapy in improving hip function and postponing the need for additional surgical intervention at a mean of 3 years treatment. Results of hip arthroplasty in patients with SS are not as encouraging as results of arthroplasty performed for arthritic hip.\textsuperscript{280} Placement of an internal prosthesis may be difficult owing to the presence of hard sclerotic bone in patients with SCD. Other problems associated with hip arthroplasty in these patients include an increased incidence of infection,\textsuperscript{281,282} a failure rate of about 50\%, and a high morbidity due to loosening of both cemented and uncemented prosthesis. Recent techniques of arthroplasty may improve the life expectancy of hip prostheses.\textsuperscript{283}

LEG ULCERS

Leg ulceration is a painful and sometimes disabling complication of SS that occurs 5% to 10% of adult patients. The most common site for the appearance of leg ulcers is the distal third of the leg, especially on the inner area, just above the ankle and over the medial malleoli (Fig. 57.15). Ulceration involves the skin and underlying tissues of the involved areas. The deeper the ulcer, the more severe. Leg ulcers are classified into stages depending on their depth and not surface area (Table 57.13). Severe pain may necessitate the use of opioid analgesics. The use of topical analgesics seems to be effective in relieving pain and decreasing the use of oral analgesics.284
FIGURE 57.15 Leg ulcers in a patient with sickle cell anemia. (From Ballas SK. Sickle cell pain. In: Progress in Pain Research and Management. Vol. 11. Seattle, WA: IASP Press; 1998. This figure has been reproduced with permission of the International Association for the Study of Pain® (IASP). The figure may not be reproduced for any other purpose without permission.)

</tr>
</thead>
<tbody>
<tr>
<td><strong>Stage 1:</strong> Nonblanchable erythema of intact skin, the heralding lesion of skin ulceration. In individuals with darker skin, discoloration of the skin, warmth, edema, induration, or hardness may also be indicators.</td>
</tr>
<tr>
<td><strong>Stage 2:</strong> Partial-thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.</td>
</tr>
<tr>
<td><strong>Stage 3:</strong> Full-thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.</td>
</tr>
<tr>
<td><strong>Stage 4:</strong> Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon, joint capsule). Undermining and sinus tracts may also be present.</td>
</tr>
</tbody>
</table>

Leg ulcers are more common in males and older patients and less common in patients with α-gene deletion, high total Hb level, or high levels of Hb F. Leg ulcers seem to be more common in patients who are also carriers of the CAR β-gene cluster haplotype. As was mentioned earlier, leg ulceration seems to be associated with priapism, pulmonary hypertension, and death in a subtype of SCD characterized by high levels of LDH as a marker of hyperhemolysis.

Treatment of leg ulcers includes wound care using wet to dry dressings soaked in saline or Burow’s solution. With good localized treatment, many ulcers heal within a few months. Oral zinc sulfate therapy (660 mg per
day) may be beneficial for some patients. However, a Cochrane review showed that oral zinc for arterial or venous leg ulcers due to causes other than SCD had no significant difference compared to placebo. Leg ulcers that persist more than 6 months present a challenge to the treating physician and the patient. In addition, survival of patients with chronic leg ulcers seems to decrease compared to patients without leg ulcers.

Failure to respond to the measures mentioned earlier may justify the other modalities listed in Table 57.14. However, most of these modalities have been included in uncontrolled trials (controlled trials are highlighted in bold). These trials reported healing of leg ulcers in patients with SCD in response to transfusion, erythropoietin in combination with HU, arginine butyrate, hyperbaric oxygen, arginine-glycine-aspartic acid synthetic peptide matrix, recombinant human granulocyte macrophage colony-stimulating factor, collagen matrix dressing, lyophilized type I collagen, antithrombin III, and electrical stimulation. A Cochrane review of the controlled trials listed in Table 57.14 showed evidence that topical application of arginine-glycine-aspartic acid peptide matrix reduced ulcer size in treated patients compared to control subjects. However, the evidence of efficacy was limited by the high risk of bias associated with the report. Moreover, heterogeneity among the controlled trials prevented performance of meta-analysis.

If all else fails, skin grafting may be considered. Some studies report a degree of success, and others a high rate of failure. To be successful, skin grafting should be performed on clean, débrided ulcers and should be preceded and followed by transfusion or exchange transfusion to keep the percentage of Hb S low (<30%) to break the cycle of sickling, vaso-occlusion, and tissue necrosis and to promote healing.

Recent modalities for the management of leg ulcers that are not
commonly used in SCD include topical application of PLT-derived growth factor prepared either autologously (Procuren)\textsuperscript{304} or by recombinant technology (Regranex)\textsuperscript{305} and the use of cultured skin grafts.\textsuperscript{306} In addition, ma\textsuperscript{¯}nuka honey from New Zealand has been reported to heal diabetic foot ulcers.\textsuperscript{307,308} Amputation, a last resort for recalcitrant and severely painful ulcers, is rarely used.\textsuperscript{309,310}

The induction of Hb F production by HU\textsuperscript{10} would imply that it may prevent or heal leg ulcers in patients with SCD. However, HU has been reported to be associated with leg ulcers in patients with myeloproliferative disorders.\textsuperscript{311,312} Whether the same association exists in patients with SCD is controversial. Leg ulcers were a common complication among 123 adult patients treated with HU in a retrospective French study.\textsuperscript{313} Although controlled studies have not been reported to support the role of Hb F induction in the management of leg ulcers, future randomized, multicenter trials of HU may provide further information on this subject.

**INTRACTABLE PAINFUL EPISODES**

Some patients with SCD have intractable painful episodes and take opioid with or without nonopioid analgesics on a chronic basis. They have no evidence of precipitating cause such as infection, dehydration, or ischemia. Many of these patients are often referred to as “problem” patients or “difficult” patients, and their management is a challenge to the treating physician.

**NEUROPATHIC PAIN**

Neuropathic pain is characterized by sensations of burning, tingling, shooting, lancinating, and numbness. These symptoms may occur in the presence or absence of obvious central or peripheral nerve injury. Neuropathic pain in SCD seems to manifest itself in two forms. A number of reported neuropathic pain syndromes seem to be possibly associated with and due to the disease itself. These include mental nerve neuropathy,\textsuperscript{314,315} trigeminal neuralgia,\textsuperscript{316} acute proximal median mononeuropathy,\textsuperscript{317} entrapment neuropathy,\textsuperscript{318} acute demyelinating polyneuropathy,\textsuperscript{318} ischemic optic neuropathy,\textsuperscript{319} orbital infarction,\textsuperscript{320}
orbital apex syndrome, and spinal cord infarction.

The complications mentioned earlier are essentially neuropathies and not typical neuropathic pain as described in type 2 diabetes. Neuropathy and neuropathic pain are not synonymous. Diabetic neuropathy, for example, is not always associated with pain. The prevalence of neuropathy among diabetics is 40% to 60%, whereas neuropathic pain occurs in 10% to 16% of diabetics. The prevalence of neuropathy and neuropathic pain in SCD is not well known. The nociceptive type of pain in SCD may overshadow and/or mask the neuropathic component.

Management of Sickle Cell Pain

Effective management of sickle cell pain is complex and entails thorough understanding of the issues that are associated with the treatment of pain of an incurable disease on a chronic basis. Major prerequisites for an effective and rational management of sickle cell pain pertain to the patient, the pathophysiology of the disease, the pharmacology of analgesics, and the attitude of the health care providers. A patient is as a unique human entity. The more a provider knows the patient, the more effective pain management becomes.

Knowledge of the patients should not be limited to age, sex, precise diagnosis, complications, and previous pain management methods. It should also take into consideration the biopsychosocial fabric of the patients’ lives, including their level of education, employment status, occupation, family structure, source of income, ethnicity, housing conditions, fears, religion, beliefs, habits, hobbies, and perception of the severity and prognosis of their disease. This approach allows the physician to individualize pain management and avoid unfounded generalizations about patients and their consumption of opioid analgesics. Such generalizations, for instance, may result in oversedation of a patient naive to opioids or in undertreatment of a patient too tolerant of them.

Sickle cell pain is unique and, like other types of pain, is a complex human experience that is strongly affected not only by pathophysiologic factors but also by psychological, social, cultural, and spiritual ones. It is, however, consequent to tissue damage generated by the sickling process.
and occlusion of the microvasculature, as was described in the pathophysiology reaction. An important aspect of effective management of sickle cell pain is the intent of the care provider. Do the providers in question endeavor to treat patients in an empathetic manner by listening to, respecting, and believing them? Or do they stigmatize them as drug addicts demonstrating drug-seeking behavior and thereby justify the expulsion of some patients from their system? Do the providers actively seek management of sickle cell pain, or are they passively forced by the system to which they belong to treat patients in a cursory manner? Do some providers retain patients with mild disease and get rid of the complicated ones so that their records of hospital stay look good? As Lee et al.\textsuperscript{189} succinctly noted that “no one knows how often physicians and hospitals try to improve measured results by declining high risk cases.” These are difficult questions to answer and research. The outcome of management of sickle cell pain relies heavily on the ethical principles to which the providers in question subscribe.

Perhaps the difficulty of treating sickle cell pain can best be addressed with reference to a clinical anecdote. The patient is a young African American male who makes frequent visits to the ED for painful episodes and is labeled as an addict. The connection of the disease with race results in many ramifications that impact on care. Disparities in care arise because of the wide cultural gulf between health care providers who are predominantly white and the predominantly black patient group.\textsuperscript{327–330} Communication and stereotyping complicate pain assessment and treatment. Frequent flyers in the ED often become labeled as drug seekers regardless of their diagnosis or the chronicity of their disease. Concerns about addiction are justified in the SCD population because these patients carry many associated risks, including disease chronicity and dismal prognosis, comorbid psychiatric disease including depression and anxiety, young age, and unremitting pain. Yet the approach needs to be one not of avoiding opioids but rather recognizing the risk while providing adequate pain management (with opioids if necessary) under controlled conditions that aim to minimize risk.

**NONPHARMACOLOGIC MANAGEMENT OF PAIN**
Nonpharmacologic management of pain includes cutaneous stimulation (transcutaneous electrical nerve stimulation), heat, cold and vibration, distraction, relaxation, massage, music, guided imagery, self-hypnosis, self-motivation, acupuncture, and biofeedback. Although there are no well-controlled clinical trials of the efficacy of these methods in the management of sickle cell pain, there are many anecdotal reports of their efficacy in pain management both by patients and providers.

**PHARMACOLOGIC MANAGEMENT OF PAIN**

Pharmacologic management of pain includes three major classes of compounds: nonopioids, opioids, and adjuvants. A major difference between nonopioids and opioids is that the former have a ceiling effect, a term that refers to a dose above which there is no addictive analgesic effect. Nonopioids include acetaminophen, NSAIDs, topical agents, tramadol, and corticosteroids. Opioids include agonists, mixed agonists-antagonists, partial agonists, and antagonists. Adjuvants commonly used in the management of sickle cell pain include antihistamines, benzodiazepines, antidepressants, anticonvulsants, and phenothiazines. Aspects of these pharmacologic agents that pertain to SCD will be discussed here.

**Nonopioids and Sickle Cell Disease**

**Acetaminophen:** This drug has been implicated in papillary necrosis of the kidney and in hepatotoxicity with a dose that exceeds 4 g per day or with the recommended dose in patients with liver disease. Because patients with SCD are at risk for renal and hepatic complications, the dosage given to them and their renal and hepatic functions have to be monitored carefully.

**Nonsteroidal anti-inflammatory drugs:** These drugs are well tolerated by most patients. Care has to be taken if the patients are sensitive to them, if the renal function is impaired, and if the patient has pulmonary complication especially ACS. NSAIDs should not be given to patients with impaired renal function. NSAIDs cause bronchospasm that may worsen or precipitate ACS.
Opioids and Sickle Cell Disease
Depending on point of view, opioids may be considered first-line treatment for severe acute sickle cell pain. There is certainly no alternative to opioids for the treatment of severe pain, although nonopioid and nonmedical treatments should be added whenever possible as opioid-sparing adjuncts. Specific considerations for choice of opioid in SCD patients are outlined here.

Meperidine: This should be avoided whenever possible. If it has to be given, the dose has to be adjusted in the presence of abnormal renal function, and the patient has to be monitored for early signs of neurotoxicity such as myoclonus, tremors, and hyperexcitability.\textsuperscript{99,100}

Morphine: The major metabolite of morphine (morphine-6-glucuronide) is excreted in the kidney. Accordingly, the dose of morphine has to be monitored in the presence of renal failure. Other recently reported side effects of morphine include increased risk of ACS in patients with SCD,\textsuperscript{334,335} acceleration of renal injury,\textsuperscript{336} and retinopathy\textsuperscript{337} in transgenic sickle mice. In a retrospective study of hospitalized children with SCD, Buchanan et al.\textsuperscript{335} reported that patients on morphine were more likely to develop ACS and had longer hospital stays than patients receiving nalbuphine hydrochloride (Nubain).

Methadone: Methadone is associated with several potential toxicities, including cardiotoxicity due to prolongation of the QTc interval with arrhythmia that could be fatal. In treating sickle cell pain with methadone, the provider should follow the adage “start low and go slow.” Most reported fatalities due to methadone are due to overaggressive introduction of methadone to patients who have never before received the drug. This is a reflection of the drug’s unusual and unpredictable pharmacokinetics. Another important point in using methadone is to be aware of the side effects of other drugs used in combination with methadone. Patients with SCD often receive antibiotics or antidepressants which also prolong the QTc interval. The electrocardiogram of such patients should be carefully monitored.\textsuperscript{91,338}

Adjuvants and Sickle Cell Disease
Antidepressants that are known to cause priapism should not be used in
patients with history of priapism. These include trazodone, SSRIs, and tricyclic antidepressants in decreasing order of risk to cure priapism.\textsuperscript{91,338}

**Management of Pain at Home**

Treatment of acute VOCs at home is empiric and depends on the severity of pain and the presence or absence of complications of the disease. Ideally, painful episodes of mild severity are treated at home with nonpharmacologic measures including bed rest, hydration, massage, relaxation, diversion, heating pads, tub baths, self-hypnosis, and motivation. Patients often sense an impending VOC, and early treatment with analgesics may abort or ameliorate an evolving VOC.\textsuperscript{92,106,339} Home treatment of pain should follow the three-step analgesic ladder (Table 57.15) proposed by the World Health Organization.\textsuperscript{340} This approach involves the use of analgesics in escalating potency. These medications are given alone or in combination, initially on an as-needed followed by an around-the-clock administration for moderate to severe pain. This model controls pain in 90% of cancer patients.\textsuperscript{327,341}

</tr>
</tbody>
</table>

Chronic pain associated with SCD includes arthropathies, aseptic necrosis, vertebral body collapse, and leg ulcers. In addition, some patients almost always experience persistent VOC pain. These chronic pain syndromes may be treated with one of the weak or strong opioids, depending on the severity of pain. A long-acting opioid, such as methadone or oral controlled-release morphine (MS Contin, Avinza, Kadian, Oramorph) or oxycodone (OxyContin), is ideal for chronic pain. The use of transcutaneous electrical nerve stimulation may be of value in reducing the pain intensity of these syndromes, especially if associated with leg ulcers. The use of fentanyl transdermal patches is also of potential value. It should be noted that the presence of fever or the application of heating pads over these patches increases the absorption of fentanyl by the skin and may lead to an accumulation of a toxic plasma level, which can be fatal.

Outpatient Management of Sickle Cell Pain
Management of patients with SCD in the outpatient clinic or office is the fulcrum on which the success of comprehensive care is balanced. Because they are not in severe acute pain, patients in the clinic are receptive to counseling, education, and reinforcement of good habits by nurses, technologists, social workers, and physicians. Ideally, patients should be followed by the same personnel to maintain continuity of care. The clinic or office is where the steady state of disease is defined clinically, hematologically, and biochemically and where a multidisciplinary approach to care is maintained by regular checkups and appropriate consultations.
Management of patients with SCD as outpatients in the clinic or office is also the basis on which future treatments and interventions are based. The most important aspect of outpatient management is the collection of baseline data including detailed medical history, physical examination, known complications, medications, and comprehensive laboratory data. The future care of patients in the ED or in the hospital depends heavily on knowing the steady state parameters of the patient. Moreover, should patients enroll in clinical trials, comparison to the steady-state status is invaluable. It is highly desirable that patients be seen and evaluated in the office or clinic by a social worker and a psychologist or psychiatrist. It is in the outpatient setting that details of care, in general, and in the ED, day unit, and hospital, in particular, are explained and discussed. The pros and cons of all medications the patient is taking will be reviewed. Prescriptions will be given as needed. Vaccines will be administered when required.\textsuperscript{109}

Management and follow-up of outpatients in the office or clinic should culminate in an individualized treatment plan for each patient. Such a plan should summarize pertinent aspects of the medical history, physical examination, laboratory data, complications, and treatment plans for patients as outpatients, in the day unit, ED, and hospital. In some cases, the treatment plan may be transformed into an identification card to be carried by the patient and presented to the care provider as needed.\textsuperscript{109}

**Pain Management in the Day Unit**

The major advantage of treating sickle cell VOCs in the day unit (or day hospital) is that patients do not have to wait for a long time before receiving treatment.\textsuperscript{127,339,350} In the day unit, analgesic therapy is usually initiated within 15 to 20 minutes after arrival. Adult patients are admitted to the day unit if they have an uncomplicated VOC based on inclusion and exclusion criteria protocols. After a thorough assessment, treatment is initiated with intravenous hydration and a loading dose of opioid analgesic followed by assessment within 30 minutes. After the initial assessment, the patient may be medicated with 25% to 75% of the loading dose of opioid analgesic depending on the level of pain relief and sedation. The patient’s vital signs are assessed every 30 minutes for the first 2 hours of treatment and hourly thereafter. If the respiratory rate falls below 10 breaths per
minute, systolic blood pressure falls below 90 mm Hg, and/or sedation occurs, the opioid is withheld and the patient is monitored closely. The duration of treatment usually lasts approximately 6 hours. Most patients (>95%) are discharged, and a few may require hospital admission.127

**Pain Management in the Emergency Department**

Treatment of VOCs in the ED follows similar principles of thorough assessment, treatment with analgesics/adjuvants, coordination of cure, monitoring, outcome, and disposition.99,100,326,339 The major problem in the ED is the length of waiting time to initial analgesia, which could be up to several hours. Needless to say, waiting while in pain constitutes a stressful situation that could worsen the painful crises and render it no longer amenable to resolution and discharge from the ED but to hospital admission. Many EDs are in the process of determining and implementing strategies that could shorten the time to initial treatment. Specific treatment in the ED should be based on the history or the computerized version of the treatment plan, if available. Usually, analgesics are given individually every 2 hours for a total of three doses. Adjuvants may also be given intravenously or orally as needed. If the pain is resolved or reduced to a level with which the patient is comfortable, the patient is discharged with instructions for follow-up by the primary care physician and/or hematologist. Otherwise, the patient will be admitted to the hospital.

**Management of Sickle Cell Pain in the Hospital**

Failure to break the VOC in the ED is an indication for hospital admission. Management of pain in the hospitalized patient is essentially a continuation of the process initiated in the ED.99,100,326,339 However, prerequisites for the rational management of acute VOCs in the hospital include knowledge of the patient, knowledge of the nature of sickle cell pain, and knowledge of the pharmacology of analgesics in general and opioids in particular. To that end, it is desirable to have patients with VOC admitted to the care of providers (preferably hematologists) who are familiar with these prerequisites and with the principles of pain management. Patient-controlled analgesia (PCA) is a useful method of delivering opioid analgesics in hospitalized patients.351 Successful
management of the acute VOC in the hospital should include the following steps:

- Multidimensional assessment to determine the location of pain, its intensity, its quality, precipitating factors, modifying factors, and triggers and to determine mood, relief, and sedation. A major component of assessment is to listen to, believe, and respect the patient with a nonjudgmental attitude.

- Choice of analgesics (opioids/nonopioids), adjuvants, and hydration, if needed. Such choices are individualized based on the patient’s medical history and assessment. If the VOC is superimposed on chronic pain for which the patient is taking long-acting/controlled-release opioids with short-acting opioids for breakthrough pain, keep the long-acting/controlled-release opioids the same and discontinue the oral short-acting ones.

- Determination of the route and method of administration of short-acting analgesics. These, again, should be individualized; parenteral analgesics are usually administered either on a fixed schedule or via a PCA pump as discussed in the following discussion.

- Titration of the dose of analgesics to achieve a level of relief with which the patient is comfortable

- Maintenance of the dose that achieves adequate relief. Consider opioid rotation; that is, change the opioid selected initially to an equianalgesic opioid if its use does not achieve or maintain relief.

- Plan to treat breakthrough pain, neuropathic pain if present, and side effects of the VOC or the analgesics, if present.

- Taper the dose of analgesics once the patient uses the PCA pump less frequently or the intensity of pain decreases by two or more points.

- Gradually switch to oral analgesics using equianalgesic dose tables as an initial guide. One example would be to decrease the parenteral dose by 25% and replace it with an equianalgesic oral dose. The latter should be adjusted according to its effect of achieving a level of pain relief with which the patient is comfortable.

- Prevention of withdrawal by continued gradual reduction of the oral opioid dose after discharge or by using either a clonidine patch or methadone, if needed.
• Plan for discharge and follow-up.

Details of these steps may vary among patients, providers, and institutions. It should be emphasized that desirable outcome of management of VOCs in the hospital depends on early and aggressive treatment of pain without delay, avoidance of hasty or premature discharge from the hospital, and having a plan for follow-up after discharge, preferably within 1 week or less.

**Specific Approaches to Treatment**

Despite impressive “quantum leaps” in our understanding of the pathophysiology of SCD in general and SS in particular, a specific, safe, and nontoxic curative therapy has not yet been identified, with the possible exception of gradually increasing examples of bone marrow/stem cell transplant. Nevertheless, the overall medical care of patients with SCD in developed countries has improved such that their life expectancy has almost doubled since 1951.\(^{27}\) Currently, there are at least five major approaches for the general management of SCD and its complications.\(^{352}\) These include (1) symptomatic management, (2) supportive management, (3) preventive management, (4) abortive management, and (5) curative therapy (Table 57.16). Additional approaches pertain to the management of the patient with SCD and comorbidities\(^{339}\) that complicate SCD but are not themselves complications of SCD. Examples of this new and expanding category, due to decreased morbidity and mortality of patients with SCD, include such things as the management of the patient with SCD and diabetes, obesity, cancer, etc. Most important among these measures include the preventative and curative therapies which are discussed here.

### TABLE 57.16 Approaches to the Management of Sickle Cell Disease and Its Complications

<table>
<thead>
<tr>
<th>Approach</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Supportive management</td>
<td>Management intended to maintain the essential requirements for good health such balanced diet, sleep, hydration, folic acid, etc.</td>
</tr>
<tr>
<td>2. Symptomatic management</td>
<td>Management targeted to alleviate the symptoms of the disease as they occur. These include blood transfusion for symptomatic anemia, analgesics for pain, antibiotics for infections, etc.</td>
</tr>
</tbody>
</table>
Preventative management
Approaches to prevent the occurrence of complications of the disease. These include things like vaccination, avoidance of stressful situations, Hb F induction with hydroxyurea or other agents, transfusion to prevent the recurrence of stroke, etc.

Abortive management
Major purpose of this approach is to abort painful crisis, thus preventing them from getting worse or precipitating other complications. The only promising abortive approach has been nitric oxide so far.

Curative therapy
This is the ultimate goal of all inherited disorders. This has already been achieved in SCD by stem cell transplantation. Gene therapy is another challenging goal.

Preventive Therapies
The goal of preventive therapy is to ameliorate the clinical picture of SCD in general and to decrease the frequency and severity of VOCs in particular. For many years, the major goal of primary therapy for SCD was to identify an antisickling agent that would prevent or reverse the polymerization of sickle Hb in RBCs. Sodium cyanate inhibits polymerization of Hb S in vitro but is not beneficial in vivo at levels that provide acceptable toxicity. The use of sodium cyanate was associated with peripheral neuropathy and subcapsular cataracts, which prevented its use as an antisickling agent. Although the search for beneficial antisickling compounds continues, the most promising approaches to prevent the frequency and severity of VOCs include the prevention of infection, induction of Hb F production, blood transfusion, anti-adhesion therapy and myriad agents that await confirmation of benefit in clinical trials.

Induction of Fetal Hemoglobin
High levels of Hb F have a beneficial effect in patients with SS. Platt et al. demonstrated a significant inverse correlation between the frequency of VOCs and Hb F levels greater than 4%; the higher Hb F level, the milder the disease. Hb F interferes with the polymerization of Hb S; the higher (and the more pancellular) the Hb F level, the lower the
intracellular concentration of Hb S. Exceptions to this rule include some patients with high Hb F level and severe disease and vice versa.

Agents that increase the level of Hb F in humans are listed in Table 57.17. Among these, HU as monotherapy seems to be the least toxic and most effective.\textsuperscript{10,354,355} Moreover, HU is the only drug studied for efficacy in a relatively large-scale, placebo-controlled, randomized clinical trial. All the other agents listed in Table 57.17 have been reported anecdotally to increase Hb F levels. None of the others was used in a controlled phase III clinical trial to date.

**Hydroxyurea**

HU is a cell-cycle specific cytotoxic agent that inhibits ribonucleotide reductase. The molecular mechanism(s) by which HU increases the production of Hb F is (are) unknown. Possible mechanisms include perturbations in cellular kinetics and/or recovery from cytotoxicity, recruitment of early erythroid progenitors, and recruitment of primitive erythroid progenitors (BFU-E) that lead to production of Hb F-containing reticulocytes (F-reticulocytes). Long-term HU therapy with the maximum
tolerated dose (mean dose 21.3 mg/kg) with respect to myelosuppression raises Hb F by as much as 15% to 20% (mean 14.9%, range 1.9% to 26.3%).

In the randomized, placebo-controlled, double-blind MSH study, among 299 adult patients with SS with three or more VOCs per year, HU resulted in a significant (P < .001) reduction in the incidence of VOCs, ACS, and transfusion requirement. HU improved the quality of life of the patients taking it. There was no difference between the placebo and HU arms in the incidence of death, stroke, or hepatic sequestration. Maximum tolerated doses of HU were not required to reduce the incidence of VOCs. Although an increase in Hb F seems to be the obvious and logical explanation for the salutary effects of HU, other reasons for its beneficial effects include changes in RBC volume, cellular hydration, the cell membrane, and a direct effect on endothelial cells.

**Hydroxyurea and the HUG Trials**

The success of MSH prompted pediatricians to follow suit and determine the efficacy of HU in children. A multicenter phase I/II trial of HU in children with SS (HUG-KIDS) showed that HU therapy is safe for children with SS when treatment is directed by a pediatric hematologist. Treatment of children with HU induced similar laboratory changes as in adults, and children could tolerate doses of HU as high as 30 mg/kg/day. Another 2-year, prospective, multicenter, open-label, single-arm, pilot study (Hydroxyurea Safety and Organ Toxicity [HUSOFT]) of HU in very young children with SS showed that HU treatment for infants with SS is feasible and well tolerated, has hematologic efficacy, and may delay functional asplenia. An extension study of the HUSOFT trial, in which the dose of HU was increased to up to 30 mg/kg/day, showed that infants with SS tolerated prolonged HU therapy, with sustained hematologic benefits, fewer ACS events, and possibly preserved organ function. These early studies in infants and children led to the Pediatric Hydroxyurea Phase III Clinical Trial (BABY HUG). The main objective of BABY HUG was to determine if HU can prevent the onset of chronic end-organ damage in young children with SS. The primary endpoints of the study were splenic function (determined by qualitative uptake on 99Tc
spleen scan) and renal function (determined by glomerular filtration rate by 99mTc-diethylene triamine pentaacetic acid [DTPA] clearance). Other endpoints included blood counts, Hb F, chemistry profiles, spleen function biomarkers, urine osmolality, neurodevelopment, transcranial Doppler ultrasonography, growth, and mutagenicity.\textsuperscript{360} A total of 96 patients received HU, and 97 patients received placebo. The study confirmed the safety and efficacy of HU therapy for infants with SS. However, treatment with HU showed no significant differences for the primary endpoints: splenic function or glomerular filtration rate.\textsuperscript{361} A different prospective HU study of long-term effects (HUSTLE) showed that HU at maximum tolerated dose is associated with a decrease in hyperfiltration in young children with SS.\textsuperscript{362} In the BABY HUG trial, treatment with HU was associated with decreased pain (177 events in 62 patients on HU vs. 375 events in 75 patients in the placebo group; \(P = .002\)); decreased dactylitis (24 events in 14 patients on HU vs. 123 events in 42 patients in the placebo group; \(P < .0001\)); and decreased incidence of ACS, hospitalizations, and blood transfusions.\textsuperscript{360} Treatment with HU increased Hb and Hb F and improved hematologic values, decreased white blood cell count, and perhaps increased preservation of organ function.\textsuperscript{360,363}

Toxicity was limited to mild to moderate neutropenia.

**Benefits and Side Effects of Hydroxyurea**

Benefits of the long-term use of HU (listed in Table 57.18) are numerous. Some of the parameters mentioned for adults are not available for children. These may become available later when follow-up data from the BABY HUG study are complete. The most important is decreased mortality among patients who take HU for years.\textsuperscript{364,365} Other benefits include improved quality of life in adults,\textsuperscript{356} cost-effectiveness,\textsuperscript{366} decreased hospital length of stay in children and adults,\textsuperscript{125,360} decreased use of analgesics in general and opioids in particular during hospitalization, outpatient acute care and at-home care in adults,\textsuperscript{125,126,367} a trend for more consistent employment in adults,\textsuperscript{368} improved RBC survival in adults,\textsuperscript{369} and improved RBC deformability in adults.\textsuperscript{370}

3081
Side effects of HU are listed in Table 57.19. Toxic effects are dose- and time-dependent but can be prevented by careful monitoring of blood counts every 2 weeks after initiation of treatment. The frequency of monitoring of blood counts and blood chemistries can be decreased to once every 1 to 2 months once the patient is in a stable condition and receiving an acceptable maintenance dose. Excretion of HU is likely a linear, first-order, renal process. According to renal failure is a contraindication for the use of HU, or the dose should be adjusted according to the degree of renal impairment. Anemia is a rare toxic effect of HU; in most patients, Hb level increases. Some patients experience idiosyncratic effects of HU, but the reported incidence was similar between placebo and HU. Surprisingly, during the BABY HUG, a 2-year-old girl ingested an entire 35-day supply of HU at one time (612 mg/kg). Although the serum level of HU was 7,756 µM 4 hours postingestion, the only toxicity noted was transient mild myelosuppression at days 3 and 5, with complete remission by day 7; she had no hepatic or renal dysfunction, remained asymptomatic, and resumed study treatment 13 days after ingestion. No HU was detected in the serum 84 hours after ingestion. The short half-life of HU and the presence of glomerular hyperfiltration a 2-year-old child may have been the reason why HU was cleared rapidly. In addition, HU sequesters in RBCs and leukocytes.
Had the patient been an adult with compromised renal function, the clinical picture might not have been so benign.

The following limitations should be considered when using HU to prevent painful crises in patients with SCD. First, HU was approved in the United States by the U.S. Food and Drug Administration for the prevention of VOCs in patients with SS and not in other types of SCD. Second, the long-term effects of HU in patients with SCD are not known, and finally, some patients do not respond to HU. Methods to identify these nonresponders are being studied in order to improve the selection process for HU therapy. In some patients, combining HU with other agents that augment Hb F production may be indicated.

Other Novel Approaches to Therapy
A large number of novel preventive therapeutic modalities may have promising roles in the management of SCD in general and sickle cell pain in particular. These include, among other things, antiadhesion
molecules, surfactants, levocarnitine, zileuton (a 5-lipoxygenase inhibitor), green tea, aged garlic, and herbal extracts. Some of these agents are being used on an investigational basis. There are anecdotal reports of success in a few patients using some of these agents. However, the efficacy of any of these agents awaits proof in phase III, randomized, double-blind, placebo-controlled trials. Such trials will determine if a certain drug is safe, efficacious, and capable of improving the quality of life of treated patients. Recently, Singh and Ballas reviewed about 38 drugs that were tried or about to be tried in several clinical trials for the prevention of VOCs and related complications. As mentioned earlier, the phase III trial of senicapoc was terminated because patients who took senicapoc had more VOCs than control subjects. A phase III trial of sildenafil to treat patients with elevated tricuspid regurgitant velocity and low exercise capacity was terminated for the same reason.

**CURATIVE THERAPIES**

**Allogeneic Hematopoietic Stem Cell Transplant**

The only curative therapy available at present for SCD in general, and SS in particular, is stem cell transplant. The first two patients with SS treated by bone marrow transplant underwent this treatment not for SS but for comorbid conditions. The first patient was an 8-year-old girl with SS who had both acute myeloid leukemia and frequent VOCs. Her clinical course after transplant was complicated by transient acute and chronic graft-versus-host disease (GVHD) involving mainly the skin and gastrointestinal tract. She also had AVN of the right hip. Further follow-up showed that she was in excellent general health and had no evidence of recurrence of SCD or leukemia. The second patient had SS and Morquio disease, a metabolic storage disease for which bone marrow transplant was performed. This patient failed to engraft but underwent a successful retransplant from the same donor.

In 1998, 70 patients with SS had undergone bone marrow transplant worldwide. By the end of the 20th century, at least 100 patients with SS had undergone transplant worldwide. At that time, most patients were children who received bone marrow allografts from siblings with identical human leukocyte antigen (HLA) match and who underwent
myeloablative conditioning. Although the estimated risk of mortality from HLA-identical bone marrow transplant was relatively low (~5%), there was some concern regarding short-term and long-term toxicity, lack of availability of suitable donors, and barriers to wider application. 

Nevertheless, an interim report on the impact of bone marrow transplant for symptomatic SCD found that allogeneic bone marrow transplant establishes normal erythropoiesis and is associated with increased growth and stable central nervous system imaging results and pulmonary function in most patients. 

Things have changed for the better since 2000; some of the barriers have been overcome, and more patients are awaiting appropriate donors for transplant. The advent of high-resolution HLA typing, the choice of stem cell sources (bone marrow, peripheral blood or cord blood), less toxic conditioning regimens, new immunosuppressive agents, facilitated immune reconstitution, and improved supportive care have made transplant a more viable option for patients with SCD.

By 2010, less than 500 patients with SCD who have undergone transplant have been reported in the Center for International Blood and Marrow Transplant Research database.

Allogeneic hematopoietic stem cell transplant is the only curative treatment for SCD at present. It is successful in approximately 90% of patients. Unfortunately, conventional approaches to transplant are associated with comorbidities including, among other complications, infertility, gonadal failure, and chronic GVHD. The use of umbilical cord blood has been shown to be as effective as, and possibly safer than, traditional bone marrow transplant in children with SCD. The use of nonmyeloablative conditioning regimens induce mixed chimerism in transplant recipients, resulting in decreased complications of allogeneic hematopoietic stem cell transplant in adults.

Gene Therapy

Although allogeneic bone marrow transplant can cure SCD, its widespread use is limited by the availability of suitable donors and by the complication of GVHD. Gene therapy is an alternative approach to achieve a cure of SCD. In simple terms, gene therapy is the introduction of normal genes into abnormal cells, either in vitro or in vivo. One potential approach to
cure SS is to introduce a functional $\beta^A$-globin gene into hematopoietic stem cells of the affected individual to replace the abnormal $\beta^S$-globin gene.\textsuperscript{393} Methods to achieve this goal include the following:

- Targeted insertion of the transferred gene into the endogenous globin locus by homologous recombination such that the transferred $\beta^A$-globin gene is located in the proper chromosomal environment and expressed at the same level as endogenous $\beta$-globin. This would be the ideal approach, but it is not yet feasible in hematopoietic stem cells.
- Chimeraplasty or gene repair, which introduces chimeric oligonucleotides composed of DNA and modified RNA residues into stem cells to direct correction of the mutation in the $\beta^S$ gene\textsuperscript{394}
- Transfer of normal $\beta^A$-globin gene into hematopoietic cells via retroviral vectors that have been modified such that they do not become infective

Recent years have witnessed significant progress in the third method mentioned earlier. Basically, this is stem cell gene transfer or autologous transplant, in which the patient’s own stem cells are harvested from the bone marrow or peripheral blood, genetically modified, and transplanted back into the patient. Genetic modification involves the use of vectors carrying $\gamma$-globin genes for SCD or $\beta$-globin genes for $\beta$-thalassemia. This approach has already been established in mice and was successful in a phase I/II study, with anticipated benefit for Hb disorders. Successful conversion of a patient with $\beta$-thalassemia major to transfusion independence has been reported.\textsuperscript{391,395–398}

Another novel gene therapy approach involves the use of somatic cells rather than stem cells to achieve a genetic cure. In this method, adult somatic cells are reprogrammed into induced pluripotent stem cells. Specifically, Hanna et al. produced pluripotent stem cells from skin fibroblasts of patients with SCD, corrected the mutation, and converted the cells in culture to hematopoietic stem cells that could be used for gene transfer as described earlier.\textsuperscript{391,399} Research on gene therapy methods applicable to SCD and to determine the most effective and safe method of altering genetic information in hematopoietic stem cells has advanced at a faster rate than expected, and gene therapy may soon be available for
clinical trials in selected patients with SS.

**Conclusion**

SCD is an inherited disorder of Hb structure that has no established cure in adults at the present. Cure has been achieved in selected patients with bone marrow/stem cell/cord blood transplantation from HLA-matched donors in the majority of cases after myeloablative conditioning regimen.

SCD is almost synonymous with pain, and the VOC is the insignia and the number one cause of hospitalization. Advances in the pathophysiology of SCD focused on the sequence of events that occur between polymerization of deoxy of Hb S and vaso-occlusion. Adhesion of sickle RBCs to endothelial cells, cellular dehydration, inflammatory response, reperfusion injury, and tissue damage appear to be important pathophysiologic events that culminate in the perception of pain.

The VOC evolves along four phases: prodromal, initial, established, and resolving phases. Several clinical and laboratory changes occur during the VOC provided the findings are compared to well-established baseline data. The resolving VOC may culminate in a hypercoagulable state that could precipitate another VOC in some patients. Hospital readmission seems to occur within 1 week in about 16% of patients after discharge from the hospital. Serious and potentially fatal complications of SCD such as ACS and MOF occur within 3 or 4 days after the onset of a VOC. Other types of acute sickle pain include priapism, dactylitis, hepatic crisis, and splenic sequestration.

Although management of SS continues to be primarily palliative in nature, there have been promising preventative and curative approaches to therapy. Pain management should be individualized and coupled with the proper utilization of opioid and nonopioid analgesics in order to achieve adequate pain relief. Early recognition and treatment of organ failure minimizes morbidity and improves outcome. The use of HU decreases the morbidity and mortality of SCD. Cure is possible in selected children and young adults with bone marrow or cord blood transplantation. Future research seems to focus on refining the molecular and cellular approaches to therapy including gene therapy and mechanisms that prevent the
adhesion of sickle RBC to vascular endothelium.

On June 5, 1981, the Centers for Disease Control and Prevention (CDC) described five cases of a rare lung infection, Pneumocystis carinii along with other unusual opportunistic infection in previously healthy, young homosexual men, two of whom died by the time of publication. This was the first report of a disease that has become known as HIV/AIDS, tremendously impacting the health and economy of many countries around the world.

There are currently around 36.9 million people living with HIV around the world. With the development of antiretroviral combination therapy (ART), life expectancy has improved and the rates of opportunistic infections and malignancies have dramatically declined. However, despite medical advancements, this disease remains one of the most complex entities in the realm of human illness, with the potential of affecting any system of the human body.

Pain remains a common and difficult to manage symptom in HIV-infected patients, both early in the course of the disease as well as in the later stages. Resulting in psychological distress, decreased quality of life, and decreased functional ability, pain is one of the most significant causes of disability in HIV/AIDS. It can vary dramatically in presentation, with one individual sometimes experiencing multiple types of pain simultaneously. Furthermore, management is especially complicated in the setting of comorbid mental illness and substance abuse, both of which are more prevalent in the HIV population. Pain management therefore must be an essential part in the care of an HIV/AIDS patient.

This chapter focuses on pain syndromes afflicting the HIV/AIDS population with special focus on neurologic pain in these patients, along with regimens for pain management. Particular attention is also placed on higher risk populations.
Prevalence of Pain in HIV/AIDS

Pain has long been recognized as an important and disabling feature of HIV/AIDS. The development of combination therapy in the late 1990s has in many ways revolutionized the treatment of HIV, allowing patients to live long, relatively healthy lives. However, pain, estimated to affect 20% to 90% of those infected depending on the stage of the disease, remains a significant problem.6–8

Among HIV-positive individuals, studies suggest that 20% to 30% experience moderate- to severe-intensity pain.7,9 However, the etiology can be variable, including unrelated comorbid conditions, HIV infection and its associated illnesses as well as side effects of ART. Not surprisingly, poorly controlled pain is a risk factor for comorbid depression and poor compliance on ART.

One study conducted in the United Kingdom by Lawson et al.8 looked at more than 800 HIV-positive subjects in an outpatient setting, of whom 62.8% reported pain over the prior month. Of those subjects, 58% were otherwise asymptomatic (CDC category A) and 76% were on ART. Most experienced pain that day, with a median of two areas affected. However, up to 24% reported whole-body pain. Another multicenter study reported more than 300 individuals with HIV in an ambulatory setting and demonstrated prevalence of pain in 55% of subjects, 82% of whom rated the intensity at “severe–very severe.”10 Those reporting pain were more likely to have a lower CD4 count as well as comorbid medical problems. Notably, these findings are similar to those of several studies conducted in the pre-ART era, when AIDS was the inevitable outcome of HIV infection.11–12

The majority of the literature available focuses mainly on acute/subacute pain in HIV. However, as this population ages, chronic pain, defined as greater than 3 months duration, has become an important, although poorly studied, problem. Lawson et al.8 found the mean duration of pain in their subjects to be 3 years. Another prospective study conducted in Denmark in the pre-ART era found that lower extremities were the most common site of pain, followed by head, gastrointestinal (GI)
tract, and muscles/bones. Of those who suffered from pain for longer than 1 year, neuropathic pain was the predominant cause.

**Pain in Women with HIV/AIDS**

Multiple studies on the treatment of pain in HIV/AIDS have noted greater reported pain intensity among seropositive women than their male counterparts.\(^{11,13}\) Disproportionate undertreatment of pain is at least in part to blame. Breitbart et al.\(^{14}\) estimated that women were twice as likely to be undertreated as men. However, the cause for this difference is unknown. Physicians’ view of women as well as patient-specific factors, such as unwillingness to report pain, fear of addiction to pain medication, and wanting to be a “good patient” have all been considered.

In addition, several pain syndromes exist that are unique to women. Opportunistic infections and malignancies of the pelvic and genitourinary tract can be a significant cause of pain. HIV-infected women have a higher rate of gynecologic surgeries such hysterectomy for cervical neoplasia and resection of tuboovarian abscesses from pelvic inflammatory disease.\(^{15}\) Disorders of the menstrual cycle also occur. Heavy menses, or menorrhagia, seen in the setting of thrombocytopenia associated directly with HIV or secondary to ART such as indinavir, can be a significant cause of pain.\(^{16}\)

Certain disorders of aging, such as osteoporosis with secondary bone fractures, are also being seen with higher frequency in the HIV population, both from HIV-induced bone loss and long-term effects of ART.\(^{15,17}\) Although not restricted to the female gender, this risk becomes especially high in HIV-infected peri- and postmenopausal women.

**Pain in Children with HIV/AIDS**

Children infected with HIV also suffer from pain, with an estimated prevalence of 20% to 60%.\(^{18,19}\) Similar to adults, pain in children can be complex and related to the disease process itself, opportunistic infections or secondary to treatment. One large prospective cohort study of HIV-infected children found higher incidence of pain with female gender and
lower CD4 count. The most common, pain-specific diagnoses included candidiasis, varicella zoster infection, and sinusitis. Furthermore, several studies suggest that pain in children with HIV is associated with increased mortality. However, treating children is often complicated by reluctance by both physicians and parents to use strong analgesics as well as the challenges in quantitating pain in the younger ages.

**Specific Pain Syndromes in HIV/AIDS**

**GASTROINTESTINAL PAIN**
The GI tract is a common site of complications for the HIV/AIDS population. Opportunistic infections and HIV-related neoplasms are especially seen in patients that are either noncompliant or fail ART. When evaluating a patient with GI symptoms, the first step is to identify the level of immunodeficiency, including whether the patient is on ART or is treatment-naive. CD4 count is the best serologic marker for immune status. Those with CD4 less than 200 cells/mm$^3$ are at greatest risk for an opportunistic infection, with a further exponential increase at CD4 less than 100 cells/mm$^3$. Treating the underlying problem is the primary treatment goal, although analgesia is often required especially in the acute setting.

**OROPHARYNGEAL PAIN**
Oral and throat pain is a very commonly seen symptom in HIV. Candidiasis of the oral cavity, which often presents as white lesions or red patches, has been estimated to affect 50% to 95% of HIV-infected patients at some point in their disease course. It is one of the most common causes of oral pain, although can be asymptomatic. Oral candidiasis can also be one of the first signs of HIV infection and therefore warrants testing in a patient without a known immunodeficiency. Although most commonly caused by Candida albicans, other Candida species have been identified. Necrotizing periodontal diseases, such as necrotizing gingivitis and ulcerative periodontitis, are also strongly associated with HIV infection. Multiple viruses including Herpes simplex (HSV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), invasive fungal
species, and bacteria have been implicated in some of these cases.

**ESOPHAGEAL PAIN**

Although esophageal symptoms are often unrelated to HIV disease, opportunistic disease can be seen including in patients on ART. One study evaluated seropositive patients undergoing endoscopy and found an opportunistic infection in 26% of subjects on highly active antiretroviral therapy (HAART), 48% of subjects on non-ART mono- or polytherapy (no protease inhibitor), and 80% of those not on any ART. In patients with upper GI symptoms (e.g., odynophagia, nausea, vomiting, hematemesis) with AIDS, an upper endoscopy results in a diagnosis in approximately 75% of patients. C. albicans is the most common infectious agent affecting the esophageal tract in HIV, followed by viruses (e.g., CMV esophagitis and duodenitis, HSV esophagitis).

Candida esophagitis is typically seen in the setting of a CD4 count less than 200 cells/mm$^3$, whereas Mycobacterium avium complex (MAC) is typically seen at when CD4 falls below 50 cells/mm$^3$. CMV, the most common agent causing viral esophagitis, occurs with CD4 below 100 cells/mm$^3$. Upper endoscopy is the standard of care for upper GI symptoms, and in patients where an opportunistic infection is suspected, aggressive tissue sampling and biopsy should be done. In CMV disease, for example, multiple biopsies may increase the likelihood of diagnosis. Kaposi sarcoma and lymphoma can also cause invasive disease of the esophagus, resulting in dysphagia, pain, and ulceration.

**ABDOMINAL PAIN**

Abdominal pain is another common site of pain in the HIV/AIDS population and in many cases may be associated with diarrhea. Prevalence among AIDS patients has been estimated to be 12% to 20%. In addition to the common causes of abdominal pain in non-HIV patients, inflammation and direct mucosal invasion by HIV, opportunistic infections, and neoplasms are all potential causes to consider when evaluating an HIV patient. The risk of opportunistic infections and neoplasms is related to the level of immunosuppression. For patients with CD4 count less than 100 cells/mm$^3$, for example, pathogens to consider
include CMV, Cryptosporidium, and Microsporidium. \(^{20}\) Colitis secondary to MAC infection, seen with CD4 less than 100 cells/mm\(^3\), is increasingly rare in the ART era. This entity is mostly seen in patients that first present with late-stage HIV.\(^{33}\)

CMV is the most common opportunistic pathogen of the bowel, with abdominal pain often being the primary presenting symptom. In addition, small and large bowel perforation has been described with CMV ileitis.\(^{34}\) Furthermore, with patients being on ART and various prophylactic antimicrobial agents, drug-induced side effects and Clostridium difficile colitis must also be considered. Lymphoma of the GI tract can also present with abdominal pain potentially leading to intestinal obstruction or perforation. Diffuse large B-cell lymphoma (DLBCL) and mucosa-associated lymphoid tissue (MALT) lymphoma are the most common subtypes of GI lymphomas.\(^{35}\)

Pancreatitis is another potential cause of abdominal pain. Acute pancreatitis, often presenting with severe epigastric pain, nausea, vomiting, and fever, has an estimated yearly incidence of 0.6% to 15% in HIV-infected individuals.\(^{36,37}\) Medication-induced pancreatic toxicity is considered the most common cause and has been well described with various agents including but not limited to nucleoside analogues, pentamidine, nonnucleoside reverse transcriptase inhibitors (NNRTIs) and protease inhibitors (PIs).\(^{38}\) Furthermore, hypertriglyceridemia secondary to ART is associated with pancreatitis. Identification and discontinuation of the offending agent is critical. Treatment is otherwise supportive. Multiple opportunistic infections have also been implicated, usually in the setting of disseminated infection. These agents include CMV, MAC, Cryptococcus, Mycobacterium tuberculosis, and toxoplasmosis.\(^{39}\) However, their incidence in causing pancreatitis is unclear given that many of these patients have also had exposure to pancreotoxic agents. In addition, pancreatitis has also been described as part of primary HIV infection with multisystem involvement.\(^{40}\) Comorbid conditions such as alcohol abuse should also be considered.

Hepatobiliary symptoms, including right upper quadrant pain, are other common sites of pain. Opportunistic infections can be responsible for these cases, typically with CD4 count less than 50 cells/mm\(^3\), suggesting
this is part of a systemic disseminated disease process, with MAC being the mostly frequently seen pathogen.\textsuperscript{33} One study reporting liver biopsies and autopsies in AIDS patients with liver disease found 38\% of specimens testing positive for MAC.\textsuperscript{41} Hepatic tuberculosis can occur earlier in the disease course. CMV and cryptosporidial infections have also been described as causes of cholecystitis and secondary sclerosing cholangitis.\textsuperscript{42} Drug-induced liver injury (DILI) is also a common adverse effect of ART and antituberculous drugs, including but not limited to efavirenz, pyrazinamide, and isoniazid.\textsuperscript{43} It is estimated that 8\% to 23\% of patients on HAART will develop DILI.\textsuperscript{44,45}

\textbf{ANORECTAL}

It is estimated that up to 30\% of HIV-infected patients experience anorectal symptoms during the course of their illness.\textsuperscript{46} Pain is the most common presenting symptom, affecting more than 50\% of individuals.\textsuperscript{47,48} Other common symptoms include rectal bleeding, discharge, and pruritus. Anorectal ulcers are a common cause of pain. Although most commonly idiopathic, malignancy and infectious causes including HSV, CMV, mycobacteria, and syphilis must be ruled out. It is also important to note that other sexually transmitted diseases can present in the anorectal region especially in homosexual individuals, including gonorrhea, chlamydia, and M. tuberculosis especially in cases of nonhealing ulcers. Perirectal abscesses are also common, typically presenting with fever and pain, and generally require surgical drainage.

Anorectal malignancy is also a major concern in HIV patients. Anal squamous intraepithelial lesions have a very high rate of occurrence in HIV-infected men that practice anal intercourse and can progress into anal cancer, although rate of progression is unknown. Risk factors include HPV subtypes 16 and 18, perirectal HSV, low CD4 count, and cigarette smoking.\textsuperscript{46} Lymphoma and disseminated Kaposi sarcoma can also present as perianal lesions.

\textbf{Chest Pain Syndromes}

Chest pain is another complaint seen among HIV-infected patients, with
estimated occurrence of 13% in one outpatient based study.\textsuperscript{31} Multiple potential etiologies include but are not limited to cardiac, pulmonary, mediastinal, and esophageal. The latter is discussed in the section entitled “Gastrointestinal Pain.”

**CARDIAC PAIN**

Multiple studies have suggested that HIV-infected patients are at risk of early coronary artery disease (CAD), although the exact relationship is not fully understood. Hyperlipidemia and insulin resistance secondary to PIs are significant contributors, although necropsy studies prior to use of these agents also showed high rates of early CAD.\textsuperscript{49–52} Presentation of CAD may potentially differ in HIV-infected patients compared to noninfected individuals, with one study suggesting pain being a less prominent symptom in HIV patients.\textsuperscript{53}

**PULMONARY/PLEURITIC PAIN**

Pulmonary infections are another important entity, typically presenting with fever, chills, cough, and occasionally pleuritic chest pain. Bacterial pneumonia is up to 25 times more common in HIV-infected patients, with the median CD4 count in affected patients being 200 cells/\text{mm}^3.\textsuperscript{54} Recurrent bacterial pneumonias is considered an AIDS-defining illness. Streptococcus pneumoniae is the most common pathogen in both HIV-positive and HIV-negative individuals in the community, followed by Haemophilus influenzae and Staphylococcus aureus. Other, less common infectious agents include Nocardia asteroides and Legionella. Pneumocystis pneumonia, another AIDS-defining illness, can be associated with pneumothorax.

Malignancies can also be a source of pleuritic pain. Primary lung cancer is a leading cause of cancer death in HIV-positive patients. Although there is a higher rate of cigarette use among this population, HIV is considered an independent risk factor for lung cancer for unclear mechanisms.\textsuperscript{55} In addition, opportunistic malignancies such as Kaposi sarcoma and lymphoma can involve pain. Furthermore, HIV is considered a prothrombotic state especially in advanced disease states, with a higher rate of pulmonary embolism than the general population.\textsuperscript{56}
CHEST WALL PAIN
Osteomyelitis of the chest wall is a rare entity, with S. aureus and Pseudomonas aeruginosa being the most common infectious agents. Tuberculosis can also cause abscesses within the chest wall, constituting up to 5% of musculoskeletal cases of tuberculosis. Lymphoma, especially non-Hodgkin type, has also been known to present within the chest wall.

Musculoskeletal Pain
ARTHROPATHY
Arthralgia, including pain and stiffness of the joints, is a common symptom reported by HIV patients. It most commonly affects the knee, elbow, and shoulder and occurs intermittently. Studies have shown variable prevalence, and it remains unclear whether its presentation differs from that in the general population.

HIV-associated arthritis is a controversial disease entity that has been described in advanced HIV since 1988, with a reported prevalence between 0.4% and 13.8%. According to one study, it manifests as an acute-onset, large-joint arthritis, lasting less than 6 weeks, without radiologic changes, in individuals that are HLA-B27–negative and do not fit any other known rheumatologic or infectious arthritis. Assuming its existence, this condition is self-limiting and responds to oral anti-inflammatory agents and intra-articular steroid injection.

Reactive arthritis triggered by multiple infectious agents, most commonly sexually transmitted diseases, is also seen among HIV patients. Reiter’s syndrome, involving the triad of arthritis, urethritis, and conjunctivitis, has been described in association with the HIV itself, although studies have not clearly demonstrated an increased prevalence of this condition compared to the general population. A wide range of inflammatory arthropathies such as psoriatic arthritis and rheumatoid arthritis (RA) can also be seen in HIV patients. Pre-ART studies suggest that remission or improvement of RA may occur in the setting of HIV, presumably secondary to CD4+ helper lymphocyte depletion. However, more recent research has demonstrated that both conditions can
exist simultaneously.\textsuperscript{67}

Management of autoimmune arthritis in this population depends on the disease severity and level of immunosuppression. Most mild cases do well with oral, nonsteroidal anti-inflammatory medications (NSAIDs). Moderate-severity arthritis often responds better to intra-articular steroid injection. In severe cases, oral steroids and disease-modifying therapies such as hydroxychloroquine and methotrexate have been used safely in patients on ART, with close monitoring of their CD4 count and viral load.\textsuperscript{59,68,69}

Septic arthritis is uncommon in the HIV population, with an estimated prevalence of 1\% in one study, although appears to be more frequent in developing countries and among IV drug users.\textsuperscript{59,67} Staphylococcus aureus and Streptococcus pneumoniae are the two most common infectious agents, most often involving the knees.\textsuperscript{70,71} There is a poor correlation between CD4 count and septic joints secondary to these typical bacterial infections.\textsuperscript{70} However, opportunistic infections of the joints, such as atypical mycobacteria and fungal infections including Candida and Nocardia, typically occur in individuals with CD4 count less than 100/mm\textsuperscript{3}.

**OSTEOPOROSIS**

Osteoporosis and osteopenia also have an increased prevalence in the HIV population, making these individuals at higher risk of bone fractures. ART, specifically PIs are largely responsible for this.\textsuperscript{72} Furthermore, HIV itself may play a role as well as comorbidities commonly seen with HIV including hypogonadism, liver disease, kidney disease, and malnutrition.\textsuperscript{72,73}

**Neurologic Manifestations**

**PERIPHERAL NEUROPATHY**

Peripheral neuropathy (PN) is the most common neurologic complaint in HIV patients. Although studies have shown significant variability, PN is thought to affect between 30\% to 60\% of infected individuals.\textsuperscript{74,75} Although most frequently seen in older patients with later stages of illness,
this condition is known to affect all stages of HIV. Furthermore, with the development of ART, patients are living longer lives, and as a result, the prevalence of this condition is increasing.\textsuperscript{76} PN is thought to be influenced by several factors, including the HIV itself, the neurotoxic effect of the ART, as well as other comorbidities. Multiple types of neuropathy can occur, and here, we address the ones that have pain as a major symptom. Table 58.1 outlines many of these conditions.

DISTAL SYMMETRIC POLYNEUROPATHY

Distal symmetric polyneuropathy (DSP) is the most common type of polyneuropathy afflicting the HIV population. It is a predominantly sensory axonopathy that typically presents with symptoms including numbness, paresthesia, and burning-type pain. It progresses in a “stocking-glove” distribution, first in the soles of the feet and ascending up the body to later involve the hands. These individuals often also experience allodynia, sensation of pain to ordinarily nonpainful stimuli and hyperesthesia, and increased skin sensitivity. It is estimated to affect up to 35% of patients with HIV, many of whom are asymptomatic. Studies have suggested that almost all HIV-infected patients at autopsy have pathologic evidence of peripheral neuropathy.

Neurologic testing usually reveals diminished or absent ankle reflexes, increased vibratory threshold, and decreased sensation to pain and temperature. Proprioception is typically preserved until later in the disease course. Muscle weakness can also manifest in advanced stages. Electrodiagnostic studies may be useful in diagnosing this condition. Findings typically demonstrate symmetrical sensory and motor axonal damage despite predominantly sensory symptoms. Skin biopsy can also be helpful, demonstrating loss of epidermal nerve fibers that may correlate with clinical and electrodiagnostic severity of DSP as demonstrated by Zhou and colleagues.

The risk and severity of DSP is associated with high HIV viral load, although it can be found in the setting of undetectable viral load. The underlying pathogenesis of DSP from HIV infection is not fully
understood. However, it is felt to be an indirect, immune-mediated process. Neuronal damage in DSP occurs from the production of neurotoxic, proinflammatory agents including free radicals and cytokines such as tumor necrosis factor alpha (TNF-α), interleukin (IL) 1, and IL-6.\textsuperscript{80,81} Macrophage and lymphocyte infiltration along with presence of these cytokines has been found in dorsal root ganglia of AIDS patients. Plasma levels of TNF-α and IL-6 are higher in HIV-1–infected individuals.\textsuperscript{82}

ART may help to prevent this neurotoxic process, likely via indirect immune-mediated mechanisms. However, several of the commonly used agents, including nucleoside reverse transcriptase inhibitors (NRTI) and PI are felt to have neurotoxic effects that also increase the risk of neuropathy. Two studies estimated the prevalence of ART-induced neuropathy in 8% and 16% of patients, although there is significant variability.\textsuperscript{83,84} It can often be difficult to differentiate drug-induced from HIV-associated neuropathy. However, the primary feature that appears to distinguish the drug-induced form is the rapidly progressive course, with onset often within a few weeks of starting the medication and improvement after its discontinuation. It has been suggested that the greatest risk of developed ART-induced PN is within the first few months of starting the medication.\textsuperscript{75}

**TREATMENT OF HIV-ASSOCIATED SENSORY NEUROPATHY**

Current guidelines on treating neuropathic pain, such as those by American Academy of Neurology, focus on other forms of PN, such as diabetic and postherpetic neuropathy, and therefore may not be equally applicable to HIV. Many classes of drugs, including antidepressants, antiepileptics, oral analgesics, and topical agents, have been used and studied in treating this disabling condition, while only targeting positive symptoms such as paresthesias and pain. Research has also mostly focused on symptomatic relief, not disease modification. One meta-analysis conducted by Phillips and colleagues\textsuperscript{85} looked at 14 prospective, double-blind, randomized controlled trials studying 10 different pharmacologic therapies in HIV-related sensory neuropathy. Only 3 showed superiority
over placebo, including high-dose topical capsaicin, smoked cannabis, and recombinant human nerve growth factor (rhNGF). The other agents such as amitriptyline, mexiletine, gabapentin, pregabalin, lamotrigine, and low-dose capsaicin cream did not show any significant benefit over placebo. Please refer to the treatment section for additional information on these agents.

INFLAMMATORY Demyelinating Polyneuropathy

Since the 1980s, an association between HIV and inflammatory demyelinating polyneuropathy (IDP) has been recognized. It can occur at any point in the HIV disease course and can take on the form of acute inflammatory demyelinating polyneuropathy (AIDP), also known as Guillain-Barré syndrome, or the chronic form (chronic inflammatory demyelinating polyneuropathy [CIDP]). Presentation is often similar to those not infected by HIV. AIDP is typically monophasic with recovery occurring around 3 to 4 weeks and has been more commonly described during seroconversion, often with CD4 >200. CIDP has a course of greater than 8 weeks. Clinical features include progressive, ascending weakness of the extremities with areflexia on exam and relative sparing of sensation. In addition, more than 80% of patients complain of moderate to severe pain, most commonly describing a deep, aching pain of the back or legs and dysesthesias of the extremities.

The pathophysiology of IDP in early HIV cases is likely immune-mediated, as opposed to AIDS patients in whom opportunistic viral infections (such as CMV) may be the cause. Electrodiagnostic studies typically show a primary demyelinating neuropathy, with evidence of axonal loss in cases of CIDP. Cerebrospinal fluid (CSF) analysis is not as reliable in diagnosing IDP in HIV patients with high CD4 count as it is in the non-HIV population. CSF studies in HIV-negative patients with IDP typically show albuminocytologic dissociation including high protein without pleocytosis. High protein and mild lymphocytic pleocytosis can also be found in asymptomatic HIV-positive patients with high CD4 count. Treatment in early HIV is similar to non-HIV patients, including
immunomodulating therapy such as intravenous immunoglobulin (IVIG), plasmapheresis, and corticosteroids but with caution due to their associated immunosuppressant effects. Antiviral therapy targeting CMV is used in AIDS patients with advanced immune compromise, especially when virologic studies or nerve biopsy indicate evidence of CMV infection.

**MONONEURITIS MULTIPLEX**

Mononeuritis multiplex (MM) typically manifests as asymmetric and multifocal peripheral neuropathies that can involve motor and sensory disturbances. Pain is also a common symptom, often described as a deep, aching pain; however, burning pain and allodynia in affected regions can also be seen.

Similar to IDP, MM can also occur anywhere in the HIV disease process. Cases early on are also likely immune-mediated, with a milder and often self-limiting course. In late-stage HIV, an opportunistic infectious process is the likely cause, often with a worse prognosis. CMV infection of nerve fibers has been well established as a potential cause of MM in AIDS. HIV or coinfected hepatitis C–related vasculitis is also a potential cause of MM. Electrodiagnostic studies typically show multifocal axonal neuropathy.

**PROGRESSIVE POLYRADICULOPATHY**

Progressive polyradiculopathy (PP) typically occurs in advanced stages of HIV/AIDS and has a severe and rapidly progressive course. Presentation can resemble cauda equina syndrome, involving radicular pain, flaccid paraplegia, sensory changes, sphincter dysfunction, and areflexia. Magnetic resonance imaging (MRI) with contrast is a helpful diagnostic study, both to rule out a compressive lesion as well as looking for signal changes/contrast enhancement of the lumbosacral roots. CSF testing typically reveals a pleocytosis and positive CMV polymerase chain reaction (PCR) confirming the infection. Electrodiagnostic studies are also useful in supporting a polyradicular process. Due to risk of irreversible damage from root necrosis, early antiviral therapy for CMV is crucial, including agents such as ganciclovir and foscarnet.
INFLAMMATORY MYOPATHIES
HIV-associated polymyositis is the most common myopathy associated with HIV infection. Presentation is similar to that in noninfected patients, including a slowly progressive course affecting predominantly proximal muscles in a symmetrical distribution. Muscle pain in affected muscles is common. Diagnostic criteria include muscle weakness, elevated creatine kinase (CK), and evidence of myopathy on electrodiagnostic studies and muscle biopsy. Although no treatment guidelines have been established, immunomodulatory therapy including corticosteroids and IVIG has been successfully used. Mechanisms by which HIV leads to inflammatory myopathy are unclear. However, a T cell–mediated process has been proposed. A similar myopathy has also been described with immune reconstitution inflammatory syndrome (IRIS) as well as a potential side effect of zidovudine (ZDV).

There have been various other myopathies seen in the setting of HIV, including pyomyositis secondary to opportunistic infections in AIDS patients, such as S. aureus. Dermatomyositis and inclusion body myositis have also been described.

Headache
Headache is a very common symptom in the HIV population, affecting potentially up to 38% to 61% of individuals, especially in advanced stages of illness. Etiology can vary widely. From benign migraine or tension headache to a life-threatening intracranial infection or malignancy, headaches can be a diagnostic dilemma for the treating physician.

PRIMARY HEADACHES
Migraine and tension-type headaches are the most common primary headaches seen in the HIV population. Few studies have looked into the rates of primary headache phenotypes in this population and whether ART plays a role. Kirkland et al. conducted one of the few large, postART studies characterizing headaches in the HIV/AIDS population, the majority of whom were on combination therapy. The overwhelming majority had primary headaches, most commonly migraines, with only
2.8% secondary to opportunistic encephalic infection. A significant inverse relationship was found between CD4 count and headache frequency, severity, and associated level of disability. Notably, there was no relationship with duration of HIV infection.

Commonly used migraine therapies are summarized in Table 58.2, including both preventative and abortive regimens. Opiates are not recommended for the use of aborting primary headaches due to poor efficacy and risk of medication overuse headache (MOH), especially in those with comorbid substance abuse problems. When choosing a regimen, comorbidities and other medications (including ART) must be considered. For example, ergotamines (such as dihydroergotamine) are contraindicated in patients taking PIs and NNRTIs due to risk of psychosis, seizures, and gangrene and are therefore are not typically used in the HIV population.

* BID, twice a day; FDA, U.S. Food and Drug Administration; GI, gastrointestinal; G6PD, glucose-6-phosphate dehydrogenase; SIADH, syndrome of inappropriate antidiuretic hormone secretion; TIA, transient ischemic attack.

*a* Short-term prophylaxis preceding known migraine triggers (such as menstrual migraine).

*b* Should be taken within 2 hours of migraine onset, and all abortive therapy should be limited to 3 days per week to avoid medication overuse headache.

*c* Avoid with protease inhibitors and nonnucleoside reverse-transcriptase inhibitors.

## SECONDARY HEADACHES

HIV is able to easily cross the blood–brain barrier, allowing central nervous system (CNS) manifestation to occur at all stages of illness.
Headache may be part of the prodromal illness of the primary infection of HIV-1, usually occurring 2 to 4 weeks after exposure, often described as a dull, bilateral ache.\textsuperscript{92,96} Aseptic meningitis, characterized by fever, meningismus, and cranial neuropathies, can also occur with primary infection, usually self-limited but with the potential to recur at a later time.

The onset of headaches in a known HIV-infected patient warrants workup to rule out a wide range of secondary, opportunistic causes, especially with more advanced stages of illness even in the absence of focal neurologic deficits.

In the United States and other developed countries, the most common, focal infectious lesions in advanced disease include toxoplasmosis and progressive multifocal leukoencephalopathy (PML), caused by the John Cunningham (JC) virus.\textsuperscript{97} The former often presents as focal granulomas or abscesses within the parenchyma, although leptomeningeal processes can also occur. The latter presents as focal, at times confluent lesions within the white matter. Focal neurologic deficits are common; however, presentations can be vague, with indolent headache as the primary feature. CMV, another opportunistic agent affecting those with advanced AIDS, typically causes diffuse encephalitis. Cryptococcus is the most common agent causing meningitis, often presenting with headache and confusion without overt meningismus.\textsuperscript{98} Neurosyphilis can be variable in presentation, including meningeal spread, focal lesions in the parenchyma, or extracranial causing cranial neuropathies.

Opportunistic malignancies can also occur, most commonly primary CNS lymphoma. However, metastatic, systemic lymphoma, and intracranial Kaposi sarcoma can present as focal parenchymal lesions, often causing constitutional symptoms as well as symptoms of increased intracranial pressure including headache, nausea, and vomiting.

Any HIV patient with new onset headaches, independent of age or CD4 count, warrants radiologic imaging, preferably MRI over computed topography due to higher sensitivity and better visualization of the posterior fossa. Additional workup often includes lumbar puncture. Brain biopsy may be necessary in certain cases for a definitive diagnosis.

Treatment of pain in secondary headaches focuses on treating the underlying condition. However, in cases of refractory or prolonged pain
despite treatment of the underlying condition, many of the abortive therapies used for primary headaches may be used (see Table 58.2). Opiates can also be considered in the acute setting for severe, refractory pain due to a secondary headache. Preventative agents used for migraines may also be used for chronic pain. Steroids should also be used with caution due to potential of worsening immunosuppression.

Management of Pain

EVALUATION GUIDELINES
When evaluating an HIV patient for pain, a clinician must have a working knowledge of the various etiologies and treatment options of pain in this population, including those discussed in this chapter. A comprehensive assessment includes a detailed history and physical examination, as well as a clinical measurement tools to quantify and describe the pain being experienced.

A standard pain history should include intensity, quality, location, temporal pattern, and response to any previously used analgesics. The pain history as well as the ability to categorize the pain experienced based on its pathophysiology can provide significant clues regarding the underlying etiology and assist in choosing an appropriate treatment regimen. Pain assessment should be repeated at every clinical encounter. In addition, a complete medical and psychosocial assessment, including any psychiatric and substance abuse comorbidities, must be completed and readdressed during the course of treatment. It may be appropriate to involve family members and significant others in treatment planning.

PAIN MEASUREMENT/ASSESSMENT TOOLS
Given that pain is a subjective symptom, self-reporting is the standard of care. Many assessment tools, based on the patient’s own perception of the pain, have been developed that allow a practitioner to monitor pain over time using a validated scale. Two commonly used tools are the Numerical Rating Scale, where pain is rated from 0 to 10, and the Visual Analog Scale (VAS), both of which address pain intensity. Wong-Baker FACES pain scale is an alternative intensity scale that can be used in
children. The Brief Pain Inventory (BPI)\textsuperscript{100} is a commonly used tool in cancer and AIDS-associated pain, addressing both pain intensity and interference, including the effect of pain on seven domains of functioning. It has also been validated in many languages. The Short-Form McGill Pain Questionnaire\textsuperscript{101} is another validated questionnaire, which addresses 15 sensory and affective pain descriptors and may be useful in determining medication effect on various pain qualities. For patients that are unable to communicate verbally, the Behavioral Pain Scale\textsuperscript{102} can be useful.

**MULTIMODAL TREATMENT APPROACH**

Although medication is the primary approach in treating chronic pain, the optimal treatment in this complicated population is multimodal, incorporating psychotherapy, cognitive-behavioral therapy, rehabilitation, and other nonpharmacologic therapies.

**PHARMACOLOGIC TREATMENT**

When choosing a pharmacologic approach, it is important to classify pain as being either nociceptive or neuropathic (Fig. 58.1). Nociceptors are receptors that respond to potentially tissue damaging stimuli by signaling to the CNS, resulting in the perception of pain. Nociception can be augmented by various substances, including proinflammatory cytokines and prostanoids; however, a stimulus is needed to produce the sensation of pain, whether it be thermal, mechanical, or chemical.\textsuperscript{103} Neuropathic pain results from damage of the peripheral or CNS, resulting in transmission abnormalities even in the absence of additional damaging stimuli. Chronic neuropathic pain is felt to be secondary to aberrant signaling after the nervous system is reorganized after an injury.\textsuperscript{103} Pharmacotherapy works to reduce the noxious stimulus and/or dampen pain transmission through the nervous system.
Few pain management guidelines have been developed to specifically target the HIV population. Treatment approaches have been adapted primarily based on published guidelines for cancer pain and nonmalignant chronic pain. Newshan and Staats\textsuperscript{99} conducted a literature review with a proposed set of guidelines on the use of various pharmacologic and nonpharmacologic interventions in HIV pain. Among agents likely to be effective include acetaminophen, NSAIDs, and short-term opioids. Chronic opioid use is not recommended both due to poor evidence for long-term efficacy as well as safety concerns.

World Health Organization (WHO) guidelines on treating cancer pain at the end of life have also been widely used, especially for individuals in the terminal stages of HIV infection. Initially developed in 1986 and updated a decade later, these guidelines provide a comprehensive, stepwise approach with a three-step ladder based on pain intensity (Fig. 58.2). Step 1, in the setting of mild pain, suggests the use of acetaminophen or NSAIDs. Step 2, consisting of persistent and moderate-intensity pain, recommends a weak opioid agent, such as codeine or tramadol, to be added to the step 1 regimen. Step 3, in the setting of persistent, severe pain, involves treatment with a strong opioid such as morphine or hydromorphone in combination with nonopioid therapy. The guideline suggests administering the
medication at regular intervals as opposed to on an as-needed basis. Adjuvant agents such as stimulants and laxatives may be used to prevent and treat side effects of opioid analgesics. In addition, antidepressants and anticonvulsants are recommended as adjuvant agents especially in cases of neuropathic pain. For long-term pain control in nonterminal patients, this approach is not recommended due to potential long-term risks of opiate use. Other guidelines such as those published by the American Pain Society have also been applied in the setting of pain in HIV. Table 58.3 lists many of these agents, including dosing approach and side effects/risks.

### Adjuvant Agents

#### Antidepressants

**Tricyclic antidepressants (TCAs)**
- **Amitriptyline**
  - Starting dose: 25 mg QHS (10 mg daily if >65 y old); titrate up by 25 mg
  - Maximum dose: 100 mg daily
  - Sedation, cardiac arrhythmia, anticholinergic side effects (constipation, blurred vision, urinary retention), cognitive dysfunction, extrapyramidal symptoms, narrow-angle glaucoma
- **Nortriptyline**
  - Starting dose: 25 mg QHS (10 mg daily if >65 y old); titrate up by 25 mg
  - Maximum dose: 75–100 mg daily
- **Venlafaxine**
  - Maintenance dose: 75–225 mg daily
  - Insomnia, drowsiness, anxiety, dizziness, nausea, sexual dysfunction, anorexia, hypertension, tachycardia, SIADH
- **Duloxetine**
  - Starting dose: 30–60 mg daily
  - Maintenance dose: 60 mg daily
- **Gabapentin**
  - Starting dose: 300 mg daily (often divided into TID dosing); may be slowly titrated up
  - Maximum dose: 3,600 mg daily
  - Dizziness, drowsiness, weight gain, leukopenia

Elderly, mood disorders as may increase suicidality, cardiovascular disease, seizure disorders, renal impairment

FDA box warning—risk of suicidality with antidepressants

Elderly, with other serotonergic drugs, seizure disorders, renal impairment

FDA box warning—risk of suicidality with antidepressants

Renal dysfunction
- **Pregabalin**  
Starting dose: 150 mg daily (often divided into BID dosing); may be titrated up weekly  
Maximum dose: 300 mg (150 mg BID)  
Agitation, suicidality, personality changes, sedation  
Depression, behavioral disorders

- **Lamotrigine**  
Starting dose: 50 mg daily; may increase dose weekly by 50 mg/d (for BID dosing)  
Maintenance dose: 200–400 mg daily (100–200 mg BID)  
Drowsiness, dizziness, ataxia, Stevens-Johnson syndrome  
Liver dysfunction

BID, twice a day; FDA, U.S. Food and Drug Administration; G6PD, glucose-6-phosphate dehydrogenase; QHS, every bedtime; QID; four times a day; SIADH, syndrome of inappropriate antidiuretic hormone secretion; TID, three times a day.
**Acetaminophen**

Acetaminophen is often considered a first-line agent for pain and is the most commonly used analgesic in the world.\(^{105}\) WHO guidelines recommend it as a first-line agent in a wide variety of mild to moderate pain conditions. In addition to having a favorable side effect profile, its efficacy is comparable to that of NSAIDs.\(^{106}\) U.S. Food and Drug Administration (FDA) recommends a maximum daily dose of 4 g per day. However, according to the American Geriatrics Society, the maximum daily dosing recommended for chronic acetaminophen use is 3 g per day due to concern of liver toxicity. Caution should be taken in patients with severe renal disease, liver disease, and/or regular alcohol use. Although FDA guidelines list severe hepatic impairment as a contraindication to its use, one review by Chandok and Watt\(^ {107}\) suggests that 2 g per day or less is a safe option in patients with cirrhosis. Long-term data is unfortunately not available.

**Nonsteroidal Anti-inflammatory Drugs**

NSAIDs are another commonly used group of agents in the treatment of mild to moderate pain, providing analgesia, anti-inflammation, and antipyresis. Their primary mechanism is the inhibition of prostaglandin formation through the blockade of cyclooxygenase in the periphery. Concerning side effects include GI ulceration, cardiovascular toxicity, renal and hepatic dysfunction, and bleeding. Much of the data available on their efficacy have been focused on their use in musculoskeletal conditions. A Cochrane review found that NSAIDs were superior to acetaminophen for pain relief and improving function in osteoarthritis.\(^ {108}\) Another review reported that NSAIDs were effective in the short-term treatment of acute and chronic low back pain without sciatica.\(^ {109}\) Topical NSAIDs such as ibuprofen and diclofenac were also found to provide pain relief with less concern of systemic adverse events in patients with acute musculoskeletal pain. Caution should be taken when used in patients with bleeding diathesis as well as those with cardiac, renal, and GI comorbidities.

**Opioid Analgesics**
The use of opioids for the treatment of chronic pain among noncancer populations is controversial. The undertreatment of pain has been well documented in the medical literature, primarily due to fear of overdose and addiction, especially in a population with high rates of drug abuse. However, in patients with severe, disabling pain that is not responsive to other forms of therapy, opioids may be an effective treatment. Multiple, randomized controlled trials have shown good short-term efficacy (most <6 weeks) in decreasing pain and improving function in nociceptive and neuropathic chronic pain (defined as lasting greater than 3 months).\textsuperscript{110} However, little data exists for long-term effects of opioid use in individuals with chronic pain.\textsuperscript{111}

According to the 2016 CDC guidelines, nonopioid therapies are preferred. However, when used, opioids should be used in combined with nonpharmacologic and nonopioid therapy. When starting treatment, immediate-release formulations should be prescribed instead of extended release agents, at the lowest effective dose. Extra caution should be taken when prescribing total opioid doses of greater than or equal to 50 morphine milligram equivalent (MME) per day, and doses greater than 90 MME per day should be avoided. MME calculation method for various opiates in listed in Table 58.4. According to CDC guidelines, patients have at least 2 times greater risk of overdose at or above 50 MME per day compared to 20 MME per day. Benefits and risks should be assessed regularly, initially within 1 to 4 weeks of starting therapy followed by every 3 months or more frequently. Opioid regimens should be tapered or discontinued once benefits no longer outweigh the risks. Furthermore, urine drug testing is recommended prior to starting therapy followed by periodic testing. Informed consent should be obtained. “Pain agreement,” a written document given to the patient detailing the circumstances under which opioids will be prescribed as well as discontinued, have been proposed to help educate patients and minimize harm.\textsuperscript{112} However, there are insufficient data that this approach minimizes abuse. The most consistent risk factor for potential opioid abuse is a prior history of alcohol or drug abuse. Male sex, younger age, comorbid psychiatric illness, and history of sexual abuse have also been associated with higher levels of abuse.\textsuperscript{113–115}
Instructions for calculating total opioid MME per day
1. Take total daily dosage of each opioid agent used.
2. Multiple daily dosage of each opioid by conversion factor listed.
3. Add them together.

NOTE: These dose conversions are estimated and cannot account for all individual differences in genetics and pharmacokinetics.

Another concern for opioid use in the HIV population is the potential for drug–drug interactions with ART. Table 58.5 summarizes many of these interactions. By stimulating glucuronidation, ritonavir can increase morphine metabolism and provoke withdrawal. Ritonavir can also inhibit CYP2D6, which metabolizes oxycodone/long-acting OxyContin, resulting in higher blood levels. Therefore, patients may warrant lower oxycodone dosing to avoid toxicity in the setting of this ART. Methadone, which is used to treat opioid addiction as well as severe, chronic pain, has been found to interact with multiple ART agents. When combined with ZDV, methadone may increase ZDV levels, increasing the risk of toxicity. Methadone has also been found to decrease didanosine (ddI) and stavudine (d4T) levels. Although the exact mechanism of the latter effect is unclear, methadone-induced slowing of GI motility may be responsible. Enteric-coated ddI was found to have higher bioavailability.
than the tablet form in the presence of methadone and is therefore the preferred formulation. Nevirapine and efavirenz may also decrease methadone levels and precipitate withdrawal symptoms.

### Antidepressant Agents

Antidepressants are another class of medications that have long been used to treat numerous chronic pain syndromes. These include serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and selective serotonin reuptake inhibitors (SSRIs), among others, which are felt to affect pain pathways by multiple mechanisms. In addition to regulating serotonin and norepinephrine, both of which are critical in pathophysiology of chronic pain, they alter nociceptive pathways by potentiating monoaminergic activity and targeting various receptors in pain production such as adrenergic, histaminergic, and N-methyl-D-aspartate receptors. In addition, the onset of pain relief occurs both
faster and at lower doses than what is often required for the treatment of
depression, usually within a few days of initiating therapy.\textsuperscript{121} When used
to treat neuropathic pain, the rationale is derived from evidence in diabetic
and postherpetic neuralgia because few studies have looked directly at the
use of these agents in HIV-related neuropathy.

Although not FDA-approved for the treatment of chronic pain, TCAs
such as amitriptyline and nortriptyline have been widely used as first-line
agents in the treatment of chronic pain. Amitriptyline is effective in
treating a variety of neuropathic pain syndromes such as diabetic
neuropathy and postherpetic neuralgia.\textsuperscript{122,123} However, in HIV-related
neuropathic pain, it failed to show analgesic benefit.\textsuperscript{124,125} Similar
evidence exists for the use of nortriptyline, which has a more favorable
side effect profile, especially in the elderly, due to less anticholinergic and
sedative effects.\textsuperscript{126} In addition, TCAs have some benefit in other chronic
pain syndromes including headache of both tension and migraine origin,
low back pain, chronic pelvic pain, and fibromyalgia.\textsuperscript{126} Other TCAs such
as imipramine and desipramine have also been used. Of note, PIs such as
ritonavir can increase TCA blood levels and increase side effects and risk
of toxicity.\textsuperscript{116}

Duloxetine, an SNRI, is FDA-approved for chronic musculoskeletal
pain, fibromyalgia, and neuropathic pain due to diabetic polyneuropathy.
Studies to date have not looked at duloxetine for its use in HIV-related
neuropathy; however, data exist for its use in other forms of painful
peripheral neuropathy.\textsuperscript{121} Although few studies have compared it head to
head with other antidepressants, one study found equal if not greater
efficacy than amitriptyline in neuropathic pain.\textsuperscript{127} Venlafaxine, another
SNRI, has demonstrated analgesic benefit in the treatment of painful
peripheral neuropathy when used in higher doses (at least 150 mg per day)
with a better side effects profile compared to TCAs.\textsuperscript{128} In addition, these
agents have also been used successfully in migraine prevention.\textsuperscript{129}
However, in prevention of tension-like headaches, benefit has not been
demonstrated.\textsuperscript{130}

SSRIs have also been used in the treatment of pain, although evidence is
conflicting.\textsuperscript{131} One randomized study found fluoxetine to be inferior in its
ability to control neuropathic pain compared to TCAs but better
tolerated.\textsuperscript{132} No analgesic benefit has been shown in other etiologies of chronic pain, such as low back pain or arthritis.\textsuperscript{133} Furthermore, one meta-analysis showed no benefit of SSRIs over placebo at 2 months of treatment.\textsuperscript{134} Other antidepressants that have been studied for the treatment of chronic pain but failed to show efficacy include mirtazapine and trazodone.

Although antidepressants can be used alone, they are often used in combination with other analgesic agents such as opioids, in patients with moderate to severe pain. As adjuvant agents, they can increase the therapeutic value of opiates by decreasing the required dose and reducing side effects.\textsuperscript{135}

\textbf{Anticonvulsants}

Gabapentin has long been used as a first-line agent in treating neuropathic pain in a wide variety of conditions, with several studies in HIV-related distal sensory polyneuropathy (HIV-DSP). The mechanism of action of gabapentinoids in neuropathic pain is not entirely clear. Although a structural analogue of \(\gamma\)-aminobutyric acid (GABA), it is felt to exert its analgesic affect by interacting with \(\alpha_2\) voltage-gated calcium channel as well as inhibition of nociceptive transmission from damaged, peripheral nerves.\textsuperscript{136} One small study of 26 patients showed significant pain reduction and improved sleep with gabapentin in HIV-DSP.\textsuperscript{136}

Pregabalin, another gabapentinoid that exerts its effect on the voltage-gated \(\alpha_2\)-channel, is also commonly prescribed for neuropathic pain. Although efficacious in multiple other etiologies of neuropathic pain, little data support its use in HIV. Two large, multicenter randomized controlled trials looking at pregabalin in HIV-DSP, were conducted by the same group and failed to show a benefit in pain reduction over placebo, although in one study patients on pregabalin demonstrated less hyperalgesia.\textsuperscript{137,138} Furthermore, there was no significant improvement in sleep quality, an effect that has previously been demonstrated with pregabalin in other neuropathic pain states.

There are several studies of lamotrigine in neuropathic pain likely due to its sodium channel blocking effect. Efficacy has been demonstrated in multiple forms of neuropathic pain including trigeminal neuralgia, diabetic
neuropathy, complex regional pain syndrome, and poststroke pain. Pain relief has also been shown to be correlated with plasma concentration of lamotrigine in patients with trigeminal neuralgia. Two randomized studies, one small and one larger performed by the same group, studied lamotrigine in HIV-related neuropathy. Both showed a significant improvement in pain with lamotrigine compared to placebo. However, when the larger study sample was stratified based on exposure to neurotoxic ART, only the group receiving neurotoxic ARTs showed a benefit over placebo. However, lamotrigine has relatively little use in neuropathic pain, due in part to a complex titration schedule and concern of potentially serious allergic reaction including rash and Stevens-Johnson syndrome. Lamotrigine blood levels may also decrease in the setting of ritonavir/atazanavir and therefore require increased dosing.

**Topical Capsaicin**

Capsaicin, an active ingredient derived from chili peppers, has been studied as a topical therapeutic agent for various types of painful neuropathy. It acts as an agonist for the vanilloid receptor (TRPV1), a ligand-gated cation channel selectively expressed on small, nociceptive nerve fibers. Initial application results in immediate channel excitation, release of substance P and increase in pain perception, followed by the depletion of nociceptive neuropeptides and decrease in nociceptive fiber density leading to prolonged analgesia. One study successfully demonstrated a transient epidermal denervation using biopsy following the use of capsaicin in a human model. Multiple studies have been conducted looking at low-dose (up to 0.075%) topical capsaicin for a wide range of painful conditions such as postherpetic neuralgia and diabetic neuropathy, which have shown significant pain relief. Three large, randomized studies have been conducted using high-dose (8%, 640 µg/cm²) capsaicin patch in patients with HIV-DSP. Two of the studies found successful pain reduction 12 weeks posttreatment and good tolerability of the drug. The third study, however, did not find significant pain improvement compared to controls. Treatment-related pain was managed with topical lidocaine preceding patch application, along with local cooling and short-acting...
opioids as needed.

**Cannabinoids**
Due to the need for additional therapeutic options, exogenous cannabinoids have also emerged as a potential therapy for chronic neuropathic pain. Currently, 29 states, as well as the District of Colombia, Guam, and Puerto Rico, have medical marijuana and cannabis programs. Multiple studies in animal models have demonstrated efficacy of systemic cannabinoids in treating various types of pain such as thermal and mechanical pain.\(^{150,151}\) A study by Abrams et al.\(^ {152}\) randomized patients with painful HIV-DSP to smoking cannabis versus placebo for 5 days in an inpatient setting and found significant pain reduction in the cannabis group and specifically an antihyperalgesic effect. Another study looking at subjects with HIV-DSP refractory to two analgesics, similarly found improvement in pain intensity among subjects given cannabis versus placebo.\(^ {153}\) Although controversial and with significant legal hurdles, the evidence supporting the use of cannabinoids is promising. Furthermore, the high rate of comorbid substance abuse in the HIV population creates an additional level of complexity in considering these agents in affected patients.

**Recombinant Human Nerve Growth Factor**
NGF is a neurotrophic agent typically produced by damaged nerve fibers in the process in regeneration and is therefore a potential target in the treatment of neuropathic pain. McArthur and colleagues\(^ {154}\) studied rhNGF in the treatment of HIV-DSP and found an improvement in pain but no change in epidermal nerve fiber density to suggest nerve regeneration at 18 weeks. Hypothesizing that nerve regeneration may take longer than 18 weeks, the same group published results of the trial at 48 weeks. Once again, dose-dependent improvement in pain was demonstrated; however, no change in nerve fiber density was seen.\(^ {155}\)

**Combination Pharmacotherapy**
Combination therapy has become an increasingly common treatment strategy in treating neuropathic pain due to concerns of limited efficacy.
and dose-related side effects of individual agents. The rationale behind this approach includes additive or synergistic analgesia, using agents with different mechanisms of action to create better pain control, lower dose requirements, and greater tolerability.\textsuperscript{156} No studies to date have looked specifically at combination therapy in HIV-related neuropathy. In other forms of neuropathic pain, combination therapy has been demonstrated to provide better pain control, although no improvement in side effects was seen. Gabapentin and opiates, including prolonged-release oxycodone and sustained-release morphine, have been shown to be superior to individual therapy.\textsuperscript{157,158} Another study found that combination nortriptyline and gabapentin was more effective in controlling pain than either agent alone in patients with diabetic polyneuropathy and postherpetic neuralgia.\textsuperscript{156}

\textbf{NONPHARMACOLOGIC THERAPIES}

Self-management strategies such as physical activity, spending time with loved ones, and medication compliance as well as cognitive methods such as positive thinking and relaxation are all important techniques by which patients with chronic pain can work to improve their overall quality of life.\textsuperscript{159}

Alternative, nonpharmacologic therapies have also been investigated in the treatment of HIV-related pain, including cognitive-behavioral therapy, acupuncture, and hypnosis. Two studies looked at 12 weeks of cognitive-behavioral therapy among HIV patients with various chronic pain syndromes of moderate to severe intensity.\textsuperscript{160,161} Although limited by poor attendance to treatment groups, these studies found small improvements in pain at 12 and 24 weeks.

Two studies have looked at acupuncture for the treatment of HIV-DSP. One randomized placebo-controlled study looking at 250 patients found no benefit of acupuncture over placebo in pain control.\textsuperscript{124} However, a smaller, more recent study of 50 HIV patients treated with acupuncture and moxibustion (burning of mugwort leaf) versus placebo did demonstrate symptomatic improvement in neuropathic pain among the treatment group.\textsuperscript{162}

Hypnosis is useful in a variety of different pain syndromes.\textsuperscript{163} In addition to being safe, patients can be taught self-hypnosis to help manage
pain on a day-to-day basis. One small study in patients with HIV-DSP looking at three weekly sessions of hypnosis found improvement in pain levels, quality of life, and decreased depressive symptoms 7 weeks posttreatment. Although the available evidence is limited, these therapies may be a useful addition to the pharmacologic therapies offered to patients.

**UNDERTREATMENT OF PAIN**

Pain has long been recognized as an important cause of disability in patients living with HIV/AIDS, leading to psychological and physical stress as well as decreased quality of life. Unfortunately, undertreatment of pain has been a long-standing issue in this population, with multiple studies showing greater than 60% of HIV-positive individuals living with pain affecting their daily living. Individuals with higher levels of pain have higher levels of health care utilization, with one study showing a near linear relationship between pain and outpatient visits.  

Individuals with HIV/AIDS have a higher rate of psychiatric illness, with higher rates of depressive symptoms such as hopelessness, anhedonia, difficulty with sleep, and poor appetite as well as anxiety. Pain often exacerbates these psychiatric conditions and overall suffering. Individuals with comorbid major depression and chronic pain, when compared to those with major depression without chronic pain, have longer duration and more severe depressive symptoms as well as higher risk of suicidal ideation.

Multiple sociodemographic factors, including female gender, intravenous drug use, unemployment, and lower education, have also been associated with higher reported levels of pain. This raises concern regarding societal factors that may be barriers for receiving appropriate pain relief. Certain minority groups, such as Alaskan Natives, Native Americans, and Asian Americans, were found to also have lower health care utilization related to pain, possibly due to language and cultural barriers to pain treatment.

**BARRIERS TO PAIN MANAGEMENT**

Many barriers to effective pain treatment exist on the part of both
physicians and patients. Illicit drug use occurs at a higher rate among individuals with HIV/AIDS than the general population, which can affect a clinician’s perception and treatment of a patient’s pain syndrome. The fear of opioid addiction can be a barrier for both the clinician and the patient as well. Although estimates of opioid abuse among chronic pain patients have been variable depending on the definition, one systematic review suggested up to 20% to 30% rate of misuse and 8% to 12% rate of addiction.\textsuperscript{167} In individuals with a history of substance use, increased monitoring is warranted; however, pain relief should remain an important treatment priority.

One study surveyed close to 500 providers on the most important barriers in pain management in AIDS.\textsuperscript{168} Lack of knowledge about pain management, lack of access to pain specialists, and concern regarding abuse and addiction were the most commonly perceived barriers. Additional barriers include fear of medication side effects and limited access to drug treatment services. Another study looking at patient-specific barriers in a group of ambulatory AIDS patients found that the most commonly reported barriers included fear of side effects and physical discomfort of opiates as well as misconceptions about the concept of tolerance.\textsuperscript{169} Other common patient-specific barriers include wanting to minimize number of pills taken, preference for nonpharmacologic methods of pain management, not being able to afford to fill a prescription, and fear of family/friends thinking they are abusing opiates.\textsuperscript{170}

**Summary**

The development of ART has revolutionized the treatment of HIV, allowing individuals to live much longer, healthier lives. However, pain remains a significant issue, affecting the quality and daily functioning of the lives of these patients. Although many therapies are available for the treatment of pain in HIV-positive patients, efficacy is limited and additional HIV-specific research is necessary to determine the best treatment approaches. Furthermore, awareness and education about pain management for both patients and clinicians is crucial to overcome the many barriers that exist in treatment.

The Treatment of Chronic Pain in Patients with History of Substance Abuse

HO Wang A. HEIT and DOUGLAS L. GOURLAY

Chronic pain has no positive physiologic value, whereas acute pain is an adaptive, beneficial response necessary for the preservation of tissue integrity. Recurrent migraine headache, painful peripheral neuropathy, or metastatic bone cancer serves no useful physiologic purpose. In addition, pain remains the most common complaint presenting to the primary health care professional and should be treated in all populations. This is no less true in those persons suffering from an active or remote history of substance misuse disorder. A substance use disorder does not decrease the likelihood of a treatable pain condition, it simply complicates it.

The U.S. Census Bureau reported in 2016 that the nation’s population had reached ~323 million. Approximately 16% to 23% (~52 to 74 million) of the population suffers pain which is undertreated or not treated at all. In the third world, the statistics are even grimmer. Three percent to 16% of the American population may have the disease of addiction. Substance use disorders alone pose a heavy societal burden, endangering individual and family health and well-being and sapping resources from the health care system. In fact, the current data on prevalence of addiction is extremely difficult to interpret. Part of the reason for this is the continued interchangeable use of the terms addiction and dependence. For example, in a recent article in The New England Journal of Medicine, the authors cite Centers for Disease Control and Prevention (CDC) Guideline data which states that the prevalence of opioid dependence may be as high as 26% among patients in primary care receiving opioids for chronic noncancer-related pain. Because we know that there is some degree of
physical dependency associated with the chronic use of opioid agonist class of drugs in all patients, the term opioid dependency seems to be used to denote opioid addiction. This uncertainty in terminology makes data collection, interpretation, and comparisons between studies extremely difficult. This also makes the determination of incidence and percentage of chronic pain and addiction in other developed countries equally difficult. Furthermore, in certain subsets of the general population, we expect the incidence of pain to be considerably greater as has been reported, for example, in methadone maintenance treatment (MMT) programs.\textsuperscript{10} Opioids may be indicated in a small percentage of these MMT patients with moderate to severe pain. However, this population is at increased risk for relapse even in the context of a comprehensive treatment plan that includes “rational pharmacotherapy.” In addition, regulatory scrutiny often leaves the health care professional in a position of real or perceived vulnerability when prescribing a controlled substance. This may put both health care professionals and their patients at risk of a suboptimal outcome for an often-treatable medical condition.

The use of controlled substances including opioids in persons who may suffer from concurrent substance use disorders presents additional challenges to the health care professional. Success in the treatment of either condition requires an approach that encompasses the entire biopsychosocial needs of the patient. Pain management necessitates the need for careful boundary setting within the therapeutic relationship. Unfortunately, it is impossible to determine beforehand, with any degree of certainty, who will become problematic users of prescription medications.\textsuperscript{11} Despite our best efforts, no risk assessment tool has been developed which can reliably define risk of aberrant drug-taking behavior in patients prescribed opioids for the treatment of chronic pain.\textsuperscript{12,13} Risk is a part of the human condition: “If you have a pulse, you have a risk.” What is more important is to make a credible attempt at assessing these risks in all patients and to manage these risks to the best of our abilities. By recognizing the need to carefully assess all patients, in a biopsychosocial model, stigma can be reduced, patient care improved, and overall risk contained.\textsuperscript{14} The fact is that no matter how carefully we try to limit the use of opioids to the “lowest class of risk,” there will always be a need to
assess treatment goals and outcomes and modify them according to specific patient needs.

The goals of this chapter are to address the complex issues associated with the treatment of pain in persons with problematic behavior and to offer the health care professional an approach that may reduce risk and, hopefully, improve outcome.

Principle of Balance

Health care professionals who treat patients at the interface of pain and addiction and officials who formulate and enforce regulations must understand the central principle of “balance” as it relates to the use of any controlled substance including opioids.

That principle provides for a system of controls to reduce the risk of diversion, abuse, or trafficking of opioids, balanced against the assurance of the availability of opioids for legitimate medical and scientific purposes and accessibility of opioids to all who need them for the relief of pain. Health care professionals must embrace this principle as should our patients, dispensing pharmacists, and our communities.

By applying the principle of balance, it stands to reason that health care professionals should be able to treat pain in patients with the disease of addiction who are willing to simultaneously address both conditions. One can successfully treat acute pain in the face of an active addiction, but one will not achieve the stated goals in chronic pain management with an untreated substance use disorder. Mutual support programs such as Alcoholics Anonymous and Narcotics Anonymous are quite clear in terms of their position on the management of any medical condition: These are side issues and should not interfere with the 12 steps and traditions of their respective programs. Inappropriate use of prescription medications, even when legitimately prescribed by a licensed professional, can interfere in the recovery process. A legitimate indication for a given drug does not necessarily imply an “appropriate” indicate for that drug. For this reason, patients “in recovery” from drug or alcohol misuse need to ensure that their physicians are knowledgeable in the recovery process or have guidance from someone with such knowledge involved in their care.
THE IMPORTANCE OF THE DEFINITIONS

Using precise definitions at the interface of pain and addiction medicine will allow health care providers to improve their clinical practice of pain management (Table 59.1).

<tr>
<td>1.</td>
<td><strong>Addiction</strong> is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.</td>
</tr>
<tr>
<td>2.</td>
<td><strong>Physical dependence</strong> is a state of adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.</td>
</tr>
<tr>
<td>3.</td>
<td><strong>Tolerance</strong> is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug’s effects over time.</td>
</tr>
<tr>
<td>4.</td>
<td><strong>Pseudoaddiction</strong> is a syndrome that causes patients to seek additional medications due to inadequate pharmacotherapy being prescribed. Typically when the pain is treated appropriately, the inappropriate behavior ceases.</td>
</tr>
<tr>
<td>5.</td>
<td><strong>Pseudotolerance</strong> is the need to increase medication such as opioids for pain when other factor(s) are present such as disease progression, new disease, increased physical activity, lack of compliance, change in medication, drug interaction, addiction, and/or deviant behavior.</td>
</tr>
<tr>
<td>6.</td>
<td><strong>Iatrogenic addiction</strong> occurs when a patient, with a negative personal or family history for alcohol or drug addiction or abuse, is appropriately prescribed a controlled substance and subsequently in the therapeutic course meets the diagnostic criteria for addiction to that substance.</td>
</tr>
<tr>
<td>7.</td>
<td><strong>Misuse</strong> is use of a medication (for a medical purpose) other than as directed or as indicated, whether willful or unintentional, and whether harm results or not.</td>
</tr>
<tr>
<td>8.</td>
<td><strong>Abuse</strong> is any use of an illicit drug with the intentional self-administration of a medication for nonmedical purpose such as altering one’s state of consciousness (e.g., getting high). A licit substance such as alcohol can be abused.</td>
</tr>
<tr>
<td>9.</td>
<td><strong>Diversion</strong> is the intentional removal of a medication from legitimate distribution and dispensing channels for illicit sale or distribution.</td>
</tr>
<tr>
<td>10.</td>
<td><strong>Aberrant behavior</strong> is when the patient steps outside the boundaries of the agreed-on treatment plan which is established as early as possible in the doctor–patient relationship.</td>

</tbody>
</table>

Confusion between physical dependence and addiction may contribute to the undertreatment of chronic pain. Ballantyne and LaForge have...
expressed concern over the apparent lack of distinction between physical and psychological dependence in the diagnosis of addiction, preferring to consider these as entirely separable phenomena. Although the following definitions share many elements in common, “continued use despite harm” remains the behavioral marker in the chronic pain patient that will define, over time, an addictive disorder, if present. Physical dependence does not mean addiction, nor is it necessarily devoid of psychological components. Physical dependence and addiction can coincide, but physical dependence is neither necessary nor sufficient to make a diagnosis of addiction. Physical dependence is an expected, neuropharmacologic adaptation that occurs because of chronic exposure to an agonist class of drug. Addiction is a much more complex biobehavioral phenomenon.

Physical dependence is a natural expected neuroadaptive response that can occur with opioids, alcohol, benzodiazepines, corticosteroids, antidepressants, diabetic agents, cardiac medications, and many other medications used in clinical medicine. Abrupt cessation of these medications can produce a withdrawal syndrome that can include, but is not limited to, nausea, vomiting, diaphoresis, diarrhea, abdominal cramps, seizures, anhedonia, dysphoria, and, in some cases, even death. For example, a heroin addict may be both physically dependent and addicted to the narcotic, whereas the pain patient taking opioids is physically dependent but not necessarily addicted. Both will experience some degree of withdrawal if the drug is abruptly stopped. In the pain patient, physical dependence with withdrawal may also be associated with withdrawal-mediated hyperalgesia.

In fact, one of the greatest challenges in the interpretation of adverse outcomes in the context of opioid medication management is that related to equivalency of dose, given the wide range of medications we have within the opioid class of drugs.

The concept of morphine milligram equivalence (MME) has come under significant fire in recent years due to the perceived shortcomings of trying to equate molecules of different therapeutic potencies and intrinsic activities. The concept, however flawed, is in our opinion a worthwhile one.

Although the debate rages on as to what effect chronic versus acute
exposure, medication tolerance, and individual pharmacogenetics variabilities to mention only a few of the relevant variables have on equivalent doses, there are several immutable points to consider.

The first is that there is, without a doubt, a significant prescription drug abuse problem in America.\textsuperscript{23} Although many drug classes are abused, the opioid class of medication has come under direct fire in terms of increased morbidity and mortality as drugs of abuse.

The second point is that regardless of where the line is drawn, be it 90-mg morphine equivalence or 200-mg morphine equivalences per day, risk clearly rises as daily dose increases.\textsuperscript{24,25}

The final point, and perhaps one that might be open to the greatest expert debate, is that as dose of drug continues to increase, despite inadequate therapeutic response, the probability of achieving a successful therapeutic outcome diminishes.\textsuperscript{9} What impact the comorbid conditions of substance abuse and/or addiction might contribute toward adverse outcomes in this context remains to be seen.

Iatrogenic addiction is not clearly defined in the literature.\textsuperscript{3,26} The true incidence of iatrogenic addiction to opioids is not known.\textsuperscript{26} It is therefore important to set limits and boundaries for all patients before writing the first prescription.\textsuperscript{14}

It is only by careful evaluation and rational pharmacotherapeutic management of the pain that concurrent diagnoses such as addiction or pseudoaddiction\textsuperscript{27} can be confirmed. Although a diagnosis of addiction is made prospectively over time, a diagnosis of pseudoaddiction is usually made retrospectively.\textsuperscript{11} When reasonable limits and boundaries are placed on a patient, and yet they continue to step out of bounds, addiction or drug abuse should be considered.

Health care professionals with improved understanding of the definitions on basic scientific and clinical levels will be better able to more effectively evaluate and treat chronic pain patients with or without the disease of addiction.

\section*{Basic Science of the Disease of Addiction}

Drugs of misuse act at local cellular and membrane sites that are within a
neurochemical system that is called the reward and withdrawal pathway (Fig. 59.1). This pathway is in the mesolimbic dopamine system, and it involves, among other structures, the ventral tegmental area, nucleus accumbens, amygdala, and prefrontal cortex of the primitive brain. Addiction is a neurobiologic disease that causes disruption of these pathways. This disruption is mediated via receptor sites and neurotransmitters. Central to this reward and withdrawal pathway is the neurotransmitter dopamine, which has been shown to be relevant not only to drug reward but also to food, drink, sex, and social reward. Disruption of this neurochemical pathway by drugs of abuse may lead to addiction. Drug withdrawal can intensify with repeated drug use and can persist during prolonged periods of drug abstinence, a symptom complex known as the protracted abstinence syndrome. This sensitization of a neural process related to drug cravings or to environmental stimuli such as sights, smells, and sounds associated with drugs (referred to as cues) leads to the progressive increase in drug-seeking behavior that characterizes addiction. Such sensitization appears to increase the attractiveness of the drug taking and that of the drug-associated stimuli.

**FIGURE 59.1** Common reward pathway: mesocorticolimbic dopamine system. 5-HT, 5-hydroxytryptophan; DA, dopamine; GABA, gamma aminobutyric acid; GLU, glutamate; NE, norepinephrine. (Reproduced from Cami J, Farre M. Drug addiction. N Engl J Med 2003;349[10]:975–986. Copyright © 2003 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)
One of the most common reasons for relapse is stress.\textsuperscript{28} It stands to reason that if a chronic pain patient is in recovery from drug or alcohol use and his or her pain is inadequately treated, he or she may turn to the street for licit or illicit drugs and/or alcohol to cope with the pain.

The health care professional must recognize addiction as a treatable brain disease\textsuperscript{33,34}, that is, a distinct medical condition that may or may not be associated with the patient’s pain syndrome. However, when these do coexist, the successful treatment of either will require addressing both problems. In fact, as a general principle, all pain doctors should be talented amateurs in the context of identifying and treating substance use disorders (D. L. Gourlay, personal communication, verbal, July 2017).

Opioids can cause physical dependence and, upon abrupt discontinuation, withdrawal as a result of upregulation of the cyclic adenosine monophosphate (cAMP) pathway at the locus coeruleus.\textsuperscript{31} This is a normal physiologic response to this class of medications. It should be noted that most of the medications capable of producing physical dependence are not associated with the disease of addiction.

Tolerance is also a natural, expected physiologic response that can occur with exposure to certain classes of drugs, especially alcohol and opioids. The key to this definition is that all other factors remain stable so that just the physiologic response to the drug can be evaluated.\textsuperscript{17} In fact, tolerance is neither good nor bad. It occurs at different rates, to different effects in different people, over time. So, although there is relatively rapid tolerance development to the cognitive blunting effects of the opioid class of drug, tolerance to the constipating effects of opioids rarely occurs.

Unappreciated disease progress that is associated with dose escalation is termed pseudotolerance,\textsuperscript{35} a term that was coined to describe the apparent loss of analgesic effect in cancer patients with unrecognized increases in tumor burden.\textsuperscript{35} Pharmacodynamic tolerance involves adaptations that occur at both the site of the drug action (e.g., receptor, ion channel, as well as in related systems more distal to it). For example, pharmacodynamic tolerance to opioids is evident at both the level of the opioid receptor in the locus coeruleus (primary) and in the dopaminergic reward pathways afferent to the site of this discrete drug action (secondary).\textsuperscript{32} Persons addicted to heroin and chronic pain patients taking opioids can both
exhibit tolerance to the drug.

**BINARY CONCEPT OF PAIN AND ADDICTION**

In the past, the literature has suggested that pain conditions and addictive disorders might be dichotomous phenomena.\textsuperscript{11,14,36} It has been said that in the context of a “legitimate” pain diagnosis, which usually meant a condition that made sense to the assessing health care professional, the likelihood of there being an addictive disorder was so small as to not even merit investigation. Unfortunately, if the patient had an obvious substance use disorder, very real and treatable pain conditions were often ignored. With time, this thinking was tempered somewhat to suggest that in the absence of a current or past personal or family history of a substance use disorder, the risk of addiction was very low indeed.\textsuperscript{14} This dichotomous approach to pain and addiction has not served patients, health care professionals, or society well.

In reality, there is nothing about a genuine pain condition that is protective against having a concurrent substance use disorder\textsuperscript{3}; however, untreated pain, as a stressor, should always be considered in the assessment of relapse risk.\textsuperscript{28} Although there are some data in the animal literature to suggest that acute pain may blunt the euphoric reward of some drugs including opioids,\textsuperscript{37,38} this concept has largely been discounted. Patients with a substance use disorder are often disproportionate consumers of health care resources, especially in the context of trauma.\textsuperscript{39,40} The presence of a preexisting substance use disorder is not mitigated by a concurrent pain problem; it is complicated by it.

Although there is no evidence in the literature to suggest that those patients without past histories or apparent increased risk of substance use disorders become addicted as a result of rational pharmacotherapy for the treatment of any medical condition, including chronic pain, there is little credible evidence to the contrary either. Perhaps more relevant questions to ask are whether rational pharmacotherapeutic management of acute or chronic pain can reactivate a previously dormant substance use disorder or express an as yet unidentified genetic predisposition\textsuperscript{3} toward substance misuse or addiction. In the authors’ opinion, the answer to both questions very likely is “Yes.”\textsuperscript{11}
Risk, of course, varies with circumstance. For example, the prevalence of alcoholism in the hospitalized general medical population is estimated at 19% to 26%, whereas in the trauma subset, the prevalence rises to 40% to 62%. Regardless of what the actual risk is, it is clear that no one specific marker can reliably identify the at-risk pain patient, so careful boundary setting for all patients is strongly recommended. However, boundary setting is not without potential risk. It is interesting to note that in some cases, aberrant behavior on the part of the patients may be driven, if not created by overly prescriptive rules and demands placed on them by their treatment provider/team.

Take, for example, the patient that is forced to provide urine drug samples on a twice-weekly basis. It might be considered “aberrant” if the patient appears unwilling to comply. In fact, many would consider even weekly urine drug testing (UDT) onerous and so the disruption in the patients’ life might well be considered unacceptable. If boundaries and limits are set excessively tight, even “normal” patients will be forced to step out of bounds. Not only is this excessive, but there is no evidence in the literature to suggest this pattern of testing is either clinically useful or medically necessary.

Not all aberrant behavior reflects drug misuse or addiction. Some individuals who do not meet the diagnostic criteria for addiction may also use medications and other drugs problematically. This group is sometimes referred to as “chemical copers.” These individuals lack the skills commonly acquired during childhood and adolescence and tend to turn to external sources for support in dealing with life’s problems. Often, however, these patients suffer from complex, multidimensional problems that may only be partially responsive to even optimum pharmacotherapy in the absence of a biopsychosocial treatment plan. Unidimensional problems may respond to unidimensional pharmacologic solutions. Multidimensional problems however may transiently respond to pharmacologic interventions but rarely in a sustainable fashion.

It is only by aggressive investigation and rational pharmacotherapeutic management of the pain that this diagnosis can be made. The diagnosis of addiction is often made prospectively over time. When the patient’s behavior remains aberrant despite the appropriate management of the
underlying painful condition with reasonably set limits, substance misuse or addiction should be considered. In contrast, the diagnosis of pseudoaddiction is made retrospectively, meaning that with appropriate management of pain, aberrant behavior is reduced or eliminated. Boundary setting may include interval dispensing and contingency prescribing. Interval dispensing requires the patient to see other members of the health care team, such as a staff member of the prescriber or the pharmacist, on a more frequent basis than the actual prescriber. Thus, interval dispensing can be a simple and effective means to help patients keep from “borrowing (medications) from tomorrow to pay for today,” thereby reducing the risk of running out of medications early. With contingency prescribing, receiving the next prescription is contingent on something such as bringing bottles in for “pill counts” or mandatory attendance at all appointments.

It might be worth expanding on the point of “pill counts.” For many practitioners, the frequency of appointments and quantity of medication prescribed are such that the “correct” answer to any pill count is “zero.” The problem with this approach is the physician has no idea exactly when the bottle became empty. A more useful approach is to calculate the number of pills required to reach the next appointment and add 3 days’ worth of pills to that prescription. In the authors’ experience, it is far more difficult for a patient who tends to overuse the medications to bring back the correct number of tablets for the count if her or she are, in fact, struggling with control. The extra medication fulfills the added purpose of adding a buffer between the patient and practitioner in case one or the other is unable to attend the next appointment precisely as scheduled. It is always useful to clarify this practice, in advance with the patient’s pharmacist, so that the prescription will make sense in the context that it was written in.

**PAIN AND OPIOID ADDICTION—A CONTINUUM APPROACH**

Although pain and addiction can and sometimes do exist as comorbid conditions, they may also be present as part of a dynamic continuum with pain at one end of the spectrum and addiction at the other (Fig. 59.2).
In cases where the identified substance of misuse is one in which there can be no doubt about the medical appropriateness of its use, such as with alcohol or cocaine, a comorbid pain and substance use disorder should be considered. However, when the drug in question can arguably be both the problem and the solution, depending on the health care professionals’ training and perspective, a continuum model may better apply. With chronic pain, appropriateness of ongoing opioid use should be periodically evaluated, especially when there is little or no objective evidence of improvement in pain relief or function.

In cases in which pain and addiction coexist either as a continuum or comorbid condition, it is important to identify which aspect of the illness is dominant. Failure to treat both conditions, when present, will undoubtedly lead to frustration and poor outcomes in both domains. It is equally important to realize that this continuum is dynamic, with substance use disorder symptoms becoming dominant during periods of stress even after years of stable recovery.

**SEPARATING THE “MOTIVE” FROM “BEHAVIOR” WHEN DEALING WITH PAIN AND ADDICTION**

One of the greatest challenges facing practitioners treating complex pain patients is dealing with the patient who explains his or her aberrant behavior in terms of his or her chronic pain. Not infrequently, the health care professional will hear the patient say “But I’m not an addict, I’m a pain patient” when challenged with explaining why he or she has run out
of medication early, yet again. Of course, interpreting such behavior can be challenging.\(^44\) The differential diagnosis is long and includes dependence, pseudoaddiction, true addiction, comorbid psychopathology, “chemical coping,”\(^43\) and even criminal behavior such as diversion.\(^11\) More often than not, the patient and/or patient’s family can identify and are willing to discuss the aberrant behavior in the context of a “problem” rather than as evidence of a definitive substance use disorder.

Take for example the patient who has unilaterally escalated his daily dose of medication, necessitating an early return for prescription renewal. Although this may occur occasionally for quite legitimate reasons especially during the induction phase of treatment, repeated unilateral dose increases reflect behavior that must be carefully evaluated. In such a case, it may be more useful to focus on the problematic behavior (running out early) rather than the motive behind the behavior (i.e., addiction/abuse, chemical coping, etc.) when exploring this with the patient. Once the problematic behavior is identified and a remedial course of action selected, the ease with which the patient adheres to this “solution” will help to identify which aspect of the aberrant behavior differential is likely at work. Patients whose problematic behavior remains unchanged despite conservative efforts likely suffer from more complex problems that would best be referred on to a substance use disorder professional or other clinician with greater experience and resources to assess and manage these more challenging cases.\(^45\) Nonforensic, patient-centered UDT, which is discussed in Chapter 60, can be a very useful tool in these cases.\(^14,46,47\)

In the case of criminal behavior such as diversion of the prescribed medications, this behavior and the motive behind it are clearly unacceptable. In the authors’ opinion, this may be cause to sever the doctor–patient relationship and dismiss the patient from the practice. Dismissing patients for such criminal behavior is unlikely to be construed as abandonment in most jurisdictions. On the other hand, where possible, simply abandoning the molecule may be a more effective and patient-centered approach to take in cases where questionable behavior leaves the prescriber with concerns about the safety of ongoing prescription of controlled substances. In some cases, the patient will simply abandon the practitioner who no longer supplies the controlled substances; in such
cases, careful documentation of the process will ensure that any adverse consequences that might befall the patient reflect the severity of the underlying illness, not a result of any action that the prescriber might have taken. In fact, when addressing aberrant behavior, there are many “correct answers” that might be considered in addressing these issues, but in the authors’ opinion, there is only one, wrong answer, and that is to simply do nothing.

In fact, one of the sometimes unrealized opportunities that come with addressing aberrant behavior is the chance to simply “do things differently” from this point onward. In many respects, this is an opportunity for the patient and the practitioner to implement therapeutic change in the hopes of improving treatment outcome. This is particularly true when addressing the new patient in your practice, who is already on considerable doses of controlled substances.48

**OPIOIDS FOR ANALGESIA OR OPIOID-STABILIZING EFFECT?**

Not all pain syndromes are equally responsive to opioids.49 Neuropathic pain may be less opioid responsive, often requiring higher doses.50 In cases in which a patient is physically dependent on opioids, as one would expect with prolonged use of this class of drug, it can sometimes be useful to consider the appropriateness of continuation of opioid therapy, especially when treatment goals of improved function and decreased pain remain unmet.

Most pain is, to some degree, opioid-responsive. Yet despite years of experience with opioid therapy, it remains unclear who in advance will achieve a sustained response. In fact, the vast majority of efficacy data for the use of opioids involving randomized controlled trials are of 6 weeks or less duration.9,51,52 Further, chronic opioid therapy has been shown to worsen pain levels and function. This makes the evaluation of any “trial of opioid therapy” even more important because it is becoming clear that if the continued prescription of opioids is not leading to a clear benefit, it must be a problem. Of course, the challenges associated with opioid tapering are considerable.

When the patient and clinician define the need to remain on opioid
therapy not by how well the patient is doing but rather by how poorly things go when they try to reduce or discontinue the drug, it is time to reexamine the therapeutic role of opioids. When opioid levels in a physically dependent pain patient become inadequate, early withdrawal may occur. In the context of opioid-abstinence-induced hyperalgesia, it would be expected that the pain complaint might worsen.\textsuperscript{22} It is something of a myth that patients who no longer need opioids always come off them easily. In any trial of therapy, including opioid pharmacotherapy, there must be a clear exit strategy in addition to an entrance, stabilization, and maintenance strategy before writing the first prescription.\textsuperscript{11,48} This is not to say that those patients who are clearly benefiting from opioid pharmacotherapy should be weaned from these medications on the assumption that they “may no longer need them” but rather that not all persons who have inadequate pain relief or function while on opioids should remain on this class of drugs. In fact, some persons with poorly controlled pain while on opioid therapy may improve with a carefully executed opioid taper. The term taper is used here rather than detoxification, which is a term more commonly associated with the disease of addiction. Pain patients are “tapered,” and addiction patients are “detoxed.” In some jurisdictions, this can be a critical distinction in medicolegal terminology. Again, to restate a critical point: “Words matter.”

**Recommendations for Terminating Opioid Therapy**

A trial of opioid therapy is just that: a trial. In some cases, a decision to discontinue opioids must be made. Although the optimum case is one in which both the clinician and the patient feel this is the appropriate course to take, not infrequently, it is the clinician alone who has made this decision. Discontinuation of the opioid class of drugs should, when possible, be done respecting that the patient may have become physically dependent. Although no one taper schedule should be considered the “gold standard,” it is important to bear the following in mind. The speed with which the dose can be reduced at the beginning of the taper does not necessarily predict the speed with which the patient will be able to finish.

In any taper, there is a tension between neuroadaptation and time.
taper should be as fast as possible, so as to minimize lingering withdrawal symptoms while being slow enough to allow for neuroadaptation. Never forget that for some patients, regardless of slowness of taper, withdrawal symptoms cannot be eliminated, only prolonged until the goal of opioid discontinuation is obtained. Even then, post-acute withdrawal symptoms may further frustrate the goal.

As a rule, dropping 10% every 1 to 2 weeks until the patient reaches the bottom third, after which the dose is reduced by 5% every 2 to 4 weeks until completed is a gentle taper that most patients will tolerate well. During the taper, worsening pain scores, especially in the morning, may indicate too rapid a dose reduction, frustrating the efforts at tapering the drug. Although there certainly is merit in adjusting the rate of taper in a symptom-responsive fashion, there is a significant risk of even the best of intended tapers turning into an unintended maintenance program of ongoing medication management. In some cases, the correct approach is to simply “push through” the difficult times and remember the original goal, which is to get off the opioid medication. It is important to remember that opioid termination should not be synonymous with termination of care. Although for some patients, the net effect is that they will seek care elsewhere if opioids are not being prescribed.

A very real challenge in the treatment of chronic pain in the context of aberrant behavior is the determination of which aspect of the patient’s pathology dominates. Some clinicians have argued that as long as their medical record clearly records that the primary intent behind the prescription of controlled substances is for the treatment of chronic pain, any substance use–related disorder should be seen as a secondary issue. In fact, it is more complicated than that. For example, if a patient being treated for chronic pain is, by any reasonable peer assessment, a dominant substance use disorder, it will, in most cases, be the assessment of peers which will be taken as correct. In some cases, it may appear to be clear, for example, the pain patient who acknowledges the parenteral use of the oral medications. This would seem to most as incontrovertible evidence of an addictive disorder. However, some practitioners, especially those who have arbitrarily restricted their care to those patients without apparent addictive disorders, will continue to see any aberrant behavior as evidence
of inadequate treatment of pain. In the authors’ opinion, the safest course of action to take in such cases is to refer the patient on for further assessment and, if necessary, treatment of a concurrent substance use disorder. Failure to do so puts the patient at significant risk of harm due to inadequate treatment of a potentially lethal, substance use disorder. It also may expose the treating clinician to adverse regulatory scrutiny.

It is tempting to think that finding the correct molecule (i.e., the “right” drug) will achieve the desired outcomes in terms of achieving patient stability. For example, buprenorphine is a drug with considerable utility in terms of pain management and maintenance treatment of an opioid substance use disorder. Unfortunately, it is not simply the buprenorphine that leads to a good outcome in the maintenance treatment of opioid dependency. It is also the structure and support that is integral to the use of this drug in achieving satisfactory treatment outcomes. Interested readers are encouraged to read information regarding Drug Addiction Treatment Act of 2000 (DATA 2000) or to attend a DATA 2000 buprenorphine course for further insights into this potentially lifesaving treatment option.53–55

The purpose of effective pain management in any patient population, including those suffering from substance use disorders, is to reduce pain while improving function. When a drug appears to do more harm than good and yet continues to be used, an active addictive disorder must be considered. Although risk can never be eliminated, it can usually be managed. Failure to identify pain and addiction, where they exist, can render even the most ardent efforts at pain management ineffective and frustrating.

Assessment Tools

There are multiple assessment tools that are available for health care professionals to stratify the risk of drug/alcohol abuse or addiction. These tools may be used in pain management if one is considering prescribing a controlled substance, especially an opioid. There are a variety of tools that have been proposed to help the clinician identify the “at-risk” patient for aberrant behavior including but not exclusively the Alcohol Use Disorders
Identification Test (AUDIT), the Screener and Opioid Assessment for Patients with Pain (SOAPP), the CAGE-AID (Alcohol Including Drugs) (Table 59.2), and the Opioid Risk Tool (ORT).  

### TABLE 59.2 CAGE-AID (Alcohol Including Drugs) Questionnaire

- Have you tried to Cut down or Change your pattern of drinking or drug use?  
- Have others been Annoyed or Angry by others’ concern about your drinking or drug use?  
- Have you felt Guilty about the consequences of your drinking or drug use?  
- Have you had a drink or used a drug in the morning (Eye-opener) to decrease hangover or withdrawal symptoms?

ORT is a five-question clinical interview or patient questionnaire to assess patients at risk for aberrant behavior with prescription opioids prior to treatment initiation. It quantifies the level of risk for patients in an easy-to-use format. Its scoring is based on gender, family history of substance abuse, personal history of substance abuse, age, history of sexual abuse, and psychological disease (Table 59.3).

Scoring Total: ________

Of course, an increased risk does not mean that any given patient will behave aberrantly, and for those who do, not all behavior is equally significant in terms of meaning. In this respect, it is important to remember that “predisposed” does not mean “predestined” in terms of expression of risk. In fact, all assessment tools only offer a “statistical” probability of aberrant behavior in any single patient. Ultimately, individual risk is evaluated over time. The importance of clinical judgment supported by object evaluations of stability (e.g., UDT, pill counts) in the ongoing evaluation of risk cannot be overstated. However, for those patients clearly at increased risk, the need for closer monitoring should be evident. It is also important to note that on initial evaluation of all patients, the health care professional should always ask respectfully and in a nonjudgmental manner about a history of drug or alcohol abuse/addiction, physical or sexual abuse, or any current or history of mental disorders. This information allows the treating health care professional to formulate the appropriate treatment plan with boundary settings that are tailored to individual risk. It also offers the opportunity to bring another member(s) into the treatment team to begin to address the biopsychosocial issues of the patient. This increases the chances of the patient reaching his or her therapeutic goals of pain management.

**Universal Precautions in Pain Medicine**

The heightened interest in pain management is making the need for appropriate boundary setting within the clinician–patient relationship even more apparent. Unfortunately, it is impossible to determine beforehand, with any degree of certainty, who will become problematic users of prescription medications. A parallel can be drawn between the chronic pain management paradigm and our experience with problems identifying the “at-risk” individuals from an infectious disease model.

The term universal precautions as it applies to infectious disease came out of the realization that it was impossible for a health care professional to reliably assess risk of infectivity during an initial assessment of a patient.\(^6^2\) Lifestyle, past history, and even aberrant behavior such as tattoos and injection drug use were unreliable indicators that led to patient
stigmatization and increased health care professional risk. It was only after research into the prevalence of such diseases as hepatitis B, hepatitis C, and HIV that we realized the safest and most reasonable approach to take was to apply an appropriate minimum level of precaution to all patients to reduce the risk of transmission of potentially life-threatening infectious disease to health care professionals. Fear was replaced by knowledge, and with knowledge came the practice we know as universal precautions in infectious disease.

Universal precautions (UP) in pain medicine is a risk management concept introduced in 2005 which proposes adopting a minimum level of inquiry and care applicable to all patients presenting with chronic pain. UP offers an assessment and ongoing management scheme for all chronic pain patients. It recognizes the need to carefully assess all patients within a multidimensional biopsychosocial model, including past history of and present aberrant behaviors that might be associated with drug or alcohol use. By applying careful and reasonably set limits in the clinician–patient relationship, it is possible to triage chronic pain patients into three categories according to risk as presented later in this chapter.

UP were introduced to open a dialogue between the pain management and addiction communities around the assessment and management of risk. They were not proposed as complete but rather as a good starting point for those treating chronic pain. It is important to note that UP are not simply about opioid therapy but rather stress the importance of assessing and, where necessary, managing treatable comorbid conditions including substance use disorders. As with UP in infectious disease, by applying the following recommendations, patient care may be improved, stigma reduced, and overall risk contained.

**THE 10 PRINCIPLES OF UNIVERSAL PRECAUTIONS IN PAIN MEDICINE**

The 10 principles of UP are listed in Table 59.4. Treatable causes for pain should be identified where they exist and therapy directed toward the pain generator. Even in the absence of specific objective findings, pain can and should be treated. Any comorbid conditions, including substance use disorders and other psychiatric illness, must also be identified and
addressed. A complete inquiry into past personal and family history of substance misuse is essential to adequately assess and treat any patient. It is a common misconception that people with alcohol and drug use disorders will always lie about their use: In fact, it is more often the case that the practitioner simply did not bother to ask the patient, when this information is not obtained. People tend not to lie about that which they think is normal. A sensitive and respectful assessment of risk should not be seen in any way as diminishing a patient’s complaint of pain. Patient-centered UDT should be discussed with all patients regardless of what medications they are currently taking. In the authors’ opinion, the prescription of controlled substances to patients who are “philosophically opposed” to UDT is relatively contraindicated.

### TABLE 59.4 The 10 Principles of Universal Precautions

1. Diagnosis with appropriate differential
2. Psychological assessment including risk of addictive disorders
3. Informed consent (verbal or written/signed)
4. Treatment agreement (verbal or written/signed)
5. Preintervention/postintervention assessment of pain level and function.
6. Appropriate trial of opioid therapy +/- adjunctive medication
7. Reassessment of pain score and level of function
8. Regularly assess the “four A’s” of pain medicine: Analgesia, Activity, Adverse reactions, and Aberrant behavior.
9. Periodically review pain and comorbidity diagnoses, including addictive disorders.
10. Documentation

—

Informed consent is part of an initial evaluation. Health care professionals must discuss with and answer any questions about the proposed treatment plan including anticipated benefits and foreseeable risks. The specific issues of addiction, physical dependence, and tolerance should be explored at a level appropriate to the patient’s understanding.

Written opioid agreements facilitate the documentation of informed consent, patient education, and compliance in the management of chronic pain. A well-written agreement establishes the responsibilities of
clinician to patient and vice versa. It outlines the treatment plan and documents informed consent. The opioid agreement helps to establish boundaries and consequences for drug misuse or diversion. Noncompliance with the agreement can aid in the diagnosis of the disease of addiction or substance misuse, which would often require a change in the treatment plan.

Opioid agreements have the potential to improve the therapeutic relationship.64–66 The agreement, whether written and signed or informal and simply documented in the medical record, must be part of an environment of care that emphasizes honest and open communication. A practice policy for all patients prescribed with opioids to sign a medication management agreement is often a simple and effective way to approach this sometimes uncomfortable issue. In the authors’ opinion, the agreement should be reasonable, readable, and flexible. Sometimes, such agreements are erroneously called opioid contracts. However, these rarely reach the level of legally binding contracts and, as such, are better referred to as medication management agreements. Where written agreements are used, both the patient and clinicians should sign two copies. The patient should be offered a copy to share with whomever he or she thinks appropriate. Effective agreements clearly define both the clinician’s and patient’s responsibilities (Table 59.5).64–66

### TABLE 59.5 Treatment Agreement for Opioid Maintenance Therapy for Noncancer or Cancer Pain

- Goals of therapy
- Single prescriber if possible
- Informed consent on all opioid risks
- Definition of addiction, tolerance, and physical dependence
- Need for patient disclosure of substance abuse history; psychiatric history including history of sexual, physical, or verbal abuse; and medications currently prescribed
- Need for complete, honest self-report of pain relief, side effects, and function at each medical visit
- Establishment of regular medical visits
- Requirement for prescription renewal only during regular office hours
- Conditions of noncompliance (e.g., evidence of drug hoarding or use of any illegal drug may cause termination of the clinician–patient relationship)
- Use of the word may instead of will in the agreement, so clinical judgment can be used in each situation
- Patient consent to random urine drug tests and pill counts
Preintervention or postintervention assessment of pain level and function must emphasize that any treatment plan begins with a “trial of therapy.” This is particularly true when controlled substances are contemplated or used. Without a documented assessment of preintervention pain scores and level of function, it may be difficult to demonstrate success in any medication trial. The ongoing assessment and documentation of goals met will help support the continuation of any mode of therapy. Failure to meet these goals should necessitate reevaluation and possible change in the treatment plan.

An appropriate trial of opioid therapy, generally with adjunctive medication, may be warranted in moderate to severe pain. Although opioids should not routinely be thought of as treatment of first choice, they must also not be considered as agents of last resort. Recently, the CDC has published a set of guidelines for the use of opioids in the treatment of chronic noncancer pain.\textsuperscript{9,67} Pharmacologic regimens must be individualized based on subjective as well as objective clinical findings. The appropriate combination of agents, including opioids and adjunctive medications, may be “rational pharmacotherapy” and provide a stable therapeutic platform from which to base treatment changes. In an ideal world, rational pharmacotherapy should be coupled with an integrated structure of biopsychosocial support. Unfortunately, the financial resources to support such integrated approaches is often lacking.

Regular reassessment of the patient’s pain score and level of function, combined with corroborative support from family or other knowledgeable third parties, will help document the rationale to continue or modify the current therapeutic trial. The routine assessment of the “four A’s” of pain medicine: Analgesia, Activity, Adverse effects, and Aberrant behavior will help to direct therapy and support pharmacologic options taken.\textsuperscript{68} It may also be useful to document a fifth A: Affect (E. Covington, personal communication, verbal, July 2005). The prescriber should periodically

review pain diagnosis and comorbid conditions, including substance use disorders. Underlying illnesses evolve. Diagnostic tests change with time. In the pain and addiction continuum, it is not uncommon for a patient to move from a dominance of one disorder to the other. As a result, treatment focus may need to change over the course of time. If an addictive disorder predominates, aggressive treatment of an underlying pain problem will likely fail if not coordinated with treatment for the concurrent addictive disorder.

Careful and complete documentation of the initial evaluation and at each follow-up is both medicolegally indicated and in the best interest of all parties. Thorough documentation, combined with an appropriate doctor–patient relationship, will reduce medicolegal exposure and risk of regulatory sanction. If you do not document it, it did not happen.

**PATIENT TRIAGE**

One of the goals in the initial assessment of a pain patient is to obtain a reasonable assessment of risk of a concurrent substance use disorder or major psychopathology. In this context, patients can be stratified into three basic groups. The UP’s triage scheme offers a practical framework to help determine which patients they may safely manage in the primary care setting, those who should be co-managed with specialist support, and those who should be referred on for definitive management of their chronic pain condition in a specialist setting (Table 59.6).\(^{14}\)

<tr>
<td>In this group, there may be a past history of a treated substance use disorder or a significant family history of problematic drug use. They may also have a past or concurrent psychiatric disorder. These patients, however, are not actively addicted but do represent increased risk which may be managed in consultation with appropriate specialist support. This consultation may be formal and ongoing (co-managed) or simply with the option for referral back for reassessment should the need arise.</td>
</tr>
<tr>
<td><strong>Group III—Specialty Pain Management</strong></td>
</tr>
</tbody>
</table>
This group of patients represents the most complex cases to manage due to an active substance use disorder or major, untreated psychopathology. These patients are actively addicted and pose significant risk to both themselves and to the practitioners who often lack the resources or experience to manage them. The prescription of controlled substances should generally be left to those persons with the experience and resources to manage the active addict.

It is important to remember that Groups II and III can be dynamic; Group II becoming Group III with relapse to active addiction, whereas Group III patients can move to Group II with appropriate treatment. In some cases, as more information becomes available to the practitioner, the patient who was originally thought to be low risk (Group I) may become Group II or even Group III. It is important to continually reassess risk over time.

Treating the Pain Patient on Opioid Agonist Treatment

The treatment of pain in a patient on opioid agonist treatment (OAT) with methadone or sublingual (S/L) buprenorphine for the disease of opioid addiction can be particularly challenging. Here is an example when the controlled substance prescribed for pain can be the solution, the problem, or both.\textsuperscript{11}

Methadone and S/L buprenorphine (with or without naloxone) can be used for the dual purpose of treating the disease of addiction and pain, but they pose an interesting challenge for the prescriber. For appropriate prescribing of these medications, their unique pharmacokinetic and pharmacodynamic properties must be understood. This allows for proper patient selection and evaluation to optimize outcomes in the treatment of pain, addiction, or the comorbid conditions of pain and addiction.

In the disease of addiction, the dose of methadone or S/L buprenorphine is usually given once a day. In the clinical experience of the authors, methadone and buprenorphine are best dosed every 6 to 8 hours for the most effective treatment of opioid responsive pain.\textsuperscript{69} However, it should be noted that this dosing schedule for S/L buprenorphine for analgesia is
Buprenorphine’s high receptor affinity may theoretically interfere with effectiveness of other full µ analgesics, although this concept has come under review in recent publications.\(^{70,71}\) As with other partial µ agonists, buprenorphine is typically contraindicated in opioid-dependent patients because it may precipitate severe withdrawal.\(^{72,73}\)

Pain management for patients who are using S/L buprenorphine for the disease of addiction requires an individualized approach. The literature has suggested that to treat pain in a patient on OAT with S/L buprenorphine, one must discontinue the S/L buprenorphine and do a re-induction of the drug after the acute pain syndrome resolves.\(^{74}\) This may not be necessary in some instances. In certain circumstances, the patient may be spared the discomfort of having to go into withdrawal as the full µ agonist is discontinued and he or she is rotated back to S/L buprenorphine. In most cases, the pain can simply be managed by titrating the S/L dose upward to effect with a 6- to 8-hour dosing regimen up to maximum dose of 32 mg per day.\(^{69}\) If breakthrough medication is needed, consider using one with high potency such as transmucosal fentanyl lozenges, fentanyl buccal tablets, or hydromorphone because of their high affinity to the opioid receptor.\(^{69}\) It is important to remember that even at maximal maintenance agonist doses of buprenorphine, µ receptor occupancy is less than 100%.\(^{75}\) In the authors’ opinion, rapid-onset opioid formulations should be used with caution in this population, primarily for acute pain, with tightly set boundaries as per UP with limited “pill load” prescribed between evaluations of the acute pain (see Chapter 60). It is important to remember that it is always possible to add a full µ agonist to a patient who is maintained on buprenorphine without fear of precipitating withdrawal. The reverse is, however, not always true. The risk of precipitated withdrawal may in fact be as much a function of the molecule chosen as the route of administration (e.g., the rapid onset of a large S/L preparation vs. the slow onset of a transdermal delivery system.)

The patient who is on OAT and requires chronic pain management must agree to the principles of UP or some similarly integrated approach to risk management. It may also be useful to place this patient in an appropriate group for risk stratification (Group II or Group III) and monitor
The Treatment of Pain and Suffering in Our Society

There is a debate over whether opioids are “good” or “bad” and whether they should be available for widespread use. Of course, opioids are “good” when used appropriately and “bad” when they are misused. In fact, the debate has become even more granular: Is there any justification for chronic opioid therapy in the context of noncancer-related pain when we carefully consider an honest risk/benefit assessment? We believe that in a selected patient population, there are some patients who, at least in the short run, seem to benefit from the chronic use of opioids. It is likely fair to say that some patients, especially those who were initiated on opioid therapy in the past, might well do better off these medications than on them. However, this should not alter the fact that for those patients who need them, they must be made available, even if availability requires appropriate monitoring and oversight individualized to each case. The chronic pain population is incredibly heterogeneous and varies tremendously in terms of vulnerability to addiction and misuse. The best way to accomplish the goal of keeping opioids available to those who need them and may truly benefit from them is for all stakeholders involved in legitimate opioid therapy to openly address the complexity of the issue and to do so in a collaborative fashion.

Major stakeholders in achieving an appropriate balance in the treatment of pain and the prevention of drug abuse and diversion are health care professionals, patients, third-party payers, regulatory bodies, law enforcement, pharmaceutical industry, the public at large, and the media. If these groups reconcile themselves to the need for thoughtful and unemotional dialogue, opioid treatment can remain a viable option while efforts are made to stem the tide of prescription drug misuse and addiction. Everyone has a stake in this complex issue. We are all aging, and many of us will have pain. Societal solutions are needed now so that we can all enjoy the comfort of knowing that safe and effective pain treatment will be there for us if we need it. It is the responsibility of all to make this a reality. Unfortunately, the very issue of chronic opioid therapy being
“safe and effective pain treatment” is clearly open to debate.77

This brings us to the issue of compliance with medication management in the context of the treatment of chronic pain.

One wonders if pain patients are being held to an unrealistically high standard regarding compliance with their treatment plan. For example, in the treatment of any chronic illness such diabetes mellitus, 100% adherence to the treatment plan, although desirable, is obviously not achieved in most patients. In fact, a recent review indicates that approximately 20% to 50% of patients are not adherent to recommended medical therapy.78

The failure to comply is a complex interplay of a multitude of biopsychosocial factors including but not limited to patient motivation. To expect 100% compliance with any pharmacotherapeutic agent, including controlled substances is to ignore this fact. Again, the moral imperative of elimination of prescription drug misuse in America has significantly altered our understanding of the core components of treatment adherence.

In fact, there is ample evidence that the whole field of pain medicine may be being held to an unrealistic standard. Clearly, in the practice of the art of medicine, clinicians are expected to know certain things. Take for example, the execution of a trial of opioid therapy. In the prescription of these potent medications, clinicians are expected to thoroughly discuss with their patients the risks and potential benefits of this course of treatment. Initial prescriptions of potentially dangerous medications must be sufficiently detailed as to reasonably guide the patient to their safe use. Similarly, the prescriber is expected to ensure, through the course of the clinical encounter, how exactly the patient is using this medication and where necessary adjust the treatment strategy. These two aspects of the clinical encounter are clearly within the reasonably prudent prescribers’ mandate of best practices. There is, however, a third piece of information that is only known to the patient; that is, how they are “actually” using the medication.

In some circumstances, it may be helpful to treat the clinical encounter as a “worst case scenario.” For example, a patient who repeatedly runs out of medication could simply be a victim of incredibly bad luck—but it is much more likely that they are over using their medications and running
out early as a result. Under more dire circumstances, the prescriber might be becoming an unwitting accomplice to the criminal act of drug diversion. It often is very difficult to tell, in advance which explanation is the correct one. Unfortunately, in recent department of justice prosecutions, it often seems that the physician is expected to approach the patient (in the prescription of controlled substances) as if he or she were lying, until there is unequivocal evidence to prove that he or she is not lying about the use of prescription medications. Sadly, there is rarely ever absolute proof of these things—yet judicial assessment after the fact often takes the position of “doctor knew, or ought to have known” about the patient’s misbehavior. Clearly, such an approach would very much undermine the therapeutic relationship to the detriment of many patient’s care.

Worse still is the fact that many patients and more than a few prescribers view opioid therapy as the “gold standard” in pain management. This has at least been in part due to a growing use of the opioid class drugs in the management of chronic pain. Although this may be true in the context of acute pain, there is mounting evidence that long-term efficacy of the opioid class of drugs in the treatment of chronic pain is lacking. What role chronic opioid therapy will play in any patient population, especially those with the added risk of a preexisting substance use disorder, remains to be seen.

Conclusion

The purpose of effective pain management in any patient population, including those suffering from substance use disorders, is to reduce pain while improving function. Although achieving this goal may be more difficult in patients with substance use disorders, it is not impossible. Risk can never be eliminated, but it can usually be managed. By approaching these patients within a biopsychosocial model using the information presented in this chapter, the health care professional can give the patient the best quality of life possible given the reality of his or her clinical situation.

References

45. Houry D, Baldwin G. Announcing the CDC guideline for prescribing opioids for chronic pain.

The pain management practitioner faces several challenges in the safe and effective management of chronic pain. One of these relates to the important issue of monitoring compliance with a previously agreed-on course of therapy. Unfortunately, in today’s medicolegal climate, the need for clinicians to take steps to reduce the risk of diversion and misuse of controlled substances has become apparent. Although the debate continues as to what degree prescribers contribute to the overall source of controlled substance that reaches the street,\(^1\)–\(^4\) there should be no debate about the prescriber’s responsibility to ensure a decreased need for these drugs by addressing demand reduction strategies in all susceptible individuals. All pain patients are not potential diverters: All aberrant behavior does not represent drug addiction or misuse.\(^5\) However, we tend to adopt a more casual attitude toward prescription drugs, including opioids, despite the fact that there is a disturbing trend toward prescription drug abuse by adolescents and others who have found their family medicine chests a ready supply of abusable drugs.\(^4,6\) Whether this is because of an implicit sense of safety associated with prescription products or due to a simple comparison with typical illicit drugs of abuse found on the street is unclear. In fact, there has been a marked increase in counterfeit drugs on the street, typically adulterated with potent opioids such as fentanyl and carfentanil. In many cases, the first exposure to these drugs results in a fatal outcome. The emergence of naloxone rescue protocols in so many cities in North America is a testament to this growing problem.\(^7,8\)

How Communication Influences Compliance
Assessment

Clinicians have less control over how our prescriptions are used than we would like to believe. In fact, there are three dimensions to consider when examining the prescription of any controlled substance.

The first is “what the patient is told to do.” Obviously, a prescriber must inform and document the instructions around the prescription of any medication, especially controlled substances. To this end, a physician might reasonably be held to account for a bad outcome in the context of medication use if the only documented instructions to the patient were “Use as directed.” Treatment compliance assumes that the clinician is clear about how the patient was instructed and that the patient clearly understood these instructions. In the author’s opinion, this is rarely the case.

The second is “what the patient is telling the prescriber he is doing.” Communication between patient and prescriber is key not only to ensuring the best possible treatment outcomes but also in identifying possible miscommunications between prescriber and patient around treatment plans, especially with opioids. So, the patient who is advised to take medications in a “three-times-daily fashion” might remain clinically unstable—until the prescriber finds out that the patient is actually taking medications at 0900h, 1000h, and 1100h, respectively. Clearly, the prescriber and the patient are not on the same page around the dosing interval of this medication. Again, assessment of treatment requires careful communication.

But the final possibility is “what the patient might be doing with the medication, in a worst-case scenario.” Take for example the patient who is becoming obviously impaired during the first week of a recent prescription refill. Although the patient never run out of medications early (over the course of a 1-month prescription), he may be overusing his medications during the initial phase of the prescription, only to struggle on toward the end of the month because he has literally “borrowed from tomorrow to pay for today” in his dosing schedule. Simply asking what is the most medication he has had to use in 24 hours will help to get a better understanding of how the medication is actually being used.

In the aforementioned examples, the clinician is clearly responsible for
the instructions given to the patient and to some extent is responsible for clarifying those instructions if necessary based on what the patient tells the clinician he or she is doing. In the third case, however, the patient alone must be held responsible for any adverse outcomes based on what he is actually doing if this information is withheld from the prescriber.

A considerable effort has been expended in teaching clinicians how to initiate pharmacotherapy (“entrance strategy”), but unfortunately, there has not been an equal effort expended in teaching the technique of terminating these medications (“exit strategy”),\textsuperscript{10,11} some of which may have considerable withdrawal syndromes associated with their rapid taper or abrupt discontinuation. No matter how selective we appear to be in offering opioid trials to “low-risk” patient populations, prescribers will always need to (1) assess the opioid trial as either successful/failed and (2) have a defensible, rational, and compassionate exit strategy.\textsuperscript{12}

For the purposes of this chapter, compliance monitoring may be defined as those steps taken by a prescriber to ensure that treatment plans are adhered to and prescribed medications are appropriately used. Many factors contribute to a patient’s failure to adhere to an agreed-on treatment plan.\textsuperscript{13} To expect 100% adherence, even when controlled substances are involved, is to ignore this fact.\textsuperscript{13}

Compliance monitoring should begin with an individual assessment of risk. As outlined in Chapter 59, it is unwise to assume that you can assess risk, with any degree of certainty, at the first visit. Risk assessment and management is best performed over time. Treatment agreements, interval and contingency prescribing, pill counts, prescription monitoring programs (PMP), and urine drug testing (UDT) can all play important parts in helping to manage risk and so improve outcomes.\textsuperscript{14–17}

The fact is we have little evidence to support this practice.\textsuperscript{18} Beyond this, there is little evidence to support the notion that risk evaluation and mitigation strategies (REMS) accomplish any of their stated goals. In fact, the recent push toward abuse-deterrent/abuse-resistant has also been without scientific or clinical support of efficacy.\textsuperscript{19} Only time will tell if these approaches have a meaningful and positive impact on the problem of prescription drug abuse in America. In the authors’ opinion, placing too much confidence in the ability of clever delivery systems to prevent
aberrant drug-taking behavior in the high-risk patient population may cause us to revisit many of the same problems we have had to deal with over the past 25 years. As with the diabetic patient who self-reports optimum glycemic control at a follow-up visit, the clinician still performs a glycated hemoglobin (HgBA$_1$C) test (which is a measure of glycemic control over time) as an objective measure of treatment success.$^9,^{20}$

Because hyperglycemia is not illegal, there is little prejudice created in the clinician’s mind when the objective test is at odds with the patient’s self-report. Just as with HgBA$_1$C, the clinician can use a discordant UDT result to motivate change on the part of the patient and to monitor healthy changes already made.

For the most part, monitoring efforts should be based on the initial then subsequent assessments of risk over time. In this regard, frequency of drug testing might reasonably be expected to be greater in an identified “high-risk” patient population compared to a “low-risk” population. In fact, even in high-risk populations, UDT can be overused. Medically necessary testing must be tailored to the patient.

A variety of tools have been developed to aid the clinician with this important task.$^{21–26}$ Regardless of the tool used, the result is only an estimate of the risk of the patient engaging in aberrant behavior. High risk is not an absolute contraindication for the prescribing of controlled substances but might cause a prudent clinician to seek formal consultation with or referral to other appropriate health care professionals who have sufficient experience and resources to manage these often challenging cases.$^{14}$ It is important to remember that having a legitimate reason for prescribing a controlled substance does not in itself make it appropriate to do so.

**Interpreting Aberrant Behavior**

Even with the most reasonable treatment plan, a patient’s ability to comply is based on a multitude of potentially conflicting factors. When a patient fails to comply, the treating clinician needs to have an approach that allows the patient and prescriber to adequately address these issues. Not all aberrant behavior represents abuse, addiction, or criminal intent.$^9$
Similarly, what may seem like reasonable treatment goals for any given patient may be more difficult for some patients to comply with than others, even in the context of a previously signed treatment agreement. When a patient steps out of previously defined limits and boundaries, the clinician should examine the context of this behavior.

It is often surprising for clinicians to realize that some aberrant behavior can be iatrogenic in nature. Unreasonably set limits or demands on a patient can cause even the lowest risk patients to “step out of bounds.” However, in some cases, this behavior can be framed in the context of a “Golden Moment” where the patient may begin to see things for the way they are rather than the way he or she wished they were. In this way, both clinician and patient can improve their level of communication that is inherent in all positive therapeutic relationships. Rather than simply dismissing the patient for breaking the treatment agreement, which can perpetuate the patient’s revolving-door approach to health care, both parties become better educated to move forward in a strengthened therapeutic relationship based on mutual trust and honesty. This approach best serves the mutual interests of patient, practitioner, and the community in which they live.

Some patients, however, are not ready to make these changes; they may need to seek care elsewhere. It is important to remember that it is generally better for a patient to abandon a reasonable and prudent course of therapy offered by a knowledgeable practitioner than it is for that patient to be dismissed from the practice. Although it may be necessary and appropriate to discontinue the prescription of controlled substances such as the opioid class of medication, this should rarely be equivalent to dismissal from care, although a drug-seeking patient may interpret the two as being the same. From a medical legal perspective, it is usually better to “abandon the molecule” rather than be perceived as having abandoned the patient.

**POTENTIAL TREATMENT TRAPS IN COMPLIANCE MONITORING**

**Borrowing from Tomorrow to Pay for Today**

For most patients, problematic prescription drug use does not involve misuse or diversion. For those patients who do exhibit aberrant behavior
such as running out of medications early, the most common problem relates to simply taking more than prescribed. The concept of borrowing from tomorrow to pay for today is something that many patients can relate to. In these circumstances, prescribing multiple prescriptions for smaller quantities of medications, to be dispensed by the pharmacist on an interval basis, can assist the patient with treatment adherence. In many states, regulations now allow for appropriately dated prescriptions to be written and filled sequentially by a pharmacist (“Do not fill until”). Patients who need more oversight than weekly medication pickup should likely be referred on for more formal assessment of potential comorbid conditions such as substance use disorders or other significant psychopathology.

**Avoiding Excessive Pill Loads**
In the management of chronic pain, medications must be carefully titrated to their optimum dose. Traditional teaching for a trial of opioid therapy suggests using immediate-release medications to establish drug responsiveness followed by conversion to sustained-release medication, typically in a two- or three-times-daily dosing schedule with a suitable amount of immediate-release medication for breakthrough pain management. More recent guidelines from the Centers for Disease Control and Prevention have suggested that, where possible, immediate-release medications are to be used over their sustained-release counterparts. Although the addiction literature continues to suggest that from the perspective of abuse/addiction risk, patients are likely to do better on sustained-release or truly long-acting (e.g., methadone/buprenorphine) opioids for the long-term treatment of chronic pain, there are no recent long-term perspective studies in the literature to confirm this important clinical point.

By definition, a successful trial is one in which the patient is clearly improved either in terms of pain relief, functional restoration, or ideally both. Properly chosen patients may do well with this approach. Some, however, improve initially but lack the sustainable relief seen with truly opioid-responsive pain. In these cases, there is often seen a gradual dose escalation with diminishing returns as the side effect profile begins to overtake the therapeutic effect. For some patients, efficacy is measured by
the subtle cognitive effects transiently seen with a new drug or drug dose rather than the marked reduction in pain scores and improved function typically seen with treatment-responsive pain. Unfortunately, tolerance to these effects can develop quickly, leading to significant dose escalation. Sometimes, to reduce drug use, the prescriber provides the patient with smaller dose tablets in the hopes the patient will be able to titrate the dose down, reducing the overall dose taken and so the adverse effects often seen with higher medication levels.

For example, a patient who is using 80 mg of controlled-release oxycodone in an every-8-hours dosing schedule may request 20-mg tablets rather than the 80-mg tablets, indicating that the patient often feels he or she does not need to take the entire dose to keep the pain under control. To reduce the total daily dose, the 80-mg tablets are changed to 20-mg tablets. In this case now, instead of receiving 3 tablets per day, 21 tablets per week, the patient receives 12 tablets per day (to be used “as directed” in a three-times-daily divided dose). This is a total of 84 tablets per week. In a monthly prescription, this amounts to 336 tablets. Although some patients may achieve the desired goal of dose reduction, others will ultimately begin to redistribute the controlled-release drug, often taking the medication more frequently during the day than the agreed-on 8-hour interval. With such large quantities of tablets available, borrowing from tomorrow to pay for today can become a problem. In such cases when patients have asked for smaller unit doses as described earlier, it can be revealing to ask the patient to bring in extra medications at the next visit. It is a minority of patients who can comply with this request, indicating that they use the medication up eventually. In these cases, closer inquiry may show that the duration of action for the modified-release drug is only 3 or 4 hours, necessitating six or more dosing intervals per day to achieve “stability.” Clearly, the use of a modified-release medication in the same fashion as an immediate-release preparation is inappropriate. In a sense, the patient can be legitimately advised that the “clever delivery system” has failed them. In these cases, the answer is not to dose more frequently with the controlled-release preparation but rather to consider rotating to another modified-release system or to a truly long-acting medication such as methadone or buprenorphine.
Using Pill Load Limits to Modify Behavior

Many practitioners use the time between visits as a guide to how many unit doses any given prescription will need. So, if a prescription is written for 3 tablets daily and the follow-up appointment is in 30 days, many clinicians would write the script for 90 tablets (possibly adding 2 or 3 days’ worth to cover for exigent circumstances). For most, writing a prescription for less than 100 tablets is quite reasonable. In some cases, that same 30-day interval will require many more than 100 tablets. As an example, a person might use 10 hydrocodone/acetaminophen tablets per day. In this case, a 1-month supply would require you to write for 300 tablets. Practically, this would mean the patient would have to fill prescriptions on a 10-day interval (to allow for unit dose limits of 100 or fewer tablets per prescription). This is both inconvenient for the patient as well as costlier due to co-pays for filling multiple scripts.

This may also present an opportunity for the patient to consider tapering the daily dose of medication used and so allowing for more time between prescriptions filled. At least one recent guideline has indicated that individual prescriptions for excessive numbers of tablets or milligrams of drug will trigger an investigation by the appropriate regulatory body.

Compliance Monitoring Tips and Traps

There is some literature examining compliance failures and aberrant behaviors, but most seem to examine this from a patient perspective. Physicians have rarely been taught to consider their own role in the patient behaviors that they are struggling with.

Take for example the patient who is demonstrating aberrant behavior including symptom magnification and drug-seeking behaviors. Many clinicians can identify this as abnormal, either at the conscious or gut levels, and act accordingly. Few have ever considered the possibility that this may be iatrogenic in etiology.

If a patient believes that the ongoing prescription of medications is “contingent” on the doctor believing that he or she “still needs” these drugs, the patient is likely to behave in a way that he or she believes will result in continuation of the status quo. However, if the prescriber has caused the patient to believe (either consciously or unconsciously) that he
or she is uncomfortable with these prescriptions and at some point will ultimately stop writing prescriptions for them, the behavior can be seen in a totally different light. It should not be a surprise that when the patient sees that today is not the day to begin the feared taper or worse simple discontinuation of the drugs on which the patient has at least become physically dependent that the demeanor changes almost magically. Yes, it is clearly abnormal behavior, but it is not entirely clear what this behavior means. As a general rule, it is easier to identify abnormal behavior than it is to accurately interpret what it means. In the context of abnormal behavior, there can be a variety of “correct” responses: The one absolutely incorrect thing to do is to simply ignore it.

Urine Drug Testing in Pain Medicine

UDT is a useful tool in pain management that provides valuable objective information to assist in diagnostic and therapeutic decision making. Results of UDT can assist in assessing compliance with a previously agreed-on treatment plan (adherence/compliance); they may also identify relapse or drug misuse as early as possible, and finally, the results can be used to advocate for the patient with third-party interests. Of course, any diagnostic test used in the context of patient care must meet the basic test of medical necessity. The topic of medical necessity will be examined in greater detail later in the chapter.

To assess compliance, the clinician may look for the presence of prescribed medications and/or metabolites as evidence of their recent use. Not finding the prescribed drug or finding unprescribed or illicit drugs in the urine merits further discussion with the patient while recognizing that laboratory error and test insensitivity can result in misleading data. Bingeing by the patient can result in unexpected negative urine reports if the patient runs out of medication prior to sample collection. Therefore, these results by themselves cannot be relied on to prove drug diversion and may be consistent with addiction, pseudoaddiction, or the use of an opioid for nonpain purposes—so-called chemical coping. The purpose of UDT should be explained to the patient at the initial evaluation. UDT should be used, like all other diagnostic tests, to improve patient care. UDT can also
enhance the relationship between clinicians and patients by providing documentation of adherence to mutually agreed-on treatment plans.\textsuperscript{16,34}

Reports of unprescribed or illicit substances in the urine aid in the assessment and diagnosis of drug misuse or addiction. UDT results can be used to encourage change to more functional behaviors while supporting the positive changes previously made. Thus, the appropriate use of a UDT result requires documentation in the medical record and an understanding on the part of both the patient and the clinician of how these results are to be used.\textsuperscript{35}

In the pain management setting, the presence of an illicit or unprescribed drug does not necessarily negate the legitimacy of the patient’s pain complaints, but it may suggest a concurrent disorder such as drug abuse or addiction. Although acute pain can be treated in a patient with an active addictive disorder, it is unlikely that one can successfully treat chronic pain in a patient with untreated addiction. The patient must be willing to accept assessment and treatment of both disorders to receive adequate outcomes in either.\textsuperscript{11} Thus, the diagnosis of a concurrent addictive disorder, when it exists, does nothing to negate a legitimate pain disorder, but rather, it complicates it. In some cases, the very nature of the patients’ diagnosis may change because of information gained through drug testing.

**SPECIMEN CHOICE**

Urine has been the preferred biologic specimen for determining the presence or absence of most drugs since the 1970s.\textsuperscript{36} This is in part due to the increased window of detection of 1 to 3 days for most drugs and/or their metabolites.\textsuperscript{37} When compared to serum samples, the relatively noninvasive nature of sample collection, ease of storage, and low cost of testing favor urine as the specimen of choice. Although there are currently other matrix options, including saliva, hair, and even breath (tetrahydrocannabinol [THC]), urine remains the most commonly used specimen.\textsuperscript{17,38}

**WHOM TO TEST**

The question of whom to test is made easier by having a uniform practice
policy that helps reduce individual stigma. Beyond this, any risk of patient profiling based on racial, cultural, or other physical appearances is reduced. Careful explanation of the purpose of testing normally allays patient concerns.16

FREQUENCY OF TESTING
Testing frequency is a function of many factors, some of which are patient-based and others are a function of the practice. For example, in a pain practice where the patient referral base is typically more complex, a policy of testing all patients on admission and thereafter to be determined by clinical assessment of risk is recommended. On the other hand, in the average primary care setting, where the prevalence of individuals with substance use disorder should be no greater than the population, it may be sufficient to discuss UDT with all patients and reserve actual testing to a behaviorally triggered paradigm. Unfortunately, this latter approach does subject the patient and practitioner to the risk of missing a potentially treatable comorbid disorder (substance misuse/addiction).2,39,40

In those practices with a disproportionate percentage of high-risk patients, determining how frequently to use UDT can be a real challenge. Contrary to popular belief, even high-risk patients can be tested too frequently. In a perfect world, we would not be testing everyone “all the time.” It is not simply cost that requires us to use appropriate clinical judgment in the rational use of laboratory resources, including UDT. It is important to remember that drug testing is not a therapeutic measure. It is only through the judicial use of UDT with careful integration of clinical and behavioral components that optimum clinical care can be delivered.

Regardless, as time moves forward, the use of UDT is fast becoming a standard of care. What is becoming clear is that the risk to the patient and practitioner alike is a function of what is done with the data thus obtained and not fundamentally in the data itself.40

TESTING STRATEGIES
The literature is clear that there is often a disconnect between the reason a UDT was ordered, the results obtained, and, most importantly, the clinical consequences to the patient because of these tests. The fundamental
problem is a lack of testing strategy or plan for the clinician to use in response to results obtained. So, for the cocaine-misusing, chronic noncancer pain patient who refuses to give up the use of this drug, the clinical course correction necessary may, for the sake of safety, simply involve the termination of the use of controlled substances such as the opioid class of drug. On the other hand, in the palliative care case where there may be a moral imperative to the continued use of controlled substances for pain management, the decision to move this person into a more supervised setting for medication management might be made based on this new information.

The clinician must know the drugs for which to test, appropriate methods to use, and the expected use of the results obtained. If the purpose of testing is to find unprescribed or illicit drug use, a combined chromatographic and spectroscopic method such as gas chromatography/mass spectroscopy or liquid chromatography/tandem mass spectroscopy (GC/MS or LC/MS-MS) or similar technologies are the most specific for identifying individual drugs or their metabolites. Caution must be exercised when interpreting UDT results in a pain practice. True-negative urine results for prescribed medication may indicate a pattern of bingeing rather than drug diversion. Time of last use of the drug(s) can be helpful in the interpretation of negative UDT results. Table 60.1 lists retention times/detection windows of common analytes.

PRESumptive Versus Definitive Testing
For many years, the terms using in clinical drug testing were borrowed from the forensic world of UDT. The concept of preliminary or “screen testing” by various immunoassay techniques followed by more specific “confirmatory testing” by what is often termed a second, scientific method is one more suited to criminal justice rather than clinical care. More recently, the terms have begun to change in clinical care: Preliminary testing is now “presumptive testing,” and confirmatory testing has been replaced with “definitive testing.” In the former case, presumptive testing often provides indirect evidence of specific drug or drug classes, whereas the latter case uses sophisticated methodologies that definitively identify the drug and/or drug metabolite in any given sample. The specifics of these methods are beyond the scope of this chapter, but readers are invited to review Urine Drug Testing in Clinical Practice, 6th edition, for specifics.17

A routine UDT presumptive panel* might include the following drugs/drug classes:
- Cocaine
- Amphetamines / methamphetamine
- Opioids
- Methadone
- Marijuana
- Benzodiazepines

To reduce the risk of an undetected substituted or adulterated test sample, random urinary creatinine, pH, and temperature should be included in the test panel to assist with interpretation and to increase specimen reliability. The temperature of a urine sample within 4 minutes of voiding should be between 90° and 100° F.42 Urinary pH undergoes
physiologic fluctuations throughout the day but should remain within the range of 4.5 to 8.0.\textsuperscript{42} Urinary creatinine varies with daily water intake and hydration; normal human urine has a creatinine concentration greater than 20 mg/dL. Values lower than 20 mg/dL indicate dilution, and findings lower than 5 mg/dL are inconsistent with human urine.\textsuperscript{42,43} Test results outside of these ranges should be discussed with the patient and/or the laboratory, as necessary.\textsuperscript{16}

The detection time of most drugs or their metabolites in urine is usually 1 to 3 days, which is influenced by several factors including but not limited to dose, route of administration, metabolism, urine concentration, and pH.\textsuperscript{41,44} Chronic use of a lipid-soluble drug such as marijuana may extend the window of detection to a week or more.\textsuperscript{42,45} Benzodiazepines and their metabolites differ widely in their elimination half-lives, which affect their clinical effect, excretion, and detection (see Table 60.1).\textsuperscript{46}

There has been much debate about the role of “passive marijuana smoke” and the possibilities of a “contact high” through passive inhalation of smoke from cannabis users.\textsuperscript{47–52} The literature is at best contradictory about whether a low-level THC UDT specimen can be accounted for based on “secondhand smoke.” Much of this literature is based on cannabis strains that are an order of magnitude less potent than that which is available today. In the author’s opinion, further research into this area is necessary to come to a meaningful conclusion in terms of passive THC exposure as a cause for a positive presumptive or definitive test with the availability today’s high potency cannabis.

The method chosen to detect a drug will depend on the reason for undertaking the test. Immunoassay drug tests (i.e., presumptive tests) are, at the current time, most commonly used. They are designed to classify substances as either present or absent and are generally highly sensitive. They are not, however, able to definitively identify the agent leading to the positive result and so are referred to as “presumptive tests.” In pain management, specific drug identification using more sophisticated identification tests is often needed. Combined techniques such as GC/MS make accurate identification of a specific drug and/or its metabolites possible and so are commonly referred to as “definitive tests.” When the patient is being prescribed with drugs from several different classes of
compounds, such as is often the case with many pain patients, specific drug identification may be necessary, especially in cases of contested results.

Immunoassay drug tests for natural opioids are very responsive to morphine and codeine but do not distinguish between the two. UDT by immunoassay also shows a low sensitivity for semisynthetic/synthetic opioids such as oxycodone and fentanyl. A negative result does not exclude their use. Even though an immunoassay may be negative for consumed oxycodone, it should be positive by more definitive testing such as GC/MS if the drug was used within the window of detection. The clinical importance of this fact with UDT cannot be overstated because compliant patients have been dismissed from pain management practices in response to a false-negative immunoassay test when looking specifically for prescribed oxycodone. More recently, drug-specific immunoassay tests have been developed for such drugs as oxycodone or methadone, which are semisynthetic and synthetic drugs, respectively. The previous detection of an analyte, especially semisynthetic drugs, does not ensure future detection, even when dose and dosing interval have not changed. This is especially true when the drug concentration is “peri threshold” as would be the case when the concentration is 302 ng/mL and the cutoff is 300 ng/mL. Small changes in the state of hydration could easily make the sample “negative” one day and positive another.

LIMITATIONS OF TEST INTERPRETATION
The legitimate presence of a prescribed drug in the urine sample may make monitoring of that class of drugs impossible by immunoassay technique alone. Specific drug identification by chromatographic testing (i.e., GC/MS, LC/MS-MS) may also be necessary to identify which member of the detected class is responsible for the positive screen.

The clinician also must understand the basic metabolism of commonly prescribed drugs, especially opioids, so he or she will be able to explain a UDT result that is positive for the prescribed medication and/or its metabolite(s). For example, codeine is a prodrug that has no intrinsic analgesic activity but is metabolized to morphine and other compounds for its analgesic properties. See Figure 60.1 for basic opioid metabolic

The amount of drug and/or metabolite(s) (i.e., nanogram per milliliter) within a urine sample should not be used to extrapolate backward and make specific determinations regarding compliance with prescribed medication. Software and laboratory products have not been scientifically validated and reported in the peer-reviewed literature to give this information at this time. Interpreting UDT beyond the current scientific knowledge may put clinicians and patients at medical and/or legal risk.54 In addition, UDT cannot diagnose addiction, physical dependence, or diversion and should always be verified and correlated with the clinical picture. Health care professionals should use UDT results in conjunction with other clinical information when deciding to continue with or adjust the established boundaries of the treatment plan.

**Dealing with Unexpected Urine Toxicology Results**

Unlike drug testing that is forensically based, such as workplace testing, drug testing in clinical practice must have relevance to patient care. Unfortunately, these test results may come back unexpectedly negative for a prescribed drug or positive for an unprescribed one. The first step in interpreting these results is to contact the lab to ensure that no clerical errors have been made. Occasionally, a negative urine is falsely reported
as positive either due to a simple clerical error (i.e., lab wrote positive when they meant negative) or the patient has taken some other product or medication that is causing an unexpected result. In some cases, more definitive testing as recommended by the lab will give answers to these questions, but they should never be ignored. There must be a process to follow that ultimately should include discussing the unexpected result with the patient.\textsuperscript{16,34}

Unfortunately, drug tests may yield results that appear to be at odds with the patient’s apparent level of clinical stability. Once confirmed as accurate, it is important to speak with the patient, carefully documenting the results and ensuing discussion in the medical record. When the patient acknowledges recreational use of prohibited substances, he or she should be advised of the clinical consequences of continued use including referral on to a specialist in substance use disorders or, if the patient indicates an unwillingness to stop using, discontinuation of the prescription of any controlled substances. When the patient indicates that he or she will no longer use, the patient should be tested more frequently—and, when possible, randomly—to ensure that this drug use has indeed stopped.\textsuperscript{16,34} There are far more illicit/unprescribed drug users who think they are recreational users than are recreational users.

**Decision to Terminate Opioid Therapy**

The decision to change therapeutic direction should ideally be one made through mutual consultation and agreement between the patient and the physician. Unfortunately, occasions arise when the decision to discontinue a therapeutic agent or class of drugs must be made unilaterally. When mutually agreed-on therapeutic goals have not been met, the trial of therapy should be considered a failure and an exit strategy implemented. One commonly held myth is that those patients who no longer need opioid therapy come off these agents easily. This is often untrue. In fact, many articles have been written about pharmacologic efforts at attenuating the withdrawal symptoms associated with opioid withdrawal.\textsuperscript{55–58} Unfortunately, most of these articles are contained in the addiction medicine literature: The pain management literature has been surprisingly quiet on this issue. Interestingly, many medications other than the opioid
Generally, it is better to taper a drug than to abruptly discontinue it. Furthermore, the ease with which a patient can reduce a large dose to a smaller one may not predict the ease with which the patient ultimately discontinues the drug altogether. For this reason, a reasonable taper schedule for drugs with a known discontinuation syndrome is to reduce the agent by ~10% to 20% every 1 to 2 weeks until the last one-third of the dose is reached, at which point the agent should be reduced by ~5% to 10% every 2 to 4 weeks until the agent is stopped. When withdrawal symptoms present themselves, it may be helpful to suspend the taper until these symptoms resolve.

The speed with which a drug is discontinued is a function of many different variables. For example, a taper that is initiated following resolution of a chronic pain generator might be expected to be slower than one that is initiated in response to use of a prohibited substance such as cocaine. Of course, there are situations where it may not be advisable to taper the drug at all. In these cases, the drug will be abruptly discontinued. It should be noted that although abrupt cessation of the opioid class of drug is often distressing, it is unlikely to result in direct harm to the patient. This is not the case with the sedative class of drugs which usually require some form of pharmacologic assistance to safely terminate these agents.

In some cases, certain therapeutic agents can be used to blunt the withdrawal process, especially toward the end of the taper. In the case of opioid withdrawal, the α agonist clonidine can be useful to offset the hyperadrenergic symptoms associated with opioid withdrawal. For the sedative class of drugs, gabapentinoids have been used with some success to both reduce the risk of withdrawal seizures as well as the significant distress associated with this class of drug. For the most part, the stimulant class of drugs does not have physical withdrawal syndromes associated with discontinuation; however, psychological support is often needed to successfully discontinue this class of drugs.

When the decision is made to discontinue a certain class of medication, it is important to remember that this should not be misinterpreted as
discontinuation of treatment. Unfortunately for some patients, discontinuation of a certain drug may result in their abandoning the practitioner who has made the decision to no longer provide this medication. From a medicolegal perspective, it is much easier to defend against a patient who abandons a practitioner who makes a patient-centered decision to alter treatment based on sound medical judgment than it is to defend against an assertion of abandonment by a practitioner who becomes aware that his or her patient may have a problem with drugs.

FUTURE CONSIDERATIONS
An unfortunate reality of the massive expansion of drug testing in clinical care has been an excessive burden on the limited health care dollar. The sale of desktop analyzers has seen an explosion of costs, often with very little evidence of clinical necessity or value added in terms of improved patient care. Clearly, the future of rational drug testing will have to rely on more reasonable compensation models that reflect the actual costs of performing these tests.

In fact, the science of drug testing is in evolution. One of the challenges in clinical care is finding a reliable and cost-effective method to identify specific drugs and their metabolites. The “two-step” approach of presumptive testing by an indirect, immunologic method followed by definitive testing using a combination chromatographic/spectroscopic method is both labor- and time-intensive. The necessary delays which result between sample collection and being able to act on a result are costly. More recently, other methods and approaches to drug testing have appeared.

One approach is to skip presumptive testing altogether and go directly to more definitive methodologies such as LC/MS-MS. To keep costs down and to reduce reporting delays, preliminary testing can be done using a “dilute and shoot” approach which requires very little sample preparation. Now, our current “per analyte” method of laboratory compensation is lagging behind the fact that this method generates a vast amount of reliable data with very little sample preparation.

Even more exciting is the application of techniques such as substrate-enhanced Raman spectroscopy, which can identify specific compounds in
a urine sample in both a timely and cost-effective manner. Sample preparation is minimal and relies on a nondestructive testing method to accurately test samples for clinical care. 69

In conclusion, it is important to remember that a patient’s failure to adhere rigorously to a treatment protocol should not be interpreted as definitive evidence of a substance use disorder or, worse, criminal intent. Patients fail to comply for a complex variety of reasons that must be assessed on an individual basis. Remember, aberrant behavior is much easier to identify than it is to interpret. By separating the motive from the behavior in assessing and interpreting departures from an agreed-on treatment plan, a patient-centered approach to problem solving can be implemented. 5

*Any test panel element should include consideration of the population of donor’s being tested as well as the local drugs of abuse common to their setting.

Headache is a remarkably common problem in neurology and even in general medicine and, by definition, has a substantial pain component. Books are devoted to the topic, and interested readers are directed to recent editions for more detail on the subjects covered here.\textsuperscript{1–5} The headache disorders are classified by the International Classification of Headache Disorders,\textsuperscript{6} now in its third edition, as being either primary, where the headache syndrome is itself the problem, or secondary, where the headache syndrome is driven by other pathologic processes. This chapter is designed to cover the primary headaches with a broad view. Facial neuralgias and facial pain syndromes are covered elsewhere in this book. Where a primary headache causes face pain, and most primary headaches can do this, it will be included here for completeness. This chapter covers the broad principles, the generic anatomy, and physiology of head pain and then discusses in turn the currently defined primary headache syndromes. There is much opportunity in headache to make patients significantly better and much research advancement in this very exciting area of medicine.\textsuperscript{7,8}

**General Principles**

A general system for headache nosology is outlined in Table 61.1. The clinical challenge remains that although life-threatening headache is relatively uncommon in most societies, it occurs and its detection requires suitable awareness by the doctors of its clinical markers (Table 61.2). Primary headache often confers considerable disability over time and, although not life-threatening, certainly robs patients of a good quality of

PRIMARY HEADACHE SYNDROMES

The primary headaches are a group of remarkable disorders in which headache and associated features are seen in the absence of any exogenous cause. First, the general anatomy and physiology will be described as it applies to most of the syndromes. Then, the primary headache syndromes will be addressed in turn.

ANATOMY AND PHYSIOLOGY

The most common disabling primary headaches, migraine and cluster headache, have been studied extensively in recent times, and they are now relatively well understood insofar as neurologic disorders that involve the brain are concerned. The word disabling is emphasized as the writer takes the view that there are not sufficient clear data that tension-type headache provides a substantial and disabling community problem. In experimental animals, the detailed anatomy of the connections of the pain-producing dura mater and intracranial extracerebral vessels has built on the classical human observations of Wolff and Feindel et al. It is these structures, and not the brain itself, that primarily generate, or are perceived to generate, head pain.

The key structures involved are:

- The large intracranial vessels and dura mater
- The peripheral terminals of the trigeminal nerve that innervate these structures
• The central terminals and second-order neurons of the caudal trigeminal nucleus and dorsal horns of C₁ and C₂ (trigeminocervical complex)
• Higher center processing in the thalamus, ventroposteromedial and posterior thalamus, and cortex
• Modulatory centers in the diencephalon and brainstem, such as periaqueductal gray matter, locus coeruleus, and parts of the hypothalamus

The innervation of the large intracranial vessels and dura mater by the trigeminal nerve is known as the trigeminovascular system. The cranial parasympathetic autonomic innervation provides the basis for symptoms such as lacrimation and nasal stuffiness, which are prominent in the trigeminal autonomic cephalalgias,¹⁴,¹⁵ although they may also be seen in migraine.¹⁶ It is clear from human functional imaging studies that vascular changes in migraine and cluster headache are driven by these neural vasodilator systems so that these headaches should be regarded as neurovascular.¹⁷ The concept of a primary vascular headache should be abandoned because it neither explains the pathogenesis of what are complex central nervous system disorders, nor does it necessarily predict treatment outcomes.¹⁸ The term vascular headache has no place in modern medical practice when referring to primary headache.

Migraine is an episodic syndrome of headache with sensory sensitivity, such as to light, sound, and head movement, probably due to dysfunction of aminergic brainstem/diencephalic sensory control systems (Fig. 61.1). The first of the migraine genes has been identified for familial hemiplegic migraine and includes mutations in the CACNA1A gene for the Caᵥ₂.¹ subunit of the neuronal P/Q voltage-gated calcium channel,¹⁹ the Na/K ATP pump α₂ subunit gene ATP1A²,²⁰ and the voltage-gated sodium channel SCN1A.²¹ These findings and the clinical features of migraine suggest it might be part of the spectrum of diseases known as channelopathies, or now ionopathies: disorders involving dysfunction of ion channel fluxes.²² Functional neuroimaging has suggested that brainstem regions, in migraine (Fig. 61.2), and the posterior hypothalamic region, in cluster headache (Fig. 61.3), are good candidates for specific involvement in primary headache.¹⁷
FIGURE 61.1 Pathophysiology of migraine. Diagram of some structures involved in the transmission of trigeminovascular nociceptive input and the modulation of that input that form the basis of a model of the pathophysiology of migraine.\(^7\) Afferents from dural-vascular structures innervated predominantly by branches of the first (ophthalmic division) of the trigeminal nerve whose cell bodies are found in the trigeminal ganglion (Vg) project to second-order neurons in the trigeminocervical complex (TCC). The TCC extends from trigeminal nucleus caudalis to the caudal portion of the dorsal horn of the C\(_2\) spinal cord. Input from cervical structures, such as joints or muscle, project through cell bodies in the upper cervical dorsal root ganglia (DRG) to the TCC. TCC neurons project to ventrobasal thalamus (thalamus) and then to cortex. Sensory modulation can occur by descending influences onto the TCC that largely respect the midline (dashed line), such as those from hypothalamus, midbrain periaqueductal gray (PAG), pontine locus coeruleus (LC), and nucleus raphe magnus (NRM). These influences are cartooned as being direct, but both direct and indirect projections are recognized. In addition, sensory modulation can occur from at least LC, PAG, and hypothalamic projects to thalamus nuclei as ascending systems again that largely respect the midline.
FIGURE 61.2 Activations identified on positron emission tomography in migraine. Consistently, there is dorsolateral pons activation in episodic migraine without aura, triggered by nitroglycerin \(^{144}\) (A) or spontaneously studied \(^{145}\) (B), and in chronic migraine \(^{146}\) (C). Moreover, there is lateralization to the right (D) and left (E) in this structure that parallels the unilateral presentation of the pain. \(^{147}\)

FIGURE 61.3 Activations on positron emission tomography in the posterior hypothalamic gray matter in patients with acute cluster headache (A). The activation demonstrated is lateralized to the side of the pain. \(^{23}\) When comparing the brains of patients with cluster headache with a control population using an automatic anatomical technique known as voxel-based morphometry (VBM) that employs high-resolution T1 weighted magnetic resonance imaging, a similar region is demonstrated (B) and has increased gray matter. \(^{24}\)

SECONDARY HEADACHE
It is imperative to establish in the patient presenting with any form of head pain whether there is an important secondary headache. Perhaps, the most crucial clinical feature to elicit is the length of the history. Patients with a short history require prompt attention and may require prompt investigation and management. Patients with a longer history generally require time and patience rather than alacrity. There are some important general features, including associated fever or sudden onset of pain (see Table 61.2). Patients with a history of recent-onset headache or neurologic signs need a positive diagnosis of a benign disorder or require brain imaging with computed tomography (CT) or magnetic resonance imaging (MRI). Patients with a history of recurrent headache over a period of 1 year or more, fulfilling International Headache Society (IHS) criteria for migraine (Table 61.3) and with a normal physical examination, have positive brain imaging findings in only about 1/1,000 images.\textsuperscript{25} In general, it should be noted that brain tumor is a rare cause of headache and rarely a cause of isolated long-term histories of headache. A notable exception to the general rules about secondary headache is pituitary tumor, which can trigger underlying primary headache biologies and should always be considered, especially in the differential diagnosis of trigeminal autonomic cephalalgias (see the following text; Levy et al.\textsuperscript{26}). The management of secondary headache is generally self-evident: treatment of the underlying condition, such as an infection or mass lesion. One notable exception is the condition of persistent posttraumatic headache. This is an important problem that may be seen after central nervous system infection; trauma, both blunt and surgical; intracranial bleeds; and other precipitants, using the term trauma in its broader context to mean a biologic insult. The prevalence of the problem in returning service personnel has served to draw attention to the condition.\textsuperscript{27,28} It can certainly often be both prolonged and disabling.

MIGRAINE

Clinical Features
Migraine is an episodic brain disorder that affects about 12% to 15% of the population and can be highly disabling. It has been estimated to be the most costly neurologic disorder in the European Community at more than €27 billion per year, and its cost to the US economy was a staggering $19.6 billion per year more than a decade ago. Migraine presents with headache generally accompanied by features, such as sensitivity to light, sound, or movement, and often with nausea, or less often vomiting (see Table 61.3). None of the features is compulsory and indeed, given that the migraine aura, visual disturbances with flashing lights or zigzag lines moving across the fields or other neurologic symptoms, is reported in only about 25% of patients, a high index of suspicion is required to diagnose migraine. In a controlled study of patients presenting to primary care physicians with a main complaint of headache over the previous 3 months, migraine was the diagnosis on more than 90% of occasions; thus, a high index of suspicion is important. A headache diary can often be helpful in making the diagnosis, although in reality, usually the diary helps more in assessing disability or recording how often patients use acute attack treatments. Phenotyping remains an essentially clinical art mixing experience and an understanding of the problems likely to present: Good headache histories are taken not given. In differentiating the two main primary headache syndromes seen in clinical practice, migraine at its simplest is headache with associated features, and tension-type headache is headache that is featureless; furthermore, most disabling headache presentations in primary care are probably migrainous in biology. By features, here is meant throbbing pain; sensitivity to sensory stimuli: visual, auditory, olfactory; or to head movement itself.

Frequent Migraine

If headache with associated features describes migraine attacks, then headachy describes the migraine sufferer over his or her lifetime. It is important to realize that the word migraine can both describe the attacks using standard criteria (see Table 61.3) and describe the disorder itself, which is more than just the attacks. The migraine sufferer inherits a tendency to have headache that is amplified at various times by their interaction with their environment, the much-discussed triggers. The brain of the migraineur seems more sensitive to sensory stimuli and to change, and this tendency is notably amplified in females during their menstrual cycle. Migraine sufferers may have headache when they oversleep, when tired, when they skip meals, when they overexert, when stressed, or when they relax from a stressor. They are less tolerant to change, and part of successful management is to advise them to maintain regularity in their lives in the knowledge of this fluctuating biology. It is this biology that marks migraine and in clinical practice must override the phenotype of individual headaches. Chronic migraine is the largest part of the group of headaches known collectively as chronic daily headache, a term best not often employed because almost invariably, a more specific diagnosis can be made. Chronic migraine currently requires some 15 days a month of headache of which 8 are clearly migrainous and with a predating history of migraine. After making a diagnosis, the second step in the clinical process is to be sure that the disease burden has been captured, how much headache does the patient have and more important, what can the patient not do; what is his or her degree of disability? One can ask the patient directly to get a flavor for this, keep a diary or get a quick but accurate estimate using the Migraine Disability Assessment Scale (MIDAS), which is well validated and very easy to use in practice (Fig. 61.4).
Principles of Management of Migraine

After diagnosis, the management of migraine begins with an explanation of some aspects of the disorder to the patient.

- Migraine is an inherited tendency to have headache; this is caused by the patient’s genes; therefore, it cannot be cured, but
- Migraine can be modified and controlled by lifestyle adjustment and the use of medicines;
- Migraine is not life-threatening nor associated with serious illness with the exception of females who smoke and use estrogenic oral contraceptives but migraine can make life a misery; and
- Migraine management takes time and cooperation when, for example, a headache diary has to be collected or inquiry made concerning the disability.
Nonpharmacologic Management of Migraine
This approach aims to help the migrainous patient identify things making the problem worse and encouraging them to modify these. Patients need to know that the brain sensitivity to triggers in migraine varies. Patient associations are often very helpful in supporting migraineurs to identify triggers. The knowledge that there is variability will remove considerable frustration on the patient’s part and will ring true to most as they have had the experience. The crucial lifestyle advice is to explain to the patient that migraine is a state of brain sensitivity to change. This implies that the migraine sufferer needs to regulate their lives: healthy diet, regular exercise, regular sleep patterns, avoiding excess caffeine and alcohol, and, as far as practical, modifying or minimizing changes in stress. The balanced life with less highs and lows will benefit most migraine sufferers.

Preventive Treatments of Migraine
The patient needs to understand they have an inherited, noncurable but manageable problem. To start a preventive, they need to have sufficient disability to wish to take a medicine to reduce the effects of the disease on their life. The basis of considering preventive treatment from a medical viewpoint is a combination of acute attack frequency and attack tractability that is conferring an unacceptable degree of disability. Patients with attacks unresponsive to abortive medications are easily considered for prevention, whereas patients with simply treated attacks may be less obvious candidates. Another important consideration is disease progress. If a patient diary shows a clear trend of an increasing frequency of attacks, it is better to initiate a preventive than wait for the problem to worsen.

A simple rule for frequency might be that for one to two headaches a month, there is usually no need to start a preventive; for three to four, it may be needed but not necessarily; and for five or more per month, prevention should definitely be considered. Options available for treatment are covered in detail in Table 61.4 and vary by country. One problem with preventives is that they have fallen into use for migraine from other indications and often bring unwanted or intolerable side effects. It is not clear how preventives work, although it seems likely that they modify the brain sensitivity that underlies migraine. Another key clinical point is that
generally, each drug should be started at a low dose and gradually increased to a reasonable maximum if there is going to be a clinical effect.

New advances: The development of migraine-specific preventives is on us as monoclonal antibodies to the calcitonin gene-related peptide (CGRP) pathway are nearing the clinic; effective and well tolerated, a new era is beginning.\textsuperscript{32} There are four monoclonal antibodies effective in both episodic and chronic migraine: three to CGRP, eptinezumab,\textsuperscript{33,34} fremanezumab,\textsuperscript{35,36} and galcanezumab,\textsuperscript{37,38} and one to the receptor, erenumab.\textsuperscript{39,40} Neuromodulation or neurostimulation approaches are promising as patients and physicians seek nonpharmaceutical approaches to treatment\textsuperscript{41}; the best established of these being single-pulse transcranial magnetic stimulation (sTMS).\textsuperscript{42,43}

Acute Attack Therapies of Migraine

Acute attack treatments for migraine can be usefully divided into disease-nonspecific treatments, analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs), disease-specific treatments, ergot-related compounds, and triptans (Table 61.5). It is important to be aware that most acute attack medications seem to have a propensity to aggravate headache frequency and can induce a state of refractory daily, near-daily, or medication overuse headache. As evidence is gathered, this seems to occur in patients with migraine, either a previous clear history or a family or personal history of headacheyness.\textsuperscript{44} Codeine-containing analgesics are particularly troublesome when available in over-the-counter (OTC) preparations. One

- Riboflavin 400 mg daily GI upset
- Coenzyme Q10 100 mg three times daily
- Butterbur 75 mg twice daily
- Feverfew 6.25 mg three times daily

No convincing controlled evidence

- Verapamil
  Controlled trials to demonstrate no effect
- Nimodipine
- Clonidine
- SSRIs: fluoxetine

GI, gastrointestinal. SSRI, selective serotonin reuptake inhibitor.

\textsuperscript{a}Commonly used preventives are listed with reasonable doses and common side effects. The local national formulary should be consulted for detailed information.

\textsuperscript{b}Compounds not widely considered mainstream but with a positive randomized control trial against placebo.

\textsuperscript{c}Nonpharmaceuticals with at least one positive randomized controlled trial against placebo.
should advise patients with migraine to avoid taking acute attack medicines on more than 2 days a week. A proportion of patients who stop taking regular analgesics will have substantial improvement in their headache with a reduction in frequency; however, for some, it will not make any difference. It is crucial to emphasize to the patient that standard preventive medications often simply do not work in the presence of regular analgesic use.

| TABLE 61.5  Acute Migraine Treatments |
|------------------|------------------|
| **Non Specific Treatments** | **Specific Treatments** |
| Often used with antiemetic/prokinetics, such as domperidone (10 mg) or metoclopramide (10 mg) | Ergot derivatives |
| Aspirin (900 mg) | • Ergotamine (1–2 mg) |
| Paracetamol (acetaminophen—1,000 mg) | • Triptans |
| NSAIDs | • Sumatriptan (50 or 100 mg) |
| • Naproxen (500–1,000 mg) | • Naratriptan (2.5 mg) |
| • Ibuprofen (400–800 mg) | • Rizatriptan (10 mg) |
| • Tolfenamic acid (200 mg) | • Zolmitriptan (2.5 or 5 mg) |
| NSAIDs, nonsteroidal anti-inflammatory drugs. |

**Treatment strategies:** Given the array of options to control an acute attack of migraine, how does one start? The simplest approach to treatment has been described as stepped care. In this model, all patients are treated, assuming no contraindications, with the simplest treatment, such as aspirin 900 mg or paracetamol (acetaminophen) 1,000 mg with an antiemetic. Aspirin is an effective strategy, has been proven so in double-blind controlled clinical trials, and is best used in its most soluble formulations. The alternative would be a strategy known as stratified care, by which the physician determines, or stratifies, treatment at the start based on likelihood of response to levels of care. An intermediate option may be
described as stratified care by attack. The latter is what many headache authorities suggest and what patients often do when they have the options.\textsuperscript{45} Patients use simpler options for their less severe attacks relying on more potent options when their attacks or circumstances demand them.

**Nonspecific acute migraine attack treatments:** Simple drugs, such as aspirin and paracetamol (acetaminophen), are cheap and can be effective. Dosages should be adequate and the addition of domperidone (10 mg orally) or ondansetron (4 mg) or aprepitant (80 mg) can be very helpful. NSAIDs can very useful when tolerated. Their success is often limited by inappropriate dosing, and adequate doses of naproxen (500 to 1,000 mg orally or rectally, with an antiemetic), ibuprofen (400 to 800 mg orally),\textsuperscript{46} or tolfenamic acid (200 mg orally)\textsuperscript{47} can be extremely effective.

**Specific acute migraine attack treatments:** When simple analgesic measures fail or more aggressive treatment is required, the specific antimigraine treatments are required (Table 61.6). Although ergotamine remains a useful treatment, it can no longer be considered the treatment of choice in acute migraine.\textsuperscript{48} There are particular situations in which ergotamine is very helpful, but its use must be carefully controlled as ergotamine overuse produces dreadful headache in addition to a host of vascular problems. The triptans, serotonin 5-HT\textsubscript{1B/1D} receptor agonists, have revolutionized the life of many patients with migraine and are clearly the most powerful option available to stop a migraine attack. They can be rationally applied by considering their pharmacologic, physicochemical, and pharmacokinetic features\textsuperscript{49} as well as the formulations that are available.\textsuperscript{45} Recent data suggests that combining a triptan with an NSAID can improve efficacy and reduce headache recurrence.\textsuperscript{50}

**IMI, intramuscular injection; MLT, Maxalt-MLT.**

**New advances:** There are exciting new developments in acute therapy of migraine that are on the horizon. Neuromodulation approaches with supraorbital stimulation, noninvasive vagus nerve stimulation (nVNS), and transcranial magnetic stimulation each have controlled trials and an interesting physiologic basis. They offer patients a nonpharmaceutical option. What has been sought almost since the launch of the triptans is effective acute antimigraine treatments without vasoconstrictor effects. The development of lasmiditan, a serotonin 5-HT$_{1F}$ receptor agonist, or ditan, that is without vasoconstrictor effects, yet works in clinic in phase II and now in two phase III studies, is an important development. Similarly, the development of small molecule CGRP receptor antagonists, or gepants, notably now rimegepant and ubrogepant, which are both effective in treating acute migraine, and come from a clearly safe class of
treatments,\textsuperscript{61} again offers the real promise of an important advance for patients.

**Medication Overuse**

An important clinical issue, which is probably a consequence of the interplay between migrainous biology and acute attack treatment, is what is described as medication overuse. Medication overuse is defined as consuming an acute attack therapy on 10 days or more per month. This issue can be conflated with “medication overuse headache” as if every patient using analgesics at that frequency has a headache driven by acute attack medicines. The issue has been recently questioned.\textsuperscript{62} It can certainly be helpful clinically to encourage analgesic overuse be reduced and eliminated if one is to see the underlying headache phenotype and commence to manage the problem.\textsuperscript{63} Patients can reduce their use either by, as an example, 10% every week or two, depending on their circumstances, or if they wish, and there is no contraindication, by immediate cessation of use. Either approach can be facilitated by first keeping a careful diary over a month or two to be sure of the size of the problem. A small dose of an NSAID, such as naproxen 500 mg two to three times daily if tolerated, will take the edge off the pain as the analgesic use is reduced, as does a greater occipital nerve injection. It is useful aside that NSAID overuse does not seem to be a common issue in practice.\textsuperscript{64} When the patient has reduced their analgesic use substantially, a preventive should be introduced. It is widely considered that medication overuse is a common cause of intractability to preventive treatments. This seems true in practice, although it is not invariable and not well studied.

Some patients with medication overuse will require admission for treatment. Broadly, this consists of two groups, those who fail outpatient withdrawal or those who have a significant complicating medical indication, such as brittle diabetes mellitus, or complicating medicines, such as opioids, where withdrawal may be problematic as an outpatient. When such patients are admitted, acute medications are withdrawn completely on the first day, unless there is some contraindication. Antiemetics, such as domperidone,\textsuperscript{65} ondansetron, or aprepitant,\textsuperscript{66} and fluids are administered as required as well as clonidine for opioid
withdrawal symptoms. For acute intolerable pain during the waking hours, aspirin (1 g intravenously) is useful, and at night, chlorpromazine by injection, after ensuring adequate hydration. If the patient does not settle over 3 to 5 days, a course of intravenous dihydroergotamine (DHE) can be employed.

TENSION-TYPE HEADACHE

Clinical Features
As its name suggests, tension-type headache (TTH) is the headache form most seeking of understanding. TTH is diagnosed often, and although the phenotype is common, much of the disabling headache that goes under the name TTH is likely to be chronic migraine in terms of its biology. TTH has two forms, episodic TTH, where attacks occur on less than 15 days a month, and chronic TTH, where attacks, on average over time, are seen on 15 days or more a month. The IHS seeks to subdivide episodic TTH into an infrequent variety, arguably of little practical impact on the patient’s life, and a more frequent but nonchronic version. Patients with the chronic form are part of the broader clinical syndrome of chronic daily headache, but chronic TTH and chronic daily headache are not equal concepts.

TTH has been defined by the IHS both for its episodic and chronic forms, although the admixture of symptoms allowed has consistency problems. A useful clinical approach is to diagnose TTH using the appendix criteria, when the headache is completely featureless: no nausea, no vomiting, no photophobia, no phonophobia, no osmophobia, no throbbing, and no aggravation with movement. Such an approach neatly divides migraine, which has one of more of these features and is the main differential diagnosis, from TTH.

Pathophysiology
The pathophysiology of TTH is poorly understood. This results from the fact that the name implies to most that it is a product of nervous tension, for which there is no clear evidence, and the definitions employed have undoubtedly admitted patients with migraine to the studies. Moreover, the concept that TTH in some way involves muscle contraction is incorrect because the evidence is that muscle contraction is no more likely that it is
in migraine. It seems likely that TTH will be due to a primary disorder of central nervous system pain modulation alone in contrast with migraine, which is a more generalized disturbance of sensory modulation.

**Management**

Adopting the clinical approach to TTH outlined in the preceding text results in diagnosing a headache form that is usually less disabling, more often described by patients as irritating. Its episodic form is generally amenable to simple analgesics, paracetamol (acetaminophen), aspirin, or other NSAIDs, which can be purchased OTC. There are clear clinical studies to demonstrate that triptans in TTH alone are not helpful, although, germane to the earlier discussion, triptans are effective in TTH where the patient also has migraine. For chronic TTH, amitriptyline is the only treatment with clear evidence of efficacy; the other tricyclics, selective serotonin reuptake inhibitors, or the benzodiazepines have not been shown in controlled trials to be effective. Similarly, there is no controlled evidence for the use of electromyography (EMG) biofeedback, relaxation therapy, or acupuncture. Botulinum toxin has been shown reasonably clearly to be ineffective. Stress management has been shown to be an effective approach in a controlled trial.

**TRIGEMINAL-AUTONOMIC CEPHALALGIAS**

**Cluster Headache**

Cluster headache is a rare form of primary headache with a population frequency of approximately 0.1%. As a clinical anchor, it is about as common as multiple sclerosis in the United Kingdom and must be regarded as a disorder best managed by neurologists or headache specialists. It is perhaps the most painful condition of humans; in the cohort of more than 1,000 patients seen by the author, and in patient-based assessments, not a single one has had a more painful experience, including childbirth, multiple fractures of the limbs, or renal stones. It is one of a group of conditions known now as trigeminal-autonomic cephalalgias (TACs) and thus needs to be differentiated from other TACs and the short-lasting headaches without cranial autonomic symptoms, such as lacrimation or conjunctival injection (Table 61.7).
### TABLE 61.7 Cluster Headache, Other Trigeminal Autonomic Cephalalgias, and Short-Lasting Headaches

</tbody>
</table>

SUNA, short-lasting unilateral neuralgiform headache attacks with cranial autonomic features; SUNCT, short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing.

<sup>a</sup>Beware of pituitary tumor-related headache in the differential diagnosis of these trigeminal autonomic cephalalgias.

The core feature of cluster headache is periodicity, be it circadian or in terms of active and inactive bouts over weeks and months (Table 61.8). The typical cluster headache patient is male, with a 3:1 predominance, with bouts of one to two attacks of relatively short duration unilateral pain every day for 8 to 10 weeks a year. They are generally perfectly well between times. Patients with cluster headache tend to move about during attacks, pacing, rocking, or even rubbing their head for relief. The pain is usually retroorbital, boring, and very severe. It is associated with ipsilateral symptoms of cranial (parasympathetic) autonomic activation: a red or watering eye, the nose running or blocking, or cranial sympathetic dysfunction (eyelid droop). Cluster headache is likely to be a disorder involving central pacemaker regions of the posterior hypothalamus and perhaps other neurons of this region (see Fig. 61.2).<sup>23,24</sup>

</tr>
<tr>
<td>C. Headache is accompanied by at least one of the following:</td>
</tr>
<tr>
<td>1. Ipsilateral conjunctival injection and/or lacrimation</td>
</tr>
<tr>
<td>2. Ipsilateral nasal congestion and/or rhinorrhea</td>
</tr>
<tr>
<td>3. Forehead and facial sweating</td>
</tr>
<tr>
<td>4. Ipsilateral eyelid edema</td>
</tr>
<tr>
<td>5. Ipsilateral forehead and facial sweating</td>
</tr>
</tbody>
</table>
6. Ipsilateral miosis and/or ptosis
7. A sense of restlessness or agitation
D. Attacks have a frequency from one every other day to eight per day.
E. Not attributed to another disorder

Episodic Cluster Headache

Description: occurs in periods lasting 7 d to 1 y separated by pain-free periods lasting 3 mo or more
Diagnostic criteria:
A. All fulfilling criteria A–E of 3.1
B. At least two cluster periods lasting from 7 to 365 d and separated by pain-free remissions of ≥3 mo.

Chronic Cluster Headache

Description: Attacks occur for more than 1 y without remission or with remissions lasting less than 3 mo.
Diagnostic criteria:
A. All alphabetical headings of 3.1
B. Attacks recur over >1 y without remission periods or with remission periods <3 mo.

The TACs (cluster headache, paroxysmal hemicrania [PH], and short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing [SUNCT] syndrome) present a distinct group to be differentiated from short-lasting headaches that do not have prominent cranial autonomic syndromes, notably trigeminal neuralgia, idiopathic (primary) stabbing headache, and hypnic headache. By determining the cycling pattern, length of attack, frequency of attack, and timing of the attacks, most patients can be usefully classified. The importance of clinical classification of this group is threefold. First, the clinical phenotype determines the likely secondary causes that must be considered and appropriate investigations ordered. Second, the appropriate classification gives clarity to the patient with a clear diagnosis and allows the physician to draw on available literature to comment on natural history. Third, the correct diagnosis determines therapy that can be very different in these conditions, being very good if the diagnosis is correct but largely ineffective if it is not (Table 61.9).

<table>
<thead>
<tr>

TABLE 61.9 Differential Diagnosis of Short-Lasting Headaches
### Managing Cluster Headache

Cluster headache is managed using acute attack treatments and preventive agents. Acute attack treatments are usually required by all cluster headache patients at some time, whereas preventives can seem almost lifesaving for the patients with chronic cluster headache and are often needed to shorten the active periods in patients with the episodic form of the disorder. Episodic cluster headache is diagnosed if patients have a treatment-free period of 3 consecutive months in a year and chronic when that is not the case.\(^6\)

**Preventive treatments:** The options for preventive treatment in cluster headache depend on the bout length (Table 61.10). Patients with short bouts require medicines that act quickly but will not necessarily be taken for long periods, whereas those with long bouts or indeed those with chronic cluster headache require safe, effective medicines that can be taken for long periods. Verapamil is now widely considered as the first-

line preventive treatment when the bout is prolonged or in chronic cluster headache. By contrast, limited courses of oral corticosteroids can be very useful strategies when the bout is relatively short.\(^\text{82}\)

?, unproven but promising.

Verapamil has been suggested as a useful option for the last decade and compares favorably with lithium. What has clearly emerged from clinical practice is the need to use higher doses than had initially been considered and certainly higher than those used in cardiologic indications. Although most patients will start on doses as low as 40 to 80 mg twice daily, doses up to 960 mg daily are often required. Side effects, such as gingival hyperplasia, constipation, and leg swelling, are recognized as are cardiac dysrhythmias. Verapamil can cause heart block by slowing conduction in the atrioventricular (AV) node, monitored clinically by the PR interval on the electrocardiogram (ECG). Given that the effects on the AV node take up to 10 days to manifest, 2-week intervals are recommended between dose changes on the first exposure, with ECGs prior the next escalation, and routine six monthly ECGs after the dose is established.\(^\text{83}\)

The development of nVNS for the preventive treatment of cluster headache is a promising way forward.\(^\text{84}\) It compares with standard of care\(^\text{85}\) and is particularly useful when patients have contraindications or intolerability to standard therapies.

**Acute attack treatment:** Cluster headache attacks often peak rapidly and thus require a treatment with quick onset. Many patients with acute cluster headache respond very well to treatment with oxygen inhalation. This should be given as 100% oxygen at 10 to 12 L per minute for 15 to 20
Injectable sumatriptan 6 mg is effective, rapid in onset, and has no evidence of tachyphylaxis. Sumatriptan 20 mg and zolmitriptan 5 mg nasal sprays are effective in acute cluster headache in controlled trials and offer a useful option. Sumatriptan is not effective when given preemptively as 100 mg orally three times daily, and there is no evidence that it is useful when used orally in the acute treatment of cluster headache; indeed, it can be associated with medication overuse headache problems. The most recent development in the treatment of acute cluster headache has been the completion of two randomized sham-controlled studies of nVNS. The two studies worked for acute attacks in patients with episodic cluster headache but not in chronic cluster headache.

**Surgical treatment:** The surgical treatment of cluster headache has been completely transformed by the introduction of neurostimulation therapies. Surgical treatment of cluster headache is reserved for the most refractory patients, typically with chronic cluster headache. Destructive procedures, such as sphenopalatinectomy or radiofrequency lesions of the trigeminal ganglion, have been used. The former is without clear effects, with the latter being helpful but often at significant cost, including ocular complications or anesthesia dolorosa. Trigeminal rhizotomy has also been employed, with all the complications of radiofrequency lesions and the occasional death. Set against this, the functional imaging work describing activations in the posterior hypothalamic region directly lead to deep brain stimulation approaches in the same region that seem highly effective, although not without morbidity and mortality. Occipital nerve stimulation is a less invasive approach to the management of intractable chronic cluster headache, although with time its limitations have become clearer. The most promising surgical option at this time is sphenopalatine ganglion stimulation, which is reported in a controlled trial to be effective for both acute attack treatment and prevention, with good long-term outcomes.

**PAROXYSMAL HEMICRANIA**

Sjaastad and Dale first reported eight cases of a frequent unilateral severe but short-lasting headache without remission coining the term chronic paroxysmal hemicrania (CPH). The mean daily frequency of
chronic paroxysmal hemicrania (CPH). The mean daily frequency of attacks varied from 7 to 22 with the pain persisting from 5 to 45 minutes on each occasion. The site and associated autonomic phenomena were similar to cluster headache, but the attacks of CPH were suppressed completely by indomethacin.

The essential features of PH that we have seen from a substantial cohort of patients are:

- Unilateral very severe pain
- Short-lasting attacks typically 20 minutes in length
- Very frequent attacks (usually more than 5 times a day)
- Marked autonomic features ipsilateral to the pain
- Robust, quick (less than 72 hour), excellent response to indomethacin

The pathophysiology of PH is marked by activations on positron emission tomography (PET) in the contralateral posterior hypothalamus and contralateral ventral midbrain. The posterior hypothalamic activity is shared with cluster headache, SUNCT, and hemicrania continua, whereas the ventral midbrain activity is only seen in hemicrania continua, which remarkably is also an indomethacin-sensitive primary headache.

The therapy of PH may be complicated by gastrointestinal side effects seen with indomethacin, in which topiramate may be helpful. When indomethacin is poorly tolerated, nVNS may be very useful and is well tolerated in patients with PH. Secondary PH is more likely if the patient requires high doses (>200 mg per day) of indomethacin and raised cerebrospinal fluid (CSF) pressure should be suspected in apparent bilateral PH. It is worth noting that indomethacin reduces CSF pressure by an unknown mechanism. It is appropriate to image patients, with MRI if practical, when a diagnosis of PH is being considered.

**SHORT-LASTING UNILATERAL NEURALGIFORM HEADACHE ATTACKS WITH CONJUNCTIVAL INJECTION AND TEARING OR CRANIAL AUTONOMIC ACTIVATION**

Sjaastad and colleagues reported three male patients whose brief attacks of pain in and around one eye were associated with sudden conjunctival injection and other autonomic features of cluster headache. The attacks
lasted only 15 to 60 seconds and recurred 5 to 30 times per hour and could be precipitated by chewing or eating certain foods, such as citrus fruits. They were not abolished by indomethacin. Brain imaging has suggested that they share with cluster headache and PH the feature on activation studies of involvement of the posterior hypothalamic region. Of the patients recognized with this problem, males dominate slightly and the paroxysms of pain may last between 5 and 300 seconds, although longer duller interictal pains are recognized, as are longer attacks with a sawtooth pattern. The conjunctival injection seen with SUNCT is often the most prominent autonomic feature, and tearing may be very obvious. If one of either conjunctival injection or tearing is absent, or neither is present but another cranial autonomic symptom is seen, the term short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA) is used. The two key clinical features of SUNCT/SUNA are the attacks being triggerable with no refractory period to triggering. The latter serves as a very useful distinction between SUNCT/SUNA and trigeminal neuralgia. SUNCT/SUNA can be treated very often with lamotrigine and if that is unhelpful topiramate or gabapentin. Carbamazepine often has a useful but incomplete effect. Given what has been reported, cranial MRI with pituitary and posterior fossa views is highly recommended when SUNCT/SUNA is considered as a diagnosis.

OTHER PRIMARY HEADACHES

Primary Stabbing Headache
Short-lived jabs of pain, defined by the Headache Classification Committee of the IHS as primary stabbing headache, are well documented in association with most types of primary headache.

The essential clinical features are:
• Pain confined to the head, although rarely is it facial
• Stabbing pain lasting from 1 to many seconds and occurring as a single stab or a series of stabs
• Recurring at irregular intervals (hours to days)

These pains have been called ice-pick pains or jabs and jolts. They generally respond to indomethacin (25 to 50 mg twice to three times daily). The symptoms tend to wax and wane, and after a period of control
outcome. Most patients will not want treatment when the nature of the problem is explained, and they are reassured that the attacks are not sinister in any way.

**Primary Cough Headache**
Sharp pain in the head on coughing, sneezing, straining, laughing, or stooping has long been regarded as a symptom of organic intracranial disease, commonly associated with obstruction of the CSF pathways. The presence of an Arnold-Chiari malformation or any lesion causing obstruction of CSF pathways or displacing cerebral structures must be excluded before cough headache is assumed to be benign. Cerebral aneurysm, carotid stenosis, and vertebrobasilar disease may also present with cough or exertional headache as the initial symptom. The term benign Valsalva’s maneuver–related headache covers the headaches provoked by coughing, straining, or stooping, but cough headache is more succinct and so widely used it is unlikely to be displaced. The essential clinical features of primary cough headache are:

- Bilateral headache of sudden onset, lasting minutes, precipitated by coughing
- May be prevented by avoiding coughing
- Diagnosed only after structural lesions, such as posterior fossa tumor, have been excluded by neuroimaging

Indomethacin is the medical treatment of choice in cough headache. Raskin followed up an observation of Sir Charles Symonds reporting that some patients with cough headache are relieved by lumbar puncture. This is a simple option when compared to prolonged use of indomethacin. The mechanism of this response remains unclear.

**Primary Exertional Headache**
The relationship of this form of headache to cough headache is unclear and certainly much is shared. Indeed, the relationship to migraine also requires delineation.

The clinical features are:

- Pain specifically brought on by physical exercise
- Bilateral and throbbing in nature at onset and may develop migrainous
• Bilateral and throbbing in nature at onset and may develop migrainous features in those patients susceptible to migraine
• Lasts from 5 minutes to 24 hours
• Prevented by avoiding excessive exertion, particularly in hot weather or at high altitude

The acute onset of headache with straining and breath holding as in weightlifter’s headache may be explained by acute venous distension. The development of headache after sustained exertion, particularly on a hot day, is more difficult to understand. Anginal pain may be referred to the head, probably by central connections of vagal afferents and may present as exertional headache, so called cardiac cephalgia.\textsuperscript{113} The link to exercise is the important clinical clue. Pheochromocytoma may occasionally be responsible for exertional headache. Intracranial lesions or stenosis of the carotid arteries may have to be excluded as discussed for benign cough headache. Headache may be precipitated by any form of exercise and often has the pulsatile quality of migraine. The most obvious form of treatment is to take exercise gradually and progressively whenever possible. Indomethacin at daily doses varying from 25 to 150 mg is generally very effective in benign exertional headache. Indomethacin 50 mg or frovatriptan 2.5 mg po are useful short-term preventive measures.

**Primary Sex Headache**

Sex headache may be precipitated by masturbation or coitus and usually starts as a dull bilateral ache while sexual excitement increases, suddenly becoming intense at orgasm. The term orgasmic cephalgia is not accurate because not all sex headaches require orgasm. Two types of primary sex headache are recognized: a dull ache in the head and neck that intensifies as sexual excitement increases and a sudden severe (“explosive”) headache occurring at orgasm.\textsuperscript{6} Low CSF volume headache may also be precipitated by a sexual activity and is considered as a form of new daily persistent headache (NDPH) (see the following text).

The essential clinical features of sex headache are:
• Precipitation by sexual excitement
• Bilateral at onset
• Prevented or eased by ceasing sexual activity before orgasm
Headaches developing at the time of orgasm are not always benign, and consideration of a diagnosis of subarachnoid headache is essential. Sex headache affects men more often than women and may occur at any time during the years of sexual activity. It may develop on several occasions in succession and then not trouble the patient again, despite no obvious change in sexual technique. In patients who stop sexual activity when headache is first noticed, it may subside within a period of 5 minutes to 2 hours, and it is recognized that more frequent orgasm can aggravate established sex headache. About one-third of the patients with sex headache have a history of exertional headaches, but there is no excess of cough headache in patients with sex headache. In about 50% of patients, sex headache will settle in 6 months. Migraine is reported in about 25% of patients with sex headache.

Primary sex headaches are usually irregular and infrequent in occurrence, so management can often be limited to reassurance and advice about ceasing sexual activity if a milder, warning headache develops. When the condition recurs regularly or frequently, it can be prevented by the administration of propranolol; the dosage required varies from 40 to 200 mg daily. An alternative is the calcium channel blocking agent diltiazem 60 mg three times daily, which this author finds particularly useful in such patients. Indomethacin (25 to 50 mg) or frovatriptan (2.5 mg) taken about 30 to 45 minutes prior to sexual activity can also be helpful.

**Hypnic Headache**

This syndrome was first described by Raskin in patients aged from 67 to 84 years who had headache of a moderately severe nature that typically came on a few hours after going to sleep. These headaches last from 15 to 30 minutes, are typically generalized, although may be unilateral, and can be throbbing. Patients may report falling back to sleep only to be awoken by a further attack a few hours later with up to three repetitions of this pattern over the night. In a series of 19 patients, 16 (84%) were female, and the mean age at onset was 61 ± 9 years. Headaches were bilateral in two-thirds and unilateral in one-third and in 80% of cases mild or moderate. Three patients reported similar headaches when falling asleep.
during the day. None had photophobia or phonophobia, and nausea is unusual.

Patients with this form of headache generally respond to a bedtime dose of lithium carbonate (200 to 600 mg) and in those that do not tolerate this, verapamil at bedtime may be alternative strategies). Dodick and colleagues reported that one to two cups of coffee or caffeine 60 mg orally at bedtime was helpful. This is a simple approach that is effective in about one-third of patients. An important secondary cause of hypnic headache is hypertension which should be carefully pursued and appropriately investigated as treatment of the blood pressure will arrest the headache problem.

**Primary Thunderclap Headache**

Sudden-onset severe headache may occur in the absence of sexual activity, and the differential diagnosis includes the sentinel bleed of an intracranial aneurysm, cervicocephalic arterial dissection, and cerebral venous thrombosis. Headaches of explosive onset may also be caused by the ingestion of sympathomimetic drugs or tyramine-containing foods in a patient who is taking monoamine oxidase inhibitors and can also be a symptom of pheochromocytoma. Whether thunderclap headache can be the presentation of an unruptured cerebral aneurysm is unclear. Day and Raskin reported a woman with three episodes of sudden-onset very severe headache who was found to have an unruptured aneurysm of the internal carotid artery, with adjacent areas of segmental vasospasm. In the absence of CT scan or CSF evidence of subarachnoid hemorrhage, studies indicate that such patients do very well, and there indeed seems a form of benign or primary thunderclap headache.

Wijdicks and colleagues followed up 71 patients for an average of 3.3 years whose CT scans and CSF findings were negative. Twelve patients had further such headache, and 31 (44%) later had regular episodes of migraine or TTH. Factors identified as precipitating the headache were sexual intercourse in 3 cases, coughing in 4, and exertion in 12, whereas the remainder had no obvious cause. A history of hypertension was found in 11 and of previous headache in 22. Markus compared the presentation of 37 patients with subarachnoid hemorrhage...
and could not discern any characteristic to distinguish the two conditions.

Investigation of any sudden-onset severe headache, be it in the context of sexual excitement or isolated thunderclap headache, should be driven by the clinical context. The first presentation should be vigorously investigated with x-ray CT and CSF examination and, where possible, MRI/magnetic resonance venography (MRV)/magnetic resonance angiography (MRA). Formal cerebral angiography should be reserved for when no primary diagnosis is forthcoming, and the clinical situation is particularly suggestive of intracranial aneurysm. Bearing in mind the entity of diffuse multifocal reversible cerebral vasospasm, which may be seen in apparent primary thunderclap headache without there being an intracranial aneurysm, caution in interpretation of findings is crucial.

**Hemicrania Continua**

Two patients were initially reported with this syndrome, a woman aged 63 years and a man of 53 years, who developed unilateral headache without obvious cause. Both patients were relieved completely by indomethacin, whereas other NSAIDs were of little or no benefit. Newman and colleagues reviewed the 24 previously reported cases and added 10 of their own, including some with pronounced autonomic features resembling cluster headache. They divided their case histories into remitting and unremitting forms. Of the 34 patients reviewed, 22 were women and 12 men with the age of onset ranging from 11 to 58 years. The symptoms were controlled by indomethacin 75 to 150 mg daily. The essential features of hemicrania continua are:

- Unilateral pain
- Pain is continuous but with exacerbations that may be severe
- Complete resolution of pain with indomethacin
- Exacerbations may be associated with autonomic features

Apart from analgesic overuse as an aggravating factor, and a report in an HIV-infected patient, the status of secondary hemicrania continua is unclear. Antonaci and colleagues proposed the “indotest” by which the intramuscular injection of indomethacin 50 mg could be used as a diagnostic tool. In hemicrania continua, pain was relieved in 73 ± 66 minutes and the pain-free period was 13 ± 8 hours. A placebo-controlled
minutes and the pain-free period was 13 ± 8 hours. A placebo-controlled modification of this test is preferred where possible to the open-label version. Using the latter method in conjunction with PET, it has been shown that there is activation of the contralateral posterior hypothalamus and ipsilateral dorsal rostral pons in association with the headache of hemicrania continua as well as activation of the ipsilateral ventrolateral midbrain. The alternative is a trial of oral indomethacin, initially 25 mg 3 times daily, then 50 mg 3 times daily, and then 75 mg 3 times daily. One should allow up to 2 weeks for any dose to have a useful effect. Acute treatment with sumatriptan has been employed and reported to be of no benefit. Cyclooxygenase 2 (COX-2) antagonists seem effective, although undesirable now, and topiramate is helpful in some patients as is greater occipital nerve injection. nVNS is helpful in these patients and well tolerated.

New Daily Persistent Headache
NDPH is a clinically useful concept with a range of important possible causes because some are very treatable (Table 61.11). From a nosologic point of view, all that are mentioned here could be placed within various categories of the IHS classification, and indeed, the IHS refers to primary NDPH. However, the term as employed here serves both patients and clinicians by highlighting a group of conditions, some of which are curable and encompasses the IHS term under as the primary featureless form of NDPH.

<sup>a</sup>Includes postinfective forms.

CSF, cerebrospinal fluid.

The patient with NDPH presents with a history of headache on most if
not all days that began from one day to the next. The onset of headache is abrupt, often moment-to-moment but at least in less than a few days where three is suggested as an upper limit. The typical history is for the patient to recall the exact day and circumstances, so from one moment to the next, a headache develops that never leaves them. This presentation triggers certain key questions about the onset and behavior of the pain. The pressing issues arise from considering the secondary headache possibilities. Although subarachnoid hemorrhage is listed for some logical consistency, as the headache may certainly come on from one moment to the next, it is not likely to produce diagnostic confusion in this group of patients. Suffice to say that subarachnoid hemorrhage is so important that it must always be considered if only to be excluded, either by history or appropriate investigation.

**Primary new daily persistent headache:** Case series of primary NDPH showed it to occur in both males and females. Migrainous features are common, with unilateral headache in about one-third and throbbing pain in about one-third. Nausea was reported in about half the patients, as was photophobia and phonophobia observed again in about half. A number of these patients have a previous history of migraine but not more than one might expect given the population prevalence of migraine. It is remarkable that the initial report noted that 86% of patients were headache free at 24 months. It is general experience among those interested in headache management that primary NDPH is perhaps the most intractable and least therapeutically rewarding form of headache. In general, one can classify the dominant phenotype, migraine or TTH, and treat with preventives according to that subclassification.

**Secondary new daily persistent headache:** The secondary causes of the syndrome of NDPH are worthy of consideration, as they have distinctive clinical pictures that can guide investigation (see Table 61.11).

**Low Cerebrospinal Fluid Volume Headache**
The syndrome of persistent low CSF volume headache is an important diagnosis not to miss. The more immediately obvious version of this problem is encountered commonly after lumbar puncture. In that situation, the headache usually settles rapidly with bed rest. In the chronic situation,
the next. The pain is generally not present on waking, worsens during the day, and is relieved by lying down. Recumbency usually improves the headache in minutes, and it takes only minutes to an hour for the pain to return when the patient is again upright. The patient may give a history of an index event: lumbar puncture or epidural injection or a vigorous Valsalva, such as with lifting, straining, coughing, clearing the Eustachian tubes in an aeroplane, or multiple orgasms. Patients may volunteer, or a history may be obtained, that soft drinks with caffeine provide temporary respite. Spontaneous leaks are recognized, and the clinician should not be put off the diagnosis if the headache history is typical when there is no obvious index event. As time passes from the index event, the postural nature may be less obvious; certainly, cases whose index event was several years prior to the eventual diagnosis are recognized. The term low volume rather than low pressure is used because there is no clear evidence at which point the pressure can be called low. Although low pressures, such as 0 to 5 are often identified, a pressure of 16 cm CSF has been recorded with a documented leak. One should be aware of the possibility of the development of subdural collections in patients with low CSF volume headaches, which makes imaging before any invasive studies all the more important.

The investigation of choice is MRI with gadolinium (Fig. 61.5), which produces a striking pattern of diffuse pachymeningeal enhancement, although in about 10% of cases a leak can be documented without enhancement. The finding of diffuse meningeal enhancement is so typical that in clinical context immediate treatment is appropriate. It is also common to see Chiari malformations on MRI with some degree of descent of the cerebellar tonsils. This is important because surgery in such settings simply worsens the headache problem. It seems appropriate that any patient being considered for such surgery for a headache indication should be reviewed by a neurologist first. To investigate further, CSF pressure may be determined or preferably a leak sought with In-DPTA CSF studies that can demonstrate the site, early emptying of tracer into the bladder, or lack of progression of tracer over the cerebral convexities, although with MR-myelography, this method is becoming redundant.
FIGURE 61.5  Magnetic resonance image showing diffuse meningeal enhancement after gadolinium administration in a patient with low cerebrospinal fluid volume (pressure) headache.

Treatment is bed rest in the first instance. False-positive transient improvement in persistent low CSF volume headache with chiropractic and other similar therapies is recognized where the treatment necessitates the patient lying down for a prolonged period for the therapy. Intravenous caffeine (500 mg in 500-mL saline administered over 2 hours) is the standard and often very efficacious treatment. The ECG should be checked for any arrhythmia prior to administration. A reasonable practice is to carry out at least two infusions separated by 4 weeks after obtaining the suggestive clinical history and MRI with enhancement. Because intravenous caffeine is safe, and can be curative, by an unknown mechanism, it spares many patients the need for further tests. If that is unsuccessful, an abdominal binder may be helpful. If a leak can be identified, either by the radioisotope study, or by CT myelogram, or spinal T2-weighted MRI, an autologous blood patch is usually curative. In more intractable situations, theophylline is a useful alternative that offers outpatient management, although its onset of action is rather slow. An important phenotypically identical headache can be seen in the postural orthostatic tachycardia syndrome (POTS) and should be considered
when investigating this group of patients.

**Raised Cerebrospinal Fluid Pressure Headache**

As is the case for low CSF pressure states, raised CSF pressure as a cause of headache is well recognized by neurologists. Brain imaging can often reveal the cause, such as raised pressure due to a space-occupying lesion. The particular setting in which patients enter the spectrum of NDPH are those with idiopathic intracranial hypertension who present with headache without visual problems, particularly with normal fundi. It is recognized that intractable chronic migraine can be triggered by persistently raised intracranial pressure. These patients typically give a history of generalized headache that is present on waking and gets better as the day goes on. It is generally worse with recumbency. Visual obscurations are frequently reported. Fundal changes on raised intracranial pressure would make the diagnosis relatively straightforward, but it is in those without such changes that the history must drive investigation. Patients often report a curious whooshing sensation in the occipital region.

Brain imaging is mandatory if raised pressure is suspected, and it is most simple in the long run to obtain an MRI and include MRV. The CSF pressure should be measured by lumbar puncture taking care to do so when the patient is symptomatic so that both the pressure and response to removal of CSF can be determined. A raised pressure and improvement in headache with removal of CSF is diagnostic of the problem. The fields should be formally documented even in the absence of overt ophthalmic involvement. Initial treatment can be with acetazolamide (250 to 500 mg twice daily). The patient may respond in weeks with improvement in headache. If this is not effective, topiramate has many actions that may be useful in this setting: carbonic anhydrase inhibition, weight loss, and neuronal membrane stabilization, probably through actions on phosphorylation pathways. A small number of severely disabled patients who do not respond to medical treatment will come to intracranial pressure monitoring and even shunting. This is exceptional and not undertaken without careful work up.

**Posttraumatic Headache**
NDPH may be seen after a blow to the head but more commonly after an infective episode, typically viral, or even malarial meningitis. A recent series identified one-third of all patients with NDPH reported the headache starting after a flu-like illness. The patient may note a period in which they had a significant infection: fever, neck stiffness, photophobia, and marked malaise. The headache starts during that period and never stops. Investigation reveals no current cause for the headache. It has been suggested that some patients with this syndrome have a persistent Epstein-Barr infection, but this syndrome is anything but clearly delineated. A complicating factor will often be that the patient had a lumbar puncture during that illness, so a persistent low CSF volume headache needs to be considered first. Posttraumatic headache may be seen after carotid artery dissection, subarachnoid hemorrhage, and following intracranial surgery for a benign mass. The underlying theme seems to be that a traumatic event involving the dura mater can trigger a headache process that lasts for many years after that event.

The treatment of this form of NDPH is substantially empirical. Tricyclics, notably amitriptyline, and anticonvulsants, valproate, topiramate, and gabapentin, have been used with good effects.

OTHER IMPORTANT FORMS OF SECONDARY HEADACHE

Giant Cell Arteritis

This is an important cause of headache because delay in steroid treatment may result in blindness due to retinal artery ischaemia (Table 61.12). It is also known as temporal arteritis or cranial arteritis. Patients are usually elderly with focal tenderness of the scalp which may be provoked markedly by resting the head on the pillow. Jaw claudication provoked by chewing is a characteristic but relatively uncommon feature. Constitutional symptoms are common, particularly weight loss, malaise, or polymyalgia rheumatica. An elevated erythrocyte sedimentation rate (ESR) is a strong pointer to the diagnosis. The temporal artery may be tenderly inflamed, swollen, or pulseless. On suspicion of this diagnosis, steroid treatment should be started pending the result of temporal artery biopsy. Treatment is very often long term and requires careful monitoring for reactivation and
the side effects of corticosteroids.

TABLE 61.12 Other Secondary Headaches

- Giant cell arteritis
- Cervicogenic headache
- Reader’s paratrigeminal neuralgia\textsuperscript{139}
- Tolosa-Hunt syndrome\textsuperscript{140,141}
- Headache as a presentation of cervical dystonia\textsuperscript{5}
- Headache in temporomandibular dysfunction
- Cardiac cephalalgia\textsuperscript{113}
- Headache with endocrine disturbance, particularly pituitary tumor\textsuperscript{26}
- Neck-tongue syndrome\textsuperscript{142}
- Red-ear syndrome\textsuperscript{143}

Cervicogenic Headache

It is a time-honored concept that the neck is responsible for much headache. Unfortunately, as with much of history, the good story is often ruined by the facts. Although there is little doubt that there is a rich overlap between the innervation of intracranial pain-producing structures by the ophthalmic division of the trigeminal nerve, and the posterior fossa and high cervical innervation by branches especially of the C\textsubscript{2} dorsal root,\textsuperscript{134} causality is another issue. The Headache Classification Committee of the IHS recognizes that head pain can arise from the neck and labels this cervicogenic headache.\textsuperscript{6} The term has been used by others to define a syndrome\textsuperscript{135} that is so poorly described as to be useless in practice.\textsuperscript{136} Most patients with neck discomfort and headache referred to specialty practice have migraine. They will have neck stiffness or discomfort as a premonitory symptom that can clearly persist in all stages of the attack.\textsuperscript{137} They may respond to local therapies, such as greater occipital nerve injection\textsuperscript{138}, however, this implies no more than triggering and is to be expected. The pursuit of neck pathology and the treatment of patients who have migraine by manipulative or physical means has no support in the controlled literature and is rarely of long-lasting value.

CHAPTER 62
Noncardiac Chest Pain

RONNIE FASS and TAKAHISA YAMASAKI

Noncardiac chest pain (NCCP) is defined as recurring angina-like retrosternal chest pain of noncardiac origin. A patient’s history and characteristics do not reliably distinguish between cardiac and esophageal causes of chest pain.\(^1\) This is compounded by the fact that patients with a history of coronary artery disease (CAD) may also experience chest pain of noncardiac origin. The heightened awareness about the potentially devastating ramifications of chest pain may drive patients to seek medical attention despite a negative cardiac workup.\(^2\) Furthermore, almost half of NCCP patients are not convinced by their negative cardiac diagnosis, and reassurance alone has proved to be an ungratifying therapeutic strategy.\(^3\) There are many causes for NCCP, and they are not limited to the esophagus (Table 62.1).\(^4\) Compared to patients with cardiac angina, those with NCCP are usually younger, less likely to have typical symptoms, and more likely to have a normal resting electrocardiogram.\(^5\) Additionally, levels of anxiety of NCCP patients seen in a rapid access chest pain clinic significantly exceeded those of patients with cardiac angina and remained above community norms for at least 2 months after clinic visit.\(^6\) NCCP patients view their condition as significantly less controllable and less understandable than those whose pain is of cardiac origin.\(^6\)

NCCP may be the manifestation of non-gastrointestinal (GI) or GI-related disorders (Fig. 62.1). An important step toward understanding of the underlying mechanisms of NCCP was the recognition that gastroesophageal reflux disease (GERD) is the most common contributing factor for chest pain. Although chest pain has been considered an atypical manifestation of GERD, it is an integral part of the limited repertoire of esophageal symptoms. In patients with non–GERD-related NCCP, esophageal motility disorders and functional chest pain (FCP) are the main underlying mechanism for symptoms. The Rome IV Committee uses the term functional chest pain to describe recurrent episodes of substernal chest pain of visceral quality with no apparent explanation (Table 62.2). As with all other functional esophageal disorders, GERD, major esophageal motor disorders, and eosinophilic esophagitis should also be ruled out before the diagnosis is established.7
FIGURE 62.1 The different underlying mechanisms of noncardiac chest pain.

TABLE 62.2 Rome IV Diagnostic Criteria for Functional Chest Pain of Presumed Esophageal Origin

Must include all of the following:
- Retrosternal chest pain or discomfort
- Absence of associated esophageal symptoms, such as heartburn and dysphagia
- Absence of evidence that major esophageal motility disorders, gastroesophageal reflux, or eosinophilic esophagitis are the cause of the symptom

Criteria must be fulfilled for the last 3 months with symptoms onset at least 6 months prior to diagnosis with a frequency of at least once a week.

Up to 20% of the patients with FCP exhibit other functional disorders, primarily irritable bowel syndrome (IBS) (27%) and abdominal bloating (22%). The mechanisms responsible for FCP include abnormal mechanophysical properties of the esophagus, central and peripheral hypersensitivity, altered central processing of visceral stimuli, and psychological comorbidity (Table 62.3). The latter may include depression, anxiety, panic attack, and somatization.

TABLE 62.3 The Main Proposed Underlying Mechanisms of Functional Chest Pain

- Abnormal mechanophysical properties
  - Hyperactive esophagus
  - ↓ Compliance
- Visceral hypersensitivity
  - Peripheral and central sensitization
  - Altered central processing of visceral stimuli (altered autonomic activity)
- Psychological abnormalities
  - Panic attack
  - Anxiety
  - Depression
Epidemiology

Information about the epidemiology of NCCP in the United States and around the world is relatively limited. Presently, chest pain is the second most common presentation to hospital emergency departments; however, only 25% of individuals who experience chest pain actually present to a hospital.\textsuperscript{10}

The mean annual prevalence of NCCP in six population-based studies was approximately 25%. However, these studies differ in many aspects such as NCCP definition, geography, sample size, sampling order, and ethnic disparities.\textsuperscript{11} A population-based survey in the United States assessed the prevalence of GERD in Olmsted County, Minnesota, and reported an overall NCCP prevalence of 23%.\textsuperscript{12} Gender distribution among NCCP patients was similar (24% among males and 22% among females). Using the Rome criteria for functional GI disorders, Drossman et al.\textsuperscript{13} reported a prevalence of 13.6% in 8,250 households in the United States. In this study, FCP was diagnosed rather than NCCP. Eslick\textsuperscript{14} and Eslick et al.\textsuperscript{15} recently evaluated the prevalence of NCCP in Australia by using a mailing of a validated Chest Pain Questionnaire to 1,000 randomly selected individuals. The study demonstrated a prevalence rate of 33% with almost equal gender distribution (32% in males vs. 33% in females). This study also showed that the population prevalence of NCCP decreases with increasing age.\textsuperscript{14,15}

A nationwide population-based study from South America found that the annual prevalence of NCCP was 23.5% and that NCCP has been equally reported by both sexes.\textsuperscript{16} In this study, frequent typical GERD symptoms (at least once a week) were significantly and independently associated with NCCP. Another recently published epidemiologic study demonstrated that the annual prevalence of NCCP in a Chinese population was 19%.\textsuperscript{17} Although females with NCCP tend to consult health care providers more often than men, the disorder affects both sexes equally.\textsuperscript{12,14,16} Additionally, females are more likely to present to hospital emergency departments with NCCP than males, but there are no sex differences regarding chest pain intensity.\textsuperscript{18} Overall, women tend to use terms like burning and frightening more often than men.\textsuperscript{19}
Epidemiologic studies report a decrease in the prevalence of NCCP with increasing age. Women under 25 years of age and those between 45 and 55 years of age have the highest prevalence rates. Patients with NCCP are younger, consume greater amounts of alcohol and tobacco, and are more likely to suffer from anxiety than their counterparts with ischemic heart disease. Patients with NCCP continue to seek treatment on a regular basis after the diagnosis was established for both chest pain and other unrelated symptoms, but few are in contact with hospital services. A meta-analysis of the epidemiology of NCCP in the community revealed pooled prevalence of 13%, lack of age and gender predilection, and increased prevalence in subjects with GERD (odds ratio [OR], 4.71).

In one study, almost a fourth of individuals with NCCP had sought health care for chest pain within the previous 12 months. None of the GI (heartburn, dysphagia, and acid regurgitation) or psychological (anxiety, depression, and neuroticism) risk factors was significantly associated with pursuing consultation for NCCP. A recent US-based survey revealed that cardiologists manage by themselves about half of the patients who are diagnosed with NCCP. Of those NCCP patients who were referred, 45.9% were sent back to the primary care physician (PCP) and only 29.3% to a gastroenterologist (Fig. 62.2).

**FIGURE 62.2** A: A survey of 246 cardiologists determined that approximately half self-managed the care of NCCP patients.

In a survey of PCPs, Wong et al. demonstrated that most NCCP patients were diagnosed and treated by PCPs (79.5%) without being referred to a gastroenterologist. The most preferred subspecialty for the initial diagnostic evaluation of a patient presenting with chest pain was cardiology (62%), followed by gastroenterology (17%). The mean percentage of such referrals was only 22%. The most preferred subspecialty for further management of NCCP was gastroenterology (76%), followed by cardiology (8%). The mean percentage of the actual referral rate was 29.8% for gastroenterologists and 14% for cardiologists.

A study by Eslick and Talley reported that 78% of patients who presented to a hospital emergency department with acute chest pain had seen a health care provider in the last 12 months. The most common health care provider seen was a general practitioner (85%), followed by cardiologist (74%), gastroenterologist (30%), pulmonologist (14%), alternative therapist (8%), and psychologist (10%). A multiple logistic regression analysis revealed that patients with chest pain who are also suffering from heartburn were 16 times more likely to see a general practitioner (OR, 16.40; 95% confidence interval [CI], 1.98 to 135.99) and 3 times more likely to consult a gastroenterologist (OR, 3.10; 95% CI, 1.26 to 7.62). Additionally, work absenteeism rates (29%) and interruptions to daily activities (63%) were high because of NCCP.

Many patients with NCCP report poor quality of life and admit taking cardiac medications despite lack of evidence for a cardiac cause. Only a small fraction of patients feels reassured. Consequently, the economic burden of the disease has been proposed to be very high, although studies evaluating the cost impact of NCCP on the health care system are very scarce. In one study, the health care cost for NCCP was estimated to be more than $315 million annually primarily because of multiple clinic visits, emergency room visits, hospitalizations, and prescription medications. This cost estimate does not include indirect costs such as
lost days of work or the impact of symptoms on patients’ quality of life, which have been demonstrated to be more significant when evaluating the economic burden of patients with functional bowel disorders. In Australia, the annual cost associated with NCCP presentations to the Nepean Hospital amounts to approximately $1.4 million. The researchers extrapolated these costs to the Australian health care system and conservatively estimated that NCCP accounts for at least a $30 million of the health care budget annually.

Natural History

Thus far, very few studies have prospectively evaluated the natural course of NCCP. Obviously, the main concern is the likelihood of these patients developing true ischemic heart disease if followed long term. One of the early studies by Wielgosz et al. followed 821 patients with chest pain and normal coronary arteries for a period of 1 year. The authors demonstrated that only three (0.3%) patients died, and all were due to non-ischemic reasons. However, most of the patients (67%) continued to experience chest pain to some degree (39% less pain, 26% the same pain, and 2% more severe pain). In a study that followed 46 NCCP patients over a period of 11 years, only 2 (4.3%) of the subjects died from a cardiovascular-related event (stroke and ischemic heart disease). Again, as in the previous study, 74% of the surviving NCCP patients continued to report chest pain 11 years later, and of those, 34% reported chest pain symptoms weekly. Other studies also documented a very limited long-term mortality in NCCP patients but with continuous debilitating symptoms, impaired functional status, chronic use of drugs (GI, cardiac, and psychiatric), repeated admissions to the hospital, and repeated cardiac and noncardiac procedures. In a survey study, 119 NCCP patients, of which 63 were diagnosed as having pain from the esophagus, were followed for a period of 21.8 months. Patients with esophageal-related chest pain usually continued to have recurrent pain. Interestingly, a specific diagnosis did not significantly increase the likelihood of pain resolution. However, patients who understood that the esophagus was the source of their pain were significantly less likely to feel disabled by their
pain and therefore were less likely to require continued physician
evaluation. This study was published prior to the proton pump inhibitor
(PPI) era. It is unlikely that patients with NCCP due to GERD will
continue to have symptoms long term if they are compliant with their
antireflux treatment. In another study that compared long-term natural
history between NCCP and GERD patients, the authors found no
significant difference in survival between the two groups (hazard ratio,
1.1; 95% CI, 0.8 to 1.5). Interestingly, the diagnosis of NCCP disappeared
from the electronic hospital record in 96% of the patients within 2 years of
follow-up.³⁵

In a recent study that followed 355 NCCP patients, the authors
demonstrated that 49% sought care in the emergency department, 42%
underwent repeated cardiac workup, and only 15% were seen by a
gastroenterologist.³⁶ Survival free of cardiac death in the subset with
NCCP and a GI disorder was 90.2% at 10 years and 84.8% at 20 years
compared to 93.7% at 10 years and 88.1% at 20 years for those with
NCCP of unknown origin. Less than a handful of studies reported similar
mortality between patients with NCCP and those with CAD.³³,³⁷ A more
recent study by Eslick and Talley³⁸ followed 126 NCCP and 71 cardiac
patients who were seen in the emergency room for a period of 4 years. The
majority of the NCCP (71%) and the CAD patients (81%) continued to
have symptoms 4 years later. The authors found no difference in the
mortality rate between the two groups (CAD, 11.0%, vs. NCCP, 5.5%; P =
.16). However, the study may suffer from type II error, and the results
need to be confirmed in a larger cohort of patients.

Overall, the aforementioned data support the overall conclusion that
increased mortality is uncommon in NCCP patients. However, patients
with NCCP demonstrate poor quality of life primarily due to continuation
of symptoms many years after diagnosis.

Pathophysiology

GASTROESOPHAGEAL REFLUX DISEASE
Many studies have shown an association between GERD and NCCP.
However, association does not confer causality. Resolution or
improvement of chest pain symptoms in response to treatment with antireflux medications provides the missing causal link. Locke et al.\textsuperscript{12} have demonstrated that NCCP is more commonly reported by patients (37\%) who experience heartburn symptoms at least weekly, as compared with 30.7\% of those who have infrequent heartburn (less than once a week) and 7.9\% of those without any GERD symptoms. In another community-based study, the authors found that 53\% of all patients with NCCP experienced heartburn and 58\% acid regurgitation.\textsuperscript{15} Stahl et al.\textsuperscript{39} found in a small sample of NCCP patients that 61.5\% had GERD-related symptoms. In three different studies evaluating the role of the PPI test in patients with NCCP, the authors found GERD-related symptoms in 68\% to 90\% of the patients.\textsuperscript{40–42}

Ambulatory 24-hour esophageal pH testing studies have demonstrated that about half of NCCP patients have an abnormal esophageal acid exposure. Stahl et al.\textsuperscript{39} evaluated 13 consecutive NCCP patients and found that 69.2\% had an abnormal pH test. Beedassy et al.\textsuperscript{43} evaluated 104 patients with NCCP and documented that 48\% of them had an abnormal pH test. It should be noted that only 21\% of the 52 patients who reported chest pain during the study had a concomitant acid reflux event. Interestingly, only 10 of the 52 subjects had a positive symptom index (>50\%). Similarly, DeMeester et al.\textsuperscript{44} demonstrated that 46\% of patients with chest pain had symptoms associated with an acid reflux event as documented during pH testing. Pandak et al.\textsuperscript{45} found an abnormal pH test in 42\% of NCCP patients. In three different studies evaluating the role of the PPI test, the authors found abnormal pH test in 37.5\% to 67\% of the NCCP patients.\textsuperscript{40–42} In a study from Asia, 34.3\% of the NCCP patients had at least one abnormal pH parameter.\textsuperscript{46} Even in patients with CAD who continued to have atypical chest pain symptoms, 49\% to 67\% had some of their painful episodes associated with acid reflux.\textsuperscript{47,48}

The presence of esophageal mucosal abnormalities consistent with GERD appears to be less common in NCCP patients than GERD symptoms or excess esophageal acid exposure. From different studies, the range has been between 2.5\% and 75\%.\textsuperscript{46,49–52} In three different studies evaluating the role of the PPI test in patients with NCCP, the authors found GERD-related endoscopic findings in 44\% to 75\% of the NCCP patients.
In all of these studies, low-grade erosive esophagitis was the main GERD-related endoscopic finding. A recent study by Dickman et al. evaluated upper GI findings in patients with NCCP as compared with those having only GERD-related symptoms using a large multicenter consortium. Of the NCCP group, 28.6% had hiatal hernia, 19.6% erosive esophagitis, 4.4% Barrett esophagus (BE), and 3.6% esophageal stricture/stenosis. The prevalence of these findings was significantly lower in the NCCP group when compared with the GERD group. From this study, it appears that GERD-related mucosal abnormalities are not uncommon in the esophagus of NCCP patients. However, the prevalence of these anatomical findings is lower than what has been observed in GERD patients. Importantly, NCCP patients may also demonstrate BE, albeit uncommonly.

The mechanism by which gastroesophageal reflux causes NCCP remains poorly understood. It is still unclear why esophageal exposure to gastric content in some patients causes heartburn, and in others, chest pain. This is compounded by the fact that some patients may experience chest pain at one time and heartburn at other times. Characteristics of the individual reflux episodes (duration and pH) have been proposed to influence patients’ symptoms. Smith et al. studied 25 individuals with NCCP to determine the relation between the sensation of pain in GERD and pH of the refluxate. They found that all 25 patients had reproduction of their pain during intra-esophageal infusion of solutions with pH 1 and 1.5. Reflux events resulting in pain were significantly longer than those without pain and were more often associated with a recently preceding painful episode.

Esophageal hypersensitivity has been suggested to be another important mechanism for chest pain in patients with GERD. In one study, healthy subjects underwent perfusion of the distal esophagus with normal saline or 0.1 N hydrochloric acid. Perceptual responses to intraluminal esophageal balloon distension were evaluated using an electronic barostat. As compared with saline, acid perfusion reduced the perception threshold (innocuous sensation) and tended to reduce the pain threshold (aversive sensation). This study demonstrated short-term sensitization of mechanosensitive afferent pathways by transient exposure to acid. The
authors suggested that in patients with NCCP, acid reflux induces sensitization of the esophagus, which may subsequently alter the way the esophagus perceives otherwise normal esophageal distention. Sarkar et al. recruited 19 healthy volunteers and 7 patients with NCCP. Hydrochloric acid was infused into the distal esophagus over 30 minutes. Sensory responses to electrical stimulation were monitored within the acid-exposed distal esophagus and the nonexposed proximal esophagus before and after infusion. In the healthy subjects, acid infusion into the distal esophagus lowered the pain threshold in the upper esophagus. Patients with NCCP already had a lower resting esophageal pain threshold than healthy subjects. After acid perfusion, their pain threshold in the proximal esophagus fell further and for a longer duration than was the case for the healthy subjects (Fig. 62.3). Additionally, there was a decrease in pain threshold after acid infusion in the anterior chest wall. This study demonstrated the development of secondary allodynia (visceral hypersensitivity to an innocuous stimulus in normal tissue that is in proximity to the site of tissue injury) in the proximal esophagus by repeated acid exposure of the distal esophagus. The concurrent visceral and somatic pain hypersensitivity is most likely caused by central sensitization (an increase in excitability of spinal cord neurons induced by activation of nociceptive C fibers in the area of tissue injury). The patients with NCCP demonstrated visceral hypersensitivity and amplified secondary allodynia in the esophagus.

FIGURE 62.3 Mean change in pain threshold in the upper esophagus after 5 minutes infusion of
Another explanation how GERD may cause chest pain was provided by studies using high-frequency, intraluminal ultrasonography. Balaban et al. demonstrated a temporal correlation between sustained contractions of the esophageal longitudinal muscle and spontaneous as well as provoked esophageal chest pain. In a follow-up study, the authors suggested that the duration of sustained esophageal contraction determines the type of symptom perceived by patients. Heartburn was associated with shorter duration contractions, whereas chest pain was associated with contractions of longer duration. In a recent study, the authors suggested that esophageal muscle thickness per se, in the absence of esophageal motility abnormality, can lead to chest pain symptoms. Utilization of pH impedance in patients with GERD-related NCCP suggested that the presence of gas in the refluxate may drive the chest pain symptom.

Studies have demonstrated that NCCP patients with evidence of GERD (endoscopic findings and/or abnormal pH test) commonly respond to antireflux treatment. Between 78% and 92% of NCCP patients with objective evidence of GERD demonstrated symptoms improvement on antireflux treatment. In contrast, response to PPI treatment in NCCP patients without objective evidence of GERD ranged between 10% and 14%. Kushnir et al. have demonstrated that a positive symptom association probability and elevated acid exposure time predicted response to PPI treatment in patients with NCCP. When used hierarchically, response to antireflux treatment was best predicted when GERD parameters (acid exposure time, symptom association probability, and symptom index) were all abnormal and poorest when all normal. These data suggest a causal relationship between patients’ GERD and chest pain symptoms.

In patients with CAD and atypical chest pain, a higher incidence and longer duration of ischemic events were more commonly observed in those with GERD.

**LINKED ANGINA**
It is well known that the esophagus and the heart share similar sensory innervation, and several studies have demonstrated that acidification of the distal esophagus may influence the flow of the coronary circulation.\textsuperscript{62–64} Chauhan et al.\textsuperscript{65} have shown a reduction in coronary artery blood flow in response to acid perfusion into the distal esophagus in patients with syndrome X. Syndrome X is defined as typical chest pain and electrocardiographic changes suggestive of myocardial ischemia on stress test but patent coronary arteries on angiogram.\textsuperscript{64} The reduction in coronary blood flow was also associated with typical anginal pain, suggesting the presence of an esophagocardiac inhibitory reflex.\textsuperscript{65} These findings were later confirmed by Rosztoczy et al.\textsuperscript{66} who showed a decrease in coronary artery blood flow in 19 out of 42 (45\%) patients undergoing acid perfusion of the esophagus.

**ESOPHAGEAL DYSMOTILITY**

Several large studies demonstrated that approximately 30\% of NCCP patients had abnormal esophageal manometry.\textsuperscript{67–69} In one study that included 910 NCCP patients, the authors found that 70\% had normal esophageal motility (Fig. 62.4).\textsuperscript{67} Nutcracker esophagus (14.4\%) was the most commonly documented esophageal motility abnormality, followed by nonspecific esophageal motor disorder (10.8\%). Diffuse esophageal spasm (DES), achalasia, and hypertensive lower esophageal sphincter (LES) were very uncommon in this NCCP group. In another study, Dekel et al.\textsuperscript{68} evaluated 140 NCCP patients using the Clinical Outcomes Research Initiative database. Unlike the previous study that included patients from one major center with interest in esophageal motility, the study by Dekel et al.\textsuperscript{68} included patients from more than 60 academic, veteran affairs, and private centers from around the United States. The authors also found that 70\% of the subjects had a normal esophageal motility test. Hypotensive LES (61\%) was the most common motility abnormality diagnosed, followed by hypertensive LES, nonspecific esophageal motor disorder, and nutcracker esophagus (10\% each). In this study, achalasia and DES were also very uncommon. The difference in the distribution of motility abnormalities between the two studies reflects the different study designs. In the first study, only non–GERD-related NCCP patients were included,
whereas all newcomers were enrolled into the second study. A recent study from Chile evaluated 100 newly diagnosed NCCP patients and found that 8% of them had an abnormal esophageal manometry. In this study, 36% of patients had nutcracker esophagus, 28% hypotensive LES, and 16% nonspecific esophageal motor disorder. The reason for the discrepancy between the results of this study and the other two is unclear. It appears, however, that the high rate of esophageal motility abnormalities recorded in NCCP patients in this study may reflect a local referral bias.

There are very few studies assessing NCCP patients with high-resolution esophageal manometry (HREM). One study demonstrated impaired peristalsis in 60% of NCCP patients, including ineffective esophageal motility, fragmented peristalsis, and absent contractility.

The relationship between NCCP and esophageal dysmotility remains an area of intense controversy because documentation of esophageal dysmotility during manometry is rarely associated with reports of chest pain symptoms. In addition, unlike GERD, we are still devoid of highly effective pharmacologic compounds that can eliminate esophageal dysmotility and thus can be used to demonstrate a causal relationship. Furthermore, in NCCP patients who underwent simultaneous esophageal manometry and pH testing, chest pain was more commonly associated
with acid reflux events than motility abnormalities.\textsuperscript{69, 73} Even the past usage of ambulatory 24-hour esophageal manometry was unable to improve the sensitivity of the test in NCCP. In fact, studies have demonstrated that 27\% and 43\% of patients did not report any chest pain symptoms during the test.\textsuperscript{69, 74} Moreover, the investigators were able to relate pain episodes to recorded esophageal dysmotility in only 13\% to 24\% of patients. Consequently, the routine usage of ambulatory 24-hour esophageal manometry has been questioned, and the technique is rarely performed in clinical practice. In one study, the authors were able to demonstrate improvement of NCCP symptoms in patients with nutcracker esophagus receiving antireflux treatment but with no effect on esophageal motility.\textsuperscript{75}

Some authorities have proposed using esophageal motility abnormalities in NCCP patients as a marker for an underlying motor disorder that may be responsible for patients’ symptoms.\textsuperscript{76} However, it is plausible that our current evaluative techniques of the esophagus provide only crude information about esophageal motor function. Future tests will require providing a more comprehensive evaluation of anatomical structure and biomechanics of the esophagus and their relationship to pain.

**SUSTAINED ESOPHAGEAL CONTRACTIONS**

High-frequency intraluminal ultrasonography, a technique useful for the evaluation of smooth muscle contraction, has been employed to assess the esophageal motor corollary of chest pain in NCCP patients.\textsuperscript{57} By using high-frequency intraluminal ultrasonography, Balaban et al.\textsuperscript{57} have shown a close correlation between longitudinal muscle contractions and reports of chest pain. When evaluating the 10 participating subjects, the authors demonstrated esophageal longitudinal muscle contractions preceding 18 of 24 spontaneous chest pain events. These muscle contractions cannot be detected by conventional esophageal pressure recordings that solely evaluate the esophageal circular muscle. Balaban et al.\textsuperscript{57} further showed that edrophonium-induced chest pain was also preceded by sustained esophageal muscle contractions.\textsuperscript{57} The authors also demonstrated that swallow-associated contractions of the longitudinal muscles lasted an average of 6.4 seconds, whereas contractions associated with chest pain
lasted a mean of 68.0 seconds. Pehlivanov et al.\textsuperscript{58} demonstrated that the duration of the sustained esophageal muscle contractions might be correlated with the type of symptom perceived by patients. Shorter durations of these contractions were associated more with heartburn, whereas longer durations were linked more with chest pain.\textsuperscript{58} Furthermore, sustained esophageal muscle contractions were observed in patients who reported heartburn that was unrelated to an acid reflux event giving further credence to the hypothesis that sustained esophageal contractions are responsible for the generation of esophageal-related symptoms such as chest pain. Unfortunately, high-frequency intraluminal ultrasonography is highly operator-dependent and consequently may not always be an objective evaluative tool. None of the initial studies have been replicated by other investigators. Although sustained esophageal muscle contractions appear to be predictable markers for chest pain, it is still unclear if they are the direct underlying mechanism or just an epiphenomenon.

**ESOPHAGEAL HYPERSENSITIVITY**

Studies have consistently documented alteration in pain perception regardless of whether dysmotility was present or absent in patients with NCCP.

Visceral hypersensitivity is a phenomenon in which conscious perception of visceral stimulus is enhanced independently of the intensity of the stimulus.\textsuperscript{77} Peripheral and central mechanisms have been proposed to be responsible for visceral hypersensitivity in patients with NCCP. It has been hypothesized that peripheral sensitization of esophageal sensory afferents leads to subsequently heightened responses to physiologic or pathologic stimuli of the esophageal mucosa.\textsuperscript{78} Additionally, central sensitization at the brain level or the dorsal horn of the spinal cord may modulate afferent neural function and thus enhance perception of intraluminal stimuli.\textsuperscript{79} What causes peripheral or central sensitization remains to be determined. Studies have shown that acute tissue irritation results in subsequent peripheral and central sensitization, which is manifested as increased background activity of sensory neurons, lowering of nociceptive thresholds, changes in stimulus response curves, and enlargement of receptive fields.\textsuperscript{80} Peripheral sensitization involves the
reduction of esophageal pain threshold and increase in the transduction processes of primary afferent neurons. Esophageal tissue injury, inflammation, spasm, or repetitive mechanical stimuli can all sensitize peripheral afferent nerves. There is immune dysfunction, for example, stimulated lymphocyte expression of interleukin (IL)-5 and IL-13. There is also increased mucosal mast cells in patients with esophageal hypersensitivity and specifically those with FCP. The presence of esophageal hypersensitivity can be subsequently demonstrated long after the original stimulus is no longer present and the esophageal mucosa has healed. However, it is still unclear what factors are pivotal for the persistence of esophageal hypersensitivity.

Studies have demonstrated that patients with non–GERD-related NCCP have lower perception thresholds for pain. Richter et al. used balloon distension protocol in the distal esophagus and found that 50% of patients with NCCP developed pain at volumes of 8 mL or less in comparison with 9 mL or more in healthy subjects who developed pain (Fig. 62.5). The authors found no difference in the pressure–volume curve of the two groups as well as no difference in esophageal motility. When the balloon was inflated to 10 mL, patients with a history of NCCP were more likely to experience pain (18/30) than the control subjects (6/30). Barish et al. evaluated 50 patients with NCCP and 30 healthy volunteers using graded balloon distension protocol. Of the patients with NCCP, 56% (28/50) experienced their “typical” chest pain during balloon distension as compared with 20% (6/30) of the normal controls. Of those with NCCP who experienced pain, 85% reported pain at values below the usual sensory threshold (20 cm H₂O). There was no difference in esophageal tone between the two groups.
Rao et al.\textsuperscript{85} used impedance planimetry to evaluate 24 patients with NCCP and 12 healthy controls. Using balloon distention, they demonstrated that those with NCCP had lower perception thresholds for first sensation and moderate discomfort and pain in comparison to the healthy controls. Typical chest pain was reproduced in 83\% of the NCCP patients. In addition, the reactivity of the esophagus to balloon distension was increased in those with NCCP, as was the pressure elastic modulus. Rao et al.\textsuperscript{86} also performed graded balloon distensions of the esophagus using impedance planimetry in 16 consecutive patients with NCCP (normal esophageal evaluation) and 13 healthy control subjects. Patients who experienced chest pain during balloon distention were subsequently restudied after receiving intravenous atropine (Fig. 62.6). Balloon distensions reproduced chest pain at lower sensory thresholds in most NCCP patients as compared with controls. Similar findings were documented after atropine administration despite relaxed and more deformable esophageal wall. Thus, the investigators concluded that esophageal hypersensitivity, rather than motor dysfunction, is the predominant mechanism for FCP.
As noted earlier, it was demonstrated the development of secondary allodynia in the proximal esophagus by repeated acid exposure of the distal esophagus.\textsuperscript{56} The patients with NCCP demonstrated both visceral hypersensitivity and amplified secondary allodynia in the esophagus. However, it is unclear from the study what mechanism is responsible for the exaggerated secondary allodynia and what initiates central sensitization in patients with NCCP. It is interesting to note that other studies in NCCP, using a similar human model of acute tissue irritation by acid infusion, showed no significant effect on pain thresholds.\textsuperscript{87}

Börjesson et al.\textsuperscript{87} also demonstrated that patients with NCCP have reduced sensitivity to esophageal balloon distension during simultaneous transcutaneous electrical nerve stimulation (TENS) as compared with healthy controls. This further supports the role of visceral hypersensitivity in NCCP and suggests that the phenomenon is probably due to central sensitization.\textsuperscript{88} Mehta et al.\textsuperscript{88} also demonstrated that acid infusion into the distal esophagus reduces esophageal pain thresholds for balloon distension in patients with NCCP not previously sensitive to balloon distension or acid infusion.

In another study that was noted earlier,\textsuperscript{55} the authors demonstrated short-term sensitization of mechanosensitive afferent pathways by transient exposure to acid. Sarkar et al.\textsuperscript{89} also evaluated 14 patients with GERD-related NCCP and 8 healthy controls. All subjects underwent an esophageal electrical stimulation protocol in the proximal esophagus, and
those with NCCP demonstrated lower perception thresholds for pain than normal controls. However, there was an increase in the perception thresholds for pain during electrical stimulation in the NCCP patients after a 6-week course of high-dose PPI (omeprazole 20 mg twice daily) (Fig. 62.7). This study demonstrated that patients with NCCP and evidence of GERD have a component of esophageal hypersensitivity that is responsive to high-dose PPI therapy.

![Graph showing perception thresholds for pain in normal controls, GERD, and GERD with PPI. *p < 0.05.](image)

In another small study that enrolled 22 NCCP patients with documented nutcracker esophagus, the authors demonstrated that stepwise balloon distensions reproduced pain symptoms at a lower threshold in 90% of NCCP patients as compared with 20% of healthy controls. It was concluded that patients with NCCP and nutcracker esophagus also exhibit visceral hypersensitivity. Additionally, visceral hypersensitivity is the likely main underlying mechanism for patients’ symptoms rather than the presence of the high amplitude contractions (nutcracker esophagus). Unfortunately, the presence of GERD in these patients was not determined.
In this study, 75% of patients with FCP who underwent impedance planimetry demonstrated esophageal hypersensitivity. These patients had larger cross-sectional areas, decreased esophageal wall strain, distensibility, and lower thresholds for perception, discomfort, and pain as compared with FCP patients without esophageal hypersensitivity or healthy controls. Another recent study showed that pain evoked by bag distention in FCP patients is dependent primarily on stress and to a lesser degree on strain. The pain does not appear to be related to mucosal perfusion.

**ALTERED AUTONOMIC ACTIVITY**

Tougas et al. have performed several studies exploring autonomic nervous system function and its role in the pathogenesis of NCCP. In one study, the investigators assessed autonomic activity, using spectral analysis of heart rate variability, before and during distal esophageal acidification of patients with NCCP and matched healthy controls. Of those with NCCP, 68% developed angina-like symptoms during the esophageal acidification. These patients had a higher baseline heart rate and a lower baseline vagal activity than patients without acid sensitivity. During acid infusion, vagal cardiac outflow increased in acid-sensitive patients as compared with patients without acid sensitivity. Additionally, Tougas have also documented increased vagal activity in patients with NCCP during other intra-esophageal stimuli, both mechanical and electrical. These studies indicate that autonomic dysregulation may be present in at least a subset of patients with NCCP. The authors further hypothesized that increased perception of esophageal stimulation may also reflect an exaggerated brainstem response. However, Tougas has hypothesized that in most cases in which both central and autonomic factors are involved, central factors will likely lead to autonomic dysregulation.

**PSYCHOLOGICAL COMORBIDITY**

Psychological comorbidity has been shown to be common in NCCP and affects up to 75% of patients. It has yet to be determined if the high level of psychological comorbidity may be related to referral bias to tertiary
referral centers or if it is the result of long-term experience of pain. Regardless, studies reported a high prevalence (>50%) of panic disorder, anxiety, and major depression in NCCP patients.\textsuperscript{15,95–108} Other psychological abnormalities have also been reported including neuroticism, hypochondriac behavior, obsessive-compulsive disorder, phobic disorder, and somatization.\textsuperscript{15,100–103,109–113} In a small study of 36 subjects with NCCP, the authors found that 58% had some type of psychological abnormality.\textsuperscript{114} Of those, anxiety, depression, and panic disorder were the most common. In a large population-based study in Australia, the authors surveyed a random sample of 1,000 residents in the Sydney area.\textsuperscript{15} Among those with NCCP, the prevalence of anxiety was 23% and depression 7%. In a telephone survey from Hong Kong that included 2,209 subjects, the authors demonstrated that depression and anxiety were significantly more common in NCCP patients than those without NCCP.\textsuperscript{104}

Among all esophageal symptoms, chest pain was shown to closely correlate with psychometric abnormalities. In some patients, chest pain is part of a host of symptoms that characterize panic attack. Panic attack is a common cause for emergency room visits due to chest pain. In a large study that encompassed 441 consecutive ambulatory patients presenting with chest pain to the emergency department of a heart center, 25% were diagnosed as suffering from a panic attack.\textsuperscript{110} Although the reason for the observed association between NCCP and panic disorder remains to be fully elucidated, hyperventilation was demonstrated to precipitate chest pain in 15% of patients with NCCP.\textsuperscript{115} Additionally, it was demonstrated that hyperventilation could provoke reversible esophageal manometric abnormalities such as esophageal spasm (4%) and a nonspecific esophageal motor disorder (22%).\textsuperscript{116} Furthermore, studies have demonstrated that hyperventilation may precipitate a panic attack.

Anxiety and depression influence reports of pain and thus contribute to the pathophysiology of NCCP. Lantinga et al.\textsuperscript{117} found that patients with NCCP had higher levels of neuroticism and psychiatric comorbidity before and after cardiac catheterization than did patients with CAD. This finding appears to have prognostic significance because these patients display less improvement in pain, more frequent pain episodes, greater social
maladjustment, and more anxiety at 1-year follow-up than individuals with relatively low initial levels of psychosocial disturbances. In a large epidemiologic study from England, a significant relationship between NCCP and psychiatric disorders was demonstrated in young adults.\textsuperscript{118} Two independent variables were associated with chest pain: parental illness and fatigue during childhood.

Studies have been inconsistent when the frequency of panic disorder, anxiety, and depression were compared between NCCP patients and those with CAD. Some studies reported increased panic disorder, anxiety, and depression in NCCP patients, whereas others found no significant difference in the prevalence of psychological disorders between the two groups.\textsuperscript{9,111,119–122} In one study of 199 participants, panic disorder was more common in NCCP as compared with those with CAD (41\% vs. 22\%).\textsuperscript{119} However, other psychiatric disorders were highly prevalent (72\%) but without any difference between the two groups. In contrast, Cormier et al.\textsuperscript{123} demonstrated that 98 NCCP patients scored higher on measures of anxiety and negative life events and had a significantly greater prevalence of Diagnostic and Statistical Manual of Mental Disorders (3rd ed.; DSM-III) panic disorder (47\% vs. 6\%), major depression (39\% vs. 8\%), and two or more simple phobias (43\% vs. 12\%) than did patients with CAD. In a recent multivariate analysis, the authors were able to develop a predictive model for distinguishing between NCCP and CAD that includes alexithymia (a condition in which patients are unable to express their feelings with words), quality of life, and coping based on religion and seeking medical help (85.4\% sensitivity and 80.0\% specificity).\textsuperscript{124}

NCCP patients with psychological disorders show diminished quality of life, more frequent chest pain, and less treatment satisfaction than NCCP patients without psychological comorbidity.\textsuperscript{108} One study suggested that NCCP patients with more than one psychological disorder are more difficult to treat than those with a single psychological disorder.\textsuperscript{125}

Cheng et al.\textsuperscript{126} demonstrated that patients with NCCP, when compared to patients with rheumatism and healthy controls, tended to monitor more, use more problem-focused coping, display a coping pattern with a poorer strategy–situation fit, and receive less emotional support in times of stress.
Additionally, monitoring perceptual style and problem-focused coping were associated with higher levels of anxiety and depression. Jerlock et al.\textsuperscript{127} evaluated 231 NCCP patients and compared their psychosocial profile with 1,069 healthy subjects without NCCP. The authors found that NCCP patients had more sleep problems, mental strain at work, stress at home, and negative life events as compared with the healthy group.

Gender differences related to psychological factors have also been observed in NCCP patients. Men reported less depression and trait anxiety than women.\textsuperscript{128}

**Diagnosis of Noncardiac Chest Pain**

**CARDIOLOGY EVALUATION**

A cardiology evaluation is required in patients with angina-like pain. This recommendation is primarily driven by the recognition that the morbidity and mortality of CAD far exceeds that of esophageal-related causes of NCCP. Furthermore, a patient’s history and characteristics do not reliably distinguish between cardiac and esophageal causes of chest pain.\textsuperscript{1} NCCP patients may report squeezing or burning substernal chest pain, which may radiate to the back, neck, arms, and jaw and is indistinguishable from cardiac-related chest pain.\textsuperscript{129–131}

The description of chest pain obtained during a careful history is categorized as typical angina (80% to 90% likelihood of obstructive CAD), atypical angina (40% to 80% likelihood), or as noncardiac (20% to 70% likelihood). Typical angina is characterized by the following three characteristics:

- Retrosternal chest discomfort experienced as pressure or heaviness
- Duration of 5 to 15 minutes
- Induced by stress or exertion, a large meal, or exposure to cold and relieved by rest or nitroglycerin

Atypical angina is diagnosed when two of these are present, and NCCP is likely if none or only one of these cardinal features exists.\textsuperscript{132} Therefore, a patient who describes the spontaneous onset of “an elephant sitting on my chest” for 1 minute, with left arm involvement, diaphoresis, and nausea, actually has NCCP.\textsuperscript{132} Although some of the patients may have a
high probability of CAD for their chest pain and others low probability, the majority of the patients with chest pain fall into the intermediate range and thus require further testing to determine the presence of significant CAD. Diagnosis of NCCP is more likely in younger patients with chest pain, particularly females, and those without personal or strong family history of CAD.

A unique relationship between the esophagus and the heart has been proposed because the two organs share similar sensory innervation, and several studies have demonstrated that acidification of the distal esophagus may influence the flow of the coronary circulation. Chauhan et al. have shown a reduction in coronary artery blood flow in response to acid perfusion into the distal esophagus in patients with syndrome X. Syndrome X is defined as typical chest pain and electrocardiographic changes suggestive of myocardial ischemia on stress test but patent coronary arteries on angiogram. The reduction in coronary blood flow was also associated with typical angina pain, suggesting the presence of an esophagocardial inhibitory reflex. These findings were later confirmed by Rosztoczy et al. who showed a decrease in coronary artery blood flow in 19 out of 42 (45%) patients undergoing acid perfusion of the esophagus.

In a subset of patients, ischemic heart disease and GERD or esophageal dysmotility may coincide. It is the role of the cardiologist to determine if the chest pain is related to the underlying heart disease. Only after the cardiologist confirmed that symptoms are unrelated to the underlying ischemic heart disease, then further esophageal workup is warranted.

In conclusion, patients presenting for the first time with chest pain should initially undergo an evaluation by a cardiologist to exclude a cardiac cause.

**GERD-RELATED NCCP**

There is no gold standard for diagnosing GERD-related NCCP. The currently available diagnostic tests to detect GERD in patients with NCCP include barium swallow, upper endoscopy, the acid perfusion test, ambulatory 24-hour esophageal pH monitoring, and the PPI test.

**BARIUM ESOPHAGRAM**
Barium esophagram has very little use in the diagnosis of GERD. Barium esophagram has a low sensitivity (20%) for diagnosing GERD in general due to lack of anatomical and mucosal abnormalities in most of the GERD patients.\textsuperscript{134} Furthermore, the significance of barium reflux during the procedure as a diagnostic for GERD is questionable. Johnston et al.\textsuperscript{134} found that the proportion of patients with an abnormal 24-hour esophageal pH study was similar to the proportion of patients with a normal 24-hour esophageal pH study who had spontaneous barium reflux during the test. Additionally, spontaneous barium reflux has been demonstrated in up to 20% of healthy subjects.\textsuperscript{135}

The role of barium esophagram is unclear in patients with GERD-related NCCP primarily due to the rare presence of esophageal mucosal abnormalities. However, one may consider performing a barium esophagram as the initial diagnostic test in patients who report dysphagia in addition to chest pain.

**UPPER ENDOscopy**

Upper endoscopy is frequently used as a diagnostic tool in the evaluation of unexplained upper digestive complaints and specifically in patients with NCCP. In 1990, the American Gastroenterological Association guidelines for chest pain of esophageal origin recommended the routine use of endoscopy in the evaluation of NCCP.\textsuperscript{136} Since then, several studies have reported a variable rate of diagnostic yield in NCCP. In one of the earlier endoscopic studies, Hsia et al.\textsuperscript{50} evaluated 100 consecutive patients with NCCP (mean age 50 years). In this single-center study, the authors found that 38% of the patients had a normal test, 24% erosive esophagitis (grades II to IV), 18% gastritis and/or duodenitis, 14% a sliding hiatal hernia without evidence of erosive esophagitis, and 6% gastric or duodenal ulcer.\textsuperscript{50}

Several studies from different countries have also evaluated the value of upper endoscopy in NCCP. In a study of a northern Mexican population, only 10% of the NCCP patients demonstrated mucosal abnormalities during endoscopy. The vast majority of those were acid peptic–related.\textsuperscript{137} A study from Denmark evaluated 49 patients with NCCP (28 women, mean age 51.6 years) who were referred to a tertiary cardiology center.
The authors detected grade I erosive esophagitis in 15 patients (31%), grade II erosive esophagitis in 1 patient, and peptic ulcer in 3 patients (6%). A study from China reported that in 70 consecutive patients with NCCP (mean age 58.5 ± 10), only 11% had endoscopic abnormalities (three with duodenal ulcer, three with gastric ulcer, and two with erosive esophagitis). In a study from Italy, 61 consecutive patients with NCCP underwent endoscopy, and only 10% demonstrated mucosal findings (most erosive esophagitis). In the largest study thus far addressing the role of upper endoscopy in NCCP, Dickman et al. reported mucosal findings in 3,688 consecutive patients undergoing endoscopic evaluation for NCCP (mean age 55.1 years, range 18 to 99.6 years). Patients were seen in 76 community, university, and Veteran Health Administration Care Centers. The authors found that 44% of the NCCP patients had a normal upper endoscopy. Endoscopic findings in those with abnormal tests included hiatal hernia (28.6%), erosive esophagitis (19.4%), BE (4.4%), esophageal stricture or stenosis (3.6%), and peptic ulcer (2%) (Table 62.4). The authors concluded that the mucosal findings in NCCP patients were primarily GERD-related. An important finding of this study is that 4.4% of the patients with NCCP also had BE. This was significantly lower than the BE rate (9.1%) observed in GERD patients in the same study. Two other small studies have also reported the presence of BE in 5.2% and in 6.7% of NCCP patients undergoing endoscopy.

Presently, there is no evidence that upper GI tract neoplasia presents solely with chest pain, possibly explaining the absence of these lesions in the aforementioned endoscopic studies. In one recent series of 307 patients who presented between 1991 and 1996 with esophageal adenocarcinoma or squamous cell carcinoma, 21 (7%) reported chest pain but usually in addition to dysphagia. Only two (<1%) had chest pain as the sole presenting symptom.140

It appears that upper endoscopy has a variable diagnostic yield (10% to 44%) in NCCP patients. Almost all of the mucosal findings are acid peptic–related and likely responsive to antireflux treatment. Consequently, upper endoscopy should be reserved for patients with NCCP and alarm symptoms such as dysphagia, odynophagia, weight loss, or anemia. Because BE can be identified in GERD-related NCCP patients, albeit in lower frequency than in heartburn patients, screening endoscopy in this particular subset population of NCCP patients is appropriate.

In conclusion, upper endoscopy reveals potential explanations for NCCP in a minority of patients and should be reserved for subjects with alarm features or in whom endoscopic evaluation is indicated.

AMBULATORY 24-HOUR ESOPHAGEAL pH MONITORING

The introduction of the PPI test and the growing utilization of PPI
empirical therapy in NCCP have diminished the value of the traditional 24-hour pH test. This was further supported by a study demonstrating that the PPI test was at least as sensitive as ambulatory 24-hour esophageal pH monitoring. As a result, the use of pH testing appears to have value in patients with NCCP in whom objective evidence is required (off therapy). For example, in patients with NCCP who are candidates for antireflux surgery, objective evidence of abnormal 24-hour esophageal pH monitoring off PPI treatment is needed. The pH test could also be helpful in patients with equivocal or negative PPI therapeutic trial. In patients with NCCP undergoing the PPI test, 24-hour esophageal pH monitoring has a therapeutic predictive value in addition to its diagnostic merit. Patients with greater esophageal acid exposure appear to have a greater response to antireflux treatment. Consequently, in nonresponders to a therapeutic trial of PPI, pH monitoring on therapy may disclose patients who still have an abnormal pH test or positive symptom association with acid reflux events (symptom index or symptoms association probability). The value of the pH test in patients with NCCP nonresponsive to PPI treatment has yet to be elucidated. Although impedance + pH sensor has been proposed to be more sensitive in evaluating patients with typical or atypical manifestations of GERD who failed double-dose daily PPIs therapy, studies addressing specifically NCCP patients are still lacking. This is compounded by the fact that the role of nonacid reflux in causing NCCP remains insufficiently studied. However, future studies are needed to compare the value of impedance + pH sensor versus pH testing alone in evaluating NCCP patients, either on or off PPI treatment.

In conclusion, ambulatory 24-hour esophageal pH monitoring should be reserved for NCCP patients in whom objective evidence of GERD is required (off therapy) or in whom response to a therapeutic PPI trial is equivocal or negative (on therapy).

**THE WIRELESS pH SYSTEM**

Ambulatory 24-hour esophageal pH testing of the esophagus was developed nearly 40 years ago. This technique allows detection of acid reflux for prolonged periods of time. Until recently, all pH studies involved the use of catheter-based equipment. By using this catheter-based
system, it has been shown that abnormal esophageal acid exposure occurred in 21% to 53% of patients with NCCP. A correlation between chest pain and acid reflux event was found in 12% to 50% of the cases. However, traditional pH testing using a pH probe has been shown to impact patient’s lifestyle and consequently reflux-provoking activities.27

Recent developments led to the introduction and successful use of catheter-free pH system to diagnose GERD.146 This pH system offers the additional advantage of recording esophageal pH monitoring for an extended period of time (i.e., 48 to 96 hours) while improving patient tolerance for the test. The wireless pH monitoring system (Bravo pH System, Given Imaging, Yoqneam, Israel) consists of a small radiotelemetry capsule that is attached to the esophageal mucosa (located at 6 cm above the squamocolumnar junction). Although it does not require a transnasal wire, it can be placed transnasally.147

Presently, there is only a single study that evaluated the value of extended pH testing (48 hours) in patients with NCCP.148 In this study, Prakash and Clouse148 evaluated 63 patients with NCCP suspected of having GERD. The authors found that extended pH testing provided a 10% gain in detecting abnormal acid exposure time and 7.3% in the number of subjects reporting symptoms. The number of chest pain episodes available for association with reflux events doubled regardless of whether subjects were on or off antireflux therapy. Extended testing also improved the ability to detect more episodes of chest pain in 21% of the subjects. Overall, extending pH testing to 48 hours provided meaningful information in 19.4% of the NCCP patients.148

Potential disadvantages of the wireless pH system include the need to perform endoscopy prior to placement of the capsule to ensure proper position inside the esophagus. Premature detachment of the capsule has been reported in up to 12% of early studies, but rates have improved with additional modifications by the manufacturer.149 Chest discomfort has been described by a number of patients, some even requiring removal of the capsule.147 This could be of concern, particularly in patients who are already complaining of chest pain. However, in a study of 452 patients undergoing wireless pH testing, fewer than 2% required removal of the capsule because of discomfort.150 Of the eight patients requiring removal
of the capsule, the majority (62.5%) had chest pain as the indication for the study. Thus, patients with NCCP may be more susceptible to develop chest discomfort after capsule placement than other patients who undergo wireless pH testing.

Overall, the aforementioned studies suggest that extended wireless pH testing provides a modest but meaningful advantage over traditional 24-hour pH probe in the evaluation of patients with NCCP suspected to be GERD-related. It increases the window of opportunity for detecting more symptoms associated with gastroesophageal reflux events.

In conclusion, extending pH monitoring (48 hours) using wireless pH capsule improves detection of reflux-associated chest pain symptoms.

**THE PROTON PUMP INHIBITOR TEST**

A therapeutic trial in the form of empirical therapy (vide infra) or the PPI test is recommended prior to any invasive or noninvasive testing to diagnose GERD-related NCCP. There are two therapeutic trial approaches in NCCP that are markedly different from each other. Empirical therapy with PPIs, usually lasting 2 to 3 months, is often used by physicians as the initial treatment of patients with atypical manifestations of GERD including NCCP. In contrast, the PPI test or short therapeutic trial is defined as a short course of high-dose PPI for diagnosing GERD-related NCCP. The latter test is considered a simple and noninvasive diagnostic tool. It is readily available and at the disposal of PCPs as well as specialists. Additionally, it increases the role of PCPs in evaluating and treating patients with atypical manifestations of GERD. Studies have also shown that it offers significant cost savings when compared with the other diagnostic tests for GERD.

The doses used in the PPI test have ranged from 40 to 80 mg daily for omeprazole, 30 to 90 mg daily for lansoprazole, and 40 mg daily for rabeprazole, over duration of treatment of 1 to 28 days, in patients with symptoms suggestive of GERD or NCCP. In patients with laryngeal manifestations of GERD, the doses ranged from 40 to 80 mg omeprazole daily and the duration of treatment from 1 to 4 weeks. By far, the most commonly used PPI in most of the PPI test trials was omeprazole, which has led to the term the omeprazole test.
However, studies using other PPIs demonstrated that they are equally efficacious as short therapeutic trials.\textsuperscript{41,42,46}

An important factor in determining the sensitivity of a PPI test is the definition of a positive test. In most studies, a symptom score cutoff was used: If the symptom assessment scores for heartburn, chest pain, or other symptoms improved by more than 50% to 75% (depending on the study) relative to baseline, the test was considered positive. As with any diagnostic test, the optimal cutoff is critical in defining test accuracy.\textsuperscript{158} The symptom score cutoff values that were used among studies that evaluated PPI tests for GERD were chosen arbitrarily. Rarely, studies calculated the receiver operator curve by varying the percentage reduction in the symptom tested to ascertain the optimal value for detecting patients with GERD.\textsuperscript{153,158} This cutoff point provides the greatest sensitivity, specificity, positive predictive value, and accuracy of the short therapeutic trial tested.

The diagnostic accuracy of the PPI test is limited by the lack of gold standard for the diagnosis of GERD. In the absence of a gold standard, studies evaluating the PPI test have used a combination of upper endoscopy and ambulatory 24-hour esophageal pH monitoring as the closest one can get to a gold standard. Factors that may determine the sensitivity of the PPI test include type of antireflux medication used, dosage, treatment duration, definition of a positive test (symptom score cutoff, change in symptom grading, receiver operating characteristics curve analysis), and the GERD-related symptom evaluated.

Only one study attempted to compare the accuracy of the PPI test (omeprazole) to 24-hour esophageal pH monitoring in diagnosing GERD.\textsuperscript{141} The study used the presence of erosive esophagitis as indicative of GERD in patients who are not on aspirin or nonsteroidal anti-inflammatory drugs. Thirty-five patients were included, and they underwent both pH testing and the PPI test (omeprazole 40 mg before breakfast and 20 mg before dinner). The PPI test was significantly more sensitive than total acid contact time during pH testing (83% vs. 60%, $P < .03$). The sensitivity of the pH test increased to 80%, only after adding patients with positive symptom index and patients with abnormal acid contact time, in the supine and/or erect positions despite normal total acid contact time.
contact time. The authors concluded that the PPI test was at least as sensitive as ambulatory 24-hour esophageal pH monitoring in diagnosing GERD in patients with documented erosive esophagitis. In different studies, the sensitivity of the PPI test for GERD-related NCCP ranged from 69% to 95% and the specificity from 67% to 86%.40,45,46,156,157,163–165

In a double-blind, placebo-controlled trial, 37 patients with NCCP were randomized to either placebo or high-dose omeprazole (40 mg before breakfast and 20 mg before dinner) for 7 days.40 After a washout period and repeated baseline symptom assessment, patients crossed over to the opposite arm. The PPI test was considered positive if the chest pain improved by at least 50% after treatment. The combination of upper endoscopy and 24-hour esophageal pH monitoring was used as the gold standard. Sixty-two percent (23/37) of the patients had evidence of GERD: Seven had abnormal esophageal acid exposure by pH testing only, eight had erosive esophagitis only, and eight had both. Of the GERD-positive group, 78.3% had a positive PPI test, and 22.7% had a positive placebo response. In contrast, of the GERD-negative group, 14.2% had a positive PPI test, and 7.1% had a positive placebo response. Thus, the calculated sensitivity was 78.3%, specificity 85.7%, and the positive predictive value was 90%.40 When different reductions in chest pain were evaluated as previously mentioned, the greater accuracy of predicting GERD-related NCCP was obtained with 65% symptom reduction, producing a sensitivity of 85.7% and specificity of 90.9%.40 Using similar design, other investigators confirmed the usefulness of the PPI test for diagnosing GERD-related NCCP.45,46 Furthermore, subsequent studies demonstrated that short therapeutic trials with PPIs other than omeprazole achieved similar efficacy for the diagnosis of GERD-related NCCP.164,165 A study in the Chinese population showed that the PPI test, using lansoprazole 30 mg daily for a period of 4 weeks, was useful in diagnosing endoscopy-negative GERD-related NCCP.46

As with the PPI test in patients with classic GERD symptoms, the value of the PPI test in NCCP has been assessed by several meta-analyses.166–168 One meta-analysis of randomized, controlled trials (parallel group and crossover design), the authors evaluated the pooled risk ratio for continued
Eight studies were included in the PPI efficacy analysis. The pooled risk ratio for continued chest pain after PPI therapy was 0.54 (95% CI, 0.41 to 0.71). The overall number needed to treat was 3 (95% CI, 2 to 4). The pooled sensitivity, specificity, and diagnostic OR for the PPI test versus 24-hour pH monitoring and upper endoscopy were 80, 73, and 13.83 (95% CI, 5.48 to 34.91), respectively. All studies were small, and there was evidence for publication bias or other small study effects. The authors concluded that PPI therapy reduces symptoms in NCCP and may be useful as a diagnostic test in identifying abnormal esophageal acid reflux.

Wang et al.\(^\text{167}\) have also performed a meta-analysis of the PPI test in patients with NCCP. Unlike the previous meta-analysis, the authors found only six studies that met inclusion criteria. The overall sensitivity and specificity of a PPI test were 80% (95% CI, 71% to 87%) and 74% (95% CI, 64% to 83%), respectively, compared with 19% (95% CI, 12% to 29%) and 77% (95% CI, 62% to 87%), respectively, in the placebo group. The PPI test showed significant higher discriminative power, with a summary diagnostic OR of 19.35 (95% CI, 8.54 to 43.84) compared with 0.61 (95% CI, 0.20 to 1.86) in the placebo group. Thus, the authors concluded that the use of PPI treatment as a diagnostic test for detecting GERD in patients with NCCP has an acceptable sensitivity and specificity that could be used as an initial approach by PCPs to detect GERD in selected patients with NCCP.

When using the PPI test, there is a significant correlation between the extent of esophageal acid exposure in the distal esophagus as determined by ambulatory 24-hour esophageal pH monitoring and the change in symptom intensity score after treatment. This suggests that the higher the esophageal acid exposure, the greater the response to the PPI test in patients with GERD-related NCCP.\(^\text{142}\) Economic analysis has also shown that the PPI test for GERD-related NCCP is a cost-saving approach primarily because of the significant reduction in the usage of various costly, invasive diagnostic tests.\(^\text{40}\)

In patients with NCCP, the PPI test was evaluated using a cost
minimization analysis. The PPI test was found to save $573 per average patient with NCCP undergoing diagnostic evaluation. The test was associated with an 81% reduction in the number of upper endoscopies and 79% reduction in the number of ambulatory 24-hour esophageal pH tests. This significant reduction is because of the high positive predictive value of the PPI test for patients with GERD-related NCCP.

When a decision-analytic model utilizing Bayesian analysis was developed to compare the costs and outcomes of alternative diagnostic strategies for NCCP, noninvasive strategies utilizing the PPI test as the initial step resulted in significant cost savings compared with invasive strategies. These cost savings were a direct result of a significant reduction in the utilization of invasive diagnostic tests that are of unproven utility in the diagnosis and subsequent management of patients with NCCP.

In conclusion, a therapeutic trial with a PPI should precede any other testing for GERD unless objective evidence of GERD is required. The PPI test is a cost-effective diagnostic strategy for GERD-related NCCP.

MULTICHANNEL INTRALUMINAL IMPEDANCE

The combination of an impedance catheter and a pH probe provides a unique opportunity to study physiologic and pathologic events within the esophagus and their relationship to symptoms. In addition, the recording assembly can disclose the characteristics of the gastric refluxate (acidic, weakly acidic, alkaline, gas, liquid, and mixed gas and liquid). The specific value of the multichannel intraluminal impedance plus pH sensor and the documentation of weakly acidic reflux in patients with NCCP remains to be elucidated. The combined multichannel intraluminal impedance and manometry testing has also been useful in determining bolus transport patterns, bolus transit parameters, and bolus clearance in patients with esophageal motor disorders and a variety of symptoms including chest pain.

A recent study evaluated 120 NCCP patients with 24-hour multichannel intraluminal impedance. The authors demonstrated that 40% of the NCCP patients were having reflux as the underlying cause of their chest pain. Reflux episodes that were associated with chest pain had a higher proximal extent, a higher volume clearance time, a higher 15-minute acid burden,
more often acidic, a lower nadir pH, and a longer acid duration time than reflux episodes which were not followed by chest pain.

**ESOPHAGEAL DYSMOTILITY**

In approximately a third of the patients with non–GERD-related NCCP, various esophageal motility abnormalities have been described.\(^{67,68,172}\) Thus, in NCCP, esophageal manometry is commonly performed if GERD has been excluded as the underlying cause.\(^{16}\) The role of esophageal manometry in NCCP has evolved over the last few years primarily due to lack of effective treatment for the various esophageal motility abnormalities. This was compounded by clinical evidence that patients with non–GERD-related NCCP reported symptom improvement on pain modulators regardless if esophageal dysmotility was present or absent (except for achalasia).\(^{173}\) Consequently, the role of esophageal manometry in non–GERD-related NCCP appears to be limited to identifying the small number of patients with achalasia.\(^{174}\)

**ESOPHAGEAL MANOMETRY**

Esophageal manometry remains the best tool to detect esophageal motility disorders. However, studies have demonstrated that 70% of NCCP patients have normal esophageal motility during manometry testing.\(^{67,68}\) The esophageal motor disorders commonly diagnosed in NCCP patients include nutcracker esophagus, hypotensive LES, DES (recently renamed distal esophageal spasm), hypertensive LES, nonspecific esophageal motility disorders, ineffective motility, and achalasia. Although esophageal motility disorders are noted in up to 30% of patients with NCCP, the relationship between these motor abnormalities and chest pain remains unclear. Patients rarely have chest pain at the time these motility abnormalities are recorded. Therapeutic trials aimed at improving abnormal motility in NCCP patients have not consistently resulted in symptomatic improvement.\(^{75,175,176}\) This has led investigators to speculate that the motility abnormalities represent either a marker of sensory motor deficiency in NCCP patients or just an epiphenomenon rather than the direct cause of pain. Hitherto, the precise cause of esophageal pain in NCCP remains unknown.
It is possible that the abnormal motor response observed in NCCP patients originates from “activated” esophageal sensory afferents that trigger a secondary motor contraction in response to some type of intraluminal stimulus. Another theory speculates that chest pain may arise from intramural ischemia that is induced by increased esophageal motor activity.\textsuperscript{177} However, studies that evaluated the blood supply of the esophagus suggested that the presence of vast arterial perfusion for this organ argues against the validity of this theory.\textsuperscript{178} Recent studies have suggested that esophageal pain may originate from other muscle layers of the esophagus that escape detection during conventional esophageal manometry. Investigators have proposed that sustained longitudinal muscle contractions may be the cause of esophageal induced chest pain.\textsuperscript{57} In contrast, Rao et al.\textsuperscript{85} have suggested that the chest pain in NCCP patients is caused by hyperactive and stiffer esophageal wall as compared with controls. Thus, all of the aforementioned observations suggest that the source of chest pain in NCCP patients is the result of pathophysiologic mechanisms other than abnormal esophageal motility per se.

Achalasia is uncommon in NCCP, occurring in only 2\% of patients presenting for manometric evaluation.\textsuperscript{67,68} Achalasia typically presents with dysphagia and weight loss. Nevertheless, a number of series have shown that chest pain occurs in 48\% to 64\% of patients with achalasia.\textsuperscript{179,180} It is unclear why some patients have dysphagia alone, whereas others also experience chest pain. In a recent study that included 211 patients with achalasia, chest pain occurred in 117 (55\%), dysphagia in 173 (81\%), regurgitation in 147 (69\%), and heartburn in 121 patients (57\%).\textsuperscript{181} Thus, in patients with recurrent NCCP, diagnosis of achalasia is important because treatment of this entity differs substantially from the treatment of patients with other esophageal motility disorders. Frequently, patients with achalasia will require either esophageal balloon dilation or Heller myotomy.

The value of high-resolution esophageal manometry in NCCP awaits more research in the future.\textsuperscript{182} Several studies evaluated the distribution of esophageal motor disorders in NCCP patients using HREM. Akinsiku et al.\textsuperscript{183} compared the value of HREM with conventional manometry in 300 NCCP patients. The HREM also established that normal esophageal...
motility was the most common finding (46.67%). In addition, ineffective esophageal motility was the most commonly documented esophageal motor disorder (25.33%), followed by achalasia (7.33%), hypotensive LES (4.67%), absent contractibility (4%), and jackhammer/nutcracker esophagus (3.33%). Another study, using 24-hour ambulatory pressure-pH-impedance monitoring and HREM, revealed esophageal dysmotility (distal esophageal spasm) only in 4 out of 59 NCCP patients (6.8%).\textsuperscript{184}

Overall, esophageal manometry can identify an esophageal motility disorder in approximately one-third of NCCP patients. However, the relationship between these motility disorders and chest pain is unclear and remains to be elucidated. Although only a small number of patients with non–GERD-related NCCP have achalasia, identifying this disorder is necessary because therapeutic modalities such as Heller myotomy or esophageal balloon dilation have been shown to be efficacious.

In conclusion, esophageal manometry is indicated in patients with non–GERD-related NCCP primarily to exclude achalasia.

**PROVOCATIVE TESTING**

In order to enhance the value of esophageal manometry in providing a definitive diagnosis, pharmacologic provocative agents have been used to elicit chest pain while monitoring changes in esophageal amplitude contractions.

**EDROPHONIUM (TENSILON) TEST**

The edrophonium (Tensilon) test has been used pharmacologically to induce esophageal dysmotility and chest pain in patients with NCCP. Edrophonium is an anticholinesterase that increases cholinergic activity at muscarinic receptors.\textsuperscript{185} The pharmacologic action of this short-acting drug is manifested within 30 to 60 seconds after injection and lasts an average of 10 minutes. The aim of the edrophonium test is to induce greater esophageal body amplitude contractions in the hope of provoking the patient’s typical chest pain.\textsuperscript{186} The test is performed by injection of either 80 mg/kg or 10 mg edrophonium intravenously, immediately followed by 5 to 10 swallows of 5 to 10 mL of water over a period of 5 to 10 minutes. The pain occurs during swallowing within 5 minutes after the
administration of the drug and disappears as the drug is quickly metabolized. Overall, the side effects are minimal, and the antidote atropine is rarely required. Side effects include increased salivation, nausea, vomiting, and abdominal cramps.

The sensitivity of the edrophonium test is relatively low. Studies have shown that the edrophonium test is positive in approximately 30% of patients with normal baseline esophageal manometry. Consequently, the usage of the edrophonium test has declined in the last decade.

**ERGONOVINE STIMULATION TEST**

The ergonovine stimulation test has been demonstrated to induce augmentation of esophageal contractions and chest pain in patients with NCCP. Ergonovine is a sympathomimetic agent of the ergot alkaloid group. The drug is reportedly as effective as edrophonium in the provocation of chest pain in NCCP patients, but the side effects are more common and could potentially be fatal (coronary artery spasm). Thus, ergonovine is rarely used today in clinical practice in the evaluation of NCCP.

**PENTAGASTRIN STIMULATION TEST**

Pentagastrin directly stimulates esophageal smooth muscle, especially in patients with primary esophageal dysmotility. Its sensitivity to inducing pain in patients with NCCP is low, and presently, the drug is no longer used for NCCP provocative testing.

**Sensory Testing of the Esophagus**

The esophagus, like the rest of the viscera, receives dual sensory innervation, traditionally referred to as parasympathetic and sympathetic because the sensory nerves are anatomically associated with the autonomic nervous system but more properly based on the actual nerves, vagal, and spinal (Fig. 62.8). The vagal afferent neurons compose 80% of the vagal trunk and have cell bodies in the nodose ganglia. Vagal afferents whose receptive fields are located in the esophageal smooth muscle layer are sensitive to mechanical distension, whereas polymodal (responding to
multiple modalities of stimuli) vagal afferents with receptive fields in the mucosa are sensitive to various chemical or mechanical intraluminal stimuli, which, under normal circumstances, are not associated with conscious perception. In general, vagal afferents do not play a direct role in visceral pain transmission at the level of the gut, except for certain types of vagal afferents that appear to have a pain modulatory effect. Recent reports suggest that vagal afferents may also play a role in perception of esophageal distension. In contrast, spinal afferents, which have their cell bodies in the dorsal root ganglia, are primarily acting as nociceptors and are central to the perception of discomfort and pain. Spinal afferents with receptive fields in the muscle layer and serosa are primarily mechanosensitive. The intraepithelial nerve endings of spinal afferent are likely to be involved in mediating acid-induced pain during topical exposure to intraluminal acid. Many of the afferents contain calcitonin gene-related peptide and substance P, which are neurotransmitters that are important in mediating visceral nociception.

**FIGURE 62.8** Esophageal sensory afferent pathways. (Redrawn after Fass R. Sensory testing of the esophagus. J Clin Gastroenterol 2004;38[8]:628–641, with permission.)

Data regarding cortical loci involved in processing of esophageal sensation in humans are relatively scarce. Nonpainful esophageal balloon distensions elicit bilateral activation along the central sulcus, the insular cortex, and the frontal and parietal operculum. In contrast,
painful esophageal balloon distensions result in intense activation of the same areas and additional activation of the right anterior insular cortex (important in affective processing) and anterior cingulate gyrus (important in pain processing and generating an affective and cognitive response to pain).\textsuperscript{200–202} Nonpainful infusion of 0.1 N hydrochloric acid resulted in cerebral cortical activity that was concentrated in the posterior cingulate and the parietal and anteromesial frontal lobes.\textsuperscript{203} The superior frontal lobe regions activated corresponded to Brodmann area 32, the insula, the operculum, and the anterior cingulate.

Chest pain symptoms may represent an activation of a common pathway in response to different intraesophageal stimuli. Different intraesophageal stimuli (e.g., acid and balloon distension) may elicit similar symptoms in different patients or different symptoms in the same patient.\textsuperscript{196,204} Thus, esophageal symptoms such as heartburn or chest pain are not stimulus-specific.

A recent study demonstrated that chest pain and heartburn may be provoked in normal subjects during esophageal balloon distension either in the proximal or distal portion of the esophagus.\textsuperscript{196} Volume thresholds for heartburn and chest pain in both esophageal locations were similar, suggesting that, for a specific volume, some patients develop chest pain, and others, heartburn. Furthermore, volume thresholds for both chest pain and heartburn did not differ significantly at each esophageal location and between locations. In this study, esophageal balloon distension reproduced typical heartburn symptoms in some patients with documented GERD and chest pain in others. This study clearly demonstrates that balloon distension may result in different types of esophageal symptoms.

The mechanism by which an esophageal stimulus causes heartburn in some patients and chest pain in others remains poorly understood. Balaban and colleagues\textsuperscript{57} have demonstrated a temporal correlation between sustained contractions of the esophageal longitudinal muscle and both spontaneous and provoked esophageal chest pain. In a subsequent study that assessed the temporal relationship between sustained esophageal longitudinal muscle contractions and heartburn, the investigators suggested that shorter duration of the sustained esophageal contraction was associated with heartburn and longer duration with chest pain.\textsuperscript{58}
Perception of intraesophageal events, either physiologic or pathologic, is a complicated process that involves central and peripheral mechanisms. Several studies have shown that most intraesophageal stimuli are not perceived by subjects. For example, less than 20% of all acid reflux events result in GERD symptoms regardless of whether mucosal injury is present.\textsuperscript{205} It is yet to be elucidated what factors determine perception of an intraesophageal event, leading to symptom generation. In GERD, it has been demonstrated that the actual hydrogen ion concentration (H\textsuperscript{+}) of the refluxate, the summation of several short reflux events, the distribution of acid along the esophagus (proximal migration), or the nadir or duration of acid reflux events.\textsuperscript{198} Several studies have demonstrated that fat and other nutrients can modulate perception of intraluminal events that are mediated by gut neurotransmitters, hormones, or enzymes. Meyer and colleagues\textsuperscript{206} have shown that intraduodenal fat significantly shortened latency to onset of heartburn and intensified the perception of acid-induced heartburn in subjects with GERD who underwent intraesophageal acid perfusion.

Central neural mechanisms seem to have an important role in modulating esophageal perception also.\textsuperscript{207} Psychological comorbidity (e.g., anxiety and depression) can modulate esophageal perception and cause subjects to perceive low-intensity esophageal stimuli (pathologic or physiologic) as being painful.\textsuperscript{208} Another important factor is stress that seems to enhance perception of intraesophageal stimuli by reducing perception thresholds for pain.\textsuperscript{200} Stress has recently emerged as an important factor in symptom generation and exacerbation of both functional and organic GI disorders.\textsuperscript{201} Traditionally, stress is considered a domain of psychology and, thus, commonly lumped together with the role of psychiatric comorbidity.\textsuperscript{209} However, recent developments in the understanding of brain–gut interactions in functional bowel disorders resulted in reassessment of the role of chronic stress in the pathophysiology and management of GI disorders such as NCCP. Certain stressful life events have been associated with the onset or symptom exacerbation of functional bowel disorders. In addition, daily experiences of stress seem to have an important modulating effect on perception of intraluminal events.

Other central factors, such as sleep quality, may also alter perception of
intraesophageal events. Further research is needed to better define the brain–gut (or gut–brain) relationship as it relates to symptom generation in esophageal disorders.

**ACID PERFUSION TEST (BERNSTEIN TEST)**

The acid perfusion test was introduced as an objective method to identify esophageal chemosensitivity to acid. A nasogastric tube was passed through the nares of a fasting, sitting subject and into the stomach. After the gastric content was aspirated, the tube was withdrawn until it measured 30 cm from the nares to the tip. This maneuver assumed that the solution would be delivered at a level near the junction of the upper and middle thirds of the esophagus. The tube was connected to an intravenous bottle. A control administration of 0.9% NaCl was perfused for 10 to 15 minutes at a rate of 6 to 7.5 mL per minute. This was followed by administration of 0.1 N hydrochloric acid, at a similar rate, for 30 minutes or until discomfort was induced. If symptoms appeared, the test was discontinued and saline solution was given.

The acid perfusion test was originally devised to distinguish between chest pain of cardiac and esophageal origin. However, since the initial description, many modifications have been made to the original Bernstein test. Although the basic principle of the test remained similar, many investigators have tried different acid perfusion rates, concentrations, and durations in the hope of increasing the sensitivity of the test. Furthermore, some have even suggested the addition of bile salts to the acid solution.

Many attempts were made to change the test from a qualitative to a quantitative tool. Time to onset of symptoms during acid perfusion was used to compare the extent of chemosensitivity to acid between GERD and Barrett patients. Fass and colleagues placed a manometry catheter 10 cm above the upper border of the LES to ensure sufficient exposure of the esophageal mucosa to acid. Saline was infused initially for 2 minutes, and then without the patient’s knowledge, 0.1 N hydrochloric acid was infused for 10 minutes at a rate of 10 mL per minute. Patients were instructed to report whenever their typical symptoms were reproduced. Esophageal chemosensitivity was assessed by both the latency until typical symptom
perception was induced (expressed in seconds) and the total sensory intensity rating reported by the subject at the end of acid perfusion by using a verbal descriptor scale. The scale consisted of a 20-cm vertical bar flanked by descriptors of increasing intensity (no sensation, faint, very weak, weak, very mild, mild, moderate, barely strong, slightly intense, strong, intense, very intense, and extremely intense). Placement of words along the side of the scale was determined from their relative log intensity rating in a normative study.\textsuperscript{221} The validity of these scales for assessing the perceived intensity of visceral sensations has been confirmed.\textsuperscript{222}

An acid perfusion test intensity score (cm × seconds) was then calculated as follows: $I \times T/100$, where $I$ is the total intensity rating at the end of acid perfusion and $T$ is the duration of report of typical symptom perception during the test. For convenience, the score was divided by 100. The test is highly specific, but the sensitivity ranges from 6\% to 60\%.\textsuperscript{73,129,222–230} A negative test has no clinical relevance and does not exclude esophageal origin.

Presently, the acid perfusion test is rarely performed in clinical practice because of its limited diagnostic value in NCCP and other esophageal disorders. Because of the low sensitivity and the emergence of noninvasive and highly sensitive modalities, such as the PPI test and empirical therapy with a PPI, many authors have considered the acid perfusion test to be obsolete.\textsuperscript{135,211,228}

**ELECTRICAL STIMULATION**

Electrical stimulation of the esophagus has been used by several research groups to study visceral perception and cortical responses to different intensities of intraesophageal stimuli. The technique has yet to be standardized, and published protocols are difficult to compare.

Electrical stimulation of the esophageal mucosa is performed by using a 5-mm stainless steel electrode attached to a standard manometric catheter assembly.\textsuperscript{229} The electrode is made from fine stainless-steel wire wrapped around the end of the catheter and fixed with surgical silk.\textsuperscript{230} The electrodes are connected to an electrical stimulator. The catheter assembly is then passed through the nostril, and the electrode is placed in the esophagus. Electrical stimuli are applied repeatedly in a series of 24
stimuli (duration 200 µs at 0.2 Hz). A reference electrode is placed on the abdominal wall, 5 cm below the xiphoid process. Electrical stimulation of the upper and lower esophagus can be achieved by two pairs of silver/silver chloride bipolar ring electrodes located at 5 and 20 cm proximal to the tip of the catheter. The ascending stimulus paradigm includes stimuli that are delivered at a frequency of 0.2 Hz at intensities between 0 and 100 mA. Severity and qualitative perceptual responses are usually assessed by a verbal descriptor. Descriptors are used in ascending order of severity. Sensory threshold is the intensity (measured in milliampere [mA]) at which the participant reports faint sensation, and pain threshold is the intensity at which the participant reports an intense sensation. A somewhat different stimulus paradigm is used in patients who undergo recording of cerebral evoked responses to esophageal electrical stimulation.

**INTRALUMINAL ULTRASONOGRAPHY**

High-frequency intraluminal ultrasonography has been introduced as a novel modality to study the relationship between esophageal motor events and symptoms. The technique has been a useful tool for evaluating smooth muscle contractions. Esophageal ultrasonography can be performed continuously using a catheter-based probe, which allows direct visualization of changes in smooth muscle conformation. The capability of intraluminal ultrasonography to evaluate changes in the thickness of the longitudinal muscle of the esophagus has been used to determine the relationship between esophageal symptoms and motor changes of the esophageal wall. Although the technique has yet to be standardized, investigators have used an esophageal catheter assembly that included a 12.5-MHz ultrasound transducer, solid-state pressure catheter, and monopolar antimony pH catheter. The ultrasound transducer was placed 5 cm above the LES. The 24-hour recordings were analyzed every 2 seconds for a period of 2 minutes before and 30 seconds after the onset of the studied symptom. Rules for image analysis remain at the discretion of the investigator. Because of the limited number of centers that are proficient with this technique, image analysis is primarily operator-dependent, and interobserver and intraobserver agreements have yet to be
determined. Using intraluminal ultrasonography, Balaban and colleagues\textsuperscript{57} demonstrated that most chest pain episodes in patients with NCCP were preceded by sustained thickening of the esophageal smooth muscle wall due to longitudinal muscle contraction that was not detected by esophageal manometry catheter. The same muscular changes were noted after edrophonium-induced chest pain. The authors suggested that the duration rather than the magnitude of the longitudinal muscle contraction is the determining factor for generating esophageal pain. In this study, swallow-associated longitudinal muscle contractions lasted an average of 6.4 seconds, whereas contractions associated with chest pain persisted for a mean of 68.0 seconds. Similar studies in patients with GERD revealed that the mean duration of sustained longitudinal muscle contractions during heartburn was 44.9 seconds.\textsuperscript{58} The motor changes were also observed in patients who reported heartburn that was unrelated to acid reflux events, further supporting the investigator’s hypothesis that this sustained esophageal muscle contraction is responsible for generation of esophageal symptoms, such as chest pain and heartburn.

Even though high-frequency intraluminal ultrasonography has been a valuable research tool to assess the biomechanics of the human esophagus, its exact role in evaluating esophageal-related symptoms has not been fully elucidated.\textsuperscript{233} Initial studies provided intriguing data, but other investigators have yet to replicate these findings. Additionally, sustained contractions of the esophageal longitudinal muscle may represent an epiphenomenon that occurs with symptoms rather than being the trigger for symptoms.

**BALLOON DISTENSION**

Balloon distension has been used primarily for research purposes to determine perception thresholds for pain. This modality has been used extensively in studies of various functional bowel disorders, most notably IBS, functional dyspepsia, and NCCP.\textsuperscript{84,234,235}

More than 40 years ago, intraesophageal balloon distension in humans was reported to produce pain referred to the chest.\textsuperscript{236} Early data indicated that, in patients with documented ischemic heart disease, balloon
distension of the esophagus produced pain indistinguishable from anginal
pain but without ECG changes. This may be explained by convergence
of sensory pathways at the level of spinal cord or in the midbrain. Despite
this similarity in pain, it seems that esophageal balloon distension itself has
no effect on coronary function or blood flow.

Balloon distension was reintroduced during the mid-1980s in a seminal
study that evaluated perception thresholds for pain in patients with
NCCP. The latex balloon was attached to a manometric catheter and
filled with air. The balloon was positioned 10 cm above the LES and
distended in a stepwise fashion using a handheld syringe.

A further development in the balloon distension technique was the
introduction of a pump that was powered by compressed air. The pump
ensured inflations at a predetermined rate, which was difficult to achieve
with a handheld syringe. However, neither system was able to provide
concomitant pressure measurements that could have been helpful to
determine whether the balloon remained within the esophageal lumen
during each inflation. This was particularly critical in protocols that
inflated balloons within the distal portion of the esophagus. Fass and
colleagues demonstrated that balloon distension in the esophagus
resulted in phasic esophageal contractions that increased with increase in
balloon volume. These powerful contractions, in association with
shortening of the esophagus, may propel the balloon into the stomach
without being recognized by the subject or the investigator. Concomitant
pressure measurements would have been helpful to detect the migration of
the balloon into the gastric fundus by demonstrating a sudden decrease in
intraluminal pressure despite continued increase in the balloon’s volume.

The introduction of the electronic barostat, a computer-driven volume-
displacement device, has helped to ensure proper location of the balloon
regardless of inflation paradigm that was used. The basic principle of
the barostat is to maintain a constant pressure within the balloon/bag in the
lumen despite muscular contractions and relaxations. To maintain a
constant pressure, the barostat aspirates air with contractions and injects
air with relaxations. Presently, many prefer the use of a polyethylene bag
to that of a latex balloon. Bags are infinitely compliant and show no
increase in intra-bag pressure until about 90% of the maximum bag
volume has been achieved.\textsuperscript{239,240} In contrast, latex balloons resist inflation and thus show a rapid increase in intra-balloon pressure with small volumes of distension.\textsuperscript{196,239,241} When the pressure increases above the elastance threshold, the balloon becomes plastic and accommodates large volumes of air with very little change in pressure.\textsuperscript{239,240} For tubular organs in the GI tract, such as the esophagus, experts recommend the use of a cylindrical bag (rather than the spherical) with a fixed length.\textsuperscript{196,239}

Barostats have been used extensively in studies evaluating rectosigmoid and gastric perception thresholds for pain. However, this technique has been rarely used to assess esophageal mechanosensitivity in humans. Unlike the rectum and the stomach, the esophagus does not serve as a storage organ but rather as a conduit. Consequently, intraesophageal distensions do not mimic a normal, physiologic stimulus, and thus, perceptual responses to such a stimulus may have no scientific merit. This factor, in addition to the patient’s difficulties in tolerating balloon distension, which commonly results in poor recruitment rates as well as the potential for esophageal perforation, has made esophageal balloon distensions by a barostat a less attractive research tool.

Various distension protocols have been used in different studies. Like any other technique that assesses esophageal sensation, balloon distension has yet to be standardized. Slow ramp distension is an ascending method that involves slow (rate varies from one study to another) increase in volume or pressure of the balloon usually until the desired perceptual response has been reported by the subject.\textsuperscript{55,196,242} In contrast, phasic distensions are rapid inflations of the balloon that can be delivered in random sequence or double random staircase.\textsuperscript{55,196} The latter includes two series of distension stimuli (staircases), and the computer alternates between the two staircases on a random basis.\textsuperscript{196,239,242} With the tracking method, the barostat is programmed to deliver a series of intermittent phasic stimuli separated by interpulse rest period within an interactive stimulus tracking procedure.\textsuperscript{196,243,244} If the subject indicates a sensation below the tracked intensity, then the following stimulus will increase in pressure. If the subject reports the desired sensation, then the following pressure step is randomized to stay the same or decrease. The random element is placed to mask the relationship between ratings and subsequent
stimulus change and, therefore, decrease potential scaling bias.\textsuperscript{81}

Quantification of perceptual responses depends on the characteristics of the mechanoreceptors in a specific region of the GI tract. Volume or pressure distension can be considered the most physiologic stimuli.\textsuperscript{245} The most reliable reports of esophageal sensory thresholds are obtained during volume distension. Although the overall pressure–volume curve is linear, the pressure at any given volume may vary because of the presence or absence of a superimposed esophageal phasic contractions.\textsuperscript{196} Despite this physiologic phenomenon, other investigators rely primarily on pressure when performing balloon studies in the esophagus.

Commonly, qualitative and quantitative perceptual responses are evaluated during balloon distension studies. Qualitative perceptual responses include symptom reports in response to balloon distension, such as chest pain, heartburn, bloating, and fullness, among others.\textsuperscript{196,246} Heartburn is a common sensation that occurs during balloon distension and may mimic the patient’s typical heartburn symptom.\textsuperscript{246} Quantitative perceptual responses are commonly obtained during slow-ramp distension and include the minimal distension volume or pressure at which the individual first reports moderate sensation (innocuous sensation), discomfort, and pain (aversive sensation).\textsuperscript{196} Discomfort threshold is commonly defined as the first unpleasant esophageal sensation, and pain threshold is defined as the first sensation of pain.\textsuperscript{196}

Pitfalls that may modify perceptual responses to balloon distension include the following: Increased rate of balloon distension results in reported perception at lower volumes or pressures,\textsuperscript{247} longer durations of balloon distension are more likely to elicit sensation than shorter durations,\textsuperscript{247} elderly subjects demonstrate diminished visceral pain perception and female patients seem to have lower perception thresholds for pain compared with male patients,\textsuperscript{248–250} and the proximal esophagus has been suggested to be more sensitive to chemical and mechanical stimuli than the distal esophagus.\textsuperscript{196,251} Additionally, reduced sensitivity to intraluminal stimuli has been demonstrated in specific patient populations, such as those with Barrett mucosa or esophageal stricture.\textsuperscript{220,252,253} A recent study demonstrated the development of secondary hypersensitivity in the adjacent portion of the esophagus that was not sensitized by a
Balloon studies are primarily designed to assess the presence of visceral hypersensitivity in various esophageal disorders. Early studies demonstrated that pain develops with balloon distension more frequently in NCCP patients than in normal control subjects and that their pain occurs at smaller volumes. Short-term sensitization of mechanosensitive afferent pathways by transient exposure to irritants has been shown in both humans and animal models of visceral hypersensitivity. Human studies that evaluated the effect of esophageal acid perfusion on perception of esophageal distension in healthy control subjects and patients with GERD had varying results.

Mehta and colleagues reported that perfusion of the esophagus with 0.1 N hydrochloric acid for 30 minutes resulted in enhanced sensitivity to esophageal balloon distension. Similarly, Sarkar and colleagues reported that acid perfusion into the distal esophagus was associated with the development of mechanical hypersensitivity in the proximal esophagus, which had not been exposed to acid, suggesting the development of secondary visceral hypersensitivity. Peghini and coworkers found a lowering of the pain threshold to distension only in those individuals who were symptomatic during acid perfusion. In contrast, DeVault reported that a 15-minute acid perfusion had no significant effect on pain perception during esophageal distension. The mechanisms underlying the sensitizing effect of acute tissue irritation on visceral afferent pathways have been well characterized in the form of peripheral and central sensitization. Such sensitization manifests as increased background activity of sensory neurons, the lowering of nociceptive thresholds, changes in stimulus response curves, and enlargement of receptive fields. During a noxious event, a series of counterregulatory mechanisms are activated that are aimed at containing the development of both the acute and any long-lasting sensitization.

Studies evaluating balloon distensions in patients with chronic acid exposure or esophageal mucosal injury are scarce. Fass and colleagues demonstrated that mild to moderate chronic tissue injury in GERD differentially affects mechanosensitive and chemosensitive afferent pathways. GERD patients showed enhanced perception of acid perfusion

3302
but not of esophageal distension. Chemosensitivity but not mechanosensitivity was correlated with reflux symptoms and with the degree of endoscopically shown tissue injury at baseline. Trimble and coworkers\textsuperscript{208} evaluated patients with heartburn and excess reflux defined by abnormal upper endoscopy or 24-hour esophageal pH monitoring and compared them with patients with heartburn and a normal 24-hour pH test. The results demonstrated that the latter group had lower volume thresholds for perception of esophageal balloon distension and discomfort. This study suggests that patients with typical heartburn who lack any evidence of excess acid are highly sensitive to mechanical stimuli.

Balloon distension has been commonly used to assess the effect of various drugs on esophageal sensory perception. Imipramine, octreotide, and nifedipine have all been shown to increase perception thresholds for pain in normal controls or patients with NCCP.\textsuperscript{258–262} Balloon distention is rarely used in clinical practice primarily because of the complexity of the procedure and lack of standardization despite a recent study demonstrating its diagnostic utility in third of the NCCP subjects.\textsuperscript{263}

**ESOPHAGEAL EVOKED POTENTIALS**

Cerebral evoked potentials reflect electrical activity of the brain in response to visual, auditory, somatosensory, and visceral stimuli. There is a clear relationship between stimulus frequency, using esophageal electrical stimulation, and amplitude of cerebral evoked potentials.\textsuperscript{264} Studies have demonstrated that a significant and progressive decrease of evoked potential amplitudes is associated with increasing stimulus frequency. This suggests a rapid attenuation of the cerebral autonomic responses with increased frequency of electrical stimulation.\textsuperscript{264} Furthermore, a stimulus intensity–response relationship has been shown in brain response to increasing stimulus intensity, which is probably explained by increased recruitment of afferent fibers.\textsuperscript{264,265}

Balloon distension and electrical stimulation protocols have been used in studies assessing cerebral evoked potentials in response to esophageal stimulation. It is unclear if one of the sensory testing methods is better than the other.

Esophageal balloon distension triggers a characteristic triphasic evoked
potential. Two negative peaks (N1 and N2) and one positive peak (P1) can be demonstrated. Latency is the time in milliseconds from the stimulus to the peak. There is a considerable intersubject variability but almost no intrasubject variability when recording cerebral evoked potentials. Studies in normal subjects have shown significantly shorter latencies during balloon distension in the proximal esophagus as compared with the distal esophagus.

Assessment of patients with NCCP, using the esophageal balloon distension paradigm, revealed that amplitude and quality of cerebral evoked potentials increased with increasing sensation, whereas the latencies remained stable. Additionally, the amplitude and quality of evoked potentials were lower in NCCP patients as compared with controls. Similar levels of sensation were produced by lower balloon volumes in NCCP patients.

Esophageal stimulation and cerebral evoked potentials may provide clues to the pathway and type of neurons involved in nociception. Additionally, cerebral evoked potentials were used to identify brain areas that are responsible for esophageal pain sensation.

**BRAIN IMAGING**

In addition to cortical evoked potentials, other techniques have been increasingly used to evaluate the brain–gut relationship in patients with esophageal disorders. These techniques include positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). The GI is intricately connected to the central nervous system by pathways that are continuously sampling and modulating gut function.

PET scanning is an established method to study the functional neuroanatomy of the human brain. Radio-labeled compounds allow the study of biochemical and physiologic processes involved in cerebral metabolism. Tomographic images represent spatial distribution of radioisotopes in the brain. Regional cerebral blood flow is studied with labeled water (H$_2^{15}$O) and glucose metabolism with 18Fl-labeled fluorodeoxyglucose. Unlike PET, fMRI does not require radioisotopes and, hence, is considered a safer imaging technique. fMRI detects increases in oxygen concentration in areas of heightened neuronal
activity. This imaging technique is best suited for locating the site but not the sequence or duration of neuronal activity. Overall, fMRI provides both anatomic and functional information.

Thus far, only a few studies have attempted to assess the cortical process of esophageal sensation in humans. Aziz and colleagues examined the human brain loci involved in the process of esophageal sensation using PET and distal esophageal balloon distension in eight healthy volunteers. Nonpainful stimuli elicited bilateral activation along the central sulcus, insular cortex, and the frontal and parietal operculum. Painful stimuli resulted in intense activation of the same areas and additional activation of right anterior insular cortex and anterior cingulate gyrus. The former is important in affective processing, whereas the latter is important in pain processing and generating an affective and cognitive response to pain. In another study, Kern and colleagues evaluated activation of cerebral cortical responses to esophageal mucosal acid exposure using fMRI. Ten healthy subjects underwent intraesophageal perfusion of 0.1 N hydrochloric acid over 10 minutes. None of the study subjects reported GERD symptoms during acid perfusion. Cerebral cortical activity was concentrated in the posterior cingulate, parietal, and anteromesial frontal lobes. The superior frontal lobe regions activated in this study corresponded to Brodmann area 32, the insula, the operculum, and the anterior cingulate.

Further studies are needed to assess cerebral activation in patients with different esophageal disorders. In addition, it would be of great interest to determine whether there are differences in central processing of an intraesophageal stimulus in patients with NCCP, nonerosive reflux disease, or functional heartburn. It is also important to begin to examine the role of psychophysiologic states such as stress, anxiety, and depression and their effects on central nuclei involved with perception of esophageal stimuli.

**SENSORY TESTING—PITFALLS IN STUDY DESIGN**

Surprisingly, many studies using esophageal sensory testing to evaluate sensory perception thresholds are afflicted with design flaws that make interpretation of the results very difficult. Studies using balloon distension paradigms in the distal esophagus, without simultaneously measuring...
intraesophageal pressure, are inherently flawed because of the tendency of the balloon to migrate into the stomach due to esophageal contraction and shortening in response to distension of the balloon. Other common pitfalls include using different rates of balloon distension or acid perfusion, different balloon distension paradigms, or more commonly using an inappropriate control group. For example, a study that compares esophageal sensory testing of patients with BE versus normal controls, and uses a younger control group, is likely to bias the study results. Patients with BE are commonly older, and age per se (being older) increases perception thresholds for pain. Thus, it will be difficult to discern if the Barrett epithelium or the difference in age is responsible for patients’ alteration in pain perception.

Studies that evaluate esophageal sensory testing in IBS patients, as compared with normal controls and use a more gender-diverse control group, are also hard to interpret. IBS patients are commonly women, and a control group that is composed of a significant number of men may bias the results toward the IBS group unrelated to the underlying disorder (IBS). Men, as compared with women, demonstrate an increase of perception thresholds for pain in response to esophageal stimuli.

Ensuring a similar study protocol and age- as well as gender-matched control group will reduce the potential bias in esophageal sensory testing studies. However, because of lack of standardization in study design, comparison between studies remains a difficult task.

**PSYCHOLOGICAL EVALUATION**

Between 17% and 43% of the patients with NCCP are estimated to suffer from some type of psychological abnormality. Psychological comorbidity can modulate esophageal pain perception and cause subjects to perceive low-intensity esophageal stimuli as being painful. Anxiety, depression, neuroticism, and hypochondriac behavior have all been described in NCCP patients. Consequently, patients, especially those who are unresponsive to medical intervention and those suspected to have psychological comorbidity, should be referred to a psychologist or psychiatrist for further evaluation.
Treatment

Treatment for NCCP should be targeted toward the specific underlying mechanism responsible for the patient’s symptoms. Table 62.5 provides a general treatment plan for NCCP.

**TABLE 62.5 Treatment Plan for NCCP**

GERD, gastroesophageal reflux disease; NCCP, noncardiac chest pain; PPI, proton pump inhibitor.

**GERD-RELATED NCCP**

Lifestyle modifications include elevation of the head of the bed; weight loss; smoking cessation; and avoidance of alcohol, coffee, fresh citrus juice, and other food products as well as medications that can exacerbate reflux such as opioids, benzodiazepines, and calcium-channel blockers.\(^{278,279}\) Although these lifestyle modifications are commonly advocated as first-line treatment in GERD patients, there is no evidence to support their efficacy in GERD-related NCCP. Regardless, enthusiasm about lifestyle modifications is very high among physicians, and thus, it is highly likely that GERD-related NCCP subjects will be instructed to follow them.

The efficacy of histamine (H\(_2\)) receptor antagonists in controlling symptoms in patients with GERD-related NCCP has been shown to range from 42% to 52%.\(^{280}\) In one study, cimetidine (unknown dose) and antacids were shown to be effective in only 42% of the patients with GERD-related NCCP who were followed for a period of 2 to 3 years.\(^{281}\) Stepping down GERD therapy from a PPI to an H\(_2\) receptor antagonist has been disappointing in GERD-related NCCP patients.

Omeprazole (Prilosec) 20 mg twice daily or placebo was administered
over a period of 8 weeks to GERD-related NCCP patients in the only double-blind, placebo-controlled trial that has been performed. Patients who received omeprazole had a significant reduction in both the number of days with chest pain and in their chest pain severity scores compared to the patients who received placebo. Thus far, most of the studies assessing the efficacy of PPIs in NCCP primarily utilized omeprazole. However, it is likely that all other PPIs would demonstrate similar efficacy. In fact, a recent open-label study with esomeprazole (Nexium) administered 40 mg once daily over a period of 1 month demonstrated complete resolution of symptoms in 57.1% of subjects with either NCCP or laryngeal manifestations of GERD. In another open-label study, 85% of NCCP patients reported symptom relief or improvement after receiving PPI twice daily (different brands) for a period of 3 months.

A retrospective review of patients’ files revealed that PPIs reduce the number of chest pain episodes, emergency department visits, and hospitalizations due to chest pain in subjects with documented CAD. It is likely that GERD-related symptoms contribute to the medical-seeking behavior of this patient population.

Patients with GERD-related NCCP should be treated with at least double the standard dose of PPI until symptoms remit, followed by dose tapering to determine the lowest PPI dose that can control symptoms. As with other extraesophageal manifestations of GERD, NCCP patients may require more than 2 months of therapy for optimal symptom control. A single randomized placebo-controlled study evaluated symptom scores in 599 NCCP patients treated with esomeprazole 40 mg twice daily for 2 weeks. Several questionnaires, including the Reflux Disease Questionnaire (RDQ), Short Form-36 (SF-36), Hospital Anxiety and Depression Questionnaire (HAD), McGill Pain Questionnaire (MPQ), Chest pain visual analogue scale (VAS), Brief Pain Inventory (BPI), and Quality of Life in Reflux and Dyspepsia (QOLRAD), were used for symptom assessment in this study. Chest pain symptom relief was defined as being less than or equal to 1 day of minimal symptoms during the last 7 days of treatment. Patients were stratified into two groups based on clinical judgment of the presence or absence of GERD-related symptoms. Importantly, pH testing was not done to demonstrate pathologic acid
reflux. Patients without GERD symptoms demonstrated significant
improvement in chest pain symptoms on esomeprazole as compared to
placebo (38.7% vs. 25.5% respectively; P = .018). Post-hoc analysis of the
combined populations (patients with and without GERD symptoms)
indicated positive treatment response to esomeprazole for chest pain in
patients with acid reflux–related symptoms as compared with placebo
(33.1% vs. 24.9% respectively; P = .035). Long-term maintenance PPI
treatment has been shown to be highly effective. Borzecki and
colleagues developed a decision tree to compare empiric treatments for
NCCP patients with H₂ receptor antagonists or standard-dose PPI for 8
weeks with initial investigations (upper endoscopy or upper GI series).
Empiric treatment was more cost-effective in the initial investigation
strategy, with a cost of $849 per patient versus $2,187 per patient.

Only one trial has been published using the EndoCinch endoluminal
gastroplication (ELGP) as a treatment modality for atypical GERD
symptoms, including NCCP. ELGP is an endoscopic suture technique that
places sutures, using the EndoCinch device, 1 cm below the
esophagogastric junction (OGJ). In an open-label trial evaluating ELGP
in patients with atypical GERD symptoms (n = 39), including NCCP
(18/39), the authors demonstrate that 72% (n = 13/18) of patients reported
improvement in symptoms of chest pain at 6 months postprocedure as
compared to baseline symptoms (P = .0003).

The value of antireflux surgery in GERD-related NCCP is unclear.
Several studies have demonstrated a significant improvement in symptoms
following laparoscopic fundoplication in patients with GERD-related
NCCP. For instance, Patti and associates reported improvement in chest
pain symptoms following laparoscopic fundoplication in 85% of patients
with GERD-related NCCP. In addition, Farrell and coworkers reported
that 90% of NCCP patients who underwent antireflux surgery experienced
improvement in chest pain and 50% reported complete symptom
resolution. In contrast, So and colleagues reported that after
laparoscopic fundoplication, relief of atypical GERD symptoms (e.g.,
chest pain) was less satisfactory than relief of typical GERD symptoms
(e.g., heartburn). In their study, the authors evaluated symptom
improvement with a questionnaire given 3 months and 12 months after
antireflux surgery. Overall, heartburn was relieved in 93% of patients, whereas only 48% of patients reported relief of chest pain symptoms.

**NON–GERD-RELATED NCCP**

The treatment of non–GERD-related NCCP is primarily based on esophageal pain modulation (Table 62.6). An important development in this field was the recognition that NCCP patients with spastic esophageal motor disorders (except achalasia), as documented by esophageal manometry, are more likely to respond to pain modulators than to muscle relaxants. Unfortunately, no large, well-designed studies to assess pain modulators in patients with non–GERD-related NCCP have been performed thus far.

GERD, gastroesophageal reflux disease; NCCP, noncardiac chest pain; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Several recent studies have shown that most NCCP patients are managed by cardiologists and PCPs who appear to know little about the role and treatment of esophageal hypersensitivity in NCCP.22,23,293 Even gastroenterologists appeared somewhat uninformed about the role of visceral hypersensitivity in NCCP.294

Nitroglycerin and long-acting nitrates cause relaxation of GI smooth muscles by stimulating cyclic guanosine monophosphate (GMP)-dependent pathways. Several open-label studies have reported that nitrates improve symptoms and esophageal motility patterns in patients with chest pain and esophageal dysmotility. Several investigators reported symptomatic improvement in patients with DES, accompanied by normalization of esophageal motility during treatment with nitrates.295,296 In one small study, five patients with DES experienced a 4-year clinical and manometric remission.297 However, other studies have failed to demonstrate similar efficacy.298,299 Long-acting nitrates in doses of 10 to
20 mg two to three times daily, as well as short-acting, sublingual nitrates for acute episodes of chest pain in NCCP patients, were used in these studies.

Overall, studies that evaluated the value of nitrates in NCCP have been limited by small numbers of patients and inconsistent results in regard to drug efficacy. A placebo-controlled trial that excludes patients with GERD has yet to be performed.

Because calcium plays an important role in esophageal muscle contraction, the role of calcium channel blocking agents in patients with NCCP and esophageal spastic motility disorders has been the focus of investigation. Nifedipine (10 to 30 mg, by mouth, three times a day) decreases the amplitude and duration of esophageal contractions in patients with nutcracker esophagus after only 2 weeks. Unfortunately, the effect of the drug disappeared after 6 weeks of treatment with the complete recurrence of symptoms. Davies and associates used a placebo-controlled trial to assess the efficacy of nifedipine in the prevention of symptomatic episodes of esophageal spasm in eight NCCP patients over a 6-week period. The authors were unable to find statistically significant differences in symptom improvement between the two therapeutic arms. In contrast, symptom improvement was noted in 20 NCCP patients with various esophageal motility disorders, including hypertensive LES, nutcracker esophagus, DES, and vigorous achalasia, treated with nifedipine (10 mg, by mouth, three times a day). Nifedipine was also found to significantly decrease LES resting pressure, with a direct correlation to the plasma levels of drug.

Diltiazem (60 to 90 mg, by mouth, four times a day) for 8 weeks significantly improved mean chest pain scores and esophageal motility studies in patients with nutcracker esophagus when compared to placebo. However, in a study evaluating eight patients with DES, the effect of diltiazem in relieving chest pain was not different from the effect of placebo, probably due to the small number of patients who participated in the study.

Other calcium channel blockers have been evaluated in patients with primary esophageal motor disorders including verapamil, fendiline, nimodipine, and nisoldipine, with various effects on LES resting pressure.
and esophageal amplitude contractions. Regardless, calcium channel blockers appear to have a transient esophageal motor effect that translates to a short-lived improvement in symptoms, compounded by a variety of side effects such as hypotension, bradycardia, and pedal edema.

Sildenafil is a potent selective inhibitor of cyclic GMP-specific phosphodiesterase 5 (PDE5), which inactivates nitric oxide–stimulated GMP. Intracellular accumulation of the latter induces smooth muscle relaxation. The drug has been shown to improve esophageal motility in patients with nutcracker esophagus or hypertensive LES by lowering LES resting pressure, reducing distal esophageal amplitude contractions, and prolonging the duration of LES relaxation.\textsuperscript{306,307} However, thus far, there have been no studies that specifically addressed NCCP patients, so the value of this compound in NCCP remains unknown. Additionally, the usage of this compound in NCCP will likely be limited by its cost and side effects.

The antispasmodic cimetropium bromide has been shown to be efficacious in eight NCCP patients with nutcracker esophagus when taken intravenously,\textsuperscript{308} but clinical data regarding the efficacy of an oral formulation are still lacking. Hydralazine, an antihypertensive compound that directly dilates peripheral vessels, was shown to improve chest pain and dysphagia by decreasing the amplitude and duration of esophageal contractions in a small study of only five patients.\textsuperscript{299} Overall, evidence to support the therapeutic benefit of anticholinergic agents for the treatment of NCCP remains very limited.

Multiple case series evaluating peroral endoscopic myotomy (POEM) for the treatment of spastic oesophageal motility disorders (diffuse oesophageal spasm, jackhammer esophagus, nutcracker esophagus, and hypertensive LES) have shown symptomatic improvement in chest pain symptoms reaching 91%.\textsuperscript{308} Some controversy exists on whether a longer myotomy extending into the full length of the spastic oesophageal muscle or short-segment myotomy should be pursued in patients with spastic oesophageal motor disorders.\textsuperscript{309} It appears that patients with achalasia demonstrate better symptom response to POEM compared to patients with spastic oesophageal motor disorders. However, larger trials are needed to further determine the value of POEM in NCCP patients with esophageal
PAIN MODULATORS

Visceral hypersensitivity is thought to be the primary underlying mechanism of patients with non–GERD-related NCCP regardless of the presence or absence of esophageal motor disorder. Consequently, drugs that can alter esophageal pain perception have become the mainstay of therapy in these patients.

Several drugs have been shown to have a pain modulatory or a visceral analgesic effect, thus alleviating chest pain symptoms. These drugs include tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), theophylline, and trazodone. Table 62.7 provides a hierarchy of antidepressants of choice for chest pain reduction and global health improvement.

</table>

The only TCA that has been studied in a randomized double-blind, placebo-controlled trial is imipramine. In one study, 60 NCCP patients were divided into three groups and treated with either imipramine 50 mg, clonidine 0.1 mg, or placebo daily. Treatment with imipramine, clonidine, and placebo showed a mean reduction in chest pain frequency (± standard deviation [SD]) compared to the placebo phase of 52% (±25%), 39% (±51%), and 1% (±86%), respectively. Only imipramine treatment showed significant reduction in chest pain frequency (approximately 50%) compared to the placebo phase (P = .03) as well as decreased right ventricular sensitivity to pain. Both imipramine and clonidine had...
improved symptoms of chest pain intensity compared to placebo \((P = .001\) and \(.002\), respectively). There was no difference in treatment effect when patients with normal and those with abnormal esophageal motility studies were compared. There was no change in esophageal sensitivity to balloon distension during treatment as compared to baseline. Fifteen patients treated with imipramine had a slight but significant prolongation of the corrected QT interval \((P = .02)\). No patients reported symptoms suggestive of a proarrhythmic effect.\(^{260}\) Cox et al.\(^{311}\) performed a randomized, double-blind, crossover trial of imipramine versus placebo in 18 women with chest pain and normal coronary angiograms who were suffering anginal episodes despite conventional anti-anginal medication. All patients were randomized to treatment with either imipramine 50 mg or placebo daily for a period of 5 weeks, followed by a 2-week washout period. Patients were then crossed over to the other arm for an additional 5 weeks. The total number of chest pain episodes was significantly less with imipramine compared to placebo \((11 \text{ vs. } 21, \text{ respectively}; P = .01)\). However, no significant improvement was detected in any of the six quality of life domains when imipramine was compared to placebo. This was most likely due to the high incidence of side effects with imipramine compared to placebo \((83\% \text{ vs. } 44\% \text{ respectively}; P = .01)\). Furthermore, three patients were withdrawn from the study due to side effects. The most common side effects reported were dry mouth and dizziness.

Park et al.\(^{312}\) conducted a randomized, open-label trial in FCP patients refractory to standard-dose PPI. The study compared treatment outcomes between standard-dose PPI (rabeprazole 20 mg daily) plus low-dose amitriptyline \((10 \text{ mg at bedtime}) (n = 17)\) versus double-dose PPI therapy alone \((\text{rabeprazole 20 mg twice a day}) (n = 19)\). Patients who had both negative pH testing for GERD and less than 50\% improvement in global symptoms scores after treatment with standard-dose rabeprazole for 1 month were enrolled into the study. Daily symptom diaries were used to evaluate global symptom scores each week. Mean global symptom scores were not statistically significant between the two treatment groups \((3.75 \pm 0.31 \text{ vs. } 4.35 \pm 0.29; P = .172)\); however, within the groups, differences in global symptom scores were significant at week 8 \((P < .001)\). After 8 weeks, 71\% of patients treated with both amitriptyline and standard-dose
rabeprazole had greater than 50% global symptom improvement, whereas only 26% of patients treated with double-dose rabeprazole had a similar degree of symptom improvement ($P = .008$). In addition, those patients who received both amitriptyline and standard-dose rabeprazole were noted to have significant improvement in scores of body pain and general health perception compared with those receiving double-dose rabeprazole ($P = .031$ and .01, respectively). Other new TCAs known to have fewer anticholinergic side effects, such as nortriptyline, are attractive treatment options due to more favorable side effect profiles but have not been formally studied in NCCP.

**Trazodone**

Trazodone, dosed between 100 and 150 mg, was evaluated in 29 patients with contraction abnormalities and NCCP using a double-blind, placebo-controlled trial for 6 weeks. Questionnaires that were used to evaluate symptom improvement with treatment included the Oesophageal Distress Symptom Score, Symptom Checklist 90-Revised (SCL-90-R), Global Symptom Index, positive symptom index, and the Montgomery-Åsberg Depression Rating Scale (MADRS). All patients underwent the Bernstein test with acid perfusion into the esophagus at the time of esophageal manometry. Those patients with positive acid perfusion testing, findings of esophagitis on upper endoscopy or barium studies, were excluded. Trazodone-treated patients reported a significantly greater global improvement (per VAS) compared to placebo at 6 weeks posttreatment (trazodone: 48% vs. placebo: 11%; $P = .02$) despite no effect on esophageal motility. In addition, patients treated with trazodone had a statistically significant reduction in esophageal distress symptom scores (including NCCP) compared to placebo ($P = .03$). However, there was no significant difference in chest pain intensity or frequency in patients treated with trazodone versus placebo. Side effects were generally mild and consisted of dry mouth in two patients and dizziness, drowsiness, and fatigue in five patients receiving trazodone.

**Serotonin Norepinephrine Reuptake Inhibitors**

Venlafaxine 75 mg per day was compared with placebo for the treatment
of 43 patients with FCP. Symptom diaries documented scores of frequency and severity of chest pain. Symptom intensity scores were calculated by adding daily severity for the week multiplied by daily frequency. Additional questionnaires included SF-36 and the Beck Depression Inventory (BDI). Symptom score improvement of greater than 50% was considered to be treatment success. On the intention-to-treat analysis, more than 50% improvement in symptoms was seen in 52% of patients treated with venlafaxine versus 4% treated with placebo (OR 26.0; 95% CI, 5.7 to 118.8; \( P < .001 \)). Furthermore, patients in the venlafaxine group had a significantly greater improvement in body pain and emotional state compared with the placebo group (\( P = .002 \) and .002, respectively). Overall, the side effects were minimal and primarily consisted of sleep disturbances.

**Selective Serotonin Reuptake Inhibitors**

A double-blind, randomized placebo-controlled trial evaluating paroxetine in dosages ranging from 5 to 50 mg was performed in 43 NCCP patients. Patients were evaluated by the physician-rated scales (Clinical Global Impression of Illness Severity and Clinical Global Impression of Improvements), BDI, Short Form MPQ, Medical Outcomes Study SF-36, and a patient-rated scale of symptom severity (VAS) to assess symptoms throughout the study period. No GI evaluation had been performed before or during enrolment into the study. Only on Clinical Global Impression of Improvements questionnaire did paroxetine treatment show superiority to placebo (\( P < .05 \)).

Sertraline was evaluated as a treatment for NCCP in a single-site, double-blind, placebo-controlled study consisting of 30 patients. The sertraline group received 50 mg at the beginning of the study, with titration of the dose to 200 mg based on clinical response. Patients were evaluated with daily pain diaries (VASs), SF-36 Health Survey Manual, and the BDI at enrollment. Patients treated with sertraline had greater reduction in chest pain scores (week 0: 3.94, week 9: 1.49) compared to those treated with placebo (week 0: 3.50, week 9: 2.96; 95% CI, \(-3.49, -0.36\); \( P = .02 \)), with pain scores decreasing by approximately 0.2 units for each week of the study. The SF-36 subscore for general health had significantly improved at
the end of treatment compared to placebo. Side effects were generally mild and reported as restlessness, nausea, decreased libido, and delayed ejaculation.\textsuperscript{315}

**Adenosine Antagonists**

A few studies have evaluated the role of theophylline in the treatment of esophageal chest pain. Rao et al.\textsuperscript{316} first conducted a 3-month open-label trial of theophylline infusion in 21 patients with FCP. Patients underwent impedance planimetry as well as balloon distension of the esophagus, with esophageal hypersensitivity being defined as reproduction of chest pain symptoms with balloon distension \(\leq 55\) cm H\textsubscript{2}O pressure. Chest pain intensity and improvement in chest pain symptoms were measured by VASs. Sensory responses to balloon distension were graded on a scale of 0 to 3 (0 = no pain, 1 = fullness/distension, 2 = discomfort, 3 = pain). Of those who demonstrated reproducible chest pain with graded balloon distension (16/21), 12 (75\%) had increased chest pain thresholds (\(P < .05\)). The median threshold for discomfort increased to 45 cm H\textsubscript{2}O (vs. pretreatment: 20 cm H\textsubscript{2}O; \(P < .05\)) and for chest pain to greater than 65 cm H\textsubscript{2}O (vs. pretreatment: 40 cm H\textsubscript{2}O; \(P < .05\)). Eight of the 12 patients who received oral theophylline (6 mg/kg/day) completed the second portion of the study. Six of eight patients (75\%) had greater than 50\% reduction in chest pain frequency and intensity (\(P < .05\)) with intravenous theophylline compared to baseline scores (\(P < .05\)). These six patients were subsequently transitioned to the oral theophylline phase of the trial.

Adverse effects were noted in four patients including transient insomnia, nausea, palpitations, and tremor. Two patients who were transitioned to oral theophylline discontinued treatment due to symptoms of nausea, transient insomnia, and palpitations.\textsuperscript{316}

Rao et al.\textsuperscript{317} also performed two randomized placebo-controlled trials in a single cohort of NCCP patients several years later involving intravenous and oral theophylline. The first trial with intravenous administration of theophylline treatment in 16 NCCP patients demonstrated increased chest pain thresholds (\(P = .027\)), increased esophageal cross-sectional area (\(P = .03\)), and a more distensible esophageal wall (\(P = .04\)) after treatment, as compared with placebo, suggesting a more relaxed esophagus after
theophylline infusion. The second trial evaluated oral theophylline treatment response in 19 NCCP patients compared to placebo. Patients treated with oral theophylline (200 mg capsules twice daily for 4 weeks) had a 58% reduction in symptoms, compared to 6% on placebo (P < .02). Patients were noted to have less chest pain episodes (P = .025) as well as decreased duration (P = .002) and severity (P = .031) of symptoms (Fig. 62.9). Theophylline was reasonably tolerated, with reported side effects of nausea, insomnia, tremor, and light-headedness.\textsuperscript{317}

![Graph showing the effect of oral theophylline versus placebo on the number of painful days in each individual with non–gastroesophageal reflux disease-related noncardiac chest pain at baseline and after drug administration (200 mg twice daily for 4 weeks).](image)

**Octreotide**

Octreotide, a synthetic analog of somatostatin, has been shown to increase rectal and sigmoid perception thresholds for pain in IBS subjects as well as healthy subjects.\textsuperscript{318,319} It has been postulated that the effect of octreotide is mediated by the activation of somatostatin receptors at the spinal cord and/or the supraspinal level. Octreotide, administered 100 mg subcutaneously, was found to significantly increase perception thresholds for pain as compared to placebo in healthy subjects undergoing
intraesophageal balloon distension.\textsuperscript{320} Unfortunately, due to cost and the lack of an oral formulation, octreotide is rarely utilized for NCCP in clinical practice.

**Benzodiazepines**

Alprazolam has been shown in a study to ameliorate chest pain at a mean dose of 4.3 mg daily in patients with NCCP and panic disorder.\textsuperscript{321} In this study, 15 out of 20 patients reported at least a 50% reduction in panic attack episodes and a corresponding decline in the frequency of chest pain episodes. Clonazepam, given 1 to 4 mg daily, was also shown to be effective in the treatment of patients with NCCP and panic disorder.\textsuperscript{322} The treatment of a functional disorder such as NCCP with benzodiazepines has been greatly discouraged primarily due to the likelihood of becoming addicted to this class of drugs.

**ENDOSCOPIC TREATMENT AND SURGERY FOR NCCP**

Botulinum toxin (BOTOX; Allergan, Irvine, CA) interacts selectively with cholinergic neurons to inhibit the release of acetylcholine at the presynaptic terminals. Botulinum toxin injection into the LES has been used in several uncontrolled trials that included patients with NCCP and documented esophageal spastic motility disorder. Injecting botulinum toxin into the LES in a small, uncontrolled study resulted in 50% reduction of chest pain episodes in 72% of the subjects for a mean duration of 7.3 months (Fig. 62.10).\textsuperscript{323}
Laparoscopic fundoplication relieves heartburn and acid regurgitation in most patients with GERD, but its effect on chest pain is less clear. DeMeester and associates\textsuperscript{44} identified a temporal correlation between chest pain and acid reflux events in 12 of 23 patients with NCCP. Chest pain resolved in all 12 patients treated either by surgery (eight patients) or acid-reducing agents (four patients). Patti and coworkers\textsuperscript{290} reviewed patients who complained of chest pain in addition to heartburn and acid regurgitation. Overall, chest pain improved in 85\% of these patients after undergoing laparoscopic fundoplication for GERD. Improvement in chest pain increased to 96\% in patients whose chest pain correlated with GERD most of the time. Farrell and colleagues\textsuperscript{291} evaluated the effectiveness of antireflux surgery for patients with atypical manifestations of GERD. Chest pain improved in 90\% of patients after laparoscopic fundoplication, with symptom resolution in 50\% of patients. Although surgical studies demonstrated a high success rate of antireflux surgery in GERD-related NCCP patients, the patients included were carefully selected.

Very few studies to date have specifically evaluated the value of endoscopic treatment for GERD in patients with GERD-related NCCP. Liu et al.,\textsuperscript{289} who treated 18 NCCP patients with ELGP, demonstrated short-
term symptomatic response (6 months) in 72% of them. During long-term follow-up (1 to 3 years) 75% of nonresponders became symptom-free, and 40% of responders became symptomatic.

JOHREI THERAPY
Johrei therapy is a technique by which a healer transmits healing energy to the patient. Gasiorowska et al.\textsuperscript{324} conducted a randomized controlled pilot study evaluating the effect of Johrei versus wait-list (no intervention) in controlling symptoms of 39 patients with FCP. All patients enrolled had normal ambulatory esophageal pH testing, upper endoscopy, and esophageal manometry. Patients were evaluated by the SF-36, SCL-90-R, Perceived Stress Scale (PSS), and HAD scale. Symptom intensity scores were calculated by adding the reported daily symptom severity multiplied by frequency. Eighteen Johrei sessions delivered by the same certified practitioner were conducted over a 6-week period. The study demonstrated a significant posttreatment reduction in symptom intensity scores (7.0) in the Johrei group as compared to baseline (20.28; $P = .0023$). In contrast, the wait-list group demonstrated no difference in symptom intensity scores compared to baseline (23.06) and posttreatment (20.69; $P = \text{not significant}$) scores.\textsuperscript{324} Johrei was well tolerated with no side effects reported.

PSYCHOLOGICAL TREATMENT
Psychological comorbidity, mainly depression and anxiety, is common in patients with NCCP. Psychotherapy may be helpful in the treatment of patients with NCCP, particularly those who also have hypochondriasis, anxiety, or panic disorder.

Several studies have demonstrated that patients with NCCP who are treated with cognitive-behavioral therapy report significant improvement in quality of life and reduction in chest pain symptoms. Additionally, cognitive-behavioral therapy has been successfully used for the treatment of NCCP patients without an existing panic disorder.\textsuperscript{325} A study evaluating patients who were treated with cognitive-behavioral therapy reported that 48% of these patients remained pain-free at 12-month follow-up, as compared to only 13% of the patients in the nonintervention group. Other
psychological interventions that have been suggested to be effective in patients with NCCP include reassurance, education, relaxation techniques, breathing training, and biofeedback. Biofeedback was assessed in a study that compared it to primary care visits only in patients with NCCP.\textsuperscript{326} Patients in the biofeedback group demonstrated a significantly lower symptom frequency and severity. However, a large group of patients assigned to the biofeedback arm (52\%) did not complete the study.

Keefe et al.\textsuperscript{327} randomized 116 NCCP patients to a combination of coping skills plus sertraline, sertraline alone, coping skills plus placebo, or placebo. Patients recorded chest pain intensity and unpleasantness scores using VASs (0 to 100) and completed the State-Trait Anxiety Inventory (STAI), Pain Catastrophizing Scale (PCS), BDI, Sickness Impact Profile (SIP), Stone and Neale’s Coping Inventory, and Coping Strategies Questionnaire. The rate of change in chest pain intensity and unpleasantness with coping skills and sertraline, either alone or in combination, was statistically significant compared to those treated with placebo alone. Of note, patients treated with coping skills plus sertraline also had a significant improvement in catastrophizing of pain symptoms and anxiety compared to the other groups (P = .02).\textsuperscript{327}

Hypnotherapy has been recently evaluated in the treatment of NCCP patients. Jones and colleagues\textsuperscript{328} reported an 80\% improvement in symptoms, with a significant reduction in pain intensity, among patients who were receiving 12 sessions of hypnotherapy, compared to only a 23\% symptom improvement in the control group (Fig. 62.11). The study concluded that hypnotherapy appears to have a role in treating NCCP and that further studies are needed.
FUTURE THERAPY

Future research in NCCP will continue to focus on mechanisms for pain and will attempt to identify new therapeutic modalities aimed to reduce visceral pain. Research will likely concentrate primarily on the role of central and peripheral sensitization in enhancing perception of intra-esophageal stimuli. Furthermore, currently available treatments for other functional GI disorders, such as IBS and non-ulcer dyspepsia, may be tested in NCCP as well.

The serotonin-related drugs, such as 5-HT3 receptor antagonists and 5-HT4 receptor agonists, appear to have a pain-modulatory effect, probably by altering the initiation, transmission, or processing of extrinsic sensory information from the GI tract. Phosphorylation of N-methyl-D-aspartate (NMDA) receptors expressed by dorsal horn neurons leads to central sensitization via an increase in their excitability and subsequent increase in receptive field size. Potentially, this central sensitization may be prevented or even reversed by antagonism of NMDA receptors within the spinal cord.

Potential targets that are currently under consideration include vanilloid receptor ion channels, acid-sensing ion channels, sensory neuron-specific Na+ channels, P2X purinoceptors, cholecystokinin receptors, bradykinin and prostaglandin receptors, glutamate receptors, tachykinin, and calcitonin gene-related peptide receptors as well as peripheral opioid and
cannabinoid receptors. The peripheral opioid receptor agonists are of high interest because they may offer visceral analgesic effect without crossing the blood–brain barrier and thus affecting the CNS.

Spinal afferents, which may play a role in visceral nociception, express tachykinins that include substance P, neurokinins A and B, and neuropeptide K. Tachykinin receptor antagonists may confer a visceral analgesic effect that can be used in PPI-resistant patients. Neurokinin (NK)-1, NK-2, and NK-3 receptor antagonists were only evaluated in preclinical trials. Cholecystokinin receptor antagonists may alter visceral pain perception.

Another important area that is likely to attract future attention when treating patients with NCCP is complementary and alternative therapeutic modalities that can interfere with the mind and body axis. Figure 62.12 provides a proposed management algorithm for NCCP.

CHAPTER 63
Abdominal, Peritoneal, and Retroperitoneal Pain
DAVID JUSTIN LEVINTHAL and KLAUS BIELEFELDT

Abdominal pain is one of the leading causes for patients to seek consultation with a physician (Fig. 63.1). Determining the precise mechanisms that underlie such abdominal pain symptoms and providing effective therapies both remain major clinical challenges. The experience of visceral pain is shaped by multiple factors including peripheral mechanisms, such as acute injury or active inflammation, and central processes, such as visceral hypersensitivity and somatization. Ultimately, the pain experience is neurally encoded and perceived at the level of the brain. Thus, a complex interplay of factors that are capable of influencing the activity of neurons located throughout the neuraxis should be considered as drivers or modulators of visceral perception in general and particularly in the experience of visceral pain.

FIGURE 63.1  Relative contribution of abdominal pain, compared to headache and chest pain, as the primary chief complaint in emergency department (ED) visits (A) and in ED visits ultimately leading to hospital admission (B). Data is derived from the National Emergency Department Sample (NEDS) in 2016. Abdominal pain accounted for 43.1% of 1.38 million ED encounters (A), whereas complaints of chest pain accounted for a majority of ED visits that led hospital admission.

What separates visceral pain, and thus many of the abdominal pain syndromes, from somatic pain is an often vague or diffuse localization, a different quality of pain, radiation to somatic referral sites, and a
disproportionate degree of unpleasantness. Some of these distinguishing features are related to neuroanatomic differences in the peripheral and central pathways that process visceral and somatic pain information. For example, the sensory nerve innervation density of internal organs is much lower than that of many somatic structures, particularly when compared to the skin. In addition, individual visceral afferent neurons may project to more than one receptive field within an organ or between different organs and may respond to more than one sensory modality.1,2 Lastly, information from more than one anatomical site or organ converges within higher centers of the central nervous system,3 which further adds to the vague nature of visceral sensation. The aim of this chapter is to discuss the clinical features of abdominal pain and diagnostic strategies designed to identify its causes, to explore the general mechanisms that account for visceral pain, and to evaluate the efficacy of current treatment paradigms for alleviating abdominal pain.

Clinical Approach to Abdominal Pain

The abdominopelvic area contains many different organs that include most of the gastrointestinal tract, parenchymal organs such as the liver and pancreas, the urogenital tract, large vessels, and the various somatic structures that comprise the abdominal wall. Several characteristics of pain serve to identify underlying mechanisms that help clinicians in the decision making related to diagnostic or therapeutic approaches. Acute pain is more likely driven by peripheral mechanisms. Archetypical examples include the acute colicky pain of ureteral obstruction due to kidney stones or the severe pain of acute pancreatitis. Chronic pain conditions more often involve central sensitizing processes. Common chronic conditions characterized by persistent abdominal pain include irritable bowel syndrome (IBS), functional dyspepsia, and interstitial cystitis. Patients with these disorders may still experience acute fluctuations in pain that correlate with peripheral sensory input, but the magnitude of pain responses is often more closely linked to anxiety, stress, or other psychological variables that impact the processing of pain information at the level of the brain. Somatic and visceral components of
abdominal pain classically have distinct clinical features. Somatic pain is more clearly localized and often sharper in character, whereas typical visceral pain is more often perceived as dull, diffuse, and perhaps deeper in location. These differences in clinical features reflect anatomical differences in somatic and visceral nerves, as somatic nociception originates from the parietal peritoneum, abdominal body wall, or skin, whereas sensors for visceral pain are located within the walls of hollow structures or within the parenchyma of abdominal organs. A classic example showing the distinct manifestation of these pain types is the evolution of acute appendicitis: Early in the course of the disease, the pain is often vague and referred to mid-abdominal regions but then shifts to McBurney’s point (a focal position within the right lower quadrant), where it becomes highly localized and sharper in quality as the parietal peritoneum becomes inflamed later on in the disease course.

**PAIN LOCALIZATION AND CHARACTER**

As is true for all disorders associated with pain and discomfort, pain localization provides key information about the source of possible underlying problems. Peripheral visceral neural pathways reflect the embryologic origin or anatomical position of visceral structures, whereas the mapping of somatic pain is clearly organized along spinal segmental afferent pathways throughout the neuraxis. For example, pain from the proximal gastrointestinal tract tends to project to the upper abdomen (e.g., stomach), from the midgut (e.g., jejunum) to the periumbilical region, and from the hindgut (e.g., colon) to the lower abdomen. Processes involving the pelvic organs tend to trigger pain felt in the groin, suprapubic, or perineal area and often radiate toward the sacrum or genitals. Due to the retroperitoneal location of the pancreas, kidneys, and ureters, pain that arises from these structures projects more toward the flank, back, or groin. Yet, many patients experience the localization and quality of visceral pain in “atypical” ways. Experiments using a distension stimulus within the esophagus, stomach, small bowel, or colon triggered pain responses that fell within predicted somatic areas in just more than half of participants.4–7 In addition, the terms used to describe a perceived stimulus poorly correlated with the modality of the administered stimulus. For example,
about one-third of subjects experienced a feeling of heartburn during esophageal luminal distension. Conversely, direct jejunal stimulation with capsaicin often was reported as a pressure sensation rather than an expected burning sensation. These observations could be explained by the fact that many visceral afferents are polymodal, meaning they can be activated by more than a single stimulus type.

Sensory input from the viscera often is referred to distant sites within somatic structures, a phenomenon attributed to the convergence of primary visceral and somatic sensory input onto the same second-order neurons within the spinal cord. Although radiating pain is not always present or follows a consistent pattern, the pattern of radiating pain can provide important clinical clues to the true anatomical source of pain. For example, retrosternal pain radiating to the left shoulder or arm occurs during myocardial ischemia, right upper abdominal pain radiating to the right scapula in cases of cholecystitis, or flank pain radiating to the groin or genitals is a hallmark of a migrating kidney stone (Fig. 63.2).

**FIGURE 63.2** Classic patterns of cutaneous sites of pain referred from visceral structures. (Reprinted with permission from Anderson MK. Foundations of Athletic Training. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2016. Figure 6-1.)

**TIME COURSE**
The time course of more acute pain can provide important diagnostic clues about the source of the problem. For example, very sudden onset and intense pain suggests perforation, acute ischemia, or acute pancreatitis. In contrast, most inflammatory processes and obstructions tend to present with a more gradual and escalating intensity, may fluctuate in intensity over minutes, and, as already described earlier for appendicitis, change in character and location. Distension of the capsule of a parenchymal organ can trigger more constant discomfort, as can inflammation or infiltrative processes, such as pancreatic cancer. Constant pain also predicts a more significant impact on quality of life and is associated with increased health care resource utilization. Recurring, intermittent pain is more common and characterized by a regular pattern of waxing and waning, often referred to as “colicky” in nature, and is frequently related to the obstruction of luminal structures.

**CONTEXTUAL INFORMATION**

Additional information about triggering or alleviating factors, associated symptoms, prior medical problems and surgeries, and current medical therapies can provide other important clues about the source of abdominal pain. Food intake most commonly influences abdominal pain of gastrointestinal origin, typically functioning as an exacerbating factor. The lag time between the ingestion of food and the onset or exacerbation of pain can help identify the potential source. For example, close to immediate onset of pain with swallowing (i.e., odynophagia) points at the esophagus as a pain generator. Discomfort due to gastric disorders typically manifests within 30 minutes of ingesting a meal, while underlying small bowel abnormalities may have more significant delays of onset. However, gastric filling or lipid nutrient exposure of the duodenum stimulates colonic contractions (gastrocolonic response), which may secondarily trigger discomfort. Ingesting acidic or spicy material often triggers symptoms in patients with gastroesophageal reflux or functional dyspepsia, and bland food or drink may dilute or neutralize these exposures. Thus, food may have a range of effects on pain of gastrointestinal origin.

As gastroduodenal filling may increase pain symptoms, emptying may
ease pain. The rate of emptying of an ingested meal is typically relatively slow (hours), which explains a gradual and delayed improvement of postprandial discomfort. However, vomiting, although obviously unpleasant to experience, may more rapidly alleviate pain by quickly decompressing the proximal small bowel and stomach. If the physiologic processes of urination or defecation alter abdominal pain, then this implicates a bladder, distal colon, or rectal source of pain.

Body position and activity may also influence pain intensity. During many acute pain episodes or significant pain exacerbations, increased activity or stretching out in the supine position tends to worsen pain, whereas crouching in the fetal position eases pain. This common phenomenon may be related to decreased tension in the abdominal wall muscles but lacks specificity in discriminating somatic from visceral pain. Abdominal wall sources of abdominal pain by definition are of somatic rather than visceral origin, yet when not recognized as such, abdominal wall pain frequently triggers recurrent physician visits and extensive testing in search of a visceral source. Somatic abdominal pain typically has some positional component and is clearly exacerbated by physical activity, such as lifting, or tensing the abdominal muscles (Carnett’s sign). In contrast, levator ani syndrome involves somatic pain from the pelvic floor muscles experienced as perineal pressure and pain that typically worsens when sitting or standing and improves with laying down.

Learning about associated symptoms and signs often narrows down the list of possible underlying problems. Dysphagia in patients with chest pain implicates an esophageal source. Nausea and vomiting are common symptoms that may suggest an upper gastrointestinal problem, such as peptic ulcer disease or an obstruction of the gastrointestinal tract. Yet, nausea and vomiting may also result as an autonomic response to acute pain, as described with the intense and colicky pain of passing kidney stones. Similarly, concurrent changes in bowel patterns can provide important diagnostic information pointing to the colon as a source of pain. Tenesmus, an intense cramp-like pain felt in the lower abdominal or pelvic area with associated urgency to defecate and frequent evacuations of only small volumes of often loose and/or bloody feces, suggests a rectal source of pain. This symptom is analogous to the clinical manifestations of
bladder infection, which more commonly are felt as pain in the suprapubic region and similarly are accompanied by a high frequency of low volume and often painful urination that may also be bloody (hematuria). Cramps felt within the pelvis that may be associated with vaginal bleeding or discharge, but that are not associated with changed bowel patterns or micturition, may indicate a uterine or ovarian disorder.

Information about prior illnesses or operations and coexisting diseases is essential when approaching patients with abdominal pain. Late complications from abdominal surgeries due to adhesive disease may result in partial or complete bowel obstruction that are among the most common reasons for hospitalization in surgical units. An underlying inflammatory bowel disease may manifest with pain due to a flare or disease-related complications, such as abscess formation or strictures. Patients with medical illnesses such as cardiovascular disease and hypertension have higher risks of aortic aneurysm and mesenteric ischemia. Those with hyperuricemia or hypercalcemia risk the formation of kidney stones. Functional syndromes, such as IBS, functional dyspepsia, or bladder pain syndrome, are often associated with other chronic pain disorders, such as fibromyalgia or migraines. Psychiatric disorders similarly correlate with such functional diseases, partially mediated through hypervigilance, catastrophizing, or somatization.

Medication and drug use, including over-the-counter agents and illicit drugs, may either cause or exacerbate problems that manifest with abdominal pain. For example, nonsteroidal anti-inflammatory drugs (NSAIDs) increase ulcer risk through well-described mechanisms. Less common but more serious complications of medical therapy include acute pancreatitis, as seen with azathioprine, eluxadoline, and diuretics, or ischemic colitis with alosetron. More commonly, medications (including opioids, antidepressants, anticholinergics, and antibiotics) may influence the motility of the stomach or bowel to generate dyspeptic symptoms and changes in bowel movement patterns. Opioid withdrawal, an increasing problem in the context of the current opioid use epidemic, is characterized by a number of intense physical symptoms. Acute opiate withdrawal may not only lead to psychomotor activation but also to intense abdominal pain that is associated with repeated vomiting and
diarrhea. Similarly, the clinical presentation of cyclic vomiting syndrome (CVS) in adults overlaps with such withdrawal symptoms. Although refractory CVS appears to more common in those chronically using opioids, CVS is more commonly associated with long-term cannabinoid use and in such cases is referred to as cannabinoid hyperemesis syndrome.25

**PHYSICAL EXAMINATION**

The physical examination provides critical information in the evaluation of new and sudden onset pain. Simple inspection may immediately reveal signs of distress; show pallor, jaundice, or diaphoresis; or implicate more chronic processes, such as malignancy, if cachexia is present. Vital signs add important details and guide decisions about the potential need for immediate interventions, such as fluid resuscitation or antibiotics for sepsis. A distended abdomen indicates either the presence of ascites or potential intestinal obstruction. Scars or hernias provide additional important information. A vesicular rash with dermatomal distribution suggests shingles, which can cause significant pain. The direct examination of the abdomen should proceed in a stepwise manner to minimize undue stress and limit the impact of anticipated pain and voluntary abdominal muscle contractions. A light touch or stroking movement over the skin may reveal significant cutaneous allodynia. This allodynia could be indicative of a peripheral somatic neuropathy, such as is seen in postherpetic neuralgia, or that may additionally represent a central sensitization process, such as is typically seen in patients presenting with chronic abdominal discomfort and functional pain syndromes. Intense pain with rigid abdominal musculature and transiently intensified discomfort when the pressure is released (rebound tenderness) suggests involvement of the parietal peritoneum. More detailed palpation can reveal masses or an enlarged liver or identify possible hernias and assess whether they can be reduced. Highly localized pain without involuntary guarding or rebound tenderness should prompt an additional assessment by asking the patient to tense their abdominal wall muscles (Carnett’s sign), which can identify a possible role of the abdominal wall as a source of pain.13,26 Listening for a bruit or abnormal bowel sounds should complete the abdominal
examination. Other findings ranging from cutaneous changes of scleroderma to joint hypermobility, an irregular pulse, or a perirectal fistula may provide additional clues that will lead to the diagnosis or guide decisions about further testing.

**DIAGNOSTIC TESTING IN ABDOMINAL PAIN**

The goal of diagnostic evaluations in patients with abdominal pain is to identify the anatomical site of pain generation and, ideally, to determine the mechanism of illness (i.e., gallstone pancreatitis, nephrolithiasis, endometriosis, etc.). The choices of diagnostic modalities range from blood or stool tests to endoscopic evaluations or radiographic studies. Yet, the most common disorders presenting with abdominal pain are “functional disorders” defined by chronic pain and a variety of other symptoms in the absence of distinct structural or other findings on standard diagnostic testing. A better understanding of mechanisms that contribute to such functional disorders has driven the search for biomarkers that may support, perhaps even establish their diagnosis, or at least act as prognostic indicators that can predict treatment outcomes. Isolated tests largely have fallen short of expectations. Composite scores derived from survey data and fecal or serologic biomarkers may hold more promise but have yet to be established as clinically useful tools.

**Mechanisms of Visceral Pain**

The principles underlying visceral sensation and pain share key mechanisms with somatic sensory pathways (see Chapters 3 and 9). Yet, there are several important differences between somatic and visceral sensation that aid in understanding the clinical presentation and treatment of patients with visceral pain. Abdominal viscera largely emerge as midline structures and receive bilateral sensory input from both spinal and vagal sensory afferents (Fig. 63.3). These two complementary sensory systems both convey information to the brain and contribute to the perception of visceral stimuli from organs. The cell bodies of spinal afferents are located in the dorsal root ganglia and send central terminals into the dorsal spinal cord. Vagal afferents, which innervate most abdominal and some pelvic structures, have their cell bodies in the nodose
ganglion and send central terminals to the nucleus of the solitary tract in the brainstem. Traditionally, only spinal afferent pathways were believed to relay information about painful stimuli, whereas vagal fibers presumably contributed only to homeostatic regulation. However, recent findings suggest some overlapping roles of these anatomically distinct pathways, as vagal afferents may encode chemo-nociceptive or higher intensity mechanosensitive signals that trigger unpleasant feelings such as nausea and shape the complex human experience of pain.

FIGURE 63.3  Schematic diagram that demonstrates the pattern of afferent pathways from abdominal and pelvic organs to the central nervous system. Visceral spinal afferents (left side) travel in parallel along sympathetic pathways but have cell bodies contained in dorsal root ganglia and central projections that innervate the spinal cord. Vagal afferents (right side) travel along vagal pathways and have cell bodies within the nucleus of the solitary tract of the brainstem, whereas pelvic visceral nerves travel along the pelvic nerve and target sacral segments of the spinal cord. CG, celiac ganglion; IMG, inferior mesenteric ganglion; NTS, nucleus tractus solitarii; SMG, superior mesenteric ganglion. (Reprinted from Gebhart GF. Visceral pain—peripheral sensitization. Gut 2000;47(suppl 4):iv54–iv55, with permission from BMJ Publishing Group Ltd.)

VISCERAL NOCICEPTION
Detailed physiologic investigations of visceral spinal afferents have identified distinct response patterns to low- or high-intensity stimuli. These foundational data suggested that painful stimuli can specifically engage specialized nociceptive pathways that are activated only by high-threshold stimulation (specificity coding). However, many visceral afferents that are activated by low-intensity stimuli encode a range of stimulus intensities that extends well into the noxious range. These
visceral afferents appear to sensitize after exposure to heat, acid, or inflammatory mediators. These findings argue against an exclusive role of specialized, high-threshold nociceptors in mediating painful sensations and instead suggest that the summation of sensory inputs ultimately shapes the perception of discomfort and pain (intensity coding). Furthermore, several neurophysiologic properties that presumably characterize nociceptive neurons are also commonly found in most visceral afferents, including an ability to respond to more than a single stimulus modality, the expression of ion channels and other neurochemical markers classically associated with nociceptors, and axonal conduction velocities in the C-fiber range.

Due to their relatively low innervation density, smaller axonal size, and the difficulty in gaining access to their target organs for precise experimental manipulation, investigators have only recently started to gain insight into the structure–function relationship of afferent nerve endings within the viscera. Detailed anatomic and physiologic studies have identified branching patterns with linear arrays of nerves that run parallel to muscle fibers of the muscular layer of the gut and encode changes in length or stretch. Actively generated muscle tension activates fibers with sensory terminals that spread through ganglia of the enteric nervous system. Less distinct branching patterns are found along other structures, such as the epithelium or vasculature, and the role of these possible transduction sites in generating visceral sensations and/or pain is only partially understood.

Most visceral spinal afferents terminate in the superficial layers (lamina I and II) of the dorsal horn. The central terminals branch within the spinal cord and may extend several spinal segments rostral or caudal to their original entry point within these laminae. This anatomical feature contributes to the vague localization of visceral inputs, including pain. The second-order neurons within the spinal cord typically also receive convergent input from somatic, often cutaneous sites, explaining the pattern of referred pain described earlier (see Fig. 63.2). Second-order neurons project rostrally primarily through the spinothalamic tract. However, some visceral nociceptive afferents terminate in second-order neurons located within lamina X, surrounding the spinal canal. These
second-order neurons send their ascending axons through the dorsal columns, creating a recently recognized pain pathway that may account for descriptions of visceral pain that persists despite bilateral injury or transection of the spinothalamic tract.\textsuperscript{38}

The neural activity of second-order neurons acts as a “gate” that can diminish or enhance pain signals from being relayed to higher brain centers. Importantly, descending projections from the midbrain and brainstem directly influence the critical synaptic connection between primary afferents and these second-order neurons. Thus, there is a neural substrate for the brain to effectively inhibit or augment visceral and somatic pain signaling at the level of the spinal cord (for more information, see Chapters 5 and 6), and such descending pathways may well provide some of the neuroanatomical basis for the influence of stress, cognitive, and emotional factors on pain perception (see Chapter 7).

**CENTRAL PROCESSING OF SOMATIC AND VISCERAL PAIN**

The precise cerebral cortical mapping of spinothalamic inputs from the viscera is poorly understood. Classical neurophysiologic experiments in nonhuman primates found that visceral spinal afferents can ultimately project to the trunk representation within primary and secondary somatosensory cortical regions.\textsuperscript{39} Yet, neuroanatomical tracing experiments in nonhuman primates that mapped spinothalamocortical projections from purely somatic spinal afferents found that only a minority of neurons project directly to the primary somatosensory cortex. Rather, the majority of direct spinothalamic input was received in the dorsal insular cortex, secondary somatosensory cortex, and within the midcingulate motor areas.\textsuperscript{40} Functional brain imaging studies of humans obtained during painful cutaneous and visceral stimulation have led to a wider understanding of central mechanisms that contribute to pain. These studies have largely corroborated the neuroanatomical and neurophysiologic observations from studies in nonhuman primates. Both cutaneous and visceral pain were associated with an overlapping pattern of activation within some subcortical and cortical structures, preferentially including the ventromedial thalamus, anterior cingulate cortex, secondary
sensory cortex, and regions of the insula. However, some important differences emerged, such as a greater activation of the primary sensory cortex during visceral pain compared to cutaneous pain. Many of the areas involved in visceral pain processing are also involved in emotional processing, an association that may well account for the disproportionate unpleasantness of visceral pain. Interestingly, the pattern of brain activation triggered by visceral pain is qualitatively similar to patterns observed during less intense or even unperceived visceral stimulation. This observation argues against specific “labeled lines” for visceral nociception and raises the possibility that visceral stimulation in general influences the visceral pain experience (for a more detailed discussion on central pain processing, see Chapter 6).

SENSITIZATION AND VISCERAL HYPERSENSITIVITY
Detailed in vitro and in vivo physiologic studies, including investigations in human volunteers, have clearly demonstrated that both peripheral and central visceral sensory mechanisms exhibit significant functional plasticity. Sensitization is defined as an increase in the response magnitude to the same stimulus intensity, and it is the primary form of plasticity that drives the development of visceral hypersensitivity. Visceral hypersensitivity is the key to the clinical manifestations of many functional visceral pain disorders, ranging from functional dyspepsia to chronic pancreatitis and interstitial cystitis. Peripheral and central sensitization can be experimentally dissociated (for detailed discussions on mechanisms of sensitization, see Chapters 3, 4, and 6). Although they are mechanistically distinct, published investigations typically have shown a close interaction between peripheral and central sensitization processes. For example, acid perfusion sensitized the esophagus to subsequent mechanical stimulation and, at the same time, increased its somatic referral area. Similarly, repeated rectal stimulation led to increased pain ratings and an increase in the somatic territory of referred pain. Two examples of chronic disorders illustrate the clinical relevance of the complex, reciprocal interaction between peripheral and central mechanisms, which ultimately lead to heightened and long-lasting pain. First, chronic pancreatitis is a disease with ongoing inflammation and significant
changes in the structure of peripheral nerves.\textsuperscript{49–51} The disease typically manifests with pain as the predominant symptom. Despite the often striking abnormalities in pancreatic structure and abnormalities in peripheral nerves, a small but important cohort study demonstrated that a complete neuroaxial block, which abolished all but the vagal sensory input from the pancreas, completely relieved pain in only less than a quarter of the patients.\textsuperscript{52} This observation reflects the ability of increases in peripheral input to drive central sensitization as a secondary process that may ultimately even become more relevant in the clinical manifestation of a disease. Second, several cohort studies have demonstrated that there is a higher incidence of IBS after acute bacterial or viral infections.\textsuperscript{53–56} Although the severity of the initiating infection (i.e., a peripheral factor) functioned as one important independent predictor of lasting symptoms, preexisting anxiety and depression (i.e., central factors) were also independently associated with a higher risk of developing IBS.\textsuperscript{57} The presence of these affective spectrum disorders may play a role in different aspects that characterize this disorder, ranging from influences on descending modulatory pathways to altered vigilance and the cortical processing of pain to increased symptom reporting or health care–seeking behavior.\textsuperscript{58} The impact of psychiatric diseases has been demonstrated in other common pain syndromes, implying that these factors drive more generalized increases in pain sensitivity.\textsuperscript{59,60}

Detailed neuroimaging studies have revealed changes in cortical thickness within areas activated during pain processing in both chronic pancreatitis and IBS, providing a structural correlate and potential biomarker for the observations described earlier.\textsuperscript{61,62} Interestingly, such apparent differences in brain structure may not only be a consequence of ongoing painful input but could also reflect the impact of other factors, such as early adverse life events,\textsuperscript{63} or correlate with behavioral patterns, such as enhanced stress responses or catastrophizing.\textsuperscript{64} Recognizing these complex interactions between peripheral and central sensitization in individuals with chronic pain conditions may not only improve our mechanistic understanding of visceral pain but could also personalize treatment choices and improve treatment outcomes.\textsuperscript{65,66}
Susceptibility Factors

GENETIC FACTORS

Genetic studies of patients with pain syndromes do not only have to contend with the interactions between genes and environmental factors but also the fact that different pain disorders may result from a variety of underlying mechanisms (see Chapter 8). Most investigations of genetic influences on abdominal pain have focused on the IBS population primarily because this disorder is highly prevalent throughout the world. However, the theoretical advantage of studying this common disorder is unfortunately confounded its phenotypic variability, as IBS can manifest with diarrhea, constipation, or mixed bowel patterns and varying degrees of pain. Perhaps not surprisingly, studies have identified multiple mechanisms that contribute to IBS, such as differences in nutritional intake, microbial flora, and subtle changes in peripheral inflammation, and to psychological traits that affect health care–seeking behavior. Despite these caveats, a large genetic study in IBS patients showed higher symptom concordance between first-degree rather than second-degree relatives, which is consistent with some contribution of genetic traits to the development of IBS. However, partners had nearly similar rates of symptom overlap, which points to the role of shared environmental factors. These results are in line with a large twin study in IBS that failed to show differences between mono- and dizygotic twins. Thus, there is mixed evidence for a clear genetic underpinning to IBS.

Serotonin (5-HT) plays an important role in gastrointestinal signaling, and thus, many genetic investigations in IBS have used a candidate gene approach focused on polymorphisms of the gene for the 5-HT transporter. These studies showed variable results. Independent of the inconclusive findings, these same genetic markers are associated with psychiatric comorbidity, making it difficult to attribute the associations to IBS itself rather than to risk factors or cofactors that may influence its clinical manifestations, such as symptom severity. Genes encoding other components of the 5-HT signaling system have not been as closely examined but may also be associated with altered emotional responses, bowel patterns, or responses to drugs that target 5-HT receptors. The
catechol-O-methyltransferase (COMT) gene has been inconsistently linked to functional pain disorders. As was true for 5-HT signaling, COMT variants also correlate with psychological traits that influence symptom severity and reporting in IBS.

Similar links between emotional responses and genetic markers have been reported for allelic variants of signaling molecules in the hypothalamic-pituitary-adrenal (HPA) axis, which plays an important role in mediating stress reactions.

Genes involved in mucosal permeability, innate immunity, or absorptive pathways may sensitize individuals to develop IBS after apparently banal enteric infections. A possible link between innate or adaptive immunity and IBS supports a concept in which interactions between environmental factors, in this context microbial colonization or infection, and host responses contribute to IBS development. Although these studies do not allow us to determine which aspect of the clinical manifestations of IBS are associated with the various genetic traits, the available data point at differences between constipation and diarrhea-predominant IBS, suggesting that these genetic markers may correlate more with bowel patterns rather than the pain of IBS per se.

**ADVERSE LIFE EVENTS AND STRESS**

Nearly three decades ago, studies first linked the exposure to physical and sexual abuse to an increased risk of developing IBS. Subsequent controlled animal experiments have explored the impact of exposure to adverse life events and have shown changes in bowel function and responses to noxious stimuli, presumably due to the increased plasticity of the nervous system during this critical phase of development. More detailed assessments argue against specific links between IBS or other abdominal pain syndromes and such traumatic events early on in life and instead suggest that such exposures may alter the activation of the HPA axis and enhance stress responses. Although the association between abuse or other adverse life events and diseases manifesting with pain may well be more indirect, mediated by heightened vigilance or catastrophizing, it remains clinically relevant as it affects perceived symptom severity and health care–seeking behavior.

Chronic stress also affects the manifestation of IBS and other abdominal
pain syndromes. Mechanistic studies described a link between stress experiences, enhanced activation of the HPA axis, and altered attention to and processing of visceral stimuli.\textsuperscript{102} As is true for the impact of adverse life events, increased stress exposures negatively influence health outcomes.\textsuperscript{103}

**PSYCHIATRIC DISEASES**

Several cohort studies examined the incidence of IBS after large outbreaks of waterborne illnesses and demonstrated that preexisting anxiety and depression independently predict the development of IBS after the infection.\textsuperscript{104–106} Complex modeling studies indicate that depression may increase somatization,\textsuperscript{107–109} whereas anxiety may drive vigilance, catastrophizing, and avoidance.\textsuperscript{110} A simple “common sense model” (Fig. 63.4) highlights the interaction of various psychological factors that contribute to generating increases in perceived symptom intensity.\textsuperscript{111} More comprehensive conceptual models incorporate additional factors such as social and environmental interactions that shape these various psychological factors. In addition, a more comprehensive model needs to consider the impact of autonomic responses, which may alter visceral function and thereby indirectly influence visceral sensory inputs. Consistent with such explanatory models, psychiatric comorbidity plays a central role in illness perception, health care–seeking behavior, and resource utilization.\textsuperscript{112}

**FIGURE 63.4**  Schematic model that highlights the interactions and influences between psychological factors and symptom severity in those with functional pain disorders. (From Knowles SR, Austin DW, Sivanesan S, et al. Relations between symptom severity, illness perceptions, visceral sensitivity, coping strategies and well-being in irritable bowel syndrome guided by the
MICROBIAL COLONIZATION
Within the last decade, an increasing number of studies suggest that the microbial colonization of the gastrointestinal tract contributes to symptoms, presumably via effects on epithelial function, permeability, and immune activation. Animal studies and some small human investigations raise questions about an impact on pain experiences, endocrine function, and even emotional responses. Several studies have demonstrated changes in the microbiome, with secondary changes in fermentation of luminal contents, short-chain fatty acid concentrations, and bile acid metabolism, in IBS. Although most of these investigations focused on bacteria, potential differences also involve fungal organisms and may even include parasites and viruses. Defining dysbiosis as a disrupted pattern of microbial colonization, 70% of IBS patients had abnormal findings, as opposed to 17% of healthy controls; yet, results did not differentiate IBS from inflammatory bowel disease, and patterns did not seem to reflect whether the inflammatory bowel disease was active or in apparent remission. The impact of microbial colonization of the gut on gastrointestinal function becomes even more complex when we examine the influence of dietary factors. Prospective studies clearly demonstrated that the composition of luminal contents changes the microbial colonization, which, in turn, is associated with changes in gastrointestinal symptoms, raising the question whether the dysbiosis observed in IBS patients is the true cause for symptoms or if it is an epiphenomenon, largely reflecting dietary habits.

Biomarkers of Abdominal Pain
As already mentioned earlier, chronic visceral pain is frequently caused by functional illnesses, which are largely defined by characteristic symptom patterns and the absence of obvious objective abnormalities on standard medical tests. Consensus diagnostic criteria for a variety of functional pain syndromes were formulated not only to standardize research populations but also to allow a positive diagnosis. Yet, common clinical practice still
follows a path in which exhaustive testing is used to repeatedly exclude alternative etiologies, often including rare diseases. This practice is costly, inefficient, and in some cases leads to iatrogenic injury. Investigators have therefore continued to search for biomarkers that could aid in the diagnosis or treatment of functional abdominal pain syndromes.

Nearly half a century ago, Ritchie first reported a heightened sensitivity of IBS patients to rectal distension. Those findings fit a conceptual model that revolves around visceral hypersensitivity as a primary mechanism in IBS and related pain disorders. The paradigm of provoking defined peripheral sensory inputs has since been refined and applied to many different disorders with mostly similar results. About 50% to 70% of patients with functional abdominal pain syndromes experience pain with lower intensity stimuli than normal people, suggesting visceral hypersensitivity is indeed a key mechanism. Yet, such enhanced pain responses are not consistently limited to the bodily regions presumably directly involved in the underlying disorder. Furthermore, even the anticipation of a stimulus often triggered discomfort in patients. Situational anxiety and enhanced vigilance are important factors that drive the apparent hypersensitivity to anticipated rather than actual stimulation, highlighting the importance of central factors in chronic visceral pain. More importantly, a longitudinal study showed a dissociation between time-dependent changes in symptom severity ratings related to the underlying disorder and the pain levels experienced during acute visceral stimulation. Thus, responses to acute painful stimulation may correlate with mechanisms that contribute to chronic visceral pain syndromes, but these responses lack utility as diagnostic or prognostic markers and are also not appropriate surrogate targets to determine treatment effects. Several other biomarkers or diagnostic algorithms have been developed and range from enhanced sensitivity in cutaneous pain referral sites to grey matter changes determined with morphometric analyses of brain scans or composite measures of multiple biomarkers and psychological variables. Although some of these data appear conceptually appealing, confirmatory studies are required to determine if such markers not only differentiate disease from health but also differentiate between distinct pain disorders, which often share clinical
features.

**Treatment of Abdominal Pain**

As is true for all pain disorders, it is paramount to identify and treat the underlying disease to alleviate the driver of pain. However, pain may persist in chronic illnesses, or, in the case of functional pain disorders, pain may be a key symptom that is not linked to clearly understood and/or easily correctable mechanisms. In such cases, pain itself becomes the target for symptomatic management strategies. Therapeutic options range from localized interventions, psychological therapies, systemic medications that directly or indirectly influence pain, and surgery. Commonly used analgesic medications have side effects that need to be considered along with the potential benefits of the medications. Opioids, NSAIDs, and many antidepressant medications adversely affect gastrointestinal function or structure, drive nausea, dyspeptic symptoms, constipation, or diarrhea and may thus negatively affect quality of life despite their possibly beneficial effects on pain. Concerns about such side effects are even more relevant in patients who already suffer from abdominal problems, which may further limit the utility of these medications.

**LIFESTYLE MODIFICATIONS**

Stress and other environmental or lifestyle factors may influence disease development and manifestations. In functional gastrointestinal disorders, food intake is an important treatment target, as it has complex impacts on the gut, either directly from filling and distension of stomach, or indirectly by altering the gut’s microbiome, resulting in differences in fermentation of luminal contents. More than 80% of IBS patients experience symptom exacerbations in response to foods, with poorly absorbed carbohydrates, dairy, and legumes being the most commonly reported culprits. As is true for many factors that influence symptom severity, dietary patterns also correlate with resource utilization. Thus, assessing such habits and considering modifications of meal size, frequency, consistency, or nutrient composition should be a routine part of any treatment plan in
gastrointestinal disorders. Consuming foods low in poorly absorbed, poorly fermented foods (i.e., a low-fermentable oligo-di-monosaccharides and polyols [FODMAP] diet) appears to be a viable strategy to treat IBS, particularly in patients that have associated diarrhea, bloating, and increased flatulence.\textsuperscript{138,139} A low-FODMAP diet may not only alter food-derived luminal contents but also secondarily changes the microbial colonization of the gut, which could further benefit epithelial and immune function.\textsuperscript{122}

As already described earlier, adverse life events and stress heighten vigilance, influence autonomic output, and alter gut function, thereby contributing to symptom severity.\textsuperscript{111,140} Experimentally, acute stress clearly worsens symptoms in IBS patients.\textsuperscript{102,141} The close correlation between perceived stress and symptom severity ratings suggests potential feed-forward interactions in which symptoms contribute to increasing levels of stress, increased anxiety, and heightened vigilance, creating an amplifying effect on pain.\textsuperscript{142} Social and interpersonal strains may also influence the clinical picture. Shared life experiences and exposures as well as reinforcing responses with learned illness behavior contribute to illness development.\textsuperscript{143} Negative experiences, such as conflict or social stressors,\textsuperscript{144,145} affect symptom severity but will have less negative an impact in a more supportive environment.\textsuperscript{146} Consistent with such results, treatments that strengthen social support decrease perceived stress levels and improve stress tolerance, thereby indirectly alleviating pain symptoms.\textsuperscript{147}

The restorative effect of sleep is yet another important consideration, as disruptions of normal sleep patterns or sleep deprivation increase the likelihood of developing IBS.\textsuperscript{148,149} Thus, the demands of modern life, such as travel across time zones or shift work, may contribute to the high prevalence of visceral pain syndromes\textsuperscript{150} and affect symptom severity, mood, and overall quality of life.\textsuperscript{151} Although not always easily addressed and implemented, assessing lifestyle factors as cause, modulator, and/or treatment target may allow patients to better understand and hopefully also better control their disease, without encountering risks of adverse events that may come with the more conventional pharmacologic interventions.
PATIENT–PROVIDER RELATIONSHIP

Close listening is required to identify the many psychosocial factors that contribute to symptoms and may thus be appropriate treatment targets. Yet, the act of listening is inherently therapeutic. When asked to define their expectations from a provider, patients seek education and look for empathy and good listening skills.\(^\text{152}\) A well-designed study compared two different sham interventions, differing only in the formalized communication strategy. Displays of active listening behavior and empathy were shown to be clearly superior to more transactional communications focused solely on treatment options, the therapist’s experience, and expected beneficial treatment response.\(^\text{153}\) These results are consistent with detailed analyses of placebo responses in a large study, which suggest that effective communication provides patients with an improved sense of control, an increased feeling of being understood, and promotes trust in the provider.\(^\text{154}\) Based on such findings, experts advocate a patient-centered approach that may offer repeated opportunities to describe important illness experiences.\(^\text{155}\) Although these data and recommendations may seem intuitively obvious and in line with a long-standing tradition that emphasizes the therapeutic relationship between “healer” and patient, only about half of the patients with visceral pain syndromes report that health care providers meet their expectations.\(^\text{156}\)

PLACEBO RESPONSE

Placebo responses are not unique to visceral pain or functional abdominal disorders, but the magnitude and prevalence of placebo responses in this population are generally high, ranging between 30% and 40%. Such high placebo response rates complicate the interpretation of smaller case series or uncontrolled trials. Interestingly, even when informed that they will be receiving a placebo, IBS patients still improved in a recent trial when compared to a control group.\(^\text{157}\) Systematic analyses highlight the importance of supportive patient–provider relationship,\(^\text{153}\) which may be especially important in reclusive patients and individuals with prior negative treatment experiences.\(^\text{155}\) For investigators, the placebo response constitutes a challenge that requires larger sample sizes and a study design that controls for important confounders contributing to these nonspecific
effects. Yet, these very confounders also present an opportunity for clinicians, whose listening skills, empathy, and educational efforts may significantly influence treatment effects independently of the modality chosen.

**OPIOIDS**

The more widespread use of opioids for benign disorders has influenced approaches to noncancer pain involving the abdomen. Depending on the underlying problem, chronic opioid use varies between 15% and 50% as shown in large cohort studies of diseases characterized by inflammation, structural changes, or functional abnormalities only.\(^{158–161}\) Yet, opioid therapy is associated with increased health care resource utilization and even functions as a predictor for poor treatment outcomes.\(^{162–164}\) In inflammatory bowel disease, the negative prognostic impact of opioid management may even be associated with higher mortality.\(^{165}\) Such findings add to more general concerns about the opioid epidemic, which was in part driven by shifts in medical practice patterns to rely on opiate medications to treat pain. Chronic opioid exposure often comes with adverse effects on gastrointestinal function and may even negatively impact pain sensitivity, prompting some investigators to define the narcotic bowel syndrome as a distinct illness. This syndrome is characterized by ongoing and worsening pain despite high and often escalating opioid doses, which is presumably driven by opioid-induced hyperalgesia (see also Chapter 79) and changes in gut motility.\(^{166, 167}\)

Opioid receptors are expressed peripherally and alter many gastrointestinal functions, and several peripherally acting opioid agonists or antagonists have been developed that impact gastrointestinal function. The role of peripheral opiate receptors in visceral pain is less clear. Despite promising preclinical data, local administration of \(\mu\)-opioid receptor agonists did not blunt acute pain during rectal distension in human volunteers.\(^{168}\) The peripherally restricted \(\mu\)-opioid agonist loperamide decreases diarrhea but has inconsistent effects on pain in IBS. Loperamide caused constipation and subsequent discomfort in healthy volunteers, again arguing against a clinically relevant role of peripheral \(\mu\)-opioid receptors in mediating visceral pain per se.\(^{169, 170}\) Peripherally
acting κ-opioid receptor agonists decreased esophageal pain in humans\textsuperscript{171} but had no or at best marginal effects on satiety or pain in response to gastric distension.\textsuperscript{172,173} Clinical trials using such a κ-opioid agonist did not demonstrate benefit in spontaneous pain exacerbations in IBS or chronic symptoms in dyspepsia.\textsuperscript{174,175} Only a post-hoc analysis suggested some improvement in diarrhea predominant IBS, which was confounded by the expected changes in bowel patterns associated with opioid use.\textsuperscript{176} Agents with penetration into the central nervous system seemed more promising, as they lowered pain ratings in IBS during rectal distension\textsuperscript{177} and were superior compared to placebo when used in patients with functional dyspepsia or IBS.\textsuperscript{178,179} However, the utility of these κ-opioid drugs was limited due to their central side effects.\textsuperscript{180}

**NONOPIOID ANALGESICS**

Case-control studies show that patients with abdominal pain syndromes are more likely to use NSAIDs.\textsuperscript{181} These results may simply be a surrogate marker for pain but may be confounded by the known NSAID-induced adverse effects that often involve the gastrointestinal tract, causing dyspeptic symptoms, ulcers, and intestinal or colonic inflammation.\textsuperscript{182–185} Prostaglandins play an essential role in uterine contractions. Consistent with this role, NSAID therapy is more effective than placebo or acetaminophen in dysmenorrhea and chronic pelvic pain but is associated with more side effects, mostly due to the already mentioned impact on the gastrointestinal tract.\textsuperscript{186,187} Parenteral administration of an NSAID is also beneficial in biliary\textsuperscript{188} and renal colic,\textsuperscript{189} with data suggesting superiority not only over spasmolytics but also over morphine.\textsuperscript{190} Although intravenous acetaminophen was inferior to parenteral NSAIDs, pain reduction in renal colic equaled that of morphine.\textsuperscript{191} These data indicate that parenteral NSAID therapy should be preferred over opioids in the management of acute abdominal pain. However, the common adverse effects from the gut limit its utility in chronic abdominal pain treatment. Studies examining acetaminophen focused on acute pain management with intravenous infusion, therefore not allowing conclusions about the potential impact of prolonged use. The one exception is primary dysmenorrhea, in which acetaminophen apparently alleviated pain but was
inferior to an NSAID.\textsuperscript{192,193}

\textbf{NEUROMODULATORS}

Gabapentin and pregabalin as well as other anticonvulsive agents alter neuronal excitability and have found widespread acceptance as mood stabilizing, neuromodulating agents. After early reports suggested benefit in neuropathic pain, these drugs and other anticonvulsive agents have become commonly used adjuncts in analgesic therapy. Yet, there is only limited evidence supporting the use of gabapentin or pregabalin in disorders associated with chronic visceral pain. Pregabalin improved pain ratings in a randomized controlled trial of chronic pancreatitis, but this effect was not associated with a benefit in perceived quality of life or in overall functional status.\textsuperscript{194} Interestingly, pain ratings remained lower over several months in a subsequent trial that combined pregabalin with antioxidants.\textsuperscript{195} The only published trial in a small cohort with IBS did not show significant symptom relief when compared to placebo, with similar results having been reported in chronic pelvic pain.\textsuperscript{196–198} Although confounded by the unclear benefit of tricyclic antidepressants (see following discussion), gabapentin was superior when compared to such agents in patients with pelvic pain.\textsuperscript{199} Data on other anticonvulsive drugs are too limited to allow conclusions. The published information, largely based on relatively small trials, fits with the results of meta-analyses, which indicate that gabapentin is effective in postherpetic and diabetic neuropathy but not in other conditions with neuropathic pain,\textsuperscript{200} in fibromyalgia, or in phantom limb pain.\textsuperscript{201,202}

\textbf{ANTIDEPRESSANTS}

Antidepressants are commonly used as adjunct in chronic pain syndromes. Several mechanisms have been invoked to explain a possible analgesic effect of tricyclic antidepressants, which affect a variety ion channels and thus decrease neuron excitability. Serotonin norepinephrine reuptake inhibitors (SNRIs) influence central targets to increase the impact of descending modulation on nociceptive pathways. It is also possible that these medications improve pain indirectly by improving mood, which may be especially relevant in depressed individuals who show parallel changes
in mood and pain independent of the type of medication used.\textsuperscript{203}

Most studies addressing the possible benefit of antidepressants in visceral pain focus on IBS. Drugs, dosages, study designs, and endpoints differ among studies and complicate cross-study comparisons. The largest study did not show a significant decrease in pain ratings when compared to placebo.\textsuperscript{204} Meta-analyses point at a potential benefit, yet results are not consistent and raise questions about the utility of selective serotonin reuptake inhibitors (SSRIs).\textsuperscript{205,206} The apparent discrepancies similarly surface in trials targeting other disorders manifesting with chronic visceral pain. In functional dyspepsia, only a small study suggests a benefit during treatment with a tricyclic agent, while the SSRI escitalopram was not superior to placebo.\textsuperscript{207} In contrast, the largest trial examining tricyclic antidepressants in functional foregut disorders did not show a benefit of nortriptyline in gastroparesis.\textsuperscript{208} Only one appropriately designed study addressed the effects of SNRI with negative results in functional dyspepsia.\textsuperscript{209} When used as part of multidrug intervention, the duloxetine-containing treatment arm improved urinary symptoms, mood, and quality of life in patients with chronic prostatitis but was associated with a high dropout rate due to side effects.\textsuperscript{210} Overall, the contradictory results provide only limited empiric support for the commonly held view that antidepressants function as neuromodulators and have analgesic properties in visceral pain syndromes.\textsuperscript{211–217} The primary role for these agents lies in their true role as antidepressants that can improve coexisting psychiatric illness burden. Considering the role of psychiatric disorders and psychological mechanisms in the development and clinical presentation of functional visceral pain, antidepressants may exert their influence more indirectly in these disorders through their effect on mood.

**PSYCHOLOGICAL THERAPIES**

As may well be true for antidepressants, psychological treatment strategies target key mechanisms, such somatization, hypervigilance, and catastrophizing that are important in the development and maintenance of functional pain syndromes.\textsuperscript{20,218,219} A meta-analysis clearly showed beneficial effects of treatments that range from cognitive-behavioral therapy to mindfulness.\textsuperscript{220} Although true comparative studies are still
lacking, an analysis of published data suggests that cognitive-behavioral therapy may be more effective than other strategies. The initial investment in time and resources to deliver these interventions may constitute a significant burden. In addition, the specialized therapists needed to provide the care are not universally available. Thus, several alternative models have emerged to deliver psychological therapies. Shorter treatments courses may indeed work equally as well as longer interventions but obviously come with a lower cost. Educational group sessions can improve central processing and fear of visceral symptoms with an overall benefit in quality of life. The widespread use of social media and the Internet has driven the development of virtual programs, which seem promising based on pilot studies. Overall, cognitive-behavioral therapy and hypnotherapy have an established role in the management of functional and possibly also other chronic visceral pain syndromes. The remaining question is if group or virtual therapy can improve access, lower treatment costs, and still have long-term outcomes comparable to the conventional one-on-one treatment model.

**BLOCKINGafferent pathways**

Based on the importance of sensory input and peripheral sensitization, blocking visceral nerve activity should theoretically improve visceral pain. The need for more invasive steps to reach inner organs and the complex innervation complicates the practical and widespread use of approaches that directly target this afferent input. Data are thus limited and often inconclusive. Using sensory thresholds during rectal distension as a surrogate endpoint, intrarectal lidocaine blunted experimentally induced and, in a follow-up study, also spontaneous pain in IBS. The short response duration and need for repeated enemas limit the utility of this approach. Other studies demonstrated changes in the structure and function of presumed nociceptive fibers after exposure to capsaicin or resiniferatoxin. These small and uncontrolled studies do not allow clear conclusions but suggest some potential improvement of pain ratings, with more consistent changes in bladder symptoms in patients with interstitial cystitis. An alternative approach exploits the renal excretion of pentosan polysulfate to deliver a locally active agent believed to reduce
urothelial injury in cystitis. Although not superior to wait-listing only in interstitial cystitis, pentosan polysulfate improved symptoms in men in chronic prostatitis. The recent introduction of uroguanylin analogues as treatment for constipation triggered interest in a signaling cascade that involves cyclic guanosine monophosphate (cGMP). Mechanistic studies demonstrate that the secondary messenger is also released at the basolateral side of intestinal epithelial cells and has inhibitory effects of afferent nerve firing and behavioral responses to acute rectal distension, apparently restricted to experimental conditions with hypersensitivity. However, agents approved for the management of constipation, in general, were found in a meta-analysis to be associated with decreases in abdominal discomfort in proportion to the improvement in bowel patterns, thus arguing against a specific antinociceptive action of uroguanylin analogues.

Local anesthetic agents also play a potential therapeutic role in myofascial pain affecting abdominal wall muscles, labeled by some anterior cutaneous nerve entrapment syndrome based on the presumed mechanisms. A controlled trial clearly demonstrated a benefit of local infiltration with lidocaine. The effect is only transient in most of the affected persons, but up to one-third of the patients reported longer lasting benefit. Given the transient benefit of blocking afferent input, some clinicians advocate neurectomy as a more definitive approach. Controlled trials are difficult as the associated cutaneous anesthesia with neurectomy would, by definition, exclude effective blinding of participants and investigators. Keeping this caveat in mind, a small controlled trial showed superiority of neurectomy over sham surgery when patients were followed for a 6-week period with long-term data from the same group suggesting a lasting benefit.

As already mentioned earlier, the complex anatomy and difficulty in accessing the neural innervation of abdominal and pelvic viscera have been obstacles in developing and routinely using peripheral nerve blocks in the management of chronic visceral pain. The increased availability of cross-sectional imaging or endoscopic ultrasound allows the direct identification of targets, with cohort studies showing good short-term results. The longer lasting impact is less clear as retrospective case
series suggest transient benefits with ongoing pain and opioid use in more than 50% even after neurolytic interventions. The largest controlled trial in pancreatic cancer demonstrated decreased pain levels but failed to show a lasting decrease in opioid use or an impact on quality of life. Clinical practice seems to reflect these findings, as a survey of physicians with a professional focus on pancreatic disease suggested that celiac plexus block is not commonly used and is generally considered to be ineffective. Data on chronic pelvic pain are more positive. Although controlled studies are limited, studies suggest pelvic pain improvement after block or neurectomy, with response rates between 30% and 70%. 

The contradictory results of studies examining transient nerve blocks or more definitive approaches (neurolysis and neurectomy) point at the importance of central sensitization and fit with limited data on the clinical impact of spinal blockade. During a differential neuroaxial block with complete anesthesia up to the lower chest area, less than 30% of patients with chronic pancreatitis experienced complete resolution of their pain. A similar investigation targeted patients with unexplained chronic abdominal pain and reported comparable results. In the aggregate, treatments that limit or even eliminate peripheral input can decrease pain but often do not lead to a complete resolution of pain, again likely a consequence of central processes that may still be affected by the activity of sensory nerves but can become the primary mechanism driving chronic pain.

**SMOOTH MUSCLE RELAXANTS**

Many of the hollow visceral structures undergo rhythmic contractions, which can be temporally linked to the experience of abdominal pain. Indeed, detailed physiologic examination showed a correlation between changes in visceral contractile phenomena and the perception of pain in human volunteers and in patients with functional gastrointestinal diseases. Thus, weakening such contractions can be an important therapeutic mechanism in patients with patterns or descriptors of pain suggesting an enhanced perception of such contractile activity. Anticholinergic agents, typically referred to as “spasmolytics,” have
become a routine component of the medical management of IBS. The clinical practice is backed by data that show benefit in pain and global symptom ratings in IBS patients. The L-type calcium channel blocker otilonium bromide also functions as smooth muscle relaxant and was shown to be superior to placebo in IBS. Other commonly used calcium channel blockers, such as nifedipine, amlodipine, or diltiazem, have not been systematically examined in IBS but have been studied in spastic esophageal disorders. Consistent with their mechanism of action, there were significant effects of these agents on esophageal contractions, which were not matched by symptomatic improvement.

Anticholinergic or other spasmolytic agents have also been investigated in other abdominal pain disorders. Acute administration alleviated bladder cramps after catheterization. On demand, therapy alleviated abdominal cramps independent of the presumed underlying cause but was not superior to acetaminophen. In renal colic, spasmolytics were not superior to placebo when used alone and did not improve pain control when added to NSAID therapy. Although not necessarily mediated by changes in smooth muscle function, NSAIDs show a significant benefit in dysmenorrhea, which could be partly due to the role of prostaglandins in uterine smooth muscle contractions.

ACID SUPPRESSANTS
Ever since William Beaumont’s foundational observations of gastric function, changes in gastric acid production have been invoked a driver of illness and dyspeptic symptoms. Current clinical guidelines for the management of functional dyspepsia promote the initial use of acid-suppressive medications. Although heartburn and other manifestations of gastroesophageal reflux clearly respond to such a strategy, studies of acid suppression in functional dyspepsia show at best marginal improvements over placebo, with the benefit being largely restricted to patients with coexisting reflux symptoms.

ALTERING THE MICROBIOME
The highest density of microbial colonization of the human body is found within the colon. As already discussed earlier, there is mounting interest in
the effect of changes in the microbiome on gastrointestinal function and symptoms. Probiotics have become an accepted option in the management of gastrointestinal disorders, particularly in IBS, even though their beneficial effects are only marginal. Many questions remain regarding the most effective type or mixture of organisms to target for therapy. Conversely, antibiotic therapy is used to treat other symptoms of IBS, with the underlying assumption that small intestinal bacterial overgrowth or dysbiosis is a relevant mechanism. Although the subjective benefit of gut targeted antibiotics outlasts the immediate treatment effects, the presumably abnormal bacterial flora generally recovers within a few weeks after treatment cessation, and symptoms often recur. Repeat treatment cycles may well be helpful but raise concerns about the more frequent use of antibiotics in a chronic but benign and noninfectious condition such as IBS, concerns that are especially relevant in an era characterized by increasingly widespread antibiotic resistance.

**SEROTONIN**

More than 90% of the body’s 5-HT is found in the gastrointestinal tract, where it plays an important role in regulating motility and secretion. 5-HT signaling is complex, with many different receptor subtypes expressed in cells that range from neurons in the central and enteric nervous system to lymphocytes and platelets. Clinically exploited 5-HT effect on visceral sensation largely revolves around pathways mediating nausea and vomiting, with 5-HT₃ receptor antagonists having become the most commonly used antiemetics in clinical medicine. The same 5-HT₃ receptors reside in the enteric neurons and impact gut motility and secretion. Several 5-HT₃ receptor antagonists have been studied in diarrhea-predominant IBS, and results show decreases in bowel frequency, increased stool consistency, and, in most studies, improved pain ratings. Detailed mechanistic studies have failed to demonstrate a true effect on sensory mechanisms, suggesting an indirect impact of the reported changes in bowel patterns. Several partial 5-HT₄ agonists have been developed, which enhance motility and transit in the gut to alleviate constipation and related symptoms including pain. Although one study showed a shift in the pain threshold to mechanical but not chemical stimulation of the
esophagus,284 other investigators have not identified consistent changes in gastrointestinal sensation.285–289 Thus, as was true for the 5-HT₃ antagonists, these results highlight the indirect benefit on pain that is likely derived from changes in underlying gut motor function, transit, and luminal filling rather than direct action on nociceptive pathways. Documented adverse events with cardiac arrhythmias, myocardial, or bowel ischemia have led to the withdrawal of several agents targeting 5-HT signaling, leaving us largely with the antiemetics mentioned earlier. Antidepressants also affect 5-HT signals, primarily by interfering with its uptake. Although some agents, such as buspirone or mirtazapine, also interact with 5-HT receptors, they currently have no established role in pain management.

**SUBSTANCE P**

Substance P acts on neurokinin 1 (NK1) receptors that play a key role in visceral and somatic nociception (see Chapters 3 and 4). Despite a strong evidence basis from anatomical studies and physiologic experiments in normal and genetic knockout rodent models, NK1 antagonists do not appear to have notable analgesic properties in humans.290 The NK1 receptor antagonist aprepitant functions as a potent antiemetic,291 but it does not affect perception of gastric distension in human volunteers292 and had only minor effects on overall symptom severity in patients with gastroparesis.293 Therefore, NK1 receptor inhibitors do not appear to have good use for treating disorders primarily characterized by pain.

**COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPY**

Given the significant impact of chronic visceral discomfort on quality of life and the at times limited benefit of conventional therapies, many patients turn to complementary and alternative medicine (CAM) therapies, ranging from physical movement interventions to the use of herbal remedies, various devices, and acupuncture.294–297 Systematic studies are limited, and thus, it is difficult to assess the efficacy of many CAM approaches. Physical approaches, such as reflexology, massage therapy, or manipulations based on osteopathic principles, do not seem to be more
effective than placebo interventions. One exception is the application of local heat patches, which are comparable to NSAID therapy in dysmenorrhea. Although acupuncture has gained popularity, well-designed controlled trials failed to show benefit beyond the placebo effect. However, high response rates in both active and sham acupuncture demonstrate the power of placebo interventions in modulating chronic pain.

It is also difficult to assess the true utility of herbal preparations, which often contain mixtures of different plant extracts, some of which may have laxative effects that obviously change gut function and thus indirectly affect symptoms. Trials of peppermint oil on visceral pain in IBS show the most convincing evidence of efficacy. Detailed physiologic studies in human volunteers demonstrate a spasmolytic effect with a decrease in the amplitude of colonic contractions but also possible effects on visceral sensory function. When used to treat IBS, peppermint oil was superior to placebo.

Ginger may have weak inhibitory effects on muscarinic and 5-HT receptors. Although ginger extracts showed some benefit in dyspepsia and dysmenorrhea, randomized trials did not demonstrate efficacy in IBS. Iberogast, a mixture containing peppermint among other herbal extracts, alleviated dyspeptic symptoms. Small studies in IBS patients suggest a potential benefit of curcumin with fennel oil or anise extract. In contrast, another commonly used agent, St. John’s Wort, was ineffective in IBS.

Many supplements include digestive enzymes based on the underlying assumption that gastrointestinal discomfort is a sign of impaired digestion. Systematic studies in patients with chronic pancreatitis did not support an independent impact on pain but confirmed the expected benefit in patients with coexisting exocrine insufficiency. As oxidative damage may contribute to tissue injury in inflammatory processes, antioxidants could play a role in reducing injury and blunting symptoms, a concept that has some empiric backing in chronic pancreatitis. The aggregate data demonstrate that the widespread use of herbal remedies and supplements continues despite limited supportive evidence of efficacy beyond placebo responses.
Conclusion

Visceral pain is a common problem made more impactful due to disproportionate unpleasantness compared to similarly intense somatic pain. There has been increasing understanding of the neurobiologic underpinnings that account for key differences in the clinical features of visceral and somatic abdominal pain. For example, visceral pain is often poorly localized, in part due to the low innervation density of viscera, and patterns of visceral pain referral to distant, mostly cutaneous sites are the result of convergence of visceral and somatic sensory pathways within the central nervous system. These clinical features of abdominal pain can help in the identification of underlying medical problems. Many of the abdominal viscera are hollow organs that accommodate, propel, and ultimately expel their contents. Therefore, the filling state and degree of muscle tension or contractile activity are peripheral factors that influence visceral pain intensity, and as such present clues to not only diagnosis but also treatment options using dietary interventions, altering bowel patterns, or inhibiting muscle activity. Changes in the complex interactions between the microbial flora, luminal contents, the gut epithelium, and the enteric nervous system may also influence visceral pain in syndromes such as IBS. Pharmacologic management of abdominal pain relies primarily on strategies that are used in other conditions characterized by acute or chronic pain. However, the deeper location and typically bilateral innervation of viscera complicates the use of local therapies, such as nerve blocks or topical agents. Frequently used analgesic medications such as opiates and NSAIDs have some limited utility when used chronically due to direct effects on the gut mucosa and motility that lead to commonly experienced side effects. On the other hand, agents that interfere with cholinergic and serotoninergic signaling can alter visceral function, often with secondary improvement of pain or discomfort and without significant impact on somatic function or sensation. Future research into the neurobiologic mechanisms of visceral and somatic abdominal pain pathways will hopefully identify specific targets that can translate into novel therapies for a host of common, chronic pain syndromes.

Pelvic pain is common in women, frequently leading to disability, social disruption, and loss of economic productivity. Many women do not seek help, often having lived with the pain since adolescence and accepting it as normal. In New Zealand, only 34% of a community sample of women aged between 18 and 50 years reported no pelvic pain, with 55.2% reporting dysmenorrhea, 25.4% chronic pelvic pain (CPP), and 19.7% dyspareunia. In the United States, 14.7% of women of the same age range reported CPP with estimated outpatient medical costs of $881.5 million per year, 15% reporting work absenteeism, and 45% reduced productivity. Similarly in the United Kingdom, 24% of 18- to 49-year-olds reported CPP and 37 of every 1,000 women consulting their general practitioner presented with CPP; this was comparable to asthma (37/1,000) and back pain (41/1,000) and higher than migraine (21/1,000).

Pelvic pain is a frustrating symptom for both the patient and the doctor. Presentation can be variable, involving many organ systems, and severity can fluctuate over time. The frequent lack of an obvious initial diagnosis in both acute and CPP means that women frequently undergo large numbers of investigations and often unnecessary surgical procedures with associated morbidity and mortality. There is often a long interval between presentation and diagnosis with 25% remaining without a diagnosis after 3 to 4 years and more than 30% of women having had their pain for more than 5 years.

The aim of this chapter is to provide an overview of the common causes of pelvic pain as well as to detail some of the less well known but easily treated causes with up-to-date evidence and a clear rationale for investigation and treatment. Because of the complexity of the innervation of the pelvis and the anatomical proximity of pelvic viscera, there is
frequently overlap between what has traditionally been considered the
domain of gynecology, urology, or gastroenterology. Therefore, some
conditions will only be briefly discussed here when they are considered in
more detail in other chapters of this book.

We discuss acute pelvic pain and CPP separately as, although there are
overlaps, presentation and management are often very different. In
addition, we also consider pelvic pain in pregnancy, dysmenorrhea, and
mittelschmerz and pain associated with the complications of assisted
conception. Finally, we discuss dyspareunia and the vulval pain syndromes
which frequently coexist with other pelvic pain and whose etiology and
management may be similar.

**Acute Pelvic Pain**

**INTRODUCTION**

The maxim that “acute pelvic pain in a woman of reproductive age is an
ectopic pregnancy until proven otherwise” needs always to be borne in
mind as ruptured ectopic pregnancies are associated with high morbidity
and mortality and the consequences of a missed diagnosis are severe. However, there are many other causes of acute pain in the lower
abdominal/pelvic area that also need to be considered in the differential
diagnosis. Many of these are not gynecologic (Table 64.1), although the
symptom frequently presents, or is referred, to the gynecologist. Unless the
patient is extremely unwell, assessment should begin as always with a
detailed history followed by examination and appropriate investigations.

OVERVIEW OF ASSESSMENT

Where at all possible, the history should be taken in private, allowing the woman (whatever her age) to have with her only those people she requests to be present. A detailed history of the pain should be taken and associated bowel and urinary symptoms and vaginal discharge/bleeding should be enquired about directly. It is also important to ascertain with accuracy the date of her last menstrual period (LMP) and whether this was normal as well as a contraceptive history and any recent episodes of unprotected sexual intercourse (UPSI). In all cases, but particularly with adolescents, these areas need to be approached sensitively. The presence of any risk factors for ectopic pregnancy (Table 64.2) should be established and the woman’s obstetric history ascertained. With an acute exacerbation of a chronic pain, it is important to inquire whether any precipitating factors (either physical or psychological) are present. At all times, clinicians should consider safeguarding issues and be alert to the possibility of assault, knowing where to access appropriate help locally if required.

IVF, in vitro fertilization; PID, pelvic inflammatory disease.

Initial examination should ascertain that she is hemodynamically stable before examining the abdomen. The exact site of the pain should be established and evidence of an acute abdomen or abdominal/pelvic masses looked for. Pelvic pain in a sexually active woman (especially with a positive pregnancy test) should prompt a gentle digital internal examination, looking specifically for adnexal tenderness/masses and cervical excitation. Any discharge should be noted and appropriate swabs taken. If vaginal bleeding is present, a speculum examination should also be performed. Rectal examination may be indicated depending on the
history. Again, privacy should be ensured, although a chaperone is recommended.

All women should have a urinary pregnancy test, but otherwise, investigations should be prompted by the history and examination findings rather than routinely ordered. Initially, investigations should be kept to a minimum in the case of an acute exacerbation of CPP. Investigations that might be considered are listed in Table 64.3.

GYNECOLOGIC FACTORS

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is a common cause of acute pelvic pain, and the incidence is increasing. It is an upper genital tract infection and can include one or more of the following: endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. Prompt treatment and effective contact tracing are important as long-term sequelae include CPP, subfertility, and ectopic pregnancy. Although infection usually ascends from the cervix, cervical swabs can be negative even when pathogenic organisms are isolated from the fallopian tubes. The pain is thought to be due to inflammation, tissue destruction, irritation of peritoneal surfaces, and distortion of anatomy. Right upper quadrant pain and perihepatic adhesions occur in the Fitz-Hugh-Curtis syndrome, which is seen in 10% to 20% of women with PID.\(^6,7\) Clinical features of PID lack sensitivity and specificity but include lower abdominal pain and tenderness, deep
dyspareunia, abnormal vaginal/cervical discharge, cervical excitation and adnexal tenderness, and fever. Evidence of acute infection will not always be seen on diagnostic laparoscopy, and therefore, this investigation should be reserved for cases where alternative pathology needs to be excluded or if a pelvic mass is seen on ultrasound (US). Where there is a high index of suspicion, it is recommended that empirical antibiotic treatment should be commenced once swabs have been taken without waiting for culture results or performing further investigations. This is particularly important if other features of sepsis are present, in which instance admission and adherence to local sepsis guidelines is recommended. A number of different organisms are associated with PID, including Chlamydia trachomatis, Neisseria gonorrhoea, Mycoplasma genitalium, and anaerobes. The most commonly implicated organisms vary geographically, and therefore, local guidelines for appropriate antibiotic treatment regimens should always be consulted. There are now high rates of quinolone-resistant gonorrhoea in the United States, and, since April 2007, fluoroquinolone antibiotics have no longer been recommended for the treatment of PID in the United States; this is increasingly also the case in the United Kingdom. Antibiotic treatment is usually continued for 14 days (with intravenous doses converted to oral once afebrile), and therefore, patient compliance can be an issue. The presence of an intrauterine contraceptive device (IUCD) only increases the risk of developing PID in the first few weeks after insertion. Leaving the device in situ while mild PID is being treated does not appear to affect the outcome. In severe cases, however, it is recommended that the IUCD be removed.

When there is definite evidence of a pelvic abscess or severe disease, surgery is recommended (either laparoscopy or laparotomy), to drain the abscess and divide pelvic adhesions, there is no good evidence to recommend division of perihepatic adhesions, however. Depending on location, it may also be possible to drain pelvic collections under US guidance. This has been shown to be effective with fewer complications than surgery.

To prevent reinfection, contact tracing and treatment of all sexual partners from 6 months prior to presentation is recommended. This may
be best done through a local genitourinary medicine (GUM) clinic, which will have experience of contact tracing and counseling about the long-term consequences of sexually transmitted infections. If admission is not required and appropriate facilities exist, it may be more effective to refer the woman to a GUM clinic immediately, to be seen the same day, before treatment is started. Sexual intercourse should be avoided until both the patient and her partner have completed a full course of treatment.

**Adnexal Pathology**
The adnexa comprise the fallopian tubes and the ovaries, the overlying peritoneum, and accompanying blood vessels. Common adnexal problems causing pain are discussed here.

**Adnexal Torsion**
Unlike the testes, it is rare for normal adnexa to undergo torsion. However, the ovaries and the distal ends of the fallopian tubes hang free and, if enlarged by an ovarian cyst or hydrosalpinx for example, are able to twist and cause ischemia and thus pain, with necrosis ensuing if the torsion is not resolved. Initially, the pain may be a dull ache that comes and goes; however, once necrosis occurs, the pain becomes constant and severe and may be accompanied by pyrexia, nausea, leucocytosis, and raised inflammatory markers. Clinically, a tender pelvic mass will be found on internal examination, and this can be confirmed with US. Management is surgical, ideally by urgent laparoscopy. If the adnexa appear healthy, then the torsion can be untwisted and the cyst/hydrosalpinx dealt with appropriately. Traditionally, removal of the mass was performed if the tissues appeared gangrenous. However, there is increasing evidence that the appearance of the tissues does not correlate well with residual ovarian function and recovery, and follow-up studies where de-torsion was performed suggest that ovarian function recovers in the majority of cases. It is therefore now recommended that de-torsion be performed and the clinical condition observed with an interval salpingo-oophorectomy performed only if clinically indicated.12

**Other Ovarian Cyst Accident**
As well as undergoing torsion, an ovarian cyst (either functional or
pathologic) can also cause pain by rupturing or by hemorrhaging into itself. Ruptured cysts usually cause acute pain followed by a generalized dull ache; however, if enough fluid/blood is released into the pelvis to irritate the diaphragm, then shoulder pain may also be present. Diagnosis is usually clinical, although, a US may show fluid in the pelvis and the absence of a previously noted ovarian cyst. Pregnancy must always be excluded (usually with a urinary pregnancy test), but if the pain is resolving and the woman is hemodynamically stable, then management is conservative, providing symptom relief. However, if she is unstable or a significant amount of fluid is present in the pelvis, laparoscopy may be required. In this instance, it is obviously important to be sure the diagnosis is correct and that an ectopic pregnancy, for example, has not been missed.

Hemorrhage into a cyst may be self-limiting or require surgery. Again, this decision should be based on the clinical picture.

In all these cases, if there is any doubt as to the nature of the cyst, then surgery should be performed so that tissue for histology can be obtained.

Hematometra/Hematocolpos
A relatively rare cause of acute, or acute-on-chronic, pelvic pain is a hematometra or hematocolpos (literally blood in the uterus or blood in the cervix). This can be primarily from a congenital anomaly or secondary to procedures such as transcervical resection of the endometrium if cervical stenosis occurs. With congenital anomalies where a bifid uterus exists with one blind ending horn, it is possible to have normal menstrual flow from one horn and a gradually increasing hematometra in the other.

Diagnosis is by US or magnetic resonance imaging (MRI), and management is surgical, which may be as simple as cervical dilatation or incising an imperforate hymen. The discovery of a congenital müllerian anomaly should prompt a thorough investigation of the renal and urogenital system as many of these anomalies coexist.\(^\text{13}\)

Acute Exacerbation of Chronic Pelvic Pain
An emergency presentation with acute pelvic pain can be an exacerbation of a much more chronic problem. Often, the patient is known to the department, but for others, the sudden worsening of chronic pain can be
the final straw that causes the woman to present for the first time. As well as organizing appropriate analgesia (remaining alert to the possibility of an opioid addiction) and treating any associated symptoms, a careful search for the factor(s) precipitating the exacerbation should be made. This may be disease-related, such as an ovarian cyst accident; treatment-related, such as reactivation of endometriosis by add-back hormone replacement therapy (HRT) or constipation secondary to increased analgesia use; or lifestyle-related, such as increased activity worsening musculoskeletal pain or a bereavement worsening psychological status. If such precipitating factors can be identified, they should be discussed with the patient. Coping strategies can be taught to prevent future emergency presentations, which may also be reduced by easy access to a health care professional who knows the woman well.

If a women presents for the first time to a department but is managed elsewhere for their CPP, it is always advisable to contact the team responsible for her care to ensure that management of the acute exacerbation/presentation does not interfere with the long-term plan. Although certainly not the case for the majority of women, there is a small group of patients who attend a variety of different hospitals with the aim of procuring the treatment (be it surgery, opioids, or other options) they desire. Although these women clearly have the right to seek a second or third opinion, it can be helpful to be fully informed of this behavior and the results of previous investigations/surgeries when forming a management plan and deciding which other clinicians may need to be involved.

**COMPLICATIONS SPECIFIC TO PREGNANCY**

A number of complications specific to pregnancy can present with pelvic pain and need always to be borne in mind in a woman of reproductive age. It is also worth noting, however, that the physiologic and anatomical adaptations of pregnancy can alter the presenting features of many non–pregnancy-related conditions such as appendicitis. When treating pain in a possibly ongoing pregnancy, nonsteroidal anti-inflammatory drugs (NSAIDs) are contraindicated because of effects on implantation, fetal renal function, and premature closure of the ductus arteriosus.
Acetaminophen (paracetamol) and opioids, however, are safe. Reassurance and explanation are perhaps more important than ever in these cases to avoid anxiety about the pregnancy further clouding the clinical picture.

**Ectopic Pregnancy**

An ectopic pregnancy is one in which the conceptus implants outside the uterine cavity. Most commonly, this is within the fallopian tube (98.3%) but more rarely can be in the abdominal cavity, on the ovary, or on the cervix. The incidence is approximately 1 in 100 pregnancies; however, this is likely to increase with the increasing incidence of pelvic infection and assisted conception. Rarely, a heterotopic pregnancy can occur, which is effectively a twin pregnancy in two different sites (e.g., one intrauterine and one ectopic pregnancy). These cases can be easily missed with false reassurance given once the intrauterine pregnancy is seen on US. With the rising prevalence of assisted conception techniques, the incidence of heterotopic pregnancies is increasing.

Classically, presentation is with a period of amenorrhoea followed by brown vaginal loss and then onset of pelvic pain. Realistically, however, presentation is varied, ranging from asymptomatic (an incidental finding at routine scan), through any combination of pain and/or old or fresh vaginal bleeding, to collapse secondary to hypovolemia. Initial pain is thought to be secondary to stretching of the peritoneum covering the distended fallopian tube; however, with rupture of the tube, peritonitis occurs and tracking of the blood up to the diaphragm can cause shoulder tip pain.

In the collapsed patient with a positive pregnancy test, diagnosis is assumed and resuscitation commenced with surgery performed immediately when she is stable. At the opposite extreme, in a hemodynamically stable woman with minimal symptoms, diagnosis can be difficult. In early pregnancy, an intrauterine gestation may not be visible even with transvaginal ultrasound (TVUS). A combination of serial human chorionic gonadotrophin (hCG) levels and repeated US may be required to determine the location and viability of the pregnancy. If a high index of suspicion is present or the woman is isolated socially, this observation may best be done as an inpatient; however, in the majority of cases, early pregnancy clinics facilitate safe outpatient management.
Appropriate management depends on the severity of presentation. With an unstable patient, urgent laparotomy or laparoscopy should be performed depending on the skills of the available surgeon. With a stable patient, the majority of cases should be able to be managed laparoscopically, reducing postoperative pain, recovery time, and hospital stay. Some units now manage appropriate cases medically using methotrexate; however, this is not without risks and requires careful surveillance and a motivated patient.16

However, the pregnancy is managed, the risks of an ectopic pregnancy in the future are considerably higher than in the background population, and the woman should be counseled about this prior to discharge and advised to get an early scan in her next pregnancy. It should not be forgotten that a pregnancy has been lost, and many women/couples value the opportunity to talk this through either at the time or at a later date.

**Miscarriage**

Miscarriage is defined as pregnancy loss prior to viability (currently considered to be 24 weeks) and occurs in 10% to 20% of clinical pregnancies.17 Because of connotations of blame, the medical term abortion should no longer be used when pregnancy loss is spontaneous. The different types of miscarriage are shown in Table 64.4. Bleeding is not always the presenting feature. Classically, bleeding precedes pain in a miscarriage as opposed to an ectopic pregnancy where the pain occurs first. As this is not reliable, all pain or bleeding in early pregnancy should be referred to an early pregnancy unit for further assessment and management. Management may be expectant, medical (using prostaglandin analogues ± antiprogestrone) or surgical (traditionally known as evacuation of retained products of conception [ERPC] but now more frequently called a surgical management of miscarriage [SMoM] as this terminology is more acceptable to women and their partners). If the woman is hemodynamically unstable or the bleeding is very heavy, then surgery is recommended; otherwise, the choice of management should be made by the woman. Nonsurgical options are associated with longer periods of bleeding but avoid the risks of a general anesthetic and may allow the woman to feel more in control. Contrary to previous beliefs,
there is no increase in infection rate with expectant management. All nonimmunized, Rhesus-negative women who miscarry after 12 weeks’ gestation should be given prophylaxis with anti-D immunoglobulin. Prior to 12 weeks, anti-D immunoglobulin should be given for medical or surgical evacuation or if the bleeding is very heavy and associated with pain. The negative psychological impact of early pregnancy loss can be enormous, both for the woman and her family, and therefore, counseling and support should be offered. Ideally, this should be at a local level, although national support groups also exist.

**Fibroid Degeneration**

Uterine fibroids (leiomyomas) are benign tumors of the uterus, which are found in approximately 20% of women of reproductive age. They are usually asymptomatic and are more common in older women and women of African origin. They possess estrogen receptors and are thus stimulated to grow during pregnancy. As their blood supply is mainly peripheral, central areas can suffer from ischemia if enlargement is rapid, causing pain. This is known as red degeneration. The pain is generally well localized with tenderness over the area of the fibroid only (as opposed to placental abruption where the whole uterus is tender and woody hard) and may be accompanied by a mild pyrexia and leukocytosis. Opioid analgesia is often required and admission may be necessary, if only for observation and fetal monitoring if there is any doubt about the diagnosis.
**Ovarian Cyst Accident**
As in the nonpregnant state, hemorrhage into or rupture or torsion of an ovarian cyst can occur during pregnancy. In general, presentation and management are as for the nonpregnant woman; however, symptoms can be masked and nonspecific during pregnancy. Rupture of a cyst can present with severe pain and shock, and in early pregnancy, laparoscopy may be necessary to exclude ectopic pregnancy. However, if pain is resolving and no other symptoms are present, conservative management is recommended. If surgical management is required beyond early pregnancy, laparotomy may have to be considered because of the risks and technical difficulties of a laparoscopy with an enlarged uterus.

**Ligamentous Stretch**
As the uterus enlarges, it moves out of the pelvis and becomes an abdominal organ. During this process, the supporting round ligaments are stretched and cause pain in the late first/early second trimester in 10% to 30% of pregnancies. Management is by simple analgesia and reassurance; however, it is important to ensure that other causes of pain are not missed, such as rupture of a heterotopic pregnancy or acute appendicitis.

**Urinary Retention and Uterine Incarceration**
Uterine retroversion occurs in up to 15% of pregnancies in the first trimester, but by 15 weeks’ gestation, spontaneous anteversion almost always occurs. It is reported that retroversion persists into the second trimester in 1 in 3,000 pregnancies. Rarely, it may not be noticed until a cesarean section is performed at term; however, it can become impacted and present with urinary frequency, urgency, abdominal pain, and urinary retention. Pelvic adhesions secondary to infection or endometriosis and posterior wall fibroids can predispose to incarceration. Diagnosis can be aided by US or MRI (Fig. 64.1); however, fetal parts may be palpable vaginally and an enlarged bladder abdominally. Gentle manual decompression is usually possible after emptying the bladder with a Foley catheter. Intermittent catheterization is occasionally necessary for a few days subsequently, but an indwelling catheter is not recommended because of the risk of infection. If asymptomatic retroversion persists until term,
delivery should be by cesarean section and a classical incision is often required.\(^\text{19}\)

**FIGURE 64.1** Magnetic resonance imaging of persistent retroversion of the uterus at 20 weeks’ gestation. The uterine fundus containing the breech (curved arrow) can be seen in the pouch of Douglas. The placenta (asterisk) is attached to the posterior uterine wall with a large intramural fibroid (arrowheads) superiorly on the lower portion of the anterior wall, and the cervix (arrows) just below, above the level of the symphysis pubis (P). (From Hamoda H, Chamberlain PF, Moore NR, et al. Conservative treatment of an incarcerated gravid uterus. BJOG 2002;109:1074–1075, with permission.)

**COMPLICATIONS OF ASSISTED CONCEPTION**

**Ovarian Hyperstimulation Syndrome**

Ovarian hyperstimulation syndrome (OHSS) is a serious and sometimes fatal complication of assisted conception techniques. It is a systemic disease secondary to the release of proinflammatory mediators, including vasoactive products, from the hyperstimulated ovaries. It can be subdivided into early, within 9 days of the ovulatory hCG dose, or late and is classified according to severity (Table 64.5). Mild disease has been reported to complicate up to 33% of in vitro fertilization (IVF) cycles, whereas the severe form occurs in around 1%. OHSS is more likely in women with polycystic ovaries, young women, and in cycles where
conception occurs, especially of multiple pregnancies.\textsuperscript{21} Presentation is variable depending on severity (see Table 64.5) but should always be borne in mind in a woman with abdominal/pelvic pain who has recently undergone assisted conception. Mild and moderate disease can be managed on an outpatient basis, but more severe forms or concerns about a worsening condition require admission. In general, management involves symptom control: analgesia with either acetaminophen (paracetamol) or codeine but avoiding NSAIDs and antiemetics suitable for early pregnancy (e.g., prochlorperazine, metoclopramide), continuing progesterone luteal support but stopping hCG support and avoiding strenuous exercise and sexual intercourse because of the risk of ovarian torsion. In severe cases, multidisciplinary management is advised to deal with issues of fluid balance and thromboembolic risk (0.7% to 10%).\textsuperscript{22} Paracentesis may be necessary but should always be done under US guidance because of the risk of injury to enlarged, vascular ovaries. Importantly, women should be reassured that pregnancy may continue normally despite OHSS.\textsuperscript{21}

OHSS, ovarian hyperstimulation syndrome; US, ultrasound.
Pelvic Infection
Pelvic infection can occur after investigation of tubal patency with a hysterosalpingogram (HSG) or laparoscopy and dye test or after oocyte retrieval. Prior to such investigations being arranged, all women should have cervical swabs performed, and any infection should be treated with an appropriate antibiotic regimen. Oocyte retrieval is usually performed transvaginally under US guidance. Rates of pelvic infection secondary to this procedure vary between units and published series but are generally low, between 0% and 1%. Initial management is with antibiotics and US to exclude a pelvic abscess. Progressive worsening of symptoms or failure to improve should prompt a further search for a pelvic collection and consideration of the possibility of bowel damage, for which laparoscopy or laparotomy would be required.

Dysmenorrhea
Dysmenorrhea is defined as pain with menstruation and was excluded from older definitions of CPP. However, there is increasing evidence of psychological distress, reduced quality of life, and long-term alterations in central nervous system structure and function in women with dysmenorrhea such that the most recent International Association for the Study of Pain (IASP) Taxonomy does include it as a subcategory of CPP. Estimates of prevalence range from 20% to 90%, and it has a major social and economic impact, being the leading cause of school and work absenteeism in young women. Traditionally, dysmenorrhea has been subdivided into primary and secondary. Primary (functional) dysmenorrhea is not associated with other pathology; is thought to be due to overproduction of prostaglandins and leukotrienes in the myometrium causing strong, painful contractions of the uterus; and is common in adolescents. It is frequently considered to be a “normal” part of development and assumed to improve with age or after pregnancy, although this has not been shown to be true in longitudinal studies. Secondary dysmenorrhea is associated with other pathology (Table 64.6).
and therefore often occurs with other symptoms such as dyspareunia and menorrhagia. It is traditionally considered to affect women in their 30s and over, but it is worth remembering that children as young as 8 years old have been shown to have biopsy-proven endometriosis, and congenital uterine anomalies probably occur in around 4% of the population, increasing to 10% in adolescents with pelvic pain. Clinically, therefore, we find this distinction to be unhelpful and consider dysmenorrhea as a symptom which deserves to be treated and investigated as appropriate, no matter what age the patient.

**TABLE 64.6 Causes of Dysmenorrhea**

- Endometriosis
- Adenomyosis
- Müllerian anomalies
- PID
- Fibroids
- Cervical stenosis
- Pelvic venous congestion
- Intrauterine device

PID, pelvic inflammatory disease.

Initial assessment should include a detailed history, including risk factors for pathology associated with dysmenorrhea and other symptoms. In young girls who are not sexually active and without associated symptoms, a pelvic examination is not necessary before commencing empirical treatment. If there are concerns about structural anomalies, an abdominal US can offer reassurance but cannot diagnose or exclude endometriosis.

**NONSTERoidal ANTI-INFLAMMATory DRUGS**

Many women, especially teenagers, self-medicate for their dysmenorrhea, and NSAIDs are often the drugs of choice. NSAIDs act by inhibiting cyclooxygenase and therefore reduce prostaglandin production and associated uterine contractions. Mefenamic acid has been shown to also inhibit the lipoxygenase pathway. Systematic reviews have concluded that NSAIDs are an effective treatment for dysmenorrhea but that there is insufficient evidence to determine which, if any, is the most effective. A
greater improvement of symptoms can be obtained if treatment is started 24 hours prior to the onset of bleeding and, if a loading dose of twice the regular dose is used initially, followed by regular doses as needed.  

**HORMONAL TREATMENTS**

The combined oral contraceptive pill (COCP) has been used as a treatment for dysmenorrhea for many years. It acts to inhibit ovulation and limit endometrial growth, reducing progesterone and subsequent prostaglandin and leukotriene production. A number of trials have shown a significant improvement in dysmenorrhea with COCP use, both high and lower dose formulations. Many clinicians would suggest running the pill packets back-to-back without having a withdrawal bleed in between packets, as if the pain is only associated with bleeding inducing amenorrhea will effectively treat the problem. If this is not acceptable for cultural or other reasons, tricycling the COCP (i.e., taking three packets of pills back-to-back) has also been shown to reduce symptoms as well as decreasing the frequency of menstruation and thus may be a good alternative.

Depot medroxyprogesterone acetate (DMPA), a long-acting injectable contraceptive, also reliably inhibits ovulation in both its intramuscular and subcutaneous formulations, and amenorrhea is common. In one study, 64% of adolescents reported an improvement in dysmenorrhea symptoms with DMPA, however, concerns about loss of bone mineral density (BMD) limit its prolonged use in adolescence. For women also requiring long-term contraception, a levonorgestrel-releasing intrauterine system (LNG-IUS) is another alternative. The majority of women are amenorrheic with the system in place, and even for those who continue to bleed, menses tend to be lighter and less painful, although bleeding can be erratic for the first 6 months. In some instances, this may be the most appropriate option for nulliparous young adults, in which case a brief general anesthetic may be necessary for insertion. For severe symptoms, a therapeutic trial of a gonadotrophin-releasing hormone (GnRH) agonist (see the following text) could also be considered.

**SURGICAL TREATMENTS**

Surgery for dysmenorrhea should only be considered as an investigation
for other pathologies if there is no response to medical treatment (e.g., diagnostic laparoscopy) or as a last resort. Systematic reviews suggest that there is insufficient evidence to support the use of surgical nerve interruption\(^{40}\) (either laparoscopic uterine nerve ablation [LUNA] or presacral neurectomy [PSN]) in dysmenorrhea, and the rates of complications are high.

**NONPHARMACOLOGIC INTERVENTIONS**

A number of other interventions have been studied to improve dysmenorrhea with varying success. Both high-frequency transcutaneous electrical nerve stimulation (TENS) and acupuncture have shown benefit in some studies\(^ {41,42}\) as has topical heat therapy\(^ {43}\); however, neither psychological interventions nor dietary supplements have been shown to be beneficial in pure dysmenorrhea.\(^ {44,45}\) As always, the role of education and validation of symptoms cannot be emphasized strongly enough, and this is particularly true for adolescents.

**Mittelschmerz**

Mittelschmerz (literally “middle pain” in German) is one-sided, lower abdominal pain that occurs at or around ovulation. It can last from minutes to 48 hours and requires no treatment other than simple analgesics. It is thought to occur in approximately 50% of women at some point. What causes the pain is not known, but possible suggestions include tubal, uterine, or cecal spasm; increased tension in the ovary or Graafian follicle; or peritoneal irritation due to leak of blood or fluid from the follicle. However, the latter is probably unlikely as in one study, 33 out of 34 women experienced the pain prior to follicular rupture (as confirmed with US),\(^ {46}\) and pain is on the same side as follicular rupture in only 86% of women.\(^ {47}\) Mittelschmerz probably causes most concern when a woman recommences ovulation after a long period of treatment with an ovulation inhibitor. Because it is not expected, the sudden, acute pain can then lead to investigation for other conditions such as appendicitis or an ovarian cyst accident. Similar, but more severe, pain can occur with trapped ovary syndrome and endometriosis, as discussed in the following text.
Chronic Pelvic Pain

INTRODUCTION
CPP is a symptom, not a diagnosis. As is seen, the causes are diverse, often multifactorial, and not always evident on routine examinations or even laparoscopy. As well as the economic impact already alluded to, CPP has major psychological, social, and cultural consequences not only for the woman but also for her partner, family, and society as a whole. It is acknowledged that it is frequently poorly managed; yet, it is as common as migraine and back pain and affects all races and social classes.

FACTORS ASSOCIATED WITH CHRONIC PELVIC PAIN
A number of factors are thought to be associated with CPP and should be explored during the consultation at an appropriate point.

Social
CPP is seen in women of all social classes with no variation in prevalence depending on marital or employment status. However, social support can be an important factor in how a woman deals with her pain and social isolation can make the situation very difficult. It is easy to see how a vicious circle is set up with pain leading to the loss of the woman’s social role and thus her self-esteem, causing isolation and contributing to further pain.

Abuse
Although frequently alluded to, the relationship between physical or sexual abuse and CPP is still not clear. The majority of studies is retrospective and only target women who have already developed the symptom. It appears that women in secondary care with any chronic pain condition are more likely to report a history of childhood abuse than pain-free women. When CPP is considered, sexual abuse is more commonly reported than in other pain conditions. It could be, however, that childhood sexual abuse is a predisposing factor for the development of depression, anxiety, and somatization which may then lead to the development of CPP. In a rare
prospective study,\textsuperscript{49} children who had been abused were followed until their 20s and were not found to have an increase in medically unexplained symptoms when compared to a population who were not known to have been abused. However, those with unexplained symptoms were more likely to report their abuse. Thus, a revealed abuse history should not be assumed to be the cause of the pain, but failure to respond to treatments should perhaps prompt an exploration of these areas if a good therapeutic relationship already exists.

A recent study assessed whether a history of abuse is associated with the development of gynecologic disorders associated with CPP. In a cohort of 473 women undergoing laparoscopy, they found no increased risk of endometriosis, fibroids, or ovarian cysts in those with an abuse history but did find that a history of physical abuse was associated with a higher likelihood of pelvic adhesions.\textsuperscript{50}

**Psychological**

Women with CPP display an increased incidence of “negative” psychological features, such as depression, anxiety, and catastrophization.\textsuperscript{51} This is common with other chronic pain conditions, such as fibromyalgia and irritable bowel syndrome (IBS). However, it is not possible to know whether these factors predispose a woman to develop CPP, contribute to a perpetuation of the pain, or are a consequence of years of living with pain and attempts to justify its severity or even existence to friends, family, and health care professionals. What is known is that psychological state can alter the experience of pain, and this is the area that should be emphasized to the woman when a referral to a psychologist is suggested. Improving sleep patterns alone can both improve mood and have a significant effect on ability to function.

**Personality**

Similarly, whether personality types predispose to the development of chronic pain conditions or merely alter the way in which they are dealt with is not known. Some personality traits can make recovery more difficult. “Driven types,” for example, are unable to pace themselves and do too much on a “good day” so that on the following day, symptoms are
worse again. On the other hand, those who take easily to the “sick role” can be hard to persuade to engage in therapeutic options and may also fail to respond. Women with diagnosed personality disorders should be managed in conjunction with a psychiatrist.

OVERVIEW OF ASSESSMENT
The initial assessment of a woman with CPP is very important. Complete recovery at follow-up is associated with a favorable patient rating of the quality of the initial consultation.\(^\text{52}\) The woman needs to be given time to tell her story, without interruptions, but with the support of whomever she would like to be present (which may be no one but the doctor). The extra time taken to listen to the history in the patient’s own words may well give valuable information about the context of the pain, its effects on her life, and her beliefs about its cause and prognosis. In fact, an explanation for the pain has been shown to be one of things women with CPP most want out of their consultation (Table 64.7).\(^\text{53}\) The process of telling her story and of the examination can, in itself, be therapeutic. Once a cycle of chronic pain has been set up, it is unlikely that a single cause for the pain will be identified, and the clinician should be alert for any contributing factors that may be revealed.

History
A detailed history of the pain should be taken including when and how it began; its associations, such as bowel, bladder, and psychological symptoms; and the effects of posture and movement. The circumstances surrounding the start of the pain and whether they recently changed should be discussed, as should the reasons why she has presented now. Cyclicity of symptoms or exacerbation with intercourse need to be established as does her current and future fertility aspirations. Relevant information may
well be gleaned from her obstetric history, and a contraceptive and smear history should also be taken. It should be ascertained that no “red flag” symptoms, such as rectal bleeding or weight loss, exist. Although a history of past or present abuse (verbal, physical, or sexual) may also be present, it may not be appropriate to discuss this at the first consultation. If abuse is revealed, these experiences need to be accepted as stated, and it is important to know where to access specialist help locally should this be required.24

Examination
Examination requires more time than is routine in gynecology, and as it is the time when the patient is most vulnerable, new information is often revealed at this point.54 The decision as to whether to have a chaperone present is a personal one that will depend on both the doctor’s and patient’s wishes. However, the presence of a third person may alter the dynamic and prevent certain information being revealed. Examination should begin, as always, with observation. This includes evidence of not only skin alterations or damage and posture but also of both the patient’s attitude to the examination and the doctor’s response to this. Evidence of altered sensation (hypersensitivity or allodynia55) should be sought before abdominal palpation is performed. The effect of movement should be assessed, which might suggest musculoskeletal pain. The extent to which an internal examination is performed will depend on the history. With marked vaginismus, anything more than a gentle, one-finger examination may be inappropriate. Altered sensation on the vulva and perineum should be looked for and pelvic floor muscle tone assessed if possible. Rectal examination should only be performed if there is a clear indication in the history.

Investigations
Investigations should be guided by the history, but care should be taken to avoid overinvestigation initially. Many women will have already seen a number of doctors, often of many specialities, and had a variety of frequently invasive investigations. One particularly useful strategy is to ask the woman to keep a detailed pain diary over 1 to 2 months. This can
reveal information about the timing of the pain and its associations to the doctor and to the patient.24

**Therapeutic Trial**

Very cyclical symptoms are usually gynecologic in origin, although pain perception itself may vary with the menstrual cycle as can symptoms of both interstitial cystitis (IC)/bladder pain syndrome (BPS) and IBS. Where symptoms are markedly cyclical, a therapeutic trial of a GnRH analogue could be considered before a laparoscopy is performed.24 This group of drugs, given initially as monthly subcutaneous injections, cause a prolonged activation of the GnRH receptor leading to an initial worsening of symptoms (the “initial flare”). This is followed by a reduction in luteinizing hormone (LH) and follicle-stimulating hormone (FSH), such that serum estradiol levels are suppressed by 21 days and remain at levels equivalent to postmenopausal women with continued dosing. Common adverse effects are shown in Table 64.8. The most common complaints of hot flushes and emotional symptoms are often well tolerated if pain is relieved. The biggest concern, however, is the loss of BMD which can be up to 6% after 6 months of treatment.57 If the trial is successful, then treatment can continue with the addition of low-dose combined HRT, and this combination has been shown to be safe and effective for up to 2 years. After this time, many women are not prepared to continue with monthly injections (although three monthly preparations exist and can be effective in some women) and seek alternative management options. However, in those who would like to continue with treatment, there is now evidence from small studies that the combination is safe for up to 10 years, with one of these women having stopped treatment to conceive and then recommenced treatment after delivery.58

| TABLE 64.8 Hormonal Treatments for Endometriosis-Related Pain158 |
|----------------------|---------------------------------------------------------------|
| **Treatment** | **Main Adverse Effects** |
| COCP$^{36,159}$ (continuous or tricycling) | Thromboembolic disorders, altered serum lipid profile, hypertension, skin reactions, migraine, intermenstrual bleeding, depression, altered libido |
| Danazol$^{160}$ | Deepening of voice, acne, hirsutism, clitoral |
Gestrinone\textsuperscript{161} hypertrophy, vaginal dryness, hematologic disturbances, altered serum lipid profile, thromboembolic disorders, depression, weight gain, altered libido, muscle cramps

Progestogens (e.g., medroxyprogesterone acetate)\textsuperscript{161} Headache, depression, weight gain, voice changes, acne, hirsutism, intermenstrual spotting, gastrointestinal disturbances, muscle cramps

LNG-IUS\textsuperscript{56,162} Depression, weight gain, altered libido, acne, vaginal bleeding, breast tenderness, thromboembolic disorders, gallbladder disease, worsening of ovarian cysts

GnRH agonists\textsuperscript{57} Irregular vaginal bleeding, depression, weight gain, reduced libido, breast tenderness, vaginal discharge, uterine perforation, ovarian cysts

GnRH antagonists\textsuperscript{163} Initial flare in symptoms, bruising/pain at injection site, depression, emotional lability, reduced libido, vaginal dryness, hot flushes, headache, pituitary apoplexy

Same as for GnRH agonists except that no initial flare occurs

COCP, combined oral contraceptive pill; GnRH, gonadotrophin-releasing hormone; LNG-IUS, levonorgestrel-releasing intrauterine system.

**Diagnostic Laparoscopy**

If no relief is gained from a therapeutic trial of GnRH analogue or if there are other indications such as subfertility or a pelvic mass, diagnostic laparoscopy should be performed. However, laparoscopy is not without risks with large series quoting approximately 3\% risk of minor complications and 0.6 to 1.8/1,000 risk of major complications such as bowel perforation and vascular damage.\textsuperscript{59} Furthermore, although it was initially thought that a negative laparoscopy would reassure a woman, more recent studies have shown this not to be the case\textsuperscript{60} and it may reaffirm her beliefs that the doctors do not believe her and think the pain is of psychological origin.

**Empirical Treatment**

Even if no clear cause of the pain can be found on investigation, the pain should still be treated empirically. Analgesia or hormonal treatments may be appropriate, but it is often worth considering drugs such as amitriptyline, gabapentin, pregabalin, and duloxetine in addition. Although there is very limited evidence of efficacy for these drugs in CPP
specifically, there is increasing evidence of both somatic and visceral sensory disturbance in women with CPP. Thus, a trial of these drugs which are effective in neuropathic pain and may have a role in reducing visceral hypersensitivity may be worthwhile. Topical capsaicin cream on the skin of the abdomen (not the vulva) may be useful for hyperalgesia and allodynia. Nonpharmacologic treatments such as acupuncture, TENS, chiropractic, and osteopathic manipulations may be beneficial, and pain management techniques and support groups can also be of value.

THE IMPORTANCE OF VISCERAL HYPERSENSITIVITY IN CHRONIC PELVIC PAIN

Visceral hypersensitivity (and subsequent viscerovisceral/viscerosomatic referral) is thought to have an important role in CPP. It can be the primary pain generator, perpetuating factor, or cause of secondary symptoms. Visceral hypersensitivity should therefore always be borne in mind, especially when symptoms from multiple organs are present or where there is no clear demonstrable cause. This area is covered in more detail in Chapters 3, 4, and 65. Sex steroid hormones are known to act at multiple sites throughout the peripheral and central nervous system, and it is thus not surprising that these symptoms often show cyclicity and can respond to hormonal manipulation.

GYNECOLOGIC FACTORS IN CHRONIC PELVIC PAIN

Endometriosis

Endometriosis is defined as “an inflammatory disease process, characterized by lesions of endometrial-like tissue outside the uterus that is associated with pelvic pain and/or infertility.” Although it is a common cause of CPP and dysmenorrhea, it is also a common incidental finding in asymptomatic women. Therefore, it is imperative that a detailed history and examination are undertaken even in a woman who has previously been diagnosed with endometriosis, as it may not be the sole cause of, or even related to, her pain.

Endometriosis is a complex condition, with much still unknown about its etiology, natural history, and incidence. In 1927, Sampson suggested it was due to retrograde menstruation. However, this process can be
demonstrated in more than 90% of women; therefore, a combination of retrograde menstruation and an altered immune environment, allowing implantation and the development of a nerve and blood supply, is currently considered to be the most likely etiology. In order to make a definitive diagnosis of endometriosis, direct visualization of ectopic endometrial implants must occur, preferably with biopsy and histologic confirmation.

The prevalence of endometriosis is difficult to establish, as the vast majority of implants are in the pelvic cavity (although extrapelvic disease does occur) and not every woman will have a laparoscopy or laparotomy. Clinical presentation can be variable (Table 64.9), and to confuse matters further, the extent of disease seen at laparoscopy correlates poorly with the severity of symptoms. There remains considerable debate as to how endometriosis causes pain. However, increasing evidence is appearing for peripheral and central nervous system involvement and musculoskeletal factors in addition to the more traditionally considered roles of inflammation and fibrosis from the lesions themselves.

CPP, chronic pelvic pain.

Although laparoscopy and lesion histology is the criterion standard diagnostic test, current guidelines recommend that if the history and clinical examination are suggestive of endometriosis, a definitive diagnosis is not required before commencing empirical treatment. There are a large variety of treatment options currently available for endometriosis, and the appropriate treatment(s) should be decided in discussion with the woman depending on her specific constellation of symptoms and current and future fertility wishes. A full discussion of these options is beyond the
Medical Management of Endometriosis

As with dysmenorrhea, traditionally, NSAIDs have been used to treat pain secondary to endometriosis. However, there is no evidence to suggest that they have any greater effect than placebo. Women need to also be informed of the inhibitory effect of NSAIDs on ovulation when taken midcycle. The enzyme cyclooxygenase-2 (COX-2) is involved in both pain and inflammation, and specific COX-2 inhibitors have shown promising results in human studies of endometriosis-related pain. However, because of concerns over the safety of this class of drugs, they cannot currently be recommended.

The majority of endometriotic tissue is hormonally sensitive, and hormonal suppression has been shown to reduce endometriosis-associated pain. The available hormonal treatments are shown in Table 64.8. They all appear to be equally effective at controlling endometriosis-related pain but have differing adverse effect profiles. In general, however, symptoms return over time after stopping the treatment. For example, in one study, the median time to recurrence of pain was 6.1 months after stopping danazol and 5.2 months after a GnRH analogue.

Over recent years, it has become apparent that endometriotic deposits express aromatase and are thus able to synthesize estradiol, possibly explaining why some women continue to have symptoms while in a hypoestrogenic state. Recent small trials of nonsteroidal aromatase inhibitors (AIs) in combination with hormonal treatments have shown promising results, especially as the women concerned were refractory to other treatments. AI, such as anastrazole and letrozole, are used in the treatment of postmenopausal women with estrogen-sensitive breast cancers and are known to have a mild adverse effect profile, although, as with GnRH analogues, there are concerns about loss of BMD.

Surgical Management of Endometriosis

As is apparent from the discussion of medical treatments, these options
only keep the disease suppressed but do not affect a cure; once treatment is stopped, symptoms may recur. Complete surgical excision of disease can be performed and has been shown to significantly reduce pain scores, improve sexual function, and improve quality of life. In one series, for example, 67% of women reported an improvement following surgery, 8% felt their symptoms to be unchanged, 25% were worse, but only 33% required further surgery during the 5-year follow-up period. However, particularly with deeply infiltrating endometriosis (DIE), there are significant risks associated with surgery (including bowel perforation, fistula formation, and ureteric damage), and this should therefore only be undertaken at specialist centers by a multidisciplinary team with the necessary expertise. Despite these risks, recent cohort studies do suggest significant improvements in quality of life and pain scores at 1-year follow-up after resection of severe disease at specialized centers. If a diagnostic laparoscopy is being undertaken and mild disease is seen, then current recommendations are that this should be excised or ablated at the time; however, there is no convincing evidence that this offers long-term benefit for those with only mild peritoneal disease. Neither pre- nor postoperative hormonal treatment has been shown to improve outcome measures, including pain scores. However, if retrograde menstruation is an etiologic factor, it makes sense to induce an amenorrheic state in women not currently wishing to conceive. The LNG-IUS has been shown to significantly reduce the risk of recurrence of moderate-severe dysmenorrhea at 1 year and is therefore worth considering.

Novel Concepts in Endometriosis-Associated Pain
Traditionally, endometriosis has been considered to cause pain either due to inflammation, fibrosis or direct infiltration of pelvic nerves. This view is being increasingly challenged as evidence emerges of alterations in both the peripheral and central nervous system and musculoskeletal factors, too. There is also now an awareness that patients want management of their pain and are interested in nonsurgical, nonhormonal treatments. There are no published studies on the use of neuropathic adjuncts in endometriosis-associated pain and only very limited data on either physical or psychological therapies. However, the similarities
increasingly being demonstrated between women with endometriosis-associated pain and those with other chronic pain conditions.\textsuperscript{64} suggest that for those patients refractive to standard treatments or who only show a partial response, it may well be beneficial to consider a more holistic approach, potentially including the use of neuropathic adjuncts and psychological and physical therapies. We would argue that review by a clinician skilled in identifying such factors should be considered before undertaking repeated surgical treatments if pain is the sole indication for surgery.

**Adenomyosis**

Adenomyosis is defined as the presence of endometrial glands and stroma within the myometrium.\textsuperscript{94} Typically, the surrounding myometrium is hypertrophic and hyperplastic. Very little research has been undertaken on adenomyosis specifically, with much of the management being extrapolated from that of endometriosis—a condition with which it has not only many similarities but also a number of differences. Previously, the diagnosis was made histologically after hysterectomy, and it was a common finding in women undergoing hysterectomy for menorrhagia. It is now possible to make the diagnosis radiologically with MRI or TVUS.\textsuperscript{95} In experienced units, these two methods are equally accurate, but MRI is less user-dependent and usually considered to be the investigation of choice. However, a relatively high rate of false positives will be seen, with, for example, uterine contractions being falsely diagnosed as adenomyosis. Without reliable diagnostic criteria, clinical trials of treatments are difficult and a true prevalence is unknown.

There appear to be two distinct forms of the condition: diffuse, where endometrial cells are widely distributed throughout the myometrium, and focal, where a discrete collection of cells are seen, also known as an adenomyoma.\textsuperscript{96} Surgical excision of the former is not possible; thus, treatment options are limited to either medical management or hysterectomy. Although some cases of focal disease may be amenable to surgical management, it is possibly not as responsive to hormonal treatment. As many women undergoing conservative surgery (as opposed to hysterectomy) for this condition will be doing so to maintain their
fertility, it is important that they are fully counseled about complications such as the risk of future uterine rupture before embarking such a procedure. In a similar manner to fibroids, it has been suggested that it might be possible to embolize or use focused US to ablate adenomyotic tissue. Preliminary results from these therapies are promising, but substantially more research still needs to be undertaken in this area.

Adenomyosis causes menorrhagia, metrorrhagia, dysmenorrhea, and infertility and is thought to occur secondary to a breach in the integrity of the myometrial–endometrial junction, such as occurs in pregnancy, especially those complicated by abnormal placentation and surgery (including ERPC/SMoM and cesarean section), or after blunt trauma to the abdomen. As with endometriosis, the ectopic endometrial tissue is hormone-sensitive and has been shown to express aromatase. GnRH agonists, danazol, AIs, and the LNG-IUS have all been shown to be successful in the treatment of adenomyosis, although all have side effects. Perhaps, the most promising of these is the LNG-IUS because of its mild adverse effect profile and apparent tolerability by patients.

Adhesions
Adhesions are a common finding in women with and without pelvic pain. They are formed after trauma to the visceral or parietal peritoneum and so can be secondary to surgery, infection, and endometriosis. Between 70% and 85% are thought to occur after surgery and are thus iatrogenic. The relationship between adhesions and pain is still unclear, with only limited data relating their presence causally to pain. Traditionally, surgery has been performed to divide adhesions (adhesiolysis); however, this is associated with a high rate of complications (~4%) including bowel injury, and meta-analyses suggest little long-term benefit. Therefore, although adhesiolysis cannot be recommended in general as a treatment for CPP, in those women who have severe adhesions involving the bowel, it may be successful but associated with significant risk.

There are, however, two other distinct cases where adhesions are known to cause pain: trapped ovary syndrome and ovarian remnant syndrome. In the former, a retained ovary becomes trapped in dense adhesions after hysterectomy, whereas in the latter, a small piece of ovary is
unintentionally left behind at oophorectomy and again becomes trapped in adhesions. In both cases, the pain is cyclical and can be suppressed with a GnRH analogue. It may be possible to surgically remove the ovary/remnant; however, with distorted anatomy, this is not without risk, and some women may prefer to remain on the combination of GnRH analogue and low-dose HRT instead.\textsuperscript{24}

**Chronic Pelvic Inflammatory Disease**

Chronic inflammation with scar tissue and distortion of pelvic structures can be seen in women who have had repeated episodes of acute PID or those in whom infection has been asymptomatic initially (as is frequently the case with Chlamydia). US may demonstrate features of chronic salpingitis, such as dilated fallopian tubes and poor mobility,\textsuperscript{107} and severe adhesions may be seen at laparoscopy. These can be divided surgically, especially if they are causing anatomical distortion. However, although this may improve fertility as has been discussed, it may not have any effect on the pain. Chronic inflammation can cause sensitization of peripheral nerves, and therefore, a trial of a neuropathic adjunct may be indicated, especially if there are other symptoms suggesting a generalized visceral hypersensitivity syndrome. An exploration of the woman’s attitudes to and beliefs about her pain may be beneficial. Guilt about earlier sexual behavior or concerns about current or future fertility may be revealed.

**Pelvic Venous Congestion**

Pelvic venous congestion syndrome is described as CPP arising from dilated and refluxing pelvic veins and is often proposed as a cause of pelvic pain with menstrual exacerbation. However, there is little convincing data supporting a causative relationship. Research in this area is hampered by the lack of consistent diagnostic criteria for the condition and the failure of the majority of studies to exclude other causes of CPP.\textsuperscript{108} Although dilated pelvic veins are found in ~30\% of women with CPP,\textsuperscript{109,110} they are also found in at least 10\% of the general population with increasing incidence in multiparous women. Proposed treatments for the syndrome would in many cases be effective for other pathologies associated with CPP (including continuous medroxyprogesterone
acetate and hysterectomy and bilateral oophorectomy). However, a more specific treatment, embolization of incompetent pelvic veins, does appear to provide symptomatic relief, although the authors of a recent systematic review note that the quality of the evidence is low. This is therefore an area where more research is needed.

**GASTROINTESTINAL FACTORS IN CHRONIC PELVIC PAIN**

As with acute pelvic pain, CPP secondary to a nongynecologic cause can present to gynecologists because of the site of the pain and its presumed etiology. It is therefore important that a detailed history of bowel function and its relation to and/or effect on the pain is taken. The gastrointestinal (GI) tract can be both the initial pain generator and the cause of secondary symptoms in a visceral hypersensitivity syndrome. IBS and constipation are very common and may be provoked by other conditions or medication and thus need to always be borne in mind. Deep endometriosis frequently presents with bowel symptoms; however, it is important to remember that similar symptoms can be the presenting features of GI tract malignancies and inflammatory bowel disease and to fully investigate any “red flag” symptoms, such as rectal bleeding or unexplained weight loss.

**Irritable Bowel Syndrome**

IBS is a functional disorder of the GI tract and is discussed in detail in Chapter 63. We have mentioned it here, however, to draw attention to the fact that cyclical changes in the severity of symptoms are seen. Healthy, pain-free women frequently show alterations in their bowel habit around menstruation, possibly secondary to prostaglandin release, and this is often amplified in women with IBS. It has been shown that rectal sensitivity to balloon distension varies with the menstrual cycle in women with IBS but not in those without. Interestingly, in women whose IBS is clearly cyclical even without evidence of other gynecologic symptoms, the use of GnRH analogue treatment to suppress endogenous hormone production has been shown to be successful.

**Constipation**
Constipation is a common cause of pelvic pain and can be easily avoided. It may be due to poor diet, lack of exercise, or reduced fluid intake; however, it is frequently iatrogenic, secondary to opioid use. It is therefore important to emphasize the need for fluid intake and dietary fiber as well as prescribing laxatives whenever such analgesics are required.

**UROLOGIC FACTORS IN CHRONIC PELVIC PAIN**

Pain originating in the urinary tract will also often be pelvic and therefore present to gynecologists. Again, symptoms may be cyclical or associated with symptoms in other organs. This coexistence of symptoms and the common embryologic origin of the structures involved have led to the suggestion of a “urogenital pain syndrome,” including some or all of IC/BPS, vulvodynia, urethral syndrome, coccyodynia, and perineal pain.117

**Interstitial Cystitis/Bladder Pain Syndrome**

Pelvic pain experienced as arising from the bladder and associated with urinary symptoms, including urgency and frequency, was known as interstitial cystitis (IC).118 However, there is ongoing debate as to the appropriateness of this terminology given the lack of evidence for bladder inflammation (cystitis) in many patients and the clear similarities with other chronic pain conditions. Alternative terminology has been proposed including bladder pain syndrome (BPS) and painful bladder syndrome (PBS).29,119–121 A full description of these discussions and the advantages/disadvantages of each name are beyond the scope of this chapter. Here, we use IC/BPS in line with the American Urological Society121; however, we acknowledge that this is not the standard throughout the world and that there is a current push from some areas, including patient groups, to change back to IC due to issues with coding, funding, and recognition of the condition.

Until relatively recently, urologic pelvic pain had received little research funding, and progress toward both our understanding of the problem and potential novel treatments was very slow. However, there is now a large program of research in this area (Multidisciplinary Approach to the Study of Chronic Pelvic Pain [MAPP]; http://www.mappnetwork.org) that will
potentially completely change the field, hopefully with significant patient benefit. One arm of this program addresses phenotyping with the aim of being better able to subtype patients with IC/BPS. However, until this program completes, current practice tends toward subdividing based on the presence or absence of Hunner lesions.\textsuperscript{118}

Both the presentation and the impact of the condition on women’s lives are very variable, and thus, treatment needs to be individualized. In general, however, multidisciplinary treatment regimens are likely to be most successful, including a combination of dietary modification, pharmacologic agents such as pentosan polysulfate sodium, and physical therapy. A key feature of the condition is the variation over time with both predictable and unpredictable flares in pain and associated urologic symptoms.\textsuperscript{122} With the exception of sexual activity, triggers for flares appear to be relatively individual,\textsuperscript{123} suggesting that it may be worth the woman keeping a detailed diary for a number of months with the aim of identifying her triggers and then aiming to either avoid these or learn strategies to manage the associated flare.

**Urethral Syndrome**

Urethral syndrome is also characterized by urinary urgency, frequency, dysuria, and suprapubic/lower back pain without any obvious cause. Dysfunction of the pelvic floor may be involved as success is often achieved with skeletal muscle relaxants or electrostimulation and biofeedback. Because of similarities in presentation to prostatitis in men, a chronic low-grade infection of the paraurethral glands has been suggested to be a possible cause. If tenderness can be elicited just lateral to the urethra through the anterior vaginal wall, this may be a possibility, and a prolonged course of antibiotics may be justified.\textsuperscript{124}

**MUSCULOSKELETAL FACTORS IN CHRONIC PELVIC PAIN**

Dysfunction in the musculoskeletal system can be both the primary cause of CPP or secondary to pathology elsewhere. Although it may not be the first thought in a gynecologic consultation, it is surprisingly common, with one retrospective study suggesting that 75\% of 132 nonconsecutive
patients with CPP had musculoskeletal abnormalities. Importantly, we are increasingly realizing that musculoskeletal factors coexist with other pathologies (e.g., endometriosis) and a failure to identify them may contribute to the poor response often seen to treatment of the peripheral pathology. It is therefore important that the musculoskeletal system is appropriately assessed in all women with CPP and any issues dealt with in order that a good response to treatment occurs. A detailed description of appropriate assessment is not possible here but can be found elsewhere. Some of the important musculoskeletal factors to be borne in mind are discussed briefly in the following text and in more detail in Chapters 35 and 36.

**Fibromyalgia**
Many women with fibromyalgia complain of pain in their lower back and pelvis with two of the tender points that were previously used to diagnose the condition being in the gluteal muscles in the upper outer quadrants of the buttocks. Pain here can easily be confused with the lower back pain often described by women with CPP. Furthermore, fibromyalgia may have cyclical exacerbations, and therefore, symptoms are often assigned to a gynecologic cause.

**Trigger Points**
Trigger points are frequently found in abdominal and pelvic floor muscles causing or exacerbating both CPP and dyspareunia. These can be the primary pain generator or can be secondary, either to other musculoskeletal abnormalities such as sacroiliac joint (SIJ) dysfunction or to repeated episodes of visceral pain as occurs in adenomyosis. The continued presence of a trigger point can explain a partial response to treatment of the underlying pathology and is an indication for a careful reexamination of the patient at her follow-up visit.

**Pelvic Floor Abnormalities**
In women, pelvic floor abnormalities can be secondary to postural alterations caused by pain or other musculoskeletal conditions, visceromuscular referral patterns, or trauma as occurs during childbirth or
certain surgical procedures. Unilateral or bilateral pelvic floor abnormalities can cause CPP, dyspareunia (with secondary vaginismus), perineal pain, and dyschezia and yet are frequently overlooked. In a woman with dyspareunia, demonstrating that pressure on a tender, tense pelvic floor muscle recreates her pain during intercourse can help toward relieving concerns about her reproductive organs. Good response to treatment is frequently obtained from physiotherapy. Recent studies on the injection of botulinum toxin into the pelvic floor muscles have shown some promise. However, it would be prudent to combine any such treatment with a physiotherapy assessment and exercise program to ensure the underlying cause of the spasm is addressed and that the dysfunction does not recur.

**Hernia**
Acute obstruction of a hernia will cause acute pain; however, a number of different types of hernias can also be responsible for CPP, although the exact mechanism by which they cause pain is debated. Most commonly, these include inguinal, femoral, and obturator hernias. Imaging modalities such as computed tomography or MRI may be useful in making the diagnosis if a clear examination finding is not present. Surgical repair is usually the recommended treatment, and this can either be open or laparoscopic with both having their own advantages and disadvantages.

**Sacroiliac Joint Pain**
The SIJ is the largest axial joint in the body. A network of muscles support the joint and deliver regional muscular forces to the pelvic bones. The associated ligaments are weaker in women to allow mobility and facilitate parturition. The innervation of the joint is complex and still debated but probably includes fibers from L4 to S4. It is widely accepted that SIJ dysfunction causes lower back pain, and pelvic pain appears to occur in a significant percent of patients. In general, the pain is unilateral (unless both joints are affected) and below the L5 spinous process, sometimes radiating down to the foot. SIJ dysfunction and pain can occur for a number of reasons, including pregnancy, trauma, and prolonged bending and lifting. A number of possible treatments exist with varying degrees of
success. Conservative options include physiotherapy and joint stabilization which have been shown to be successful in some series. Intra-articular joint injections under radiologic guidance have been shown to produce good to excellent pain relief in most studies. Surgical fusion of the joint may be required in some cases, although adequately powered, prospective studies are lacking.

NEUROLOGIC FACTORS IN CHRONIC PELVIC PAIN
It has already been mentioned that in many conditions causing pelvic pain, secondary sensitization of the peripheral or central nervous system can occur, perpetuating or increasing pain and extending referral areas and involving other organ systems. There are also situations where damage to a nerve or nerve roots can be the primary cause of the pain. The specific nerve(s) involved will determine the precise distribution of pain and associated symptoms; however, a number of general features are usually associated with a neuropathy. Classically, the pain is shooting, burning, or stabbing in nature. Initially at least, the pain will be in a clearly defined area, although secondary changes may blur this. Trophic skin changes may also be present. Symptoms may be exacerbated or relieved by movements which stretch/relax the nerve or increase/decrease compression by surrounding structures. Local anesthetic blockade of the specific nerve may relieve the pain entirely; however, it is also possible that pain can be worsened by this procedure perhaps because the injected fluid volume worsens compression. Because of the complex innervation of the pelvis, there are many different neuropathies that can occur. We discuss in detail here only the most common, pudendal neuropathy; however, a careful consideration of innervation patterns may point to an unusual neuropathy in a woman whose symptoms cannot otherwise be explained. We also consider neuropathies secondary to a Pfannenstiel incision because of the prevalence of this procedure in obstetrics and gynecology. More information on other pelvic neuropathies can be found elsewhere.

Pudendal Neuropathy
The pudendal nerve arises from the sacral plexus in the ventral rami of
sacral nerves 2, 3, and 4 (S2–S4) and exits the pelvis through the greater sciatic foramen between the piriformis and coccygeus muscles. It then winds around the sacrospinous ligament and passes through Alcock’s canal to enter the pelvis again through the lesser sciatic foramen before branching into clitoral, superficial perineal, deep perineal, and posterior rectal branches (Fig. 64.2). It can be seen that there are many points where nerve entrapment could occur and many situations in which this nerve could be damaged including surgery and childbirth.

FIGURE 64.2 Course of the pudendal nerve.

Pain is felt in the distribution of the nerve and is exacerbated by sitting and relieved to a variable extent by standing or lying on the unaffected side. Perineal sensation is usually preserved as is muscle tone, although pain may be recreated during rectal examination. Local anesthetic nerve blocks may be successful and can also aid with diagnosis; however, they may have to be repeated regularly. Although surgical decompression may be an option, damage to the nerve may not be reversible.

Neuropathy Secondary to a Pfannenstiel Incision
A Pfannenstiel incision is a low transverse abdominal incision which was first described in 1900. It is commonly used for cesarean sections and many benign gynecologic procedures but more rarely in general surgery. Aesthetically, it is more pleasing to the woman, being below the “bikini”
line. It also has a number of advantages over other abdominal incisions, including lower incisional hernia rates, fewer wound infections, less hematoma formation, and less direct postoperative pain. However, the ilioinguinal and iliohypogastric nerves have a superficial course and are relatively easily injured by a Pfannenstiel incision.\textsuperscript{137} In the literature, the reported incidence of nerve damage after a Pfannenstiel incision is 3.7\%\textsuperscript{138}; however, the true incidence may well be higher as many cases are not reported or diagnosed. Typically, the pain is burning or lancinating near the incision and radiates to the area supplied by the nerve with associated sensory impairment. The nerves can be damaged in a number of ways: direct nerve trauma with neuroma formation, suture incorporation of the nerve during fascial closure, and constriction of the nerve during scar or wound healing.\textsuperscript{138} Optimal treatment is still unclear. In many cases, the symptoms resolve over time without treatment. The nerve can be blocked with local anesthetic, which will at least confirm the diagnosis even if the pain is not entirely removed. In some cases, surgery is required; even in these cases, however, long-term recovery is good.\textsuperscript{138} Education is clearly required, about both careful surgical techniques to reduce the incidence of nerve entrapment and the presentation, such that diagnosis and treatment occur more rapidly.

\textbf{Dyspareunia}

\textbf{OVERVIEW}

Dyspareunia is defined as genital pain just before, during, or after sexual intercourse. It can be subdivided into primary, having always occurred in association with intercourse, and secondary, having developed after a period of pain-free sexual activity. Additionally, it can also be divided into superficial, with pain only on entry, and deep, thought to be associated with organic pathology. As with so many pain conditions, these subdivisions are overly simplistic and frequently clinically unhelpful. Whatever the initial trigger for an episode of painful intercourse, fear of further pain can set up a cycle of muscular tension and vaginismus (Fig. 64.3), ensuring that future episodes will be painful, reinforcing that fear. Furthermore, the psychological consequences of an inability to have pain-
free intercourse on both the woman and her partner should not be underestimated. Psychological morbidity can worsen the experience. However, dyspareunia should not be assumed to be psychological in origin just because no pathology is evident at initial examination.

FIGURE 64.3 Cycle of vaginismus. (Adapted from Butcher J. Female sexual problems II: sexual pain and sexual fears. BMJ 1999;318[7176]:110–112, with permission from BMJ Publishing Group Ltd.)

Possible causes of dyspareunia are listed in Table 64.10. Superficial vulval pain is a common cause of dyspareunia and is discussed in detail in the following section. If superficial dyspareunia occurs after childbirth, time should be taken to explore the woman’s beliefs and to reassure her. Occasionally, hypoestrogenism may be the cause, but it is very rare for surgery to be required in these cases. Deep dyspareunia can be secondary to many abdominopelvic pathologies but is also often positional. If a woman complains of pain on contact with the cervix, this may be due to inadequate arousal and failure of the upper vagina to balloon and therefore move the cervix out of reach.\(^\text{139}\) Whatever the initial cause of pain, vaginismus is a frequent sequela and is therefore discussed here in more detail.

Vaginismus

The term vaginismus was first used in 1862 and is now thought to be one of the commonest female sexual problems. The true prevalence is unknown; however, it is identified in 10% to 20% of women requesting help for sexual dysfunction. Definitions vary as to whether spasm of the muscles surrounding the lower third of the vagina is included or whether it is difficulty in allowing vaginal entry, often associated with involuntary pelvic muscle contraction. Although pain with intercourse is usually the presenting feature, there is often fear of any object being placed in the vagina; thus, tampons are not used and gynecologic examinations not well tolerated. Some women are so fearful that they avoid smear tests and other essential health checks.

Vaginismus is thought to occur as a conditioned response secondary to adverse physical or psychological stimuli. Early traumatic experiences are thought to predispose to the condition, including traumatic sexual experiences, unsympathetic gynecologic examinations, and assault, although a history of abuse (physical or sexual) is not usually associated with vaginismus. A background of religious orthodoxy has, however, been shown to be associated. Psychosexual fantasies often coexist such as that the vagina is too small to accommodate a penis or that it is a delicate, fragile organ which will be damaged during intercourse. These can arise secondary to comments made inadvertently, for example, at the time of episiotomy repair, and clinicians should therefore think carefully about what is said at vulnerable times. Male sexual dysfunction can develop as a consequence of vaginismus, although the reverse can also occur with vaginismus arising secondary to a male partner’s impotence.

Treatment should be individualized to the specific woman or couple and her or their desires. For most women, successful vaginal penetrative intercourse and an improved sexual experience for both partners is the aim.
However, in some instances, the woman may not feel comfortable with intercourse even after the vaginismus has resolved. Current guidelines suggest that the basis of treatment should be to enable the woman to become more comfortable with her genitals, followed by graded exposure to different types of vaginal penetration in order to overcome her fear of penetration. At all times during treatment, the woman should feel that she is in control and the extent to which her partner is involved should be her decision, although involvement should be encouraged. For some couples, fertility is the ultimate aim and an appropriate referral may need to be made.

A number of different approaches are described, one of which is a combination of behavioral and desensitization exercises using relaxation and graded vaginal trainers. Education is also important, and there may be a need for exploration of fantasies before they can be dispelled. Hypnotherapy, physiotherapy using biofeedback, amitriptyline, and local injections with botulinum toxin have all been reported to have good results. If physical causes have been excluded, treatment is usually highly successful with some authors reporting up to 100% success.

**Vulval Pain Syndromes**

Although not truly pelvic pain, the vulval pain syndromes (vulvodynia and vestibulodynia) exhibit many features which are similar to CPP, and the two can coexist in a urogenital pain syndrome. Much of what has already been discussed in relation to the assessment and multidisciplinary management of CPP is just as relevant for vulval pain. It is therefore appropriate to include a brief overview of these conditions in a chapter devoted to pelvic pain in females.

As with CPP, there is frequently a delay between presentation and diagnosis, and many unsuccessful, often inappropriate, and sometimes damaging treatments may have already been tried. It is therefore not surprising that many of these women report anger and frustration and that psychological morbidity is more prevalent than in asymptomatic women. There is no evidence to suggest that these psychological features are a cause rather than a consequence of the conditions.
vulval pain syndromes are almost invariably associated with dyspareunia in sexually active women, sexual dysfunction is also common, with secondary problems such as vaginismus and anorgasmia developing. However, there is no evidence of higher rates of previous sexual or physical abuse in these women as compared to healthy controls.145

The vulval pain syndromes were first described in the late 1800s; however, there has been confusion surrounding their nomenclature, etiology, and management ever since. Further difficulties occur as vulval pain can present to gynecologists, dermatologists, or GUM specialists, each of whom historically had different preferred treatments. The International Society for the Study of Vulvovaginal Disease (ISSVD), a multispecialty society, is working to redress this and has recently reclassified these syndromes as either vulvodynia (which can be localized or generalized, and provoked or unprovoked) or vestibulodynia.146 These terms replace dysesthetic vulvodynia and vestibulitis. Many women will, however, present with symptoms of both vulvar and vestibular pain. The ISSVD defines vulvodynia as “vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder.”146 The term vestibulodynia has replaced vestibulitis as there is no evidence of inflammation and is defined by the ISSVD as “provoked vulval dysesthesia localized to the vestibule.”146 Pain can also occur on urination and defecation. It should be noted, however, that the IASP use different terminologies, aiming to bring the conditions in line with other pain syndromes (e.g., vulval pain syndrome).29

By definition, a thorough history and examination with appropriate investigations should be undertaken to exclude other causes of vulval pain, such as those listed in Table 64.11, before a label of a vulval pain syndrome is given. To date, the true prevalence remains unknown, with the large reported variation in numbers of women attending clinics likely due to variation in the type of clinic and known interests of the clinicians. However, as more specialized vulval clinics become established, the number of referrals for vulval pain syndromes continues to increase. The etiology remains unknown but is likely to be multifactorial.143 Although it is unlikely that irritation from topical agents (e.g., antifungal agents,
bubble bath) is the precipitating factor, their use may well exacerbate symptoms and should be discouraged. Examination will reveal either focal or generalized pain in response to light touch with a cotton-tipped swab but is otherwise unremarkable.

</table>

A number of treatments have been shown to be successful; however, treatment needs to be carefully tailored to the individual patient, and a multidisciplinary approach is usually of benefit. Basic advice on vulval care should be given, recommending careful hygiene but with avoidance of perfumed products and overdrying. Although topical products in general should be avoided, fragrance-free emollient creams can be soothing and local anesthetic gel such as topical lidocaine can be particularly useful prior to intercourse acting as both a pain reliever and a lubricant. There is no evidence to suggest that topical corticosteroids, antifungal preparations, or testosterone are helpful and only minimal evidence to support the use of topical estrogens. Recent work has suggested a
central component to vulvodynia,\textsuperscript{147,148} which may explain the success of drugs such as amitriptyline, gabapentin, pregabalin, and lamotrigine in the condition.\textsuperscript{149–151} There is also recent evidence suggesting topical gabapentin may be helpful.\textsuperscript{152}

Whether tension in the pelvic floor muscles (a common finding in women with vulvodynia) is involved in perpetuating the pain remains unknown; however, physiotherapists can be very successful in treating vulval pain syndromes. In one series, 71\% of women had a greater than 50\% improvement in symptoms, 62\% experienced improvement in sexual functioning, and 50\% had an increase in quality of life.\textsuperscript{153}

Surgery should be considered as a last resort. However, it can be successful in a subgroup of women and should not be dismissed entirely. In general, it appears to be less successful in women with coexisting vaginismus and more successful in women who had a good response to lidocaine gel preoperatively. Postoperative psychosexual counseling and the use of dilators and physical therapy have been shown to improve outcome.\textsuperscript{146}

As with other chronic pain syndromes, the value of patient support groups, such as the Vulval Pain Society, should not be underestimated as the vulval pain syndromes are a particularly isolating group of disorders. The effect of the conditions on relationships can be devastating and, unlike conditions such as endometriosis which are coming more and more into the public’s awareness, vulval pain is still seen as a taboo subject and not discussed.

**Conclusion**

Research in many fields over recent years has led to an improved understanding of both the basic science of visceral pain and of many of the conditions causing pelvic pain. However, time to listen to and explore a woman’s story as well as to perform a careful examination must be invested in order to make the best use of this knowledge. Sociologic research has identified the recurrent theme of the social meaninglessness of pain without a medical diagnosis\textsuperscript{154} and encouraged us to consider chronic pain in a biopsychosociocultural context.\textsuperscript{155} The more recent move
toward multidisciplinary CPP clinics is a positive step forward in these respects and acknowledges that the secondary consequences of the pain (be they musculoskeletal, psychological, gastrointestinal, sexual, etc.) must also be managed in order to facilitate a full recovery.156

References

This chapter is about pain perceived to be in the male pelvis—the pelvic pain syndromes. For the purpose of this chapter, the pelvis is considered as the anatomical bony pelvis and the structures both within and adjacent to it, including the male external genitalia, nervous system structures, and soft tissue/muscular structures, that is, the pelvis in its broadest sense.

Although this chapter focuses primarily on the male urogenital pelvic pain syndromes, the importance of other systems, particularly the musculoskeletal, nervous, and other viscera, is emphasized when appropriate.

There are many well-recognized, well-defined pathologies that may result in pain perceived within the male urogenital system, such as infections of the organs; infiltration of somatic, visceral, and nervous tissue by cancer; and referred sensations from the musculoskeletal system. However, for less defined pathologies, the mechanisms underlying the pains have been less widely appreciated outside of pain medicine. The mechanisms for this second group, which is probably the majority of male pelvic pain patients, involve neurologic mechanisms—in particular, central sensitization that may involve the whole neuraxis. These are the primary chronic pain syndromes.

The latest classification approaches have taken this dichotomy of mechanisms into account. To emphasize the differences, those conditions where the main mechanisms are related to central sensitization are known as the pelvic pain syndromes, and they are considered separately from those conditions with ongoing nociceptive, acute pain mechanisms, such as those due to chronic infection. Pelvic pain syndromes are defined by their symptoms and signs and typically by the presence of sensitization, including visceral hypersensitivity, viscerovisceral hypersensitivity (i.e., cross-organ sensitization), and viscerosomatic hypersensitivity (e.g.,
expanded area of referred sensation and/or increased sensitivity to palpation). Often, an important part of the process of diagnosing the pelvic pain syndromes is excluding other pathologies.

Classification of the pelvic pain syndromes involves terminology, phenotyping, and taxonomy. The phenotype describes the condition in terms of symptoms, signs, and, where possible, mechanisms. Incorporating the phenotype into a hierarchy of phenotypes produces a taxonomy that allows comparisons between phenotypes. This approach enables appropriate prognosis and treatment. The terminology used can be very emotive, and careful description of the meaning of the terms is often required. The classification of pelvic urogenital pain has been rapidly evolving over the past 15 years and is likely to continue to do so.\textsuperscript{1–9} This ongoing change in classification not only reflects our increasing knowledge but also has caused problems for research and evidence-based treatment. The classification will be covered in depth as it is the key to understanding male pelvic pain syndromes.

The central nervous system mechanisms of central sensitization and the psychological responses that result in the chronic pain syndrome are covered in other chapters within this book; those processes that are specific to urogenital pain are expanded on in this chapter. There are some obvious differences between the male and female urogenital systems that will result in specific pain syndromes; however, it is important to recognize that there is much overlap as well. Those differences due to gender and sex are covered in Chapter 7.

This chapter supports that in most men with chronic pain perceived in the pelvic organs, the cause of the pain is not often due to classical pathologies of infection or infiltration but more commonly due to chronic pain mechanisms involving a number of systems with referred pain, sensory and functional consequences (e.g., urinary and fecal incontinence, urge and urgency, urinary hesitance, impotence), and chronic pain psychological responses.\textsuperscript{8}

**Taxonomy and Phenotyping Chronic Pelvic Pain**

A realization has occurred that pain perceived within the pelvis may be
associated with classical pathology of the pelvic structures or that it may result secondary to central nervous system pain mechanisms. It is the latter conditions that this chapter primarily concentrates on.

CLASSICAL PATHOLOGIES

Classical pathologies include infection, inflammation, degeneration, neoplastic, and autoimmune mechanisms of any of the pelvic or adjacent pelvic structures (referred pain). In the case of classical pathology, chronic persistent pain is the result of ongoing local pathology, persistent nociceptor activation with peripheral sensitization, and possibly a central sensitization process. Treatment will primarily be focused on managing the underlying pathology and the use of analgesics where required. Removing the peripheral cause should resolve the pain.

PELVIC PAIN SYNDROMES AND NONPELVIC PAIN SYNDROMES

Most of the recent attempts at classification, taxonomy, and phenotyping have tried to separate out the classical pathologies from those conditions without classical pathology that have become known as the pelvic pain syndromes. The pelvic pain syndromes are the conditions where there is no peripheral pathology maintaining the pain experience (peripheral stimuli may however maintain the central sensitization). In its attempt to separate out the pelvic pain syndromes from those with a nociceptive cause, the European Association of Urology (EAU) in their 2004 classification system called those conditions associated with classical pathology as “well-defined” conditions and the European Society for the Study of Interstitial Cystitis (ESSIC) called them “confusable diseases.” Both of those terms have a disadvantage. The term well-defined suggests that the pain syndromes are poorly defined; however, as an understanding of chronic pain mechanisms (including visceral pain mechanisms) and central sensitization develops, this is clearly not the case. ESSIC used the term confusable to separate out the pain syndromes from those conditions that they might be confused with, a very difficult concept. In future classifications, one way forward is that chronic pelvic urogenital pain syndromes will become a differential diagnosis with the classical
pathologies, and the taxonomy will be divided into pelvic pain syndromes and nonpelvic pain syndromes.\textsuperscript{11} The World Health Authority working with the International Association for Pain in ICD11 is using the term primary chronic pain. The emphasis is thus on the pelvic pain syndromes, which is probably correct as in most individuals classical disease processes are not present. Table 65.1 illustrates the division of chronic pelvic pain into pain syndromes and nonpelvic pain syndromes. Table 65.2 provides the definitions for chronic pelvic pain and the pelvic pain syndromes. The latest World Health Organization International Classification of Diseases, 11th Revision, recognizes pain as a condition in its own right, although uses some outdated terminology. The International Continence Society has tried by working with other published guidelines to achieve international consensus. However, their “Standard for Terminology” did not have any pain medicine representation and reverted to older terminology in places.\textsuperscript{12} It will take a lot more time for consensus to be reached.

**TABLE 65.2 Definitions of Pelvic Pain**

- Chronic pelvic pain is nonmalignant pain perceived in structures related to the pelvis of either men or women. In the case of documented nociceptive pain that becomes chronic, the pain must have been continuous or recurrent for at least 6 months. If nonacute pain mechanisms and central sensitization mechanisms are well documented, then the pain may be regarded as chronic, irrespective of the time period. In all cases, there often are associated negative cognitive, behavioral, sexual, and emotional consequences.\(^3,11\)
- Pelvic pain syndrome is the occurrence of persistent or recurrent episodic pelvic pain associated with symptoms suggestive of lower urinary tract, sexual, bowel, or gynecologic dysfunction. There is no proven infection or other obvious pathology.\(^3,11\)

This chapter uses the EAU and International Association for the Study of Pain (IASP) accepted classifications, which the author was involved in.

**Male Urogenital Pain Syndromes**

3449
Traditionally, pelvic pain conditions would be classified into those of the male, female, or both. This approach is currently being reconsidered, as the mechanisms discussed earlier may be common to both sexes with the only difference being the sex organ that the pain is perceived in. However, as there has been a lot of research looking at the end-organ pain syndromes and their treatment, this is summarized in the following text as relevant for the male.

MALE-SPECIFIC PELVIC PAIN SYNDROMES

The unique male pelvic pain syndromes are those where the pain is perceived in the male sex organs. Table 65.3 summarizes these conditions. The definitions serve to emphasize that classical pathologies are absent.

**TABLE 65.3 Phenotype Classification of the Male Pelvic Urogenital Pain Syndromes**

- Penile pain syndrome is the occurrence of pain within the penis that is not primarily in the urethra, with the absence of proven infection or other obvious pathology.\(^3,11\)
- Prostate pain syndrome is the occurrence of persistent or recurrent episodic prostate pain, which is associated with symptoms suggestive of urinary tract and/or sexual dysfunction. There is no proven infection or other obvious pathology.\(^3,11\) (This definition of prostate pain syndrome was adapted from the National Institutes of Health [NIH] consensus definition and classification of prostatitis\(^4\) and includes those conditions that they term chronic pelvic pain syndrome. Using their classification system, prostate pain syndrome may be further subdivided into type A, inflammatory, and type B, noninflammatory.)
- Scrotal pain syndrome is the occurrence of persistent or recurrent episodic scrotal pain that is associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven epididymo-orchitis or other obvious pathology.\(^3,11\)
- Testicular pain syndrome is the occurrence of persistent or recurrent episodic testicular pain localized to the testis on examination that is associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven epididymo-orchitis or other obvious pathology. (This is a more specific definition than scrotal pain syndrome.)\(^3,11\)
- Postvasectomy pain syndrome is a scrotal pain syndrome that follows vasectomy.\(^3,11\)
- Epididymal pain syndrome is the occurrence of persistent or recurrent episodic pain localized to the epididymis on examination that is associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven epididymo-orchitis or other obvious pathology (more specific definition than scrotal pain syndrome).\(^3,11\)

**SUBCLASSIFICATION OF THE PELVIC PAIN SYNDROMES BY ORGAN**
Much discussion has been had about whether it is appropriate to divide the pelvic pain syndromes by the end organ that the pain is perceived in. Many would rather maintain a more generic approach and keep to the term pelvic pain syndrome to cover all pains perceived within the pelvis and not associated with a classical pathology. The EAU approach (see Table 65.1) uses a progressive step-by-step approach to classification. That is, classification starts at the left end of the table if pain is perceived within the pelvis or the external sex organs. Further subclassification only occurs if there are distinct localizing factors within an end organ. Such an approach to taxonomy is very similar to that used to classify life and the animal and plant kingdoms. For instance, we would progress from animal to mammal to elephant only as the evidence allowed. The primary localizing factor for pelvic pain is pain produced by local physical stimulation, such as palpation. If an end organ is clearly associated with the area of perceived pain, then the pain may be labeled with that end organ name as in Table 65.1. If more than one organ is deemed to be involved, then either two names may be given to the condition, or it may be more appropriate to consider the pain in more generic terms as a pelvic pain syndrome.

**THE IMPORTANCE OF TAXONOMY AND PHENOTYPING**

The mentioned taxonomy (hierarchical classification of conditions) and phenotyping (identifying of the physical characteristics—symptoms and signs—and mechanisms of the diseases within the taxonomy) is important. Appropriate taxonomy and phenotyping is a prerequisite for epidemiology, diagnosis, management, and prognosis. With traditional management of pelvic pain, there has been a tendency to use inappropriate treatments with inappropriate expectations; the result is increased distress and a worse prognosis.8

Currently, it is not unusual for inappropriate treatments to be instigated due to a failure to understand the pain syndromes.1 For example, classic mismanagement would be the recurrent use of antibiotics or the use of surgery for the complaint of pain. Whereas surgery may have a role for functional reasons (e.g., incontinence), there is a serious debate about its
use for pain management. Appropriate taxonomy and phenotyping allows appropriate expectation of both the patient and those providing medical care. Unfortunately, many patients and doctors have inappropriate expectations for treatments aimed at cure. This produces distress, and the increased distress is associated with a worse prognosis.\textsuperscript{13,14}

An appropriate taxonomy and phenotyping encourages interdisciplinary and multidisciplinary management. In the case of most pelvic pain syndromes, where there may be a reduction in symptoms with appropriate treatment, cure is often not possible. The best outcomes in terms of reduced disability and improved quality of life will come from a symptom management approach involving multiple interdisciplinary teams (e.g., urology, pain medicine, neurology) and multiple members of the team (e.g., nurses, doctors, psychologists, physiotherapists). This is a standard approach for other pain syndromes and should be the standard approach for the urogenital/pelvic pain syndromes.

\section*{Epidemiology}

Epidemiology requires a clear understanding of the disease that is being studied. Unfortunately, as the phenotyping and taxonomy of male pelvic pain is ongoing, clear-cut epidemiologic data for specific pelvic urogenital pain syndromes are not available.

\section*{INCIDENCE/PREVALENCE}

\subsection*{Prostate Pain Syndrome}

Male pain perceived deep within the pelvis is usually labeled as prostatitis despite the absence of infection and, frequently, the absence of inflammation within fluids extracted from the prostate. The National Institutes of Health (NIH) classification\textsuperscript{4} of “prostatitis” includes pain perceived in the prostate without evidence of inflammation or infection and has reinforced this misnomer. Therefore, most of the data relating to pain perceived within the prostate stems from the “prostatitis” literature. As well as pain, these patients often have urinary urge (constant need to void as a result of a sensory disturbance), frequency (secondary to the urge), hesitancy, and poor flow, but they do not have urgency (need to
void because of a fear of incontinence).

Several studies have looked at the demographic distribution of the disease. Prostatitis appears to be more common in men younger than 50 years of age, although there may be a second cohort aged greater than 74 years.\textsuperscript{15–17} The Nickel et al.\textsuperscript{16} study identified 9.7\% of men as having “chronic prostatitis-like” symptoms as defined by the NIH-Chronic Prostatitis Symptom Index. This index includes urinary “irritative” and “obstructive” symptoms as well as measures of quality of life as these are frequently disrupted.\textsuperscript{18}

\textbf{Scrotal Pain Syndrome}

Testicular pain in isolation and without obvious cause is well defined as an example of chronic visceral pain. It is essential to rule out pain referred to the testis, such as from an adductor enthesitis or from the spine. Thoracic pathology with or without involvement of the nerve roots may also produce pain perceived in the testis.

Despite being well defined, the testicular pain syndrome is poorly researched and information about its incidence is scanty. The majority of the information stems from postvasectomy surgery,\textsuperscript{19} where the incidence may be as high as 19\% following this operation. Once more, the problem appears to be more frequent in younger men.\textsuperscript{20–23} In a large cohort study of 625 postvasectomy men, the likelihood of scrotal pain after 6 months was 14.7\%. The mean pain severity on a VAS score was 3.4/10. In the pain group, 0.9\% had quite severe pain, noticeably affecting their daily life. In this cohort, different techniques were used to perform the vasectomy. The risk of postvasectomy pain was significantly lower in the no-scalpel vasectomy group (11.7\% vs. the scalpel group 18.8\%).\textsuperscript{24}

\textbf{Penile Pain Syndrome}

There are very few data on this condition, which also appears to be unusual in the pain clinic. The condition must not be confused with the penile pain of pudendal neuralgia or pain sensation referred from the bladder or urethra. This condition is also quite different from the psychiatric obsession associated with the sex organs that can occur in certain patients. A painful penis without obvious cause has been seen to
follow circumcision and may represent a central sensitization process.

**PRECIPITATING FACTORS**

Very little is known about the factors that predispose men to urogenital pain syndromes.\(^25,26\) In certain, but probably only a small proportion of, cases, some form of trauma or infection may be the precipitating factor.\(^27\) Surgical trauma in the form of vasectomy may result in testicular pain.\(^28\) Recurrent minor injury may be a predisposing factor, as for any pain syndrome.

The role of the pudendal nerve is disputed by different experts in the field. There is no doubt that pudendal neuralgia (pain associated with pudendal nerve damage) exists.\(^29\) The mechanism(s) presumably will be the same as for all nerves, and the pain would be perceived in the appropriate dermatome. Depending on the site of damage, the pain may be perceived in the anus, perineum, deeper within the pelvis, the bladder base, or the penis.\(^30\) Whether the sexual function and the central sensitization of the sexual process imparts any specific properties on the damaged pudendal nerve is not known. As may be expected, the nerve damage may be associated with a range of sensory abnormalities such as dysesthesia, allodynia, or numbness. The pudendal nerve is suggested to be at risk from recurrent injuries (such as cycling or long hours of sitting) and from acute trauma, including surgical interventions, such as for cancer or orthopedics.\(^31–34\) Sitting while working at a computer appears to be a predisposing factor among young men (personal observation).

The role of the musculature is also highly debated.\(^28,35–41\) In general, it is now well accepted that the pelvic muscles (including the core muscles of the abdomen and spine) may be involved in the pelvic pain syndromes and that these muscles are subject to the same causes as any other muscle. Trauma, as during sports injury, birth injury for women, and accidents, may produce a muscle-based pain. A report from the Chronic “Prostatitis Cohort Study” showed that 51% of patients with “prostatitis” and only 7% of controls had any muscle tenderness. Tenderness in the pelvic floor muscles was only found in the chronic pelvic pain group.\(^42\)

Stress is said to be responsible for pelvic muscle tension and hence pain in certain cases, although it must be appreciated that chronic pain will also
be associated with psychological responses and even psychiatric disorders.43–45

The role of negative sexual encounters (NSE) continues to be disputed.46,47 The prevalence of childhood male sexual abuse may be as high as 16% in some countries; in the United Kingdom, it has been estimated as 5%. Three percent of male adults may also have had an NSE. Victims of torture are frequently subjected to sexual abuse. What is not clear is the relationship of this abuse to male urogenital pain syndromes. In our editorial,8 it was suggested that there is little sound evidence to support NSEs as a cause of chronic urogenital pain in patients. However, there is no doubt that in a patient who has suffered an NSE, that incident may require management in its own right.

There are now several articles that indicate that the psychological status of the patient is relevant to the pelvic pain experience. Patients exhibiting high distress associated with catastrophizing and poor coping strategies do less well.48–51

Mechanisms

DIFFERENCES BETWEEN VISCERAL AND NONVISCERAL SOMATIC PAINS

In a proportion of patients with pain perceived to be in the pelvis, ongoing classical visceral pain mechanisms may be involved. A number of these mechanisms are listed in Table 65.4 and compared to somatic pain mechanisms. In certain patients with persistent pelvic pain, chronic central sensitization mechanisms are predominant.

</table>
Sensitization of visceral afferents and activation of silent afferents by endogenous mediators, including nerve growth factor (NGF), is considered pivotal for the development of visceral pain. NGF is able to both directly activate primary afferents and indirectly activate them (such as through the regulation of the expression of bradykinin). Multiple tachykinins are implicated in both the normal control of bladder contraction and in the heightened stimulation and sensitization of the afferent loop of the micturition reflex after inflammation. Similar mechanisms are known for the other organs. Adenosine triphosphate released from hollow organs, such as when the bladder is distended, acts on purinergic P2X3 receptors found on visceral afferents and on small-diameter dorsal root ganglion (DRG) neurons. Once more, these mechanisms may be involved in normal function as well as pain. Voltage-gated ion channels (tetrodotoxin resistant sodium channel, NaV1.8) are also implicated in the visceral pain states.

CENTRAL MECHANISMS

In visceral pain, excitatory amino-acid receptors such as N-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) play a vital role in the production of viscerovisceral, musculovisceral, and visceromuscular hypersensitivity. Both clinical studies and basic science support that central mechanisms activated as a result of an insult in one organ can result in nonnoxious sensations being perceived and noxious sensations becoming more painful both in the same organ and in different organs and the muscles. Such mechanisms explain why many patients have multiple end organ sensitivities. For example, patients with the bladder pain syndrome may also have muscle trigger points and anorectal sensitivity (e.g., irritable bowel syndrome). Once triggered, the changes in the central nervous system can persist for great
lengths of time.

**MUSCLES AND PELVIC PAIN**

As with any pain syndrome, muscle tenderness and trigger points may be implicated as a source of pain in the urogenital pain syndromes. Central mechanisms are of great importance in the pathogenesis of these muscle hypersensitivities. The muscles involved may form a part of the spinal, abdominal, or pelvic complex of muscles. It is not unknown for adjacent muscles of the lower limbs and the thorax to become involved. Pain may be well localized to the trigger points but is more often associated with classical referral patterns. As well as trigger points, inflammation of the attachments to the bones (enthesitis) and of the bursa (bursitis) may be found.\(^{(41,62–64)}\)

Numerous events have been suggested as causative factors. A local infection, such as a bladder infection, may produce local muscle spasm and subsequent muscle-associated pain. Renal stones are clearly associated with spinal muscle hyperalgesia.\(^{(65)}\) The onset of pain may be due to some form of minor strain or may be associated with a more obvious injury, such as those associated with sports.\(^{(66)}\) Certain postures will affect the different muscles in different ways and, consequently, may either exacerbate the pain or reduce it. Stress has been implicated as being both an initiator of pelvic myalgia and as a maintenance factor; as a consequence, NSE may also have a precipitating effect.\(^{(47)}\)

**Pelvic Muscle Pain Syndromes\(^{(67,68)}\)**
The following are some examples of pelvic muscle pain syndromes.

Piriformis\(^{(69,70)}\)

This muscle originates from the anterior part of the sacrum and inserts onto the greater trochanter. The muscle produces external rotation of the leg. It starts within the pelvis, leaving it by the greater sciatic foramen. It is the relationship of the piriformis at this level to the nerves that allows the possibility of nerve irritation by the piriformis (see the following text). Pain associated with this muscle refers to the buttock and is worse on passive internal rotation or active external rotation against resistance.
Trigger points are usually identified at the level of the greater sciatic foramen.

Obturator Internus\textsuperscript{71,72}
This muscle arises from the inner surface of the anterolateral wall of the pelvis, where it covers the majority of the foramen ovale and is attached to the obturator membrane, the inferior rami of the pubis, and the ischium. It leaves the pelvis via the lesser sciatic notch to attach to the greater trochanter. It may develop trigger points deep in its body (detected by internal pelvic examination) or in its external part. Pain may refer anteriorly, deep within the pelvis, and to the genitalia and/or posteriorly to the rectum and buttocks. Bursitis may occur as the muscle passes out of the pelvis and around the ischium. This muscle may be associated with pudendal nerve irritation (see following text).

Levator Ani\textsuperscript{73}
The levator ani is inserted into the inner surface of the anatomical lesser pelvis and is composed of three parts—iliococcygeus, puborectalis, and pubococcygeus. The muscles form a sling with fibers uniting in the midline and blending with the sphincters of the pelvic organs (Fig. 65.1). Trigger points produce a range of referral patterns from the anus to the penis and into the testis. It has been suggested that levator plate hypersensitivity, trigger points, and referred pain are responsible for the prostate pain syndrome.\textsuperscript{38,74}

The relationship of these muscles to the pelvic organs results in a wide range of other symptoms, such as urinary urge with associated frequency. Pain may be exacerbated by use of the muscles, such as during intercourse, ejaculation, voiding of urine, and defecation.
Cocygeus
The coccygeus originates from the spine of the ischium and inserts into the coccyx.

Psoas
The psoas originates from the transverse process of the lumbar vertebrae; leaving the pelvis below the inguinal ligament, it inserts into the lesser trochanter of the femur. Pain can refer to the back, pelvis, and groin.

Spinal and Abdominal Muscle Pain Syndromes
The spinal and abdominal muscle pain syndromes often have a close relationship with the pelvic muscle pain syndromes. Muscle pains may be seen to spread from the site of the original pain (either the pelvis or the spinal/abdominal muscles) to involve adjacent muscles. Sometimes, this progression may be picked up from the history; in other patients, it may be
impossible to separate out the history around what appears to be total body pain. Kinesophobia and subsequent immobility are predisposing factors to the spread of muscle pain. Stress and tension are also negative prognostic factors. The thoracolumbar junction is an important source of referred pain to the buttocks, hips, groin, and testicles.

As in the pelvic muscle pain syndromes, spasm of the abdominal and spinal musculature may be associated with local nerve irritation, such as the genitofemoral nerve with psoas spasm and the anterior cutaneous branches of the intercostals nerves as they transgress the rectus abdominis. Disease at the thoracolumbar junction may result in L1 and/or T12 root irritation and, consequently, pain perceived in the groin and testicles.

PELVIC NERVES AND PAIN

It is well established that nerve injury may be associated with a range of symptoms that include dysesthesia, allodynia, hyperalgesia, and constant or intermittent pain. The mechanisms are well established (see other chapters in this book). In some cases, the onset of pain is clearly associated with the nerve damage. However, in many cases, arriving at the diagnosis of peripheral nerve injury generated pain can be difficult. This is particularly so for the urogenital pains:

1. Due to the difficulty in identifying the nerves and examining their relevant dermatomes
2. Pelvic dermatomes overlap widely, and consequently, signs of nerve injury are difficult to identify.
3. Many pelvic nerves are primarily sensory or autonomic, and as a result, there is little somatic motor data available to aid the diagnosis of nerve damage.
4. Even when there are motor fibers present, significant nerve damage has to be present for there to be abnormal neurophysiology, and the muscles are difficult to access.
5. Referred sensations (including cutaneous dysesthesia, allodynia, and hyperalgesias) from the muscle hypersensitivities, tendonitis, and enthesitis are common and frequently confuse the picture.

Peripheral Nerve Pain Syndromes
Nerves and the Male Genitalia
The afferents from the skin of the male genitals pass via a complex of multiple sensory nerves, and this makes the diagnosis of nerve injury as a cause of pain difficult. The anterolateral part of the scrotum has afferents primarily associated with the genitofemoral nerve; there is some possible involvement of the ilioinguinal and iliohypogastric nerves. The posterior scrotal branches of the pudendal nerve transmit sensation from the posterior scrotum. The penis shaft is innervated on its dorsal surface by the genitofemoral, ilioinguinal, and iliohypogastric nerves and the ventral surface by the perineal branches of the posterior femoral cutaneous nerve and cutaneous branches of the pudendal nerve. The glans penis is associated with the dorsal nerve of the penis, the terminal branch of the pudendal nerve. All the nerves that are associated with the scrotum may also receive afferents from the testis, although classically, the nerves from the testis are usually associated with the genito-femoral nerve. The superficial branches of the pudendal superficial perineal nerve and the perineal branch of the posterior femoral cutaneous nerve receive afferents from the perineal skin. Deeper afferents from the perineum and from some of the pelvic organs pass to the pudendal nerve via its deep perineal branch.

The course of the afferents from the pelvic organs is well described in most anatomy books, as are the sources of innervation. For the aims of this chapter, the involvement of the pudendal nerve must be emphasized. It must also be recognized that the pelvic plexus is both associated with the parasympathetic and sympathetic nerves and that, as well as afferents associated with these pathways, afferents may travel back to both the sacral roots and the thoracolumbar roots with these autonomic nerves. Sites for injury and for possible intervention may thus include the ganglion impar, superior hypogastric plexus, inferior hypogastric plexus, and lumbar sympathetic trunk as well as more central spinal root areas.

Pain Arising from Damage to the Anterior Groin Nerves
The iliohypogastric nerve arises from L1, and its anterior branch supplies the skin above the pubis where its lateral cutaneous branch is distributed to the anterolateral part of the buttock. Nerve damage may be associated with surgical trauma during operations on the groin or loin. More proximal
lesions are rare but should be considered as they may represent sepsis or neoplastic infiltration.

The ilioinguinal nerve is smaller than the iliohypogastric nerve; arising from L1, it is distributed to the skin of the groin and mons pubis. Nerve damage may be associated with surgical trauma during operations on the groin or loin. More proximal lesions are rare but should be considered as they may also represent sepsis or neoplastic infiltration.

The genitofemoral nerve arises from L1 and L2. It passes through the psoas and then down it to emerge through the deep inguinal ring. Its genital branch supplies the cremaster and a part of the anterior and lateral scrotum. The femoral branch passes close to the external iliac artery, the deep circumflex iliac artery, and the femoral artery to be distributed to the upper part of the femoral triangle. As the two branches of the genitofemoral nerve may separate at any level, sensory phenomena associated with nerve damage will depend on the level of the lesion and individual variability. Genitofemoral neuralgia may suggest a vascular aneurysm, local sepsis, or be associated with loin or groin surgery.

The lateral cutaneous nerve of the thigh arises from L2 and L3 and passes to eventually leave the abdomen behind or through the inguinal ligament at a variable distance medial to the anterior superior iliac spine. In the thigh, it divides into an anterior branch that supplies the anterolateral skin of the thigh, approximately 10 cm down from the inguinal ligament to the knee. The posterior branch supplies the skin more laterally from the greater trochanter, down to midthigh.

Obturator nerves L2, L3, and L4 descend through the psoas, around the pelvis closely approximated to the obturator internus muscle and obturator vessels to leave the pelvis via the obturator foramen. This nerve has significant motor innervation; its cutaneous branch is distributed primarily to the inner thigh.

Pain Arising from Damage to the Posterior Triangle Nerves
The posterior triangle area is the area defined by the upper border of the piriformis superiorly; the lower border of quadratus femoris inferiorly; the greater trochanter laterally; and the lateral border of the sacrum, lateral border of the sacrotuberal ligament, and lateral border of the ischial tuberosity medially. It is in this region that the sciatic nerve, the posterior
femoral cutaneous nerve (which branches into the posterior cutaneous perineal branch as well as the cluneal nerves), the nerve to obturator internus muscle, and the pudendal nerve can be found; they pass deep to the piriformis and superficial to the superior gemellus and obturator internus muscles.

The pudendal nerve has its roots at the S2, S3, and S4 levels. It has three main branches: the inferior anal/rectal nerve; the superficial perineal nerve (which terminates as cutaneous branches in the perineum and posterior aspect of the scrotum); and the deep perineal nerve, which is distributed to the pelvic structures (possibly innervating parts of the bladder, prostate, and urethra) and terminates as the dorsal nerve of the penis, innervating the glans penis. It has been suggested that the pudendal nerve may be damaged at the level of the piriformis muscle, the sacrospinal ligament, or within Alcock’s canal, medial to the obturator internus muscle. The site of injury will determine the site of perceived pain and the nature of associated symptoms (e.g., the more distal the damage, the less likely the anal region will be involved). There is also a school of thought that suggests that the fine nerve endings of the pudendal may become trapped in the muscle planes producing neuropathic pain, possibly with mechanisms similar to complex regional pain syndrome. Magnetic resonance neurography may have a diagnostic role.

Functional Problems and Male Pelvic Pain

In addition to pain, many patients with urogenital pain syndromes suffer with abnormalities of organ function. The exact mechanisms involved may not be clear. It is well described that certain drugs (Table 65.5) and surgical interventions can produce organ dysfunction.

TABLE 65.5 Drugs Prescribed in Pain Clinics and Some of Their Effect on Organ Function
The mechanisms, both central and peripheral, involved in the production of the pain may also be the cause of some of the functional disorders. Certainly, those functions that are reliant on voluntary control may be affected by changes in sensory perception. The sensation of urge perceived with a more or less empty bladder may be associated with urinary frequency, and similarly, the sensation of rectal fullness may be associated with frequent attempts to defecate. Because of convergence of visceral afferent input within the central nervous system, abnormalities of sensation perceived primarily in one organ may result in functional abnormalities further afield and widespread muscle spasm. Abnormal visceral motor function may also occur. The role of the neuroendocrine and neuroimmune systems is poorly understood. The effect of these conditions on fertility is also poorly understood. In males, most frequent effects on sexual function are erectile dysfunction and premature ejaculation. These can be evaluated by proper questionnaires, namely, International Index of Erectile Function (IIEF) and Premature Ejaculation Diagnostic Tool (PEDT).

**Psychological Consequences of Male Pelvic Pain**

The effect of gender on illness and illness behavior is clearly established; however, there is little research on the effect of illness on gender identity and sexual psychology. One may assume that disorders of the male urogenital system will be prone to produce problems within both of these areas with a risk that the male either fails to achieve meaningful relationships or that established relationships have an increased chance of breaking down. All chronic pain is associated with depression and cognitive-behavioral problems. The severity of the pain appears to be the main determinant. Depression and catastrophizing are poor prognostic...
factors. Tripp et al.’s paper and more recent work by the same group are key studies. Problems with work, relationships, sex, and loss of meaning of life appeared to be as equally important as the pain itself. For the successful management of a patient with chronic pelvic pain, a multidisciplinary team approach is essential (see the following text).

Male Urogenital Pelvic Pain Syndromes—Treatment

SEX DIFFERENCES AND THERAPIES
There are some fundamental differences between males and females that may affect drug pharmacokinetics and pharmacodynamics. In contrast to women, men usually have greater muscle mass, lower percentage body fat, and less fluctuations in hormones. Other genetic-related factors may be at play. Men appear to require significantly more morphine than women per kg body weight, and women seem to achieve statistically significantly more analgesia with κ-opioid agonists (e.g., nalbuphine, buprenorphine, and pentazocine) than do men. The effect of sex differences on other therapies is poorly researched.

SPECIFIC PAIN SYNDROME TREATMENTS
A more complex review can be obtained in the current EAU guidelines for chronic pelvic pain.11

Prostate Pain Syndrome
Because the exact nature of this condition is poorly understood, specific drug treatment options do not exist.

Most patients will receive one or more courses of antibiotics. The current EAU guidelines indicate that because some patients have been observed to improve with antimicrobial therapy a trial treatment with antibiotics is recommended. They go on to say that “patients responding to antibiotics should be maintained on the medication for 4 to 6 weeks or even longer.” If antibiotics are used, other therapeutic options should be offered after one unsuccessful course of a quinolone or tetracycline antibiotic over 6 weeks. The only randomized placebo-controlled trials that have been done for oral antibiotic treatment are for ciprofloxacin (6
weeks), levofloxacin (6 weeks), and tetracycline hydrochloride (12 weeks). Network meta-analysis has suggested significant effects in decreasing total symptoms: pain, voiding, and quality of life scores compared with placebo.

Recently, there have been many studies that demonstrate an improvement of symptoms in patients with NIH III a/b prostatitis when α-adrenoceptor blockers are used. α-Adrenoceptors are found in the bladder neck and prostate, and α-adrenoceptor blockers are conventionally used to improve flow in the presence of lower urinary tract obstructive symptoms. These studies demonstrate an improvement in pain as well as voiding and quality of life. Combined α blockers with antibiotics may be superior to monotherapy.

Analgesics are often considered the mainstay of symptomatic management. Simple analgesics containing paracetamol (acetaminophen) are often first line but unfortunately, in many cases, with little benefit. Nonsteroidal anti-inflammatory medications can be considered but should only be used long term if there is evidence of inflammation. Opioids should only be used if one or the other of the national guidelines has been followed (e.g., The British Pain Society/Faculty of Pain Medicine guidelines).

Symptom control is primarily aimed at reducing spasm in the bladder outflow system (smooth and/or striated muscles) or the use of simple analgesics. Striated muscle relaxants may help if there is pelvic floor muscle spasm or in the presence of pelvic floor muscle trigger points.

Studies have looked at the role of hormone manipulation with the 5-α-reductase inhibitor finasteride. In a small percentage of patients, finasteride has been found efficacious with an improvement in voiding and a reduction in pain. The EAU does not recommend 5-α-reductase inhibitors for use in pelvic pain syndrome in general, but symptom scores may be reduced in a restricted group of older men with an elevated prostate-specific antigen (PSA).

The role for anticholinergics is debatable. Meares has suggested they may be beneficial in reducing urinary urgency.

In a systematic review and meta-analysis, patients treated with phytotherapy were found to have significantly lower pain scores than those
treated with placebo. In addition, overall response rate in network meta-
analysis was in favor of phytotherapy (risk ratio [RR], 1.6; 95% confidence interval [CI], 1.1 to 1.6).\textsuperscript{101}

There is little evidence for immune modulation using cytokine inhibitors.\textsuperscript{107,108}

There are advocates for therapies, such as biofeedback, relaxation exercises, lifestyle changes (e.g., diet, discontinuing bike riding, changing a work station), acupuncture, massage therapy, chiropractic therapy, and meditation.\textsuperscript{87,102} Pelvic floor exercises and biofeedback pelvic floor training, independent of other influences, may benefit this group of patients.\textsuperscript{109} The debate about exercise versus trigger point therapy continues with very little research.\textsuperscript{109} It appears that managing the associated muscle hypersensitivity is important, whether it is the primary problem or secondary. If we draw comparisons with other musculoskeletal-related pain syndromes, managing the patient as a whole appears appropriate. The physical treatment options should probably consist of exercises, postural/core work, trigger point release, and pacing. Maintaining the locus of control with the patient is important.

Heat therapy, such as transrectal hyperthermia\textsuperscript{110–112} and transurethral thermotherapy,\textsuperscript{113–115} has been reported to produce favorable results in some patients. Generally, the evidence is weak and the treatments rarely used.

In summary, the mainstay of treatment appears to be antibiotics, α-adrenoceptor blockers, various simple analgesics, hands-on physiotherapy, and pain management psychology and behavioral physiotherapy. There does not appear to be a role for surgery.

**Scrotal/Testicular/Epididymal Pain Syndromes**

There is very limited research on this condition, and as a result, the evidence for efficacy is limited.\textsuperscript{8} Some groups have advocated the use of antibiotics, but, as with the prostate pain syndrome, there appears to be limited supporting evidence in the absence of an identified infection.

If urinary symptoms are present, then those symptoms may be managed as in the prostate pain syndrome. Similarly, the use of nonsteroidal anti-inflammatory drugs (NSAIDs) may have a role if inflammation is present.
Analgesics, including opioids and neuropathic analgesics, may be tried; the effect must be monitored and appropriate guidelines adhered to.

There is still debate as to what scrotal contents may be associated with pain. However, there is a suggestion that in the presence of a hydrocele, spermatocele, or varicocele, on average, 50% of patients may see benefit from surgery.\textsuperscript{116–118} In the absence of such a lesion, the role of surgery is debatable and may even be detrimental.\textsuperscript{8}

In the scrotal pain syndrome, microsurgical testicular denervation has been advocated; however, the number of studies are limited and not double blind for technical reasons.\textsuperscript{117,119} The results of epididymectomy and orchidectomy are considered even worse (although 20% and 60% success rates, respectively, have been suggested).\textsuperscript{120,121} It should be of concern that these procedures are still undertaken despite the fact that pain may be increased by the procedure.

Nerve blocks (L1 dorsal root renal/sympathectomy, groin blocks, and pudendal/perineal [posterior triangle] blocks) are regularly used in the treatment of scrotal pain syndrome. As well as a possible therapeutic role (for which there are no supporting studies), they are also important for the differential diagnosis process. Although the evidence for therapeutic benefit is limited, the risks are either small or extremely rare.

**GENERIC TREATMENT APPROACH**

Urogenital pain syndromes should be managed with the same general approach that is used for any of the pain syndromes. Where possible, the consultation and therapeutic procedure environment should be purpose-built, allowing privacy and comfort (many of these patients would prefer to stand or lie for the consultation). Anatomical models and diagrams, including drawings or photographs of genitalia, that will facilitate the consultation should be available. As well as doctors, nurses skilled in the management of this group of patients should be at hand to reinforce the discussion from the consultation.

**Psychology and Sexual Counseling**

In view of the psychological consequences of urogenital pain, experienced pain management psychologists should be at hand. The full range of their
skills utilized for chronic pain management will be required, but psychosexual counseling and relationship work is often required as well. For the sexual problems, we operate a system where the medical and nursing staff not only undertake the medical management of the sexual problems but also provide medical information on normality and variants to enable the patient to place their sexual problems in context. Psychological interventions are instigated early and often while physical treatments are ongoing—the aim is to support and prevent psychological and sexual problem deterioration. Under such circumstances, both the patient and the psychologist have to be able to work with this model of early psychology and ongoing physical treatment.

**Trigger Point Therapy**

As discussed earlier, trigger points and hypersensitive muscles should be managed as appropriate with treatment options that include drugs, stretching, exercise, relaxation, and injections. Injections into pelvic trigger points are no different than injections into muscles elsewhere but require the expertise of a specialist with skills using imaging such as computed tomography (CT), ultrasound, or possible procedural magnetic resonance imaging (MRI). The agent injected is not agreed on but usually is a local anesthetic and steroid mixture. Botulinum toxin injections into some of the deeper pelvic muscles has been advocated.\(^{122,123}\)

**Nerve Blocks**

Nerve blocks may not only have a role in the management of specific nerve injuries but also serve to relax muscles. Nerve blocks may be therapeutic or diagnostic.

**Surgery**

Surgery was discussed earlier and, in view of the risks with minimal proven benefit, should not be undertaken without a good surgical reason. If the surgery is significant, psychological evaluation and intervention should be considered first.\(^{124,125}\) Surgery has a role in proven pudendal neuralgia with the site of entrapment being situated at the ischial spine between the sacrospinous ligament (or ischial spine) and the sacrotuberous ligament in
74% of patients.\textsuperscript{126}

**Drugs**

**Centrally Acting Analgesics**

Chong and Hester\textsuperscript{125} summarized the current knowledge in relation to the role of targeting neuropathic pain in urogenital pain syndromes. There is a debate as to when and whether such drugs have a role in the management of the pelvic pain syndromes. Tricyclic and tetracyclic antidepressant drugs may have a role if there are neuropathic qualities to the pain. The best evidence is for amitriptyline. Selective serotonin reuptake inhibitors (SSRIs) and serotonin and norepinephrine inhibitors (SNRIs) are also considered to have a role. Venlafaxine has the strongest evidence but is troubled with cardiac side effects. Duloxetine may have an advantage where stress incontinence is a problem.

Gabapentin and pregabalin have become very popular in the management of chronic pelvic pain, and several studies have suggested they may have a role (still to be published). Other antiepileptics could be considered, as for the management of any neuropathic pain.

Opioids should be considered providing appropriate precautions are undertaken and guidelines adhered to.

**Neuromodulation**

The evidence base for neuromodulation in chronic pelvic/urogenital pain is limited. However, some very good guidelines do exist for the use of neuromodulation in peripheral nerve injury and complex regional pain syndrome.\textsuperscript{127} Hence, one would expect neuromodulation to help certain urogenital pain conditions. Case history reports support this. The main problem is achieving stimulation in the appropriate area, and although some specialists do claim to gain benefit by stimulating the lower thoracic region, it appears that most specialist implanters would now stimulate the sacral roots either by a lumbar retrograde or transsacral approach. The stimulation is thus preganglionic/ganglionic and not dorsal horn or true peripheral sensory nerve only. The transsacral approach is easy to trial and also has the benefit of some excellent guidelines for bowel and bladder dysfunction neuromodulation.\textsuperscript{128,129} It is our policy to try
transforaminal/transsacral neuromodulation first, and if that fails to reduce the pain, but the patient wishes to try other approaches, we then try lumbar retrograde or lumbar anterograde approaches. The EAU\textsuperscript{3} says, “The role of neuromodulation in the management of pelvic pain should only be considered by specialists in pelvic pain management.” Neuromodulation appears to have the strongest benefit in those with bladder pain syndrome.\textsuperscript{130}

Overview and Conclusion

Male urogenital pain may arise from the specific male urogenital organs. However, there is a strong literature pointing out that in many men, the pain may arise from other sources but is perceived in the male sex organs. It is now well established that when a man presents with urogenital pelvic pain, the nervous system, musculoskeletal system, and other organs should be looked at as potential sources of the pain. The role of the central nervous system in altering afferent perception and producing efferent dysfunction is now well understood. The central nervous system is also key as a cause for the widespread distribution of the pain syndrome. Often, multiple organs and systems are involved. The nervous system may also be key in the association between the pelvic pain syndromes and systemic disorders such as fibromyalgia and chronic fatigue syndrome. In view of this complex of interacting mechanisms, a single therapeutic option is rarely rewarding. Antibiotics and surgery for pain are also rarely rewarding. Multimodal approaches to pain management appear to provide the best results. Management should be aimed at not only the pain but also the other sensory symptoms and functional disorders. The more distressed the patient, the worse the prognosis; hence, early pain management and early psychological, sexual, and relationship support is crucial to a good outcome.

Since the last edition of this book was written, advances in diagnostic modalities have improved our understanding of the etiology and pathogenesis of the neuralgias of the face, head, and neck. Recent modifications in the nomenclature have also occurred which reflect a more accurate organization and classification of the cranial neuralgias and facial pain. Although the nomenclature of these severe and often incapacitating pain syndromes remains controversial, immense efforts have been made to scientifically categorize these syndromes based on causal factors, when known, or strict diagnostic criteria, when causal factors are not known.\textsuperscript{1–3} Although imperfect, the International Classification of Headache Disorders, 3rd edition (ICHD-III) (beta version), classification system continues to be refined and to serve as a valuable instrument to further advance the scientific understanding and treatment of these disorders.\textsuperscript{4} The importance of accurate diagnosis and classification of these conditions is particularly critical as it pertains to treatment of many of the neuralgias for which successful medical and surgical treatments have been developed.

Cranial neuralgias refer to paroxysmal pain in the distribution of a specific cranial nerve. Previous classifications separated facial pain into typical, atypical, and symptomatic neuralgias. Because a great portion of the current literature continues to utilize these terms, it is important to understand the meaning of both the previously used nomenclature and the revised nomenclature.\textsuperscript{3} Other features ascribed to the previous classification system are described in Table 66.1.

The revised classification system utilizes the terms classical and painful trigeminal neuropathy. The term classical refers to trigeminal neuralgia (TN) including both idiopathic cases and those related to vascular compression of trigeminal nerve. The term classical rather than primary has been applied to those patients with a typical history even though a
vascular or other source of compression or demyelination may be
discovered during its course. The term painful trigeminal neuropathy
(PTN) can then be reserved for those patients in whom a neuroma, tumor,
multiple sclerosis (MS), or other cause has been demonstrated. In the past,
the term symptomatic trigeminal neuralgia represented these cases.

The term persistent idiopathic facial pain has replaced atypical facial
pain in the taxonomy. This change reflects a lack of known mechanisms,
continued recognition of the potential contribution of multiple etiologic
factors to this syndrome, and an emerging knowledge of the
pathophysiology of diffuse pain syndromes previously not well
understood.5–8

This chapter is organized around the current classification of neuralgias
of the cranial nerves and associated disorders. We cover most of these with
particular emphasis on TN as this single disorder is best studied among
cranial neuralgias and offers the most reports of diverse clinical
experiences. Emphasis is made on updates in classification, diagnosis, and
treatment of cranial neuralgias. A narrative bridge from past literature and
understanding is included to enhance the reader’s understanding of more
recent research, insights, and therapeutic approaches.

Classical Trigeminal Neuralgia

HISTORY

TN was described as early as the first century AD in the writings of
Aretaeus (Fig. 66.1). Treatments at that time included bloodletting and the
application of bandages containing arsenic, mercury, hemlock, cobra, and
bee venom as well as other poisons. Eleventh-century Arab physician
Jurjani advanced the vascular compression theory as the causative factor of
the severe pain and spasm of this syndrome.9 The first clinical descriptions
of TN in the European literature have been ascribed to Johannes Bausch in
1672 and John Locke in 1677. French physician Nicolas André, who in
1756 described five cases of “unbearably painful twitch,” is credited with
first recognizing this condition as a unique medical entity. It was André
who coined the term tic douloureux (“painful spasm”). English physician
John Fothergill similarly published a full account of the syndrome and
presented the paper to the Medical Society of London in 1773 and thus the disorder has sometimes been referred to him.\textsuperscript{9–11} Other historical names for TN include prosopalgia and neuralgia of the fifth.

\textbf{FIGURE 66.1} Distribution of the trigeminal nerve (cranial nerve V). The trigeminal nerve gives rise to three divisions: V1, the ophthalmic nerve; V2, the maxillary nerve; and V3, the mandibular nerve. Each division provides sensory innervations to the skin, subcutaneous tissue, and dura mater. The sensory fibers from each division pass through an autonomic ganglion and project the postsynaptic parasympathetic fibers from that ganglion (V1 for the ciliary ganglion, V2 for the pterygopalatine ganglion, and V3 for the submandibular and otic ganglia). V3 additionally supplies motor innervations to four pairs of muscles: temporal, masseter, lateral, and medial pterygoid muscles. (Reprinted with permission from Moore KL, Dalley AF. Clinically Oriented Anatomy. 6th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2009. Figure 9-9.)

In a treatise on neuralgia published by Massachusetts physician E. P. Hurd\textsuperscript{12} in 1890, the following description of the clinical presentation of TN is found: “Probably no more atrocious suffering is known . . . During the attack, the patients utter loud outcries, toss about on their beds and smite their heads. The muscles of the affected side of the face are often the seat of rapid contractions, convulsive shocks, which have given to this disease one of the names by which it is known, [tic douloureux]. These contractions may be limited to single groups of muscles, as the zygomaticus, or the frontal part of the occipito-frontales . . . then the
paroxysmal shocks diminish in frequency and intensity, and all becomes calm; the storm has passed, to be renewed again under the same form in a time not far distant."

In the 19th century, susceptibility to this condition was thought to be secondary to hereditary factors (with “the ancestors of the neuralgic subject being either neuralgic or sufferers from hysteria, epilepsy, or other neurosis”), in combination with other factors such as disease, intemperance, or insufficient diet. Medical treatment was ineffective until the introduction of trichloroethylene inhalation in the 1920s. Prior to this, treatment in the late 1800s focused on advocating a nutritious diet, adequate sleep, hydrotherapy, vigorous exercise, and moderation in all things. Patients were advised to avoid strain, reading, and brainwork, which were felt to be instrumental in initiating an attack, as well as alcohol, tobacco, and other stimulants. Successful nonsurgical treatment for TN was reported by such notable 19th-century physicians as Wilhelm Erb and Duchenne de Boulogne. These included the use of electrotherapy in the form of interrupted current and galvanism.11,12

Although early attempts at surgical treatment of TN by Mareschal, surgeon to King Louis XIV of France, around 1750 and Veillard and Dussans in 1768 were unsuccessful, Bell and Magendie’s clarification of the anatomy and function of the trigeminal and facial nerves in the early 19th century is thought to have contributed to subsequent effective surgical treatments for facial pain. Successful neurectomy of the inferior maxillary nerve was reported by Dr. Joseph Pancoast of Philadelphia in 1840 and in 1851. Dr. J. M. Carnochan described successful resection of the maxillary nerve and removal of Meckel’s ganglion from the foramen rotundum to the infraorbital foramen. Subsequent surgical advances in technique were made by Horsley, Taylor, and Coleman in 1891 (middle fossa approach) and Hartley and Krause in 1892 (subtemporal approach). Cushing’s modification to this approach, reported in 1900, involved approaching the trigeminal ganglion from below the middle meningeal artery. His contribution was credited with decreasing the mortality rate of the surgery to 5%. In 1921, Frazier suggested electrical stimulation to clearly define and spare the motor root, and in 1928, Stookey recommended differential sectioning of the sensory fibers of only the affected divisions of the
In 1925, Dandy reported a novel lateral suboccipital or cerebellar approach that preserved the motor root and was associated with little blood loss. Because of his posterior fossa approach, he was able to observe vascular loops impinging on the root entry zone (REZ) in many patients and inferred that this was the cause of TN.\textsuperscript{11,12}

In 1967, Peter Jannetta reported use of the posterior fossa approach with the aid of an operating microscope.\textsuperscript{13,14} He was able to confirm Dandy’s observations of vascular loops compressing the REZ and subsequently performed a large series of successful surgical treatment of patients with TN using a technique that became known as microvascular decompression (MVD). MVD involves decompression of the nerve by moving the offending vascular loop(s), which are then restrained with nonabsorbent Teflon felt. Due to its low complication and high success rates, MVD has become the surgical procedure of choice for the treatment of intractable TN. The history of the medical and surgical treatments for TN has been thoroughly reviewed by Cole et al.\textsuperscript{1,11,12}

**Epidemiology**

Several epidemiologic studies have collected data on the incidence of TN. Although there is some variation in the reported incidence, in all cases, it continues to be reported as a rare neurologic disorder. A UK study by Brewis et al.\textsuperscript{15} published in 1966 reported an incidence of 2 per 100,000. This number was thought to be low due to lack of inclusion of patients seen by otolaryngologists. US studies by Kurtzke\textsuperscript{16} in 1982 and Katusic et al.\textsuperscript{17} in 1990 reported an incidence of 4 and 4.8, respectively (age and sex adjusted per 100,000 per year). A prospective UK study by MacDonald et al.\textsuperscript{18} reported an incidence of 8 per 100,000 per year. An epidemiologic study that was also performed in the United Kingdom reported an incidence of 26 per 100,000 per year between January 1992 and April 2002.\textsuperscript{19} This study reviewed patients diagnosed with TN by general practitioners rather than those referred to specialists.

The incidence of TN has consistently been found to be higher in females with a 1.74:1 female/male ratio. Incidence increased with age, usually after age 40 years with peak occurrence between ages 50 and 80 years. Occurrence in patients younger than age 40 years should raise suspicion of
secondary causes such as tumor or MS. TN occurs rarely in children.\textsuperscript{20,21}

**ETIOLOGY AND PATHOPHYSIOLOGY**

The various pathologic findings reported and complex theories advanced in the TN literature attempt to explain the combination of unique clinical features of TN such as the following:

- Stereotyped paroxysms of lancinating pain which occur in a limited part of the trigeminal territory
- Separation of the trigger area from the painful region
- Nonnoxious triggers
- Absence of sensory or motor deficit
- Characteristic response of TN to antiepileptic medications

New diagnostic techniques are now challenging theories that were previously advanced to resolve the many questions which remain regarding the etiology and pathophysiology of TN.

Observation of surgical findings led to the 20th-century vascular compression theory of TN. This theory was proposed when Dandy, Gardner, and Miklos recognized the presence of a groove or distortion of the trigeminal nerve root by vessels, or rarely tumors. Jannetta produced convincing evidence that this was the cause of TN by his large series of effective MVD surgeries using the operating microscope. He also demonstrated the absence of trigeminal nerve compression in patients undergoing suboccipital craniotomy for other reasons and in a series of fresh cadaver studies.\textsuperscript{11,13,14} Jannetta’s review of 4,400 operative procedures from 1969 to 1999 revealed a rostroventral superior cerebellar artery loop compressing the trigeminal nerve either at the brainstem or distally to be the most common cause of vascular compression.\textsuperscript{22} Compression by the posterior inferior cerebellar, vertebral, and anterior inferior cerebellar arteries has been also been found. Other reported causes of compression of the trigeminal nerve have included meningiomas, epidermoid cysts, arachnoid cysts, and schwannomas arising from the nerve root itself.\textsuperscript{23} Malis\textsuperscript{24} proposed petrous ridge and fibrous dural band compression as a cause of TN and demonstrated successful alleviation of TN in a case series of 43 patients undergoing decompression of these fibrous bands.
Kerr\textsuperscript{25} and King further argued a peripheral versus a central mechanism for TN. Kerr’s\textsuperscript{25} peripheral hypothesis, based on epidemiology, surgical resections, and cadaver and animal studies, suggested that the paroxysmal neuralgic pain of TN with associated trigger zones is consistent with minor mechanical or pulsatile compression superimposed on predisposing axonal degenerative changes due to hypertension, atherosclerosis, or disease such as MS. He also noted that with aging, replacement of the bony roof of the carotid canal with connective tissue is known to occur. He argued that these degenerative bony changes would permit pulsatile contact with areas of the ventral ganglion which correlate with the anatomic area in which most trigger zones are known to occur.\textsuperscript{14,25}

King argued a central etiology for TN based on injections of alumina gel into the spinal nucleus of the fifth nerve in cats which resulted in a syndrome of dysesthesia of the face with overreaction to tactile stimulation.\textsuperscript{21,25} Calvin et al.\textsuperscript{26} proposed electrophysiologic mechanisms which required both peripheral and central events to produce the symptoms of TN. Fromm and colleagues\textsuperscript{27} published studies which implicated an initial peripheral injury followed by failure of central inhibitory mechanisms as causative factors leading to the onset of TN.

The compression theory of TN, described by the findings of Dandy, Gardner, Miklos, Jannetta, and others, postulates a mechanism for production of the complex of TN symptoms that involves degenerative changes to the central peripheral myelin transitional zone of the trigeminal nerve due to either direct or indirect effects of compression along the course of the nerve from the pons to its entry into Meckel’s cave.\textsuperscript{28} Ultrastructure analysis of trigeminal root biopsy specimens of patients with TN obtained during surgery for MVD support this theory. They reveal axonopathy, axonal loss, demyelination, and axon apposition without intervening glial processes consistent with the “ignition hypothesis” of TN. This model correlates the mentioned pathophysiologic changes with the paroxysmal symptoms of TN based on similar foci of nerve root demyelination and juxtaposition of axons which have been demonstrated in patients with MS and TN together with experimental studies which indicate that this anatomic arrangement favors the ectopic generation of spontaneous nerve impulses and their ephaptic conduction to
adjacent fibers. These studies also demonstrate that spontaneous nerve activity is likely to be increased by deformity of the nerve and frequently associated pulsatile vasculature.29–32

More conclusive evidence supporting both peripheral and central etiologies of TN can be found in electrophysiologic studies. One such study has revealed evidence of peripheral damage to small Aδ fibers of the trigeminal nerve near the REZ in the brainstem. Findings revealed demyelination and axonal degeneration or isolated advanced axonal damage on the symptomatic side in patients with classic TN (CTN). In patients with TN and concomitant chronic facial pain, facilitation of central trigeminal processing at the supraspinal level was found. This is consistent with divergent results of MVD in these two groups of patients. Outcome data from MVD in patients with TN shows excellent or good pain relief in 97% immediately postoperatively and in 80% of those with 5-year follow-up. In patients with TN and concomitant persistent facial pain, previously defined as “atypical,” only 51% show good or excellent pain relief at 5 years.33,34 Pre- and postoperative electrophysiologic recording sessions revealed that relief of pain correlates with normalization of previously prolonged trigeminal reflex responses. Electrophysiologic testing has also been able to differentiate TN from symptomatic TN with a high degree of sensitivity and specificity (94% and 98%).35 Although not practical for routine patient diagnostic purposes, this research is helpful in understanding the decreased response rates in these distinct groups of patients.

SYMPTOMS AND SIGNS
Clear and concise criteria are essential in establishing a diagnosis and conducting research for TN. This is particularly true for a condition such as TN where there is no objective laboratory test to confirm the clinical diagnosis. White and Sweet36,37 helped to achieve these goals by publishing precise and succinct criteria which facilitated early and accurate clinical recognition of TN and facilitated subsequent research (Table 66.2). The International Headache Society recently established new clinical diagnostic criteria for TN as part of the ICHD-III, which have gained wide acceptance and reflect a significant advance that should further promote
TN has well-described pathognomonic features which differentiate it from other types of facial pain. It is characterized by intense paroxysmal, electrical pain which may be accompanied by muscular spasms on the affected side of the face. The attacks generally last from fractions of a

communication and stimulate research regarding TN.
second to 2 minutes and are followed by a refractory period during which no pain can be triggered. Pain is abrupt in onset and termination. Between paroxysms, “The patient is in dreaded fear of the next flash of pain.”

Occurrence of spontaneous remission of pain for weeks, months, or years is another feature of TN which may complicate accurate assessment of therapies.

The pain of TN is limited to the distribution of one or more divisions of the trigeminal nerve and occurs most frequently in V2, V3, or a combination of V2 and V3. First division pain is rare in TN. The pain of TN occurs on the right side of the face more often than the left with predominance ranging from 59% to 66%. Reviews have reported a 3% to 5% occurrence of bilateral pain. Pain rarely occurs on both sides simultaneously. Rather, the painful spasms occur on one side for weeks or months and then, following a period of remission, occur on the opposite side.

Pain occurring on both sides simultaneously or the presence of an abnormal neurologic exam should raise concerns of a secondary etiology such as tumor or MS.

Trigger zones, or areas of the face or head that upon nonnoxious stimulation elicit a TN episode, are also a characteristic feature of TN. In two large series of patients with TN, trigger zones were reported to be present in 91%. Trigger zones may be found in more than one division of the trigeminal nerve. The pain can also be triggered in a different zone from the trigger. The central part of the face near the nose and lips is the area in which triggers most often occur (Fig. 66.2). Touch and vibration have been found to be the most effective stimuli. Attacks are reported to be set off by washing the face, shaving, talking, chewing, brushing of the hair and scalp, or a light breeze on the face of a patient. This can lead to poor hygiene, weight loss, dehydration, and social withdrawal. The ICHD-III criteria also list precipitation of pain paroxysms by “trigger areas” or “trigger factors.” These triggers may include stimuli outside of the trigeminal distribution, such as a limb movement, and may include other sensory stimulation such as bright lights, loud noises, or tastes.
Pre-TN is an additional syndrome reported initially in 1949 by Symonds.\textsuperscript{48} In these patients, a dull aching or burning pain involving a part of the upper or lower jaw develops for hours, days, or weeks and may be triggered by jaw movements or liquids. They may have several bouts of this pain with remissions for weeks, months, or years followed by sudden onset of the paroxysmal pain of TN. Carbamazepine (CBZ) and/or baclofen have been effective in most cases. Unfortunately, some patients undergo multiple dental procedures before the syndrome is recognized as an early sign of TN.\textsuperscript{48–50}

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of TN is made essentially on clinical information. Differentiating TN from PTN and other causes of facial pain is of great relevance in treating underlying disease or lesions and for instituting effective medical or surgical therapy. This requires a thorough history to obtain the patient’s detailed description of defining characteristics, frequency and duration of pain, exacerbating factors, presence or absence of triggers, and associated symptoms. A complete physical exam is necessary to confirm the presence or absence of neurologic deficits. Appropriate tests, such as magnetic resonance imaging/angiography (MRI/MRA) with fast imaging employing steady-state acquisition
(FIESTA) is often indicated to confirm the suspected diagnosis and exclude secondary causes. Development of time-of-flight (TOF) MRA, 3T MRI and 3D T2-weighted driven equilibrium (DRIVE) MRI provide excellent multidimensional images of brain structures, neighboring blood vessels, nerves, and cerebrospinal fluid. These technologic advancements help to locate exactly the site of neurovascular conflict (NVC) loop or any other secondary cause such as plaque and/or space occupying lesions.

Because TN is itself a rare disease, rare presentations of other disease processes fulfilling the diagnostic criteria of TN may require close examination. Rare cases of sinusitis presenting as TN involving first and second division of the trigeminal nerve have been reported with one report of fatal progression in a diabetic patient.\textsuperscript{51,52} Because involvement of the ophthalmic branch occurs in less than 5% of TN patients, a high degree of suspicion is indicated in such cases.

As the example earlier illustrates, it is important to differentiate TN and PTN because PTN may be secondary to a progressive lesion or disease process. Expedient treatment of the underlying disease process or lesion in these cases may limit patient morbidity and mortality and improve overall patient outcome. Although most patients with malignant and benign tumors present with sensory deficit or persistent idiopathic facial pain, the literature does contain reports of patients with tumors initially presenting with TN and no neurologic deficits.\textsuperscript{53,54}

MS is a common cause of secondary TN which should be considered in any person under 50 years who presents with TN. Brainstem auditory evoked potential and blink reflex testing are sensitive methods for examining patients with TN. When the patient’s neurologic exam is abnormal or if the patient does not respond to standard medical therapy, increasingly sensitive methods of CT or MRI/MRA result in accurate diagnosis in almost all cases.\textsuperscript{34,55–58}

The cranial neuralgias covered in greater depth later in this chapter must also be differentiated from TN. Glossopharyngeal neuralgia presents with paroxysmal, electrical pain, spontaneous remissions, and triggers associated with swallowing, chewing, coughing, and talking in some patients. Pain occurs most frequently in the ear, tonsils, larynx, and tongue and may radiate to the neck, shoulder, or face. In less than 10% of cases,
there is an association with TN. Glossopharyngeal neuralgia is also rarely found in patients with MS.\textsuperscript{59}

Intense and stabbing pain localized in the depth of the ear canal is also described in patients with geniculate ganglion or nervus intermedius neuralgia, a rare disorder affecting the sensory branch of the facial nerve. Other cranial neuralgias which may be confused with TN include “tic convulsif” and hemifacial spasm.

Patients with tic convulsif present with severe otalgia combined with unilateral facial spasm. This rare neuralgic disease is thought to be due to vascular compression of the sensory and motor components of the facial nerve at their junction with the brainstem. Hemifacial spasm is a neuralgia involving the facial nerve which is characterized by intermittent, involuntary, irregular, unilateral contractions of muscles supplied by the ipsilateral facial nerve.\textsuperscript{60–62}

Cluster headache pain is unilateral and usually occurs in the ocular, frontal, and temporal areas (although it may occur in the infraorbital and maxillary regions). It usually presents initially in men who are between 18 and 40 years old. Pain is severe, constant, stabbing, burning, and throbbing with associated ipsilateral ptosis, miosis, tearing, and rhinorrhea. Bouts often occur for several weeks to months with one to three attacks in a 24-hour period. Patients will not infrequently be woken from sleep with an attack. Pain-free intervals of several months may occur between bouts of attacks. These headaches tend to respond to ergot preparations, prednisone, and methysergide.\textsuperscript{63}

Pain arising from a group of disorders known as trigeminal autonomic cephalgias may also be confused with TN. These include cluster headaches, chronic paroxysmal hemicranias, and short-lasting unilateral neuralgiform headaches with conjunctival injection and tearing (SUNCT). Knowledge of their epidemiology and a careful history will assist with accurate diagnosis.\textsuperscript{64}

Chronic paroxysmal hemicrania usually occurs in women. It generally involves the ocular, frontal, and temporal areas. Occasionally, it may involve the occipital, infraorbital, aural, mastoid, and nuchal areas on the same side. Attacks vary in frequency in duration but may last 5 to 45 minutes. Pain is excruciating and is associated with ipsilateral conjunctival
injection, lacrimation, nasal stuffiness, and rhinorrhea. These headaches respond well to indomethacin.⁶⁵

SUNCT is a rare syndrome which typically affects males between age 23 and 77 years of age. It is characterized by unilateral burning, stabbing, or electric pain which is usually near the eye. Episodes generally last from 15 to 120 seconds, and multiple episodes can occur daily. Patients present with cutaneously triggered attacks in up to 75% of cases. These attacks are differentiated from TN by lack of a refractory period and presence of associated conjunctival injection, tearing, rhinorrhea, and facial sweating or flushing. As in TN, primary and secondary forms occur. Secondary forms may be due to cerebellopontine angle arteriovenous malformation, infection, and pituitary tumors.⁶⁴,⁶⁶,⁶⁷

Painful ophthalmoplegia such as seen in Tolosa-Hunt syndrome, ocular diabetic neuropathy, ophthalmic herpes zoster (HZ), and ophthalmoplegic migraine must also be differentiated from TN.

Tolosa-Hunt syndrome is a painful ophthalmoplegia caused by granulomatous inflammation in the cavernous sinus. It is characterized by episodic unilateral or bilateral orbital pain associated with paralysis of one or more of the third, fourth, or sixth cranial nerves. Involvement of the V2 and V3 divisions of the trigeminal nerve, the optic nerve, and the facial nerve has been reported. The pain is typically described as steady gnawing or boring. Spontaneous resolution may be followed by remissions and relapses of symptoms. Involvement of the optic, facial, acoustic, or trigeminal nerves has been reported. Treatment with corticosteroids results in resolution of pain and paresis in most cases within 72 hours. Failure of response to steroids or recurrence of symptoms should prompt further workup.²

Ocular diabetic neuropathy may present as eye and forehead pain associated with ocular cranial nerve paresis (usually cranial nerve III). As in other diabetic neuropathies, pain improves with glucose control, treatment with tricyclics, and anticonvulsant medications.²

HZ involving the trigeminal ganglion affects the ophthalmic division in the majority of cases. Ophthalmic herpes may be accompanied by palsies of the third, fourth, and/or sixth cranial nerves or with facial palsy. Burning pain, sometimes accompanied by neuralgic pain, is typically
followed by vesicular eruption within 7 days. Pain may resolve or persist
as postherpetic neuralgia.²

Ophthalmoplegic migraine is a rare clinical entity presenting as
recurrent migraine-like headaches accompanied by paresis of one or more
of the ocular cranial nerves in the absence or other intracranial lesion.
There may be a latent period of up to 4 days from onset of headache to
onset of ocular cranial nerve paresis. Demonstration on MRI of thickening
and enhancement of the cisternal part of the oculomotor nerve in these
patients suggests the etiology of recurrent demyelinating neuropathy.²

Other common causes of facial pain include pain caused by sinusitis or
other inflammatory conditions involving the eyes, tumors of the nose or
sinuses, disorders of the teeth, jaws, or related structures such as
temporomandibular joint (TMJ) pain and posttraumatic pain of the
peripheral branches of the trigeminal nerve.

Sinusitis presents with pain involving the periorcular, frontal, nasal, and
maxillary areas. It is generally described as deep and constant and is
associated with purulent discharge, fever, and fullness of the nose and ears.
CT reveals opacification of the sinuses. In older patients or
immunocompromised individuals, tumors or mycoses should be ruled
out.⁶⁸

Pain related to the teeth is often triggered by chewing or by hot, cold,
sweet, and sour substances. It may have occasional sharp and shooting
characteristics but usually will also have a diffuse, continuous aching,
throbbing, or burning component which is difficult to localize. This type of
pain is also differentiated from TN by lack of trigger zones or periods of
spontaneous remissions. TMJ pain and myofascial pain related to the jaw
is described as aching, burning, or cramping pain associated with use of
the jaw or muscles of mastication. Clicking and other signs of joint
dysfunction are associated features.⁶⁹,⁷⁰ These topics are discussed in
further detail in Chapter 67 on facial pain within this text.

Trauma to peripheral branches of the trigeminal nerve after surgery,
blunt or penetrating trauma, or dental procedures generally presents as
constant pain with burning, tingling, or stabbing components as well as a
dull background pain. One study comparing patients with facial pain after
nerve injury to patients with pain of spontaneous origin found decreased
temperature and tactile thresholds and abnormal temporal summation of pain in patients with nerve injury but not in patients with spontaneous pain.\textsuperscript{71}

Persistent idiopathic facial pain is typically described as a continuous, dull ache that is poorly localized. It fluctuates in intensity and is generally unresponsive to analgesics. It occurs most frequently in women with a mean age of 44.6 years and range of 17 to 87 years. Most of these patients have multiple diagnoses including depression, headache, neck and back pain, and irritable bowel disease. Neurologic and radiologic exams are normal by definition. These patients often have undergone multiple dental procedures.\textsuperscript{72}

**TREATMENT**

*Treatment—Medical Management*

The use of the antiepileptic medications for the treatment of TN was first suggested by Bergougan\textsuperscript{73} in 1942. His trial of phenytoin in these patients was based on Trousseau’s theory that the paroxysmal pain of TN was similar to the paroxysmal brain activity occurring in patients with epilepsy.\textsuperscript{74}

Medical therapy of TN is largely based on the efficacy of drugs that have undergone double-blind evaluation. This is particularly important in light of the need to obtain expedient relief of the excruciating pain of the paroxysms suffered by these patients with proven therapies. The occurrence of unpredictable periods of prolonged spontaneous remission in patients with TN creates a greater likelihood of attributing successful treatment of this disease to ineffective agents. Surgical consultation should be sought early for patients with structural lesions and in patients refractory to medical treatment. For patients unresponsive to medical therapy who are not surgical candidates due to coexisting medical conditions, treatment with radiation or percutaneous therapies, as described in the following paragraphs, may be effective.

Of the medications studied in the treatment of TN, CBZ is considered the drug of choice according to the European Federation of Neurological Societies and the Quality Standards Subcommittee of the American Academy of Neurology.\textsuperscript{75} Current evidence suggests that oxcarbazepine
(OXC) should be the first-line agent in patients with intolerable side effects or inadequate pain control with CBZ. The combination of CBZ with baclofen or lamotrigine has been shown to be effective in cases where patients do not respond to CBZ alone or in whom it loses efficacy.

CBZ is an anticonvulsant, structurally similar to a tricyclic antidepressant, imipramine. It is metabolized primarily by cytochrome P450 isoenzyme CYP3A4. It slows the recovery rate of voltage-gated sodium channels, modulates activated calcium channel activity, and activates the descending inhibitory modulation system. Although it is one of the oldest antiepileptic drugs and many new drugs in this class exist with fewer side effects and fewer drug–drug interactions, four placebo-controlled studies and a systematic review have established its effectiveness in reducing the intensity and frequency of attacks and the number of triggers with a combined number needed to treat of 1.7. In a cumulative analysis, CBZ showed a 58% to 100% success in achieving pain control, whereas in comparison, a placebo showed a mere 0% to 40% response.

CBZ is the only U.S. Food and Drug Administration (FDA)-approved drug for TN. Although CBZ has been shown to have an initial response rate of over 70% in TN patients, one long-term study which evaluated its efficacy over a 16-year period reported that by 5 to 16 years, only 22% of participants continued to have effective relief with 44% requiring additional or alternative treatment. The recommended starting dose is 100 to 200 mg twice daily with gradual increase by 200 mg until pain relief or intolerable side effects occur. The typical maintenance dose of CBZ is 600 to 1,200 mg daily in divided doses. Therapeutic level is 4 to 12 µg/mL. Side effects occur in up to 40% of patients initially but generally subside in most patients after a few weeks. The HLA-B*15:02 allele is a genetic susceptibility marker in Asians that is associated with an increased risk of developing Stevens-Johnson syndrome and/or toxic epidermal necrolysis. Screening for this allele in patients with Asian ancestry is recommended before to starting CBZ. If genetic testing results are positive for the presence of at least one copy of the HLA-B*15:02 allele, CBZ should be avoided. The biologic half-life of CBZ is 30 to 35 hours when first administered. This decreases to 12 hours with autoinduction of liver.
enzymes which occurs after a few weeks. Because pain relief appears to be closely related to serum level, slow-release formulations may be effective in maintaining serum drug concentration.  

The efficacy of CBZ is limited by side effects that include drowsiness, dizziness, constipation, nausea, and ataxia. More severe adverse effects include rashes, leukopenia, abnormal liver function, and, rarely, aplastic anemia and hyponatremia due to inappropriate secretion of antidiuretic hormone. Compared with placebo, it has a number needed to harm of 3 for minor side effects and 24 for major side effects. Monitoring of complete blood count, liver function, and sodium is recommended.  

OXC is the 10-keto analogue of CBZ. Due to its better tolerability, fewer drug–drug interaction, and proven efficacy, OXC is often considered as an initial medication for the treatment of TN. In three head-to-head randomized controlled trials (RCTs), CBZ and OXC both proved to be equally effective in 88% of patients who experienced greater than a 50% reduction in pain attacks. Tolerability was reported as “good” to “excellent” by 62% of patients receiving OXC compared with 48% of patients receiving CBZ. In comparison to CBZ, OXC only needs the monitoring of serum sodium levels.  

Lamotrigine also decreases repetitive firing of sodium channels by slowing the recovery rate of voltage-gated channels. In a small, double-blind, crossover, RCT evaluating patients on CBZ or phenytoin who were refractory to treatment with these medications, lamotrigine (400 mg) versus placebo increased the number of patients who improved after 4 weeks of treatment. A case series also suggests its efficacy as monotherapy for TN. Side effects include dizziness, constipation, nausea, and drowsiness. Stevens-Johnson syndrome has been reported to occur in 1 in 10,000 patients taking lamotrigine. Its utility as a single agent may be limited by its long titration schedule.  

Phenytoin is one of our oldest anticonvulsants with a molecular structure similar to the barbiturates. It acts by blocking sodium channels in rapidly discharging neurons and by inhibiting presynaptic glutamate release. Although it is has been used longer than any other antiepileptic drug in the treatment of TN, there are no controlled trials supporting its efficacy. Uncontrolled observations report that it is effective in relieving
symptoms in 23 of 30 patients when 3 to 5 mg/kg was given intravenously for acute therapy.\textsuperscript{90–92} Phenytoin interacts with many drugs including digoxin and warfarin. Severe rashes can occur in 1 of 10 to 20 patients. There is also a possibility of hyperglycemia, hepatotoxicity, gingival hyperplasia, and megaloblastic anemia. Fosphenytoin, a prodrug of phenytoin that is better tolerated intravenously, also appears to be effective in acutely ill patients.\textsuperscript{93}

Baclofen is an analog of the neurotransmitter $\gamma$-aminobutyric acid. Its effectiveness in the treatment of TN may be due to depression of excitatory synaptic transmission in the spinal trigeminal nucleus.\textsuperscript{94} In three small RCTs, baclofen was shown to be effective as both monotherapy and add-on therapy to CBZ in the treatment of patients with TN. The starting dose is 5 to 10 mg three times a day, with gradual titration to a maintenance dose of 50 to 60 mg per day. Sedation, dizziness, and dyspepsia can occur with treatment. The dose should be adjusted in patients with decreased renal function because baclofen is excreted primarily by the kidneys. Baclofen has central nervous system and cardiovascular depressant effects, and thus, careful titration should occur in patients on other sedating medications and on antihypertensive agents. Antidiabetic medications may need to be adjusted secondary to increases in blood glucose. Baclofen should be discontinued slowly because seizures and hallucinations have been reported upon withdrawal.\textsuperscript{95–97}

Intranasal lidocaine has shown some efficacy in trials. Intranasal 8\% lidocaine spray was examined in 25 patients with V2 division TN in an RCT crossover study resulting in moderate or better pain relief in 23 of 25 subjects receiving lidocaine spray and 1 subject receiving placebo. Relief lasted from 0.5 to 24 hours.\textsuperscript{98}

In a small open-label perspective study, 53 patients with TN received pregabalin 150 to 600 mg daily and were followed for 1 year. After 8 weeks of treatment, a quarter of the patients were pain-free and almost half of them had significant pain reduction with an overall response rate of 74\%.\textsuperscript{99} In a small open-label pilot study, 4 out of 10 subjects taking levetiracetam for TN responded with 50\% to 90\% improvement in pain intensity.\textsuperscript{100} In another small open-label study, 23 patients who took levetiracetam for TN reported a 62\% decrease in daily episodes of pain.\textsuperscript{101}
